With the derivation of mouse mast cells *in vitro,* investigators have been able to infer cytokine-mediated alterations in arachidonic acid-metabolizing phenotype and to ascribe these alterations to the regulation of the constituent arachidonic acid-metabolizing enzymes and proteins involved. For example, mouse mast cells derived *in vitro* from bone marrow with IL-3 produce LTC_4 in marked preference to PGD_2 (258) but are induced to generate PGD_2 by coculture with fibroblasts (220). The fibroblast effect on PGD_2 biosynthesis likely results, at least in part, from fibroblast-derived, membrane-bound SCF, because the capacity of mast cells derived in IL-3 for PGD_2 generation is also upregulated 5- to 7-fold by a 2-day incubation with SCF and IL-10 (250). Conversely, mouse mast cells derived with exogenous SCF instead of IL-3 produced small and equal amounts of LTC_4 and PGD_2 after IgE-dependent stimulation; but when these mast cells were cultured for 2 to 4 weeks in the additional presence of IL-3, they responded with 26-fold and 3-fold increases in the IgE-dependent production of LTC_4 and PGD_2, respectively (258). Human cord blood–derived mast cells grown in an SCF-dependent culture system generate abundant PGD_2 but minimal LTC_4. Their capacity for LTC_4 generation in response to FCeRI cross-linkage is dramatically upregulated by IL-4, which induces expression of LTC_4S (259). The requirement of SCF for mast cell development *in vivo* therefore likely reflects the finding that all tissue mast cell subpopulations constitutively generate at least some PGD_2, while additional factors, including IL-4, modulate LTC_4 generation.

Cytokines Produced by Mast Cells

EARLY-ACTING CYTOKINES

Mouse mast cells produce certain cytokines in response to IgE-dependent stimulation, including cytokines that are associated with the early phases of an inflammatory response, such as TNF-a (260), IL-1 (261), and IL-6 (262,263). Such early-acting cytokines initiate hepatic acute-phase protein production, endothelial cell adhesion molecule expression, and leukocyte recruitment (264). The immunolocalization of TNF-a to the mast cells of human skin (264) and nasal mucosa (265) confirms that TNF-a is also synthesized and stored by human mast cells. The proportions of TNF-a–positive mast cells were greater in transbronchial biopsy specimens from patients with asthma than in those obtained from nonasthmatic control subjects, a finding suggesting that local microenvironmental perturbations modulate TNF-a generation (266). IgE-dependent TNF-a release by mast cells may thus favor leukocyte recruitment to the bronchial wall in asthma. The secretion of TNF-a by mast cells also facilitates their critical protective role recognized in a mouse model of septic peritonitis (25,26). In this model, mast cell activation for TNF-a generation was mediated directly by a bacterial cell wall constituent, a finding indicating a role for mast cells and TNF-a in innate immunity. Indeed, resistance to bacterial peritonitis was enhanced in mice that were injected with SCF, an effect that was mediated partly through mast cells and TNF-a (267).

ALLERGY-ASSOCIATED CYTOKINES

Human and mouse mast cells provide several cytokines that mediate allergic inflammatory responses after IgE-dependent activation. For example, IL-4 and IL-5 are localized by immunohistochemistry to the mast cells in lung tissue of patients with asthma (266), as well as to the mast cells in the nasal mucosa of patients with allergic rhinitis (268). In addition to IL-5, a second eosinophil-active cytokine, GM-CSF, was immunolocalized to the mast cells in the bronchial mucosa of patients with asthma (269). These data are supported by the observation that dispersed human mast cells transcribe and translate several T-helper cell type 2 (Th2)-associated cytokines *de novo* through IgE-dependent activation. IL-3, IL-4, IL-5, and GM-CSF were transcribed when human lung mast cells were stimulated with anti-IgE, and immunodetectable IL-4 and IL-5 were released in response to the same stimulation (270). When cord blood–derived human mast cells were primed *in vitro* with IL-4, their IgE-dependent transcription and release of IL-13 were induced (9), and dispersed human lung mast cells generated IL-13 *in vitro* in response to IgE-dependent stimulation even without IL-4 priming (10). Both immunodetectable IL-4 and IL-5 and their corresponding mRNA species were localized to human skin mast cells after cutaneous allergen challenge (271). Human intestinal mast cells responded to IL-4 priming with augmented IgE-dependent production of IL-3, IL-5, and IL-13 but decreased release of IL-6 (272). Thus, *de novo* production of cytokines occurs downstream of IgE-dependent mast cell activation, with potential relevance to asthma and allergic inflammation. The process of Th2 cytokine generation in mast cells likely has some similarity to the same process in T cells, in which IL-4 is required for optimal production of the Th2 cytokines IL-13 and IL-5. In mouse mast cells, IgE-dependent transcription of IL-5 was linked to the activity of an inducible NFAT family member (273). IgE-dependent IL-2 production by mouse mast cells was linked to NFAT and AP-1 transcription factors, both of which were downstream of FceRI-mediated activation of Btk (123). Taken together, these studies confirm that mast cells are a source of both proinflammatory and Th2-type cytokines relevant to allergic inflammation *in vivo* (274,275 and 276), and their IgE-dependent production is a potential amplifying mechanism for allergic inflammation.

CHEMOKINES

The mast cells of both mice and humans generate several members of the CC and CXC chemokine families. Human mast cells store IL-8, a potent neutrophil-active chemokine (277,278). A closely related CXC chemokine, ENA-78, is produced by mouse mast cells *in vitro* after IgE-dependent activation (279). Human mast cells derived from cord blood *in vitro* generate MIP-1a in response to IgE-dependent activation (280), and mouse mast cells secrete both MIP-1a and MIP-1b *in vivo* during experimental contact hypersensitivity (281). Production of MCP-1 by human lung mast cells is enhanced by SCF and anti-IgE *in vitro* (282). Contact between mouse mast cells and fibroblasts induces the production of eotaxin by mast cells (283). Thus, mast cells are a potential source of several chemotactic mediators involved in inflammation-based leukocyte recruitment.

FIBROGENIC AND ANGIOGENIC GROWTH FACTORS

Mast cells generate factors that are involved in fibroblast proliferation, extracellular matrix deposition, and angiogenesis, including vascular permeability factor and vascular endothelial cell growth factor (284), TGF-b (285), and basic fibroblast growth factor (9). The last property supports the role of mast cells as modulators of tissue repair, fibrosis, and remodeling. Finally, the finding that mast cells store and secrete SCF (197,286,287) illustrates a potential autocrine capability.

IMPLICATIONS OF MAST CELLS FOR HEALTH AND IMMUNITY

In summary, mast cells possess diverse effector capabilities and are ubiquitously distributed to serve diverse physiologic functions. The role of mast cells in allergic inflammation is now firmly established, and their effector pathways are important therapeutic targets for the treatment of allergic diseases. Mounting evidence holds that mast cells are important in immunity, and the constitutive and reactive mast cell developmental pathways may reflect evolutionary pressures to serve distinct functions in host defense. Resident peritoneal cavity mast cells, a constitutive population, are critically required for innate defense against gram-negative bacteria in mouse models of experimentally induced peritonitis, partly because of their provision of TNF-a that is released by nonimmune contact between the bacterium and an as yet uncharacterized mast cell binding site (25,26). Moreover, the reactive intestinal mucosal mast cell hyperplasia that is a consistent feature of adaptive, T-cell–dependent immune responses to helminthic parasites is required for normal worm expulsion in several experimental models (43,70,288,289,290,291,292 and 293). It is therefore tempting to speculate that constitutive, non–T-cell–dependent mast cells participate in innate immunity, whereas reactive, T-cell–dependent mast cells function as effectors of adaptive immunity. The ultrastructural and immunohistochemical phenotypic alterations of mast cells that occur during helminth infections *in vivo* (111), and the changes in effector repertoire of mast cells that are induced *in vitro* by experimental cytokine perturbations (134,204,205,272), likely reflect the modification of their effector capacities in accord with the requirements of a given immune response. The observed differences among mast cell subpopulations may, in turn, reflect microenvironmental influences that are based on the needs of each tissue. The putative role of mast cells in tissue remodeling and in angiogenesis is another example of a potentially beneficial role in tissue homeostasis. The ability to augment innate immunity to gram-negative bacteria in mice by the exogenous administration of SCF (267) suggests that mast cells could be manipulated to augment their function to therapeutic advantage in immunity, revascularization, or wound healing.

25 IMMUNE COMPLEXES

Mark J. Walport, M.D., and Kevin A. Davies, Ph.D.

Antibodies are the humoral products of the adaptive immune system. The physiologic activities of antibodies are to bind to foreign antigens and to promote their clearance from the body. Certain antibodies may also bind to effete and damaged cells, the cellular debris of the body, and may assist in physiologic waste disposal mechanisms. Antibodies engage their effector mechanisms only when they are bound to antigen in immune complexes. In this form, antibodies may bind and cross-link Fc receptors and may also activate the complement system. It is essential to understand the physiology and pathophysiology of immune complex formation to understand the biologic activities of the humoral adaptive immune system.

The effector activities of antibody vary according to the isotype of the antibody, as described in Chapter 13. There are three key differences among the various isotypes of antibody. The first is that different antibody isotypes predominate in particular body compartments. Thus, soluble immunoglobulin M (IgM) is confined mainly to the intravascular space and to mucosal surfaces, secretory IgA is the dominant isotype at mucosal surfaces, and IgG is distributed throughout the extracellular space. The second key difference is whether the antibody mediates its effects in the fluid phase or, as in the case of IgE, is cell bound, predominantly to the high-affinity Fc receptor for IgE (FceRI) on mast cells and eosinophils. The third is the distinction between whether a single antibody bound to multiple epitopes can mediate an effect, for example, a single molecule of IgM binding to a bacterial surface, or whether the binding of multiple antibody molecules to an antigen is required, as is the case for IgG.

In this chapter, we discuss the physiology and pathophysiology of immune complexes in five parts: (a) a consideration of the physiology of immune complexes; (b) the circumstances in which immune complexes cause tissue injury, focusing on human disease; (c) how immune complexes cause tissue injury; (d) the mechanisms for the removal of immune complexes from tissues and the circulation and abnormalities of these mechanisms; and (e) the clinical usefulness of immune complex measurements in clinical practice.

PHYSIOLOGY OF IMMUNE COMPLEXES

Removal of Antigen

It is helpful to consider two separate physiologic activities of antibodies. The first is the removal of antigen, which may be a bacterial toxin or a whole pathogen such as a bacterium or virion. Antigen is removed by the formation of immune complexes that are taken up by Fc receptor–bearing phagocytic cells. These cells engulf and destroy antigen contained in immune complexes.

Many immune complexes also activate the complement system. This activation leads to the covalent binding of C3 and C4 to the immune complex and provides further ligands for recognition by phagocytic cells. Activation of complement also leads to the generation of anaphylatoxin, which recruits inflammatory cells to the site of immune complex formation. Finally, activation of the terminal complement pathway, leading to the formation of the membrane attack complex, provides another mechanism for the killing of bacteria and cells that have been tagged by the binding of antibodies. The structure of immune complexes is modified after complement activation by the incorporation of covalently bound C4 and C3. This plays an important role in augmentation of clearance of immune complexes from tissues and from the circulation (see the discussion of clearance of immune complexes later in this chapter).

The second physiologic activity of antibody is as a feedback mechanism in the regulation of antibody responses. Under different circumstances, immune complexes may either augment antibody responses or inhibit them.

Immune Complexes and the Adaptive Immune Response

COMPLEMENT FIXATION TO SOLUBLE IMMUNE COMPLEXES AUGMENTS ANTIBODY RESPONSES

The innate immune system plays a key role not only in the efferent, or effector, pathways of the adaptive immune system, but also in the afferent pathways involved in the induction of antibody responses. Mice transiently depleted of complement with cobra venom factor had diminished IgG production in response to immunization with T-cell–dependent antigens, with reduced secondary responses and development of B-cell memory (1,2). Guinea pigs (3), dogs (4), and humans (5) deficient in complement components C2, C3, or C4 showed defects in primary and secondary IgG production in response to T-cell–dependent antigens. Similar results have been described in gene-targeted mice null for the expression of C3 and C4 (6).

These results are explained by two pathways in which immune complexes containing antigen, cognate antibody, and complement provide feedback, which augments and regulates antibody responses. First, evidence indicates that complement is crucial for the correct delivery, presentation, and retention of antigen in lymphoid organs. B cells and follicular dendritic cells express a series of complement receptors specific for the split products of C3, and these play an important role in localizing immune complexes that have bound C3 to these cell types. Follicular dendritic cells retain unprocessed antigen in the form of immune complexes (7), and they are thought to be involved in the generation of antibody responses within the germinal center and the maintenance of immunologic memory (8,9). Immune complex localization to germinal centers (10) and splenic lymphoid follicles (11) was abolished in mice depleted of complement with cobra venom factor and in rats treated with anti-C3 monoclonal antibody (12).

Second, complement, bound directly to antigen or to antigen-antibody complexes, lowers the threshold required for B-cell activation. Thus, the activation of B cells is enhanced through interaction of C3 with CD21 (13). The mechanism of this enhanced activation is mediated by the association of CD21 with CD19, a B-cell membrane protein that regulates B-cell responses, differentiation, and development (14). The threshold for specific B-cell activation *in vitro* was lowered when antigen was covalently coupled with C3d (13). Competitive inhibition or blockade of CD21-C3d interaction by soluble CD21-Ig fusion protein (15), or monoclonal antibodies with specificity for CD21 (16), abolished antibody production *in vivo.* Similar data were obtained from mice null for the expression of CD21, in which humoral immune responses to thymus-dependent antigens were reduced (17,18). Evidence that it was the absence of CD21 expression on B cells, rather than on other types of cells, came from chimeric mice in which CD21 expression was absent exclusively on B cells. In these animals, antibody responses to thymus-dependent antigens were reduced and were comparable to those in mice completely null for the expression of CD21 (19).

INTERACTION OF SOLUBLE IMMUNE COMPLEXES WITH FC RECEPTORS MAY ALSO MODIFY ANTIBODY RESPONSES

The observation that complement augments antibody responses led to the hypothesis that immunization with immune complexes may augment antibody responses. This hypothesis was shown to be the case (20), and it appears to be generally true for soluble immune complexes involving IgG. Data show that ligation of Fc receptors by the IgG component of soluble immune complexes may be as important as complement fixation in augmenting antibody responses. Fc receptors are primarily found on circulating leukocytes and cells of the fixed mononuclear phagocytic system. The three main groups are FcRI (high-affinity receptors for monomeric IgG), FcgRII, and FcgRIII. The last are lower-affinity receptors that bind mainly to IgG incorporated into immune complexes.

Experiments with Fc receptor null mice showed that the enhancing effect of specific IgG on antibody responses depended on the presence of FcgRI and illustrated, by

contrast, the suppressive effect of ligation of FcgRII on antibody responses (21). The mechanism of enhancement may be by increased binding of antigen, in the form of immune complexes, to antigen-presenting cells. A similar enhancing effect on antibody responses was also seen in the presence of specific IgE antibodies and depended on the presence of the low-affinity FceRII receptor, CD23 (22,23). The effects of ligation of B-cell coreceptors on thresholds for B-cell activation have been reviewed (24).

Evidence supports a role for genetic variants of FcgRII in modifying disease susceptibility to systemic lupus erythematosus (SLE) in both mice (25,26 and 27) and humans (28,29). This raises the interesting possibility that malfunction or depressed activity of this receptor on B cells could impair the negative feedback effect of immune complexes on these cells and could contribute to the B-cell hyperreactivity that is characteristic of SLE.

ANTIBODIES TO PARTICULATE ANTIGENS MAY SUPPRESS OR ENHANCE ANTIBODY RESPONSES

In remarkable contrast to the enhancement of antibody responses by soluble immune complexes comprising IgG and antigen is the suppression of antibody responses by immune complexes containing IgG and particulate antigens, such as erythrocytes. Indeed, an example of the deliberate formation of immune complexes as therapy in medicine is the use of IgG anti-Rhesus D antigen in the prophylaxis against Rhesus hemolytic disease in the newborn (30). This is one of the major contributions of immunology to clinical medicine. If red cells are administered at the same time as specific anti–red cell IgG, no anti–red cell antibody response results. The mechanism of this occurrence is not fully understood, and three hypotheses have been considered. The first is that the binding of IgG anti-Rhesus D to erythrocytes leads to their clearance and destruction in the spleen without evoking an antibody response. The second is that the IgG anti-Rhesus D masks epitopes on the Rhesus D antigen from binding to specific Ig receptor on B cells. The third is that the IgG bound to the red cell ligates the inhibitory FcgRII receptor on B lymphocytes and directly inhibits B-cell activation. This possibility has been virtually excluded by the observation that IgG anti–red cell antibodies still inhibit antibody responses in mice genetically deficient in FcgRII receptor expression (31).

Completely opposite to the inhibitory effect of specific IgG anti–red cell antibodies on antibody responses to red cells is the enhancing effect on antibody responses of specific IgM antibodies to red cells (and also to parasites). In the case of IgM antibodies, there is no Fc receptor with specificity for IgM, and strong evidence indicates that IgM-mediated enhancement of antibody responses is mediated by IgM-induced complement fixation to the immune complex. Indeed, an important physiologic activity of IgM may be to enhance antibody responses to low doses of antigens by forming immune complexes that activate complement (32,33).

To summarize this section, the formation of immune complexes is a mechanism that modulates antibody responses. The usual consequence is an augmentation of antibody responses, with the notable exception of IgG antibodies directed against particulate antigens such as red cells, which inhibit the development of antibody responses. For further reading on this topic, the reader is referred to the review by Heyman (34).

CIRCUMSTANCES IN WHICH IMMUNE COMPLEXES CAUSE TISSUE INJURY

Immune complexes are a major cause of human diseases. These diseases may be acute or chronic, depending on whether the antigen within the immune complex is present transiently or chronically. We first consider acute diseases caused by immune complexes, as typically represented by serum sickness, and then chronic immune complex–mediated diseases, associated with chronic infection or autoimmunity.

Serum Sickness

Serum sickness is a transient, although sometimes severe, illness that follows a large systemic load of a foreign antigen, which is effectively cleared by the immune system. During the process of clearance, large amounts of immune complexes may form, either locally in tissues or systemically. Disease normally resolves spontaneously after the clearance and disposal of the immune complex load.

In humans, serum sickness is caused mainly by the medicinal administration of large volumes of foreign antigen, as drugs or systemically injected proteins. It was originally described by von Pirquet and Schick in patients injected with horse antisera to antigens such as diphtheria toxin (35). Now, serum sickness is most commonly seen in patients treated with antilymphocyte globulin (36), streptokinase (37), and drugs such as antibiotics (38,39).

The typical clinical presentation occurs approximately 10 days after administration of the inciting antigen, with a rash, which may be vasculitic and frequently has an urticarial element, indicating the activation and degranulation of mast cells. Other symptoms include fever, arthralgia, abdominal pain, and sometimes glomerulonephritis or neuropathy.

Chronic Immune Complex–Mediated Diseases

Serum sickness should be contrasted with the chronic diseases caused by immune complexes, in which the antigen is not effectively cleared; the antibody response therefore persists, and chronic organ damage occurs. Antigen may persist in two situations. The first is when the antigen is an autoantigen and, by definition, cannot be cleared. The second is when the antigen is foreign but persists. This may result from long-term and recurrent exposure to foreign exogenous antigen, for example, in hypersensitivity pneumonitis (also known as extrinsic allergic alveolitis), or to foreign antigen produced in the body, for example, in infectious diseases in which the immune response is ineffective in controlling the infection.

AUTOIMMUNE IMMUNE COMPLEX–MEDIATED DISEASES

The autoimmune diseases mediated by immune complexes may be divided into three categories. The first is the autoimmune cytopenias, in which an autoantibody response to one of the cellular elements of the blood leads to accelerated clearance of that cell from the circulation. Disease results from deficiency of the cell type, from anemia, neutropenia, or thrombocytopenia, and, less commonly, from the consequences of its accelerated destruction, for example, pigment gallstones in hemolytic anemia. These diseases may be regarded as special cases of immune complex disease in which the antigen is particulate, and the mechanisms of clearance of erythrocytes are analogous to those of the immune clearance of bacteria from the circulation (40). The clearance mechanisms of antibody-sensitized cells from the circulation have been studied in detail, initially as models to explore the mechanisms of clearance of incompatible erythrocytes (41,42). Indeed, antibody-coated erythrocytes were the first examples of “model immune complexes” to be injected experimentally into humans as probes for the clearance of immune complexes from the blood in health and disease (43). The following discussion considers the results of these studies in our description of experimental studies of immune complex clearance.

In the case of the spontaneous autoimmune hemolytic anemias and autoimmune thrombocytopenic purpura, a summary of our understanding of the mechanism of the accelerated destruction of these cells is as follows and is reviewed elsewhere (44,45 and 46). IgG autoantibodies cause accelerated clearance of cells in hemolytic anemia and thrombocytopenic purpura, mainly in the spleen. An IgG coating of between 200 and 15,000 molecules per erythrocytes causes splenic clearance by red pulp macrophages in the spleen; at higher levels of IgG coating, some hepatic clearance of cells occurs (47). Some cells are cleared completely by uptake by phagocytes; others have small pieces of membrane “pinched” from their surface, and this reduces the ratio of surface area to volume of the cells (48). This provides the explanation for the presence of spherocytes in autoimmune hemolytic anemia. The identity of the autoantibody subclass also affects the severity of the anemia. The most severe hemolysis is associated with IgG3 autoantibodies, followed by IgG1, then IgG2; IgG4 autoantibodies cause minimal hemolysis. This hierarchy corresponds to the binding hierarchy of these antibody subclasses to Fc receptors IIA and IIIA (49,50).

In some cases, removal of the spleen results in near-complete resolution of disease, in spite of continuing autoantibody production. This finding illustrates that other organs, such as the liver, loaded with Kupffer cells, that carry Fc receptors, are less able to extract IgG-coated particles from the blood. There is also direct evidence for the involvement of Fc receptors on cells in the spleen in the cellular clearance process because anti-Fc receptor antibodies can block the clearance of IgG-coated erythrocytes and platelets (51).

IgM autoantibody-coated cells, as found, for example, in cold agglutinin disease, are processed in a different fashion by the mononuclear phagocytic system. There is no Fc receptor with specificity for IgM, but this isotype efficiently activates the complement system. The characteristic phenotype of erythrocytes in cold agglutinin is microspherocytic, with more than 10,000 C3dg molecules bound per erythrocyte. The liver is the main organ of clearance of erythrocytes in cold agglutinin disease (52,53). Many erythrocytes are delayed in transit through the liver, where portions of cell membranes are pinched from the cells. Cells that escape destruction are released back into the circulation with abnormal morphologic features and carry the final catabolic product of C3 cleavage *in vivo,* C3dg. These cells circulate for prolonged periods, an observation that shows that no clearance receptor exists for particles carrying C3dg in the circulation.

The second category of autoimmune immune complex–mediated disease is that in which the autoimmune response is restricted to a particular organ or to a limited range of organs. Examples are Goodpasture syndrome, membranous nephritis, myasthenia gravis, pemphigus, Graves disease, and chronic urticaria. These diseases illustrate several key and often overlooked concepts about the nature of inflammatory disease induced by immune complex formation. The first key principle is that the nature of an inflammatory response to immune complex formation may be fundamentally modified by the anatomy of the organ. In Goodpasture disease (54), the autoantigen is type IV collagen, which is widely distributed in basement membranes throughout the body (55). In the case of the kidney, because of the fenestrated

endothelium in glomeruli, the autoantigen is exposed to circulating autoantibody, and inflammatory glomerulonephritis is the cardinal feature of the disease. However, pulmonary disease develops only in about 40% of patients, in spite of the presence of the autoantigen throughout the alveolar basement membrane. Pulmonary hemorrhage is almost exclusively found in patients with pulmonary injury from smoking or, possibly, solvent exposure (56). This finding illustrates the importance of antigen accessibility for the development of immune complex disease. Only when alveolar basement membrane is exposed, for example, by neutrophil-mediated lung injury from smoking, can anti–glomerular basement membrane antibodies bind autoantigen in the lungs and cause potentially life-threatening injury.

The second key principle is that the nature of an inflammatory response may also be constrained by the anatomy of the target organ. This concept is illustrated by comparing Goodpasture disease with membranous nephritis. In the former disease, the autoantigen is fully exposed to the circulation, and the tissue injury is a severe inflammatory glomerulonephritis involving complement activation and cellular infiltration by neutrophils and mononuclear cells. In membranous nephritis and the animal model, Heyman nephritis, which has close similarities, the autoantigen is located beneath the glomerular basement membrane; in the case of Heyman nephritis, antigens are named megalin and receptor-associated protein on tubular epithelial cells (57). At this site, cells cannot penetrate the glomerular basement membrane, and immune complexes mediate tissue injury by activation of complement (58,59), which alters the filtration properties of glomeruli (58) and causes damaging protein to leak from plasma into the urine.

The third key principle is that the diseases mediated by autoantibodies to autoantigens restricted to particular tissues depend on the function of the particular autoantigen. Autoantibodies that bind to receptors may stimulate organ activity, as in the case of Graves disease in which antibodies to the thyroid-stimulating hormone receptor stimulate thyroxine production and cause hyperthyroidism, or in chronic urticaria, in which the autoantibodies are directed to the high-affinity FceRI on mast cells (60). Alternatively, the autoantibodies may lead to inflammatory destruction of organs, as occurs in myasthenia gravis, in which antiacetylcholine receptor antibodies are implicated in the destruction of motor neuron end plates on muscles.

The third category of immune complex disease resulting from an autoantibody response comprises a group of systemic diseases. These are caused either by production of an autoantibody to an autoantigen with a systemic distribution, such as essential mixed cryoglobulinemia, in that the autoantigen is IgG, or by the production of different autoantibodies that react with antigens in many tissues. Examples of this category of disease are SLE, rheumatoid arthritis, and Sjögren syndrome. Each of these diseases is considered elsewhere in this volume. Here we consider the evidence that immune complexes play a role in their pathogenesis and emphasize the heterogeneity of the effects of the autoimmune response, depending on the identity of the autoantigen.

Systemic Lupus Erythematosus and Other Systemic Autoimmune Diseases

Diseases such as SLE and rheumatoid arthritis, in which immune complexes are thought to be important in pathogenesis, are associated with prolonged autoantibody production driven by the presence of persistent autoantigen. In these diseases, immune complexes are formed in large antibody excess and tend to be large, complement-activating aggregates. The immobilization of these immune complexes in tissues, either from *in situ* formation or from deposition from the circulation, causes inflammation and organ injury. Complement is often portrayed as a villain in this situation, activated by immune complexes and contributing to inflammatory tissue injury. However, data suggest that an intact complement system may play an important role in limiting tissue injury in autoimmune disease by inhibiting the formation of large immune complexes and by promoting their disposal, together with the disposal of cellular debris such as apoptotic and necrotic cells, by the mononuclear phagocytic system (61). This protective role of complement may explain the association of inherited deficiency of classical pathway proteins of complement with the development of SLE. However, it does not exclude a proinflammatory role for complement in SLE, in circumstances in which immune complexes overwhelm the physiologic mechanisms for their clearance from tissues. Then, the proinflammatory effects of the anaphylatoxins and of the membrane attack complex are probably the main effector pathways of complement-mediated tissue injury (62,63).

Immune complexes are implicated in the pathogenesis of both renal and extrarenal injury in SLE. In animal models, anti-DNA antibodies localize under certain conditions in glomeruli (64). However, it is difficult experimentally to induce the formation of subepithelial deposits containing exogenous antigens by the infusion of immune complexes. Highly charged cationic, preformed immune complexes can produce this picture, possibly as a result of the attraction of cationic antigens or antibodies to oppositely charged anionic components of glomeruli, such as heparan sulfate and collagen type IV. The subepithelial localization of immune deposits may result from filtration forces, whereas granularity may be a consequence of the condensation of immune complexes containing polyvalent antigens into larger deposits, which may be detectable by electron microscopy (65).

In SLE, the main candidate antigens for involvement in immune complex formation in kidneys are double-stranded (ds)DNA and histones, especially when complexed as nucleosomes. Nucleosomes bind to glomerular basement membrane by charge interactions between their cationic histones and anionic components of glomerular basement membrane. Immune complexes containing nucleosomes may be deposited from the circulation, or immune complexes may form *in situ* by the binding of autoantibodies to nucleosomes trapped by the basement membrane (66).

CHRONIC IMMUNE COMPLEX DISEASES CAUSED BY FOREIGN ANTIGENS

Disease Caused by Extrinsic Foreign Antigens

Hypersensitivity pneumonitis (also known as extrinsic allergic alveolitis and in some clinical settings as farmer's lung) results in some patients from long-term exposure by inhalation to foreign antigens, and, if it is not recognized early enough, it may prove fatal. Important antigens include the spores of thermophilic actinomycetes, the usual cause of farmer's lung, and avian serum proteins, which cause bird fancier's lung. High levels of precipitating antibodies to the relevant antigen may be detected in serum of patients with pneumonitis, although similar precipitins may be detected in some persons in the absence of respiratory disease.

The typical pulmonary lesion in this syndrome is a granulomatous inflammatory response located around peripheral bronchioles. It has been modeled experimentally by inhalation of antigen or antibody into mice and other species that have been infused systemically with either antibody or antigen (67). However, this is an acute model of immune complex–mediated pulmonary injury and may not be a good surrogate for the chronic inflammatory process of extrinsic allergic alveolitis, in which evidence suggests that T-cell–mediated effects may be more important than the inflammatory consequences of immune complex formation (68).

Disease Caused by Infections

Some persistent bacterial and viral infections induce a host immune response, including an antibody response, that is not effective in eliminating the microorganism. The immune complexes that result from an antibody response in the context of the persistence of microbial antigens may play an important part in the pathogenesis of these infections. Bacterial infections at anatomic sites that are inaccessible to the host immune response are commonly associated with immune complex disease. An example is infective endocarditis resulting from chronic bacterial colonization of cardiac valvular structures, most commonly by streptococci (69,70 and 71). The clinical manifestations associated with the presence of the chronic immune response and immune complex production (72,73 and 74) include glomerulonephritis (75), rash, and splenomegaly. Infected ventriculoatrial shunts (76,77), Dacron grafts (78), and intravascular catheters and other access devices may cause a similar clinical syndrome. The antibody response to deep-seated bacterial infections resulting from *Staphylococcus aureus* and chronic respiratory infections in cystic fibrosis may be linked to chronic immune complex production, which may be associated occasionally with the development of arthritis and vascular inflammation (79).

A second category of infection that may cause chronic immune complex–mediated disease is persistent virus infections, in which infection persists in the presence of a strong antibody response. The chronic hepatitides, hepatitis B (80) and hepatitis C (81,82), and human immunodeficiency virus (83) are examples of such viral infections in which a specific antibody response coupled with persistent generation of antigen may cause immune complex disease, typically manifest as cutaneous vasculitis or glomerulonephritis. There are several models of chronic viral disease in animals, such as lymphocytic choriomeningitis virus, that, under certain circumstances, cause a prolonged disease mediated by immune complexes (84,85).

An important manifestation of hepatitis C infection is cryoglobulinemia, which may be associated with cutaneous vasculitis, peripheral neuropathy, or glomerulonephritis (86). The cryoglobulin may contain specific anti–hepatitis C virus antibodies, viral RNA, and typically IgM rheumatoid factor, which may be oligoclonal or monoclonal (87).

In addition to the development of chronic immune complex disease, the formation of immune complexes may also enhance some infectious diseases by targeting and enhancing their uptake by host cells carrying Fc and complement receptors. This is believed to be the explanation for the finding that dengue hemorrhagic fever and dengue shock syndrome occur most commonly after a second infection with a dengue virus that has a serotype different from that of the first. The presence of a subneutralizing antibody, which can not destroy the virus, leads instead to immune complex formation and uptake of the virus in the form of an immune complex through Fc receptors on macrophages, the main target cell for growth of the virus (88,89). Human immunodeficiency virus infection may similarly be enhanced by binding to Fc and complement receptors on macrophages (90).

HOW IMMUNE COMPLEXES CAUSE TISSUE INJURY

Studies of experimental models of disease mediated by immune complexes have elucidated many of the pathways of inflammatory injury. Two types of model system

have been studied. The first is a localized model of injury by immune complexes, known as the Arthus reaction. The second encompasses models of systemic immune complex disease: induced models of disease, typified by serum sickness, and spontaneous models, such as murine SLE.

Arthus Reaction

The most commonly used experimental system for studying the inflammatory effects of immune complex formation in tissues is the Arthus reaction. The original reaction described by Maurice Arthus was induced by the repeated injection of horse serum into rabbits (91). Initial injections of horse serum induced no reaction, but later injections induced an inflammatory reaction after several hours that was characterized by the presence of edema, hemorrhage, and neutrophil infiltration, which frequently progressed to tissue necrosis. The development of the reaction depended on precipitin formation in the blood, and the reaction could be blocked by systemic depletion of the precipitin by injection of large quantities of antigen.

Most investigators now use passive models of the Arthus reaction in which either antibody is infused systemically and antigen is given locally (passive Arthus reaction) or antigen is infused systemically and antibody is injected locally (reverse passive Arthus reaction). The passive Arthus reaction typically develops much faster than Arthus reactions produced by repeated antigen injection. A detailed account citing key references of early studies of the Arthus reaction is given in the classic textbook of Kabat and Mayer (92).

The traditional view of the mechanism of the Arthus reaction is of an inflammatory reaction caused by the formation of perivascular immune complexes, which activate complement. The consequences of the activation of complement are binding of C3 and C4 to the immune complexes, the production of anaphylatoxins by cleavage of C3 and C5, and generation of the membrane attack complex. The anaphylatoxins recruit and activate neutrophils and other phagocytes.

The location of the inflammatory response adjacent to small blood vessels results in activation of endothelium, which changes phenotype to allow the adhesion and emigration of leukocytes from the blood to the tissues. Activation of platelets and endothelial cells promotes local thrombosis. The Arthus reaction resolves by uptake and clearance of immune complexes by phagocytic cells through ligation of Fc and complement receptors. This picture of the Arthus reaction developed in studies of the reaction in experimental animals in which the inflammatory response was modified by depletion of cells or complement (93,94), as well as in animals with natural hereditary deficiencies of proteins such as C4 (95).

The development of gene-targeted mice with selective deficiencies in many proteins implicated in inflammatory mechanisms has led to a reevaluation of the mechanisms of the Arthus reaction, and also, to a tendency to reinvent the wheel by rediscovery of mechanisms that were well established with traditional techniques. The major shift in our understanding of the mechanisms of immune complex–induced injury has come from the use of mice with engineered deficiencies of selected Fc receptors or complement proteins. These studies have shown that the dominant mechanism of induction of inflammation by immune complexes in the Arthus reaction is by ligation of Fc rather than complement receptors (96), with FcgRIII and, to a lesser extent, FcgRI playing the major role. However, in some situations, complement may also play an important role in mediation of inflammatory injury in the Arthus reaction, as illustrated by experiments in mice with deficiency of the C5a receptor (97). New pathways of inflammation mediated by immune complexes have also been discovered, including a role for the substance P receptor (98).

The popularity of the Arthus reaction as a model for immune complex–mediated inflammation has also illustrated the extraordinary complexity of the inflammatory response to immune complexes (67). Most investigators use the reverse passive Arthus reaction, in which antigen is infused systemically and antibody (the reagent usually in shorter supply) is given locally into the tissues. This reaction can be induced in the lungs by intratracheal administration of antibody, in the skin by intradermal antibody injection, and in the peritoneum by intraperitoneal injection of antibody. Different mechanisms may be dominant at each of these sites. Moreover, differences exist in the dominant mechanisms of the Arthus reaction among species and, indeed, among various inbred strains of mice. For example, the Arthus reaction appears to be much more dependent on the complement system in rats and guinea pigs than in mice (99). Complement has a more important role in inflammation mediated by complement in CBA mice compared with C57BL/6 mice (100).

With respect to the role of different Fc receptor types, FcgRI was found to be critical in the mediation of an inflammatory response in immune complex–induced peritonitis (100). In contrast, another series of experiments showed that the expression of FcgRIII on mast cells was critical for the expression of the Arthus reaction (96,101,102 and 103).

Experimental Models of Systemic Immune Complex Disease

The Arthus reaction provides an important model to study local tissue injury by immune complexes developing in the vicinity of blood vessel walls. Many models have been developed to study systemic disease mediated by immune complexes.

Serum sickness may be induced in rabbits by the injection of a large dose of foreign antigen (104,105 and 106); the effects are similar to those seen in serum sickness in humans. With this model, it was possible to demonstrate immune complexes deposited in the glomeruli and to show that the site of immune complex deposition in the kidneys (mesangial, subendothelial, or subepithelial) varied according to the strength of the antibody response and according to whether repeated injections of antigen were given. In the presence of chronic antigen excess, the immune deposits were located in the subepithelium. These early studies were interpreted on the basis that immune complexes were passively trapped in the kidney, with the site within the glomerulus determined by the size and composition of the complex. However, it subsequently proved remarkably difficult to induce disease by the injection of immune complexes systemically into experimental animals; although it was possible to identify complexes in the mesangium and beneath the endothelium, deposits were not seen beneath the epithelium. Experiments with antisera raised against renal antigens that caused Heyman nephritis and nephrotoxic nephritis showed that it was possible to obtain subepithelial immune deposits when antibody was targeted to antigens within glomeruli (107). This led to the hypothesis that subepithelial immune complexes formed *in situ,* rather than being passively deposited from the circulation, and this hypothesis has been supported by studies (107).

Spontaneous models of murine lupus have provided additional important information about the mechanisms of tissue injury mediated by immune complexes. In particular, studies with mice null for the expression of Fc receptors and complement proteins have, in general, shown similar results to studies of the Arthus reaction. Thus, New Zealand B/W mice lacking Fc receptors I and III had antibody deposition with complement activation in the kidneys but no inflammation (108). Parallel to these results, mice lacking complement proteins C1q, C2, and factor B developed inflammatory glomerulonephritis with antibody deposits in the glomeruli in the absence of glomerular complement deposition (109).

CLEARANCE OF IMMUNE COMPLEXES

The physiologic clearance of immune complexes is facilitated both by their interaction with Fc receptors on cells of the fixed macrophage system and as a result of activation of the complement system. The mechanisms of clearance of soluble and particulate immune complexes are similar, although they differ in some important respects. Because of these differences, we consider the mechanisms of clearance separately.

Clearance of Soluble Immune Complexes

The interaction of soluble immune complexes with the complement system has two main consequences. First, the binding of complement proteins and their incorporation into the complex lattice result in physicochemical modification of the complex, thereby influencing size and solubility. Second, opsonization of immune complexes by complement, particularly C3, facilitates the ligation of specific complement receptors on a range of cells, either in the circulation or in the organs of the mononuclear phagocytic system.

COMPLEMENT MODIFIES THE STRUCTURE OF IMMUNE COMPLEXES

In the 1940s, Heidelberger discovered that immune precipitates contained more nitrogen when they formed in normal serum than in heat-treated serum (110). This was the first demonstration that complement proteins may be incorporated into immune complexes. He then showed that the “particulation” or precipitation of immune complexes from serum was inhibited by complement activation. This phenomenon was rediscovered many years later by investigators developing radioimmunoassays, who observed that complement interfered with precipitation reactions (111,112). This interaction of nascent immune complexes with complement, described as “inhibition of immune precipitation,” is primarily mediated by activation of the classical complement pathway (113,114).

Activation of complement by immune complexes not only inhibits the formation of immune precipitates but also has the capacity to solubilize immune precipitates that have already formed (115). The solubilization of immune precipitates is mediated by the alternative pathway, in contrast to inhibition of immune precipitation, which requires classical pathway activation. The covalent binding of fragments of C4 and C3 is necessary to maintain immune complex solubility. This covalent binding involves the formation of amide bonds between C4A and IgG (116,117 and 118), and ester bonds between C3B and the IgG heavy chain (119,120 and 121).

Two complementary explanations have been suggested for the mechanism by which complement proteins modify immune complex solubility. The first is that the incorporation of complement into the lattice reduces the valency of antibody for antigen by occupying sites of interaction between antibody and antigen (122). The

second explanation is that complement incorporation interferes with noncovalent Fc-Fc interactions that promote the rapid aggregation of immune complexes (123).

Only antibody isotypes that activate the classical pathway can induce complement-mediated inhibition of immune precipitation. Thus, inhibition of immune precipitation occurs with immune complexes containing IgG and IgM, but not with those containing IgA alone (124). However, the capacity of an immune complex to activate the classical complement pathway does not parallel precisely its ability to incorporate C3b into the lattice. This is of some clinical relevance. For example, complexes of monoclonal IgM rheumatoid factor and IgG, found in patients with type II (mixed essential) cryoglobulinemia, deplete complement rapidly but do not incorporate C3 effectively into the complex (125).

The solubilization of immune precipitates is associated with covalent binding of C3b to precipitated immune complexes and is inefficient, requiring a considerable amount of complement activation. Investigators have estimated that solubilization of an immune complex requires approximately one molecule of C3b to bind per antibody molecule (126). Less than 10% of activated C3 binds covalently to an immune aggregate, and it follows therefore that considerable quantities of complement are consumed during solubilization. This process may result in formation and deposition of the membrane attack complex and generation and release of anaphylatoxins into the tissues. Alternative pathway amplification is required to generate the degree of complement activation needed for solubilization. Insoluble immune aggregates act as “protected” surfaces (127) on which factor H has reduced access to bound C3b in comparison with factor B, which favors the amplification of complement activation by the amplification pathway. All the proteins of the alternative pathway, including properdin, are required. Activation of the classical pathway alone is neither necessary nor sufficient to solubilize immune precipitates, although partial solubilization by classical pathway activation has been demonstrated *in vitro* with immune precipitates (128,129).

In summary, there are two important differences between the processes of solubilization of precipitates and inhibition of immune complex precipitation. First, the capacity of the complement system to inhibit immune precipitation is tenfold greater than its capacity for solubilization, a finding that probably reflects the ease of prevention of Fc-Fc interactions and lattice enlargement, compared with disruption of a lattice that is already formed. Second, differences exist in the proinflammatory potential of the two reactions, because inhibition of immune precipitation generates smaller amounts of the anaphylatoxins and of the membrane attack complex than does solubilization (130).

IMMUNE COMPLEXES ARE USUALLY TRANSPORTED THROUGH THE CIRCULATION ATTACHED TO CELLULAR RECEPTORS

Immune complexes that are formed within the circulation, or that enter it from tissues, have to travel some distance around the body before reaching one of the organs of the fixed mononuclear phagocytic system. In many species, immune complexes travel through the circulation attached to receptors on the surface of circulating cells, rather than free in the fluid phase in plasma. On arrival in the microcirculation of the fixed mononuclear phagocytic system, immune complexes are transferred from the carrier cell to fixed macrophages (e.g., Kupffer cells in the liver). The process of the binding of immune complexes to receptors on carrier cells was first described for complement-coated microorganisms in 1915 (131). Shortly, thereafter, investigators found that trypanosomes bound to platelets in immune rats and to erythrocytes in humans and other primates (132,133). The adhesion reaction was found to be mediated by complement (134,135 and 136).

These early observations were overlooked between the late 1930s and early 1950s, and no mention is made of complement-dependent adherence reactions in two major reviews of the complement system published during this period (137,138). The field of study was restarted in 1953, when Nelson rediscovered immune adherence reactions between human erythrocytes and opsonized treponemes and pneumococci (139). The complement-dependent nature of these reactions was confirmed, and the term “immune adherence” was first suggested. A major advance in understanding the molecular basis of these reactions resulted from the isolation, by Fearon (140), of the receptor responsible for the adherence reactions of human erythrocytes, the C3b/iC3b receptor (complement receptor type 1, CR1, CD35).

CR1 binds large immune complexes and plays a role in the transport of soluble immune complexes *in vivo* in primates (141). In humans and other primates, most of the CR1 in the circulation is located in clusters on erythrocytes (142). This spatial organization of CR1 on erythrocytes facilitates high-avidity interactions with ligand, in comparison with other cell types on which the receptor is expressed as cell-surface monomers. The absolute number of CR1 molecules per red cell is low, varying between 50 and approximately 1,000 receptors per erythrocyte in humans (143,144). In contrast, there are 5,000 to 50,000 receptors per neutrophil, depending on the state of cellular activation (145). However, erythrocytes vastly outnumber other cell types in the circulation. Therefore, the red cells, in primates including humans, play a key role in the binding and transport of C3b- and iC3b-coated immune complexes and particles through the circulation.

CR1 displays an inherited polymorphism of both structure and expression levels. Because of the role of this molecule in transporting immune complexes, the hypothesis has been tested that this inherited variation of CR1 may influence susceptibility to diseases mediated by immune complexes.

Two types of genetic polymorphism of CR1 exist, each of which causes differences in the transport of immune complexes. First is a structural polymorphism. Four alleles of CR1 have been characterized, with molecular weights of approximately 210 kd (F' or C allotype), approximately 250 kd (F or A allotype), approximately 290 kd (S or B allotype) and approximately 330 kd. This variation of approximately 40 kd between allelic variants is caused by variable internal repetition of the long homologous repeats that form the structural core of the receptor. The approximately 210-kd (F' or C) allotype has reduced binding affinity for C3b dimers, corresponding to absence of one long homologous repeat containing a C3b binding site (146). This rare variant appears to have an increased prevalence among patients with SLE (147), although it is uncommon even in this population.

CR1 also exhibits an inherited numeric polymorphism of expression on red cells in the normal population, with numbers varying between 50 and 500 CR1 per erythrocyte (136,148,149 and 150) . The molecular mechanism of this numeric polymorphism has not been established, but a restriction fragment length polymorphism within the CR1 gene is correlated with high or low expression of CR1 on red cells (149).

The discovery that patients with SLE expressed fewer receptors per cell than healthy persons raised the possibility that low expression of CR1 could constitute a disease susceptibility gene for the development of SLE. However, studies have demonstrated that low expression of CR1 in SLE and in certain other conditions associated with complement activation on erythrocytes or in the fluid phase results from acquired mechanisms (151). For example, the infusion of erythrocytes bearing “normal” numbers of CR1 into patients with SLE, hypocomplementemia, and low red cell CR1, during the course of therapeutic blood transfusion, resulted in a fall in CR1 numbers on the transfused cells (152).

IMMUNE COMPLEXES INTERACT WITH OTHER CIRCULATING CELLS AS WELL AS ERYTHROCYTES

As noted earlier, neutrophils have both Fc and complement receptors. The kinetics of the interaction between neutrophil CR1 and immune complexes is different from the kinetics of the interaction between erythrocyte CR1 and immune complexes (153). CR1-dependent binding of immune complexes to circulating leukocytes is not of major importance in immune complex processing in primates. Indeed, one of the primary roles of erythrocyte CR1 may be to prevent potentially harmful interactions among immune complexes, leukocytes, and vascular endothelium by maintaining the complexes attached to red cells within the central stream of the vessel. This hypothesis is supported by *in vitro* observations that erythrocyte CR1 can protect cultured human umbilical vascular endothelial cells from immune complex–mediated and neutrophil-mediated injury (154).

SOLUBLE IMMUNE COMPLEX PROCESSING: IN VIVO *STUDIES IN ANIMALS*

The cells of the fixed mononuclear phagocytic system clear the majority of immune complexes from the circulation. In most species, including primates, rodents, and lagomorphs, the tissue macrophages of the liver and spleen are the primary sites in the circulation for clearance of foreign substances (155) and immune complexes (156). Pulmonary intravascular macrophages are also found in pigs, cows, sheep, goats, and cats, and they are important in the clearance of particles (157) and soluble immune complexes (158).

Some important findings have come from experimental studies of immune complex processing *in vivo.* First, the sites of processing of immune complexes have been delineated. Second, the receptors on circulating cells that act as transport receptors for immune complexes have been characterized, as have the receptors on the macrophages of the mononuclear phagocytic system that are responsible for the removal of immune complexes from the circulation. Third, variables in immune complex size and composition have been shown to influence clearance pathways and kinetics. In particular, the type of antigen in the immune complex may profoundly alter immune complex clearance pathways. Fourth, immune complex uptake by the mononuclear phagocytic system may, in some circumstances, be saturable. Fifth, abnormalities of the processing of immune complexes have been identified in animal models of immune complex disease, particularly models of SLE. We briefly review some of these findings and note circumstances in which variation among different species has been characterized.

In mice, guinea pigs, and rabbits, soluble immune complexes, injected intravenously, were predominantly removed in the liver and spleen (159,160 and 161), as in humans (see later; however, the complexes were not transported in the circulation bound to erythrocytes, which, in these species, do not bear CR1). Platelets in these species carry C3b receptors, and in one study, rapid *in vivo* binding of immune complexes to platelets was observed after intravenous injection (159).

The physiologic importance in primates of erythrocyte CR1 in immune complex clearance was first shown in studies with baboons (162). In decomplemented animals, the immune complexes did not bind to red cells and were cleared more rapidly, depositing in organs other than the liver, including the kidney (163). The importance of

the complement system in immune complex clearance was confirmed in this model by the observations that IgA-containing complexes, which fix complement poorly, failed to bind to baboon erythrocyte CR1, were cleared rapidly, and were localized in organs other than the liver (164).

Direct evidence indicates that the antigen component and the character of the antibody have roles in determining the mode and kinetics of clearance of immune complexes in animals. In murine studies of the clearance of immune complexes containing as antigen either orosomucoid or ceruloplasmin or their desialylated derivatives (165), the asialoorosomucoid-containing complexes were cleared 20-fold more rapidly than those containing the sialylated molecule. Blocking studies showed that the rapid clearance phase was mediated by a hepatocyte carbohydrate receptor, now known to be a member of the scavenger receptor family.

The concept of saturation of the mononuclear phagocytic system originated in studies of the clearance of carbon particles. Intravenous injection of large amounts of particles saturated the capacity for their clearance in the liver and resulted in their deposition in other organs (155). Investigators hypothesized that a similar phenomenon may exist with respect to the clearance of immune complexes, and, as discussed later, the hypothesis developed that saturation or abnormality in the clearance mechanisms for immune complexes in humans could underlie susceptibility to autoimmune disease. In experimental models, investigators showed that the capacity of the fixed macrophage system to process complexes was saturable, after the injection of escalating doses of soluble immune complexes. After “saturation” of hepatic uptake, spillover of immune complexes into other organs was observed (161). After these studies, it was found that immune complex clearance in murine models of SLE was abnormal (166), with a particular defect in the ability of macrophages to take up and retain immune complexes effectively (167). However, no evidence of saturation of immune complex uptake in murine SLE was noted (168).

SOLUBLE IMMUNE COMPLEX PROCESSING: IN VIVO *STUDIES IN HUMANS AND ABNORMALITIES IN SYSTEMIC LUPUS ERYTHEMATOSUS AND COMPLEMENT DEFICIENCY*

A range of radiolabeled model immune complexes has been used to explore the processing *in vivo* of preformed, soluble immune complexes in humans. Three model immune complexes have been employed: heat-aggregated IgG (169), tetanus toxoid (TT)/anti-TT (170,71), and hepatitis B surface Ag (HBsAg)/anti-HBsAg immune complexes (172).

Broadly comparable results have been obtained with each of these model immune complexes. The immune complexes were cleared from the circulation after fixation of complement, binding to CR1 on erythrocytes, and clearance in the liver and spleen. In SLE and other hypocomplementemic states, the immune complex clearance followed a different pattern, with reduced binding to CR1 on erythrocytes (169,171), accelerated clearance from the blood by the liver, and reduced splenic uptake (173).

In a C2-deficient patient studied before and after therapy with fresh frozen plasma to reconstitute complement activity, there was no red cell CR1 binding and no uptake of immune complexes in the spleen before therapy. Both CR1 binding and splenic uptake of immune complexes reverted to normal after correction of classical pathway complement activity (173). This result illustrates the importance of the spleen in the clearance of particulate immune complexes. It appears that the spleen clears immune complexes only if they are delivered attached to red cells. By contrast, the liver is most efficient at clearance of soluble immune complexes and shows accelerated uptake of immune complexes not bound to erythrocyte CR1.

No evidence supports the concept that the mononuclear phagocytic system in patients with SLE is saturated. However, as was found in mice with SLE (167), hepatic retention of immune complexes was abnormal in patients with SLE (173), and the mechanism is not understood.

One criticism that may be leveled legitimately at these studies of immune complex processing is that they involve the exogenous administration of large immune complexes prepared *in vitro* in the absence of complement, which may not be representative of potentially pathogenic immune complexes forming *in vivo.* However, similar results have been obtained from studies of immune complexes formed *in vivo,* both in an animal model (160) and in human patients receiving radioimmunotherapy (174). In these studies, immune complexes that formed *in vivo* also bound to erythrocyte CR1, with hepatic and splenic clearance.

Clearance of Particulate Immune Complexes

CLEARANCE OF A POTENTIAL AUTOANTIGEN: ERYTHROCYTES

We previously discussed the mechanisms of clearance of erythrocytes from the circulation in patients with autoimmune hemolytic anemias. Erythrocytes coated with IgG or IgM autoantibodies have been used as experimental probes of the function of the mononuclear phagocytic system in patients with SLE and other diseases in which immune complexes play an important role in pathogenesis. Erythrocytes coated with IgG anti-Rhesus D show impaired clearance in the spleen of patients with SLE (43,175). A similar defect has been seen in patients with other diseases associated with the presence of high levels of immune complexes, such as Sjögren syndrome (176), essential mixed cryoglobulinemia (177), and acquired immunodeficiency syndrome (178).

This impaired splenic clearance of immune complexes was initially interpreted as being a consequence of saturation of the mononuclear phagocytic system by immune complexes, and one study showed reversal of the defect in patients with SLE after treatment by plasma exchange (179). However, other studies with soluble immune complexes described earlier failed to support the hypothesis of saturation of the mononuclear phagocytic system in autoimmune disease in mice or humans. Instead, it seems more likely that there may be a defect, either primary or secondary, in Fc-receptor–mediated clearance activity associated with SLE. This is seen in the spleen in the context of the clearance of IgG-coated erythrocytes and in the liver in the context of the impaired uptake and retention of soluble immune complexes.

MEASUREMENT AND CHARACTERIZATION OF IMMUNE COMPLEXES IN THE CIRCULATION

Many different assay systems have been described for the detection of immune complexes in the circulation (180). Some were based on the ability of immune complexes to bind the first component of complement, C1q (181,182 and 183). The detection of complement proteins associated with antibodies as a marker of immune complexes has been the basis for a family of assays for immune complexes. Raji cells are a CR2-positive lymphoblastoid cell line that has been used to detect immune complexes bearing iC3b and C3dg (184). Similarly, conglutinin, which binds iC3b (185), and monoclonal antibodies binding to neoantigens of C3 (186) have been used to capture the complement component of antibody-complement immune complexes. A different approach has been to take advantage of the macromolecular nature of immune complexes to identify immune complexes by precipitation by polyethylene glycol (187).

The most common clinical indication for the measurement of circulating immune complexes has been as an aid in the diagnosis and monitoring of SLE. Many groups have reported an increase in the prevalence of circulating immune complexes in SLE (181,182,188,189,190 and 191), and some evidence also indicates that higher immune complex levels correlate with the severity of disease. However, the difficulty in the interpretation of these assays is illustrated by studies that have shown little correlation between the results with different assays and the levels of immune complexes and disease activity (182,192).

A serious problem exists with the interpretation of results from studies that measured immune complexes with C1q used as a solid-phase ligand to “capture” immune complexes. This is an assay for anti-C1q autoantibodies and not for immune complexes at all. A significant proportion of the IgG binding to C1q was shown to be monomeric in size (193,194). Purified F(ab')2 fragments of the immunoglobulin containing the C1q-binding material had the capacity to bind to C1q, and investigators also demonstrated that this material bound not to the globular heads of the molecule (which bind to immune complexes), but to the collagen-like region of C1q. The conclusion from these observations is that the C1q-binding IgG, which cosediments with normal IgG, consists of autoantibodies to C1q. This conclusion has been confirmed by affinity chromatography (195).

One can rarely identify either specific antibodies or specific antigens in immune complexes recovered from patients' samples. Mixed essential cryoglobulinemia, in which IgM rheumatoid factor (frequently monoclonal) is found, represents an exception to this rule. In SLE, much effort has been devoted to the determination of the composition and size of immune complexes. In the serum, a range of autoantibodies is easily detected, but there is little firm evidence for the participation of these autoantibodies in fluid-phase immune complexes. DNA (both single-stranded and double-stranded) and chromatin are among the most important autoantigens in SLE, but the identification of circulating immune complexes comprising anti-DNA antibodies and DNA is extremely difficult (196,197,198 and 199).

Even in immune complex disease caused by the administration of an exogenous antigen, such as drug-induced serum sickness, it is exceptional to identify immune complexes containing the relevant antigen and antibody. However, there has been occasional success in patients with bacterial endocarditis or in patients treated with large doses of streptokinase (37).

In summary, the clinical use of immune complex assays for the diagnosis and monitoring of disease is not often useful, with the exception of essential mixed cryoglobulinemia. A major underlying difficulty may be that clinically important immune complexes have only a short transit time in the circulation before clearance by the mononuclear phagocytic system or trapping in tissues. This was illustrated by a study of the formation of immune complexes *in vivo* in human patients that showed the transient presence of immune complexes in blood (174).

SUMMARY

Immune complexes are of great physiologic importance. The effects of the antibody response are mediated by the formation of immune complexes. Most of the time, the formation of immune complexes leads to the removal of antigen and the augmentation of immune responses. However, immune complexes are also an important cause of disease, and their long-term formation in the contexts of infection and autoimmunity has major consequences. Much has been learned about how immune complexes cause tissue injury from the study of patients and experimental models of disease. The availability of many strains of mice with gene-targeted deletions of key proteins of the immune and inflammatory systems has altered our perception of some of the mechanisms of tissue injury mediated by immune complexes. In particular, strong evidence is now emerging that tissue injury is predominantly mediated by ligation of activating Fc receptors, whereas complement may be friend or foe, depending on the circumstances in which immune complexes form. Some intriguing abnormalities of Fc-mediated clearance of immune complexes in patients with SLE are not understood. Much remains to be discovered about the immunobiology and pathology of immune complexes in health and disease.

26 COMPLEMENT SYSTEM

Michael M. Frank, M.D., and John P. Atkinson, M.D.

Complement is a collective term designating a group of plasma and membrane proteins that play a key role in host defense against infection. These proteins are expressed in all vertebrates, and the origins of this system predate the appearance of chordates in the animal kingdom. The complement system participates in both innate and adaptive immunity.

The complement proteins and their activation cascades serve two major functions (Fig. 26.1). First, they modify the membranes of microorganisms to promote the process of host defense. This is accomplished through opsonization and direct lysis of the organism. Opsonization refers to the coating of a target with large component fragments that are recognized by receptors on peripheral blood cells, tissue macrophages, and follicular dendritic cells (FDCs). This interaction leads to adherence and thereby immobilization of the opsonized material that facilitates phagocytosis and antigen (Ag) processing. In some situations, organisms may be directly lysed by the complement proteins. The *second* function is to promote the inflammatory response by liberating small peptide fragments from complement proteins. These peptides bind to their respective receptors to produce cellular activation phenomena such as mast cell degranulation, directed migration of motile cells (chemotaxis), and smooth muscle contraction. Thus, after complement activation, the leukocyte is directed to an inflammatory site and finds a readily ingestible target. These same events, if excessively engaged or improperly directed, such as by auto-antibodies (auto-Abs), mediate undesirable inflammation and tissue damage in autoimmunity. Some excellent books and monographs provide an in-depth discussion of the complement system (1,2,3,4,5,6,7 and 8).

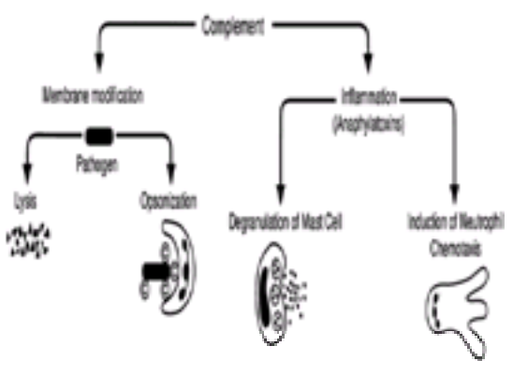

Figure 26.1. Function of the complement system. The most important function of complement is to alter the membrane of a pathogen by coating its surface with clusters of complement components (the phenomenon of opsonization). These components, in turn, facilitate interactions with complement receptors and lead to phagocytosis. In some cases, such as with certain gram-negative bacteria and viruses, the acting components induce lysis. The second function of complement is to promote the inflammatory response. The complement fragments C3a and C5a activate many cell types such as mast cells to release their granule contents and phagocytic cells to migrate to an inflammatory site (chemotaxis). (Modified from Lizsewski MK, Atkinson JP: *Primer on the rheumatic diseases,* 2nd ed. Atlanta: Arthritis Foundation, 1997, with permission.)

HISTORICAL ASPECTS

Before the discovery of antibiotics, bacterial infection was the major cause of death and disability. By the latter part of the nineteenth century, the role of specific bacteria in the pathogenesis of infectious disease was understood, and vaccination was becoming an established procedure. It seemed reasonable that a vaccination program for each bacterial pathogen would provide long-term protection and could become a general solution to the problem of infectious diseases. Analysis of the events responsible for the protective effect of vaccination against bacteria led to the discovery of the complement system (1,5,8,9).

In the 1880s, experimental pathologists demonstrated that the cell-free portion of blood lysed certain bacteria *in vitro,* and this killing property of serum was heat labile, destroyed at 56°C. This lytic factor was named *alexin.* In a classic experiment, a heat-labile factor in fresh serum of vibro immunized guinea pigs was capable of killing *Vibrio metschnikovii,* whereas the serum of control animals was not. Other investigators extended these studies to the peritoneal fluid of immunized versus unimmunized animals. Further, heat-inactivated cholera immune serum could afford protection when it was transferred to normal animals. Next, it was recognized that a heat-stable organism-specific factor (Ab) existed in the serum of immunized animals. When this was added to fresh normal serum (the source of the bactericidal or complement activity), it was able to kill the organism. The heat-labile bactericidal activity was nonspecific in that it was effective with a variety of organisms and was present in everyone. Thus, a heat-labile bactericidal factor was necessary to “complement” the heat-stable organism specific or acquired factor. In these early experiments, investigators correctly suggested that Ab combined with a specific site on a bacterial cell surface. Moreover, the Ab was correctly visualized as having a

specific Ag-recognition site as well as a distinct domain that was a binding site for complement.

At about the same time, blood transfusion specialists made a similar series of observations (10). Because the concept of blood groups had not yet been developed, some patients who received blood transfusions did well, whereas others had massive transfusion reactions. Several weeks later, when blood from a patient who had recovered from a transfusion reaction was examined, a heat-stable, specific material that recognized the transfused cells was found. In the presence of fresh serum, this factor produced lysis of erythrocytes. Thus, from these two sets of observations, the general concept of complement was born: *a heat-labile, innate, serum factor that allowed the heat-stable, acquired factor to manifest its lytic activity.* From the foregoing, it is easy to understand how the study of complement and Ab dominated immunology for the next 60 years. Moreover, the first autoimmune disease to be recognized as such in 1895 was a hemolytic anemia (paroxysmal cold hemoglobinuria) in which this same combination of Ab and complement was shown to mediate erythrocyte lysis (9).

Next, other investigations established that complement was not a single substance. Serum could be treated in a variety of ways that separated complement activity into two or more fractions. Mixing the two fractions restored activity. By the first half of the twentieth century, four distinct components of complement were recognized. During the 1960s and 1970s, techniques of modern protein chemistry allowed resolution of what was termed the *third component of complement* into six proteins acting in an ordered sequence (11). Today, we know that the lysis of Ab-sensitized erythrocytes or bacteria by the classical pathway (CP) of complement activation requires the ordered action of nine distinct components. In addition, two other pathways of complement activation and multiple inhibitors and receptors have been defined (Fig. 26.2 and Table 26.1).

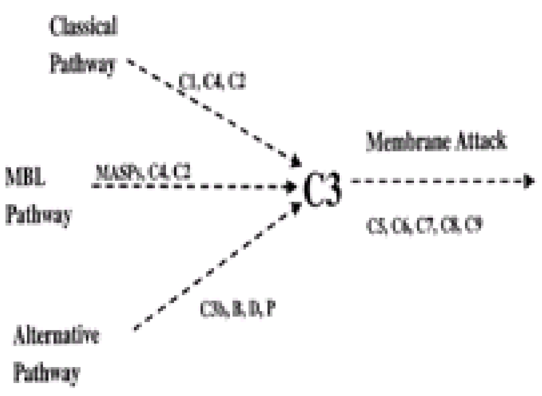

Figure 26.2. Pathways of complement activation. The three pathways of complement activation are shown. Each may lead to the activation of C3 and formation of the membrane attack complex. The classical pathway is triggered by antibody interacting with antigen, and the lectin pathway is activated by a lectin binding to a sugar. The alternative pathway is continuously turning over and becomes engaged only in the setting of a foreign material. Not shown are the anaphylatoxins, C3a, C4a, and C5a, which are liberated into the surrounding milieu. (Modified from Cooper NR. *Inflammation: basic principles and clinical correlates,* 3rd ed. Philadelphia: Lippincott Williams & Wilkins, 1999, with permission.)

TABLE 26.1. Proteins of the Complement System[a]

After the initial discovery of complement, standardized methods were needed to allow investigators to study the system. First, a choice had to be made about which test particle to examine for lysis, because this was the only function of complement then recognized. The lysis of bacteria was technically difficult to study because the bacteria had to be grown to log phase and killing determined by colony counting. In contrast, lysis of erythrocytes was easy to study. The surviving cells could be sedimented by centrifugation, and the degree of erythrocyte lysis could be determined by measuring released hemoglobin in the supernatant with a spectrophotometer. Because it was believed that the lysis of erythrocytes and the lysis of bacteria were equivalent, the decision was made to study the lysis of erythrocytes. In a similar fashion, sheep erythrocytes were chosen because, unlike the erythrocytes of most other species, they are exquisitely sensitive to the lytic action of Ab and complement. The Ab used recognized the Forssman Ag on sheep erythrocytes. This lipopolysaccharide is widely distributed in nature and is expressed by bacteria, plants, and animals. The rabbit, however, is a Forssman-negative species and responds to this Ag by developing high-titer Ab. Therefore, an assay system evolved that employed two readily prepared reagents: rabbit Ab to the Forssman Ag and sheep erythrocytes.

As the source of complement, fresh serum from various species was screened. Because guinea pig serum had the most active lytic complement, guinea pig serum became the standard for complement tests and studies. Unfortunately, important functions of complement were missed because the model system (rabbit Ab, sheep erythrocytes, and guinea pig serum) is highly artificial, and studies were limited to defining the factors that were responsible for the lysis in this system. Thus, the opsonizing role and the finding that bacteria could also be lysed by complement through activation of a series of *distinct initiating* proteins (the alternative pathway; AP) were not appreciated until relatively recently.

TERMINOLOGY

The nine proteins of the CP are designated by the uppercase letter C followed by a number (Table 26.2). These numbered components generally act in numeric order, except C4, which acts before C2 and C3. Components of the AP are designated by capital letters (e.g., factor B). Regulatory proteins are designated by a descriptive title (e.g., C4 binding protein) or, in the case of the AP, a letter (e.g., factor H). Single components or multimeric complexes that have enzymatic activity are designated by a bar (e.g., $C1\bar{s}$). The loss of hemolytic activity by a component is usually designated by a lower case prefix (e.g., iC3b). Fragments generated during complement activation are designated by a lowercase letter suffix (e.g., C3a, C3b). Except for the fragments of C2, the a fragment is smaller and is liberated into the surrounding milieu, whereas the larger b fragment becomes cell bound and continues the cascade. Receptors were named in order of their discovery, but they also are commonly noted relative to their ligand specificity or CD number (4) (Table 26.3).

Component	Molecular Weight (kd)	Serum Concentration[a] (μg/mL)
Classical pathway		
C1	750	80
C1q	410 (6 × A, B, C)[b]	
C1r	85	
C1s	85	
C4	210	200–600

TABLE 26.3. Complement Receptors

CLASSICAL COMPLEMENT PATHWAY

Binding, Activation, and Control of C1

The *classical complement pathway,* so named because it has been a major focus of study since the beginning of the twentieth century, begins with the binding and activation of the first component of complement, C1 (Fig. 26.2 and Fig. 26.3). In this pathway, the Fc portion of Ab is responsible for C1 binding and activation, although other means (e.g., urate crystals, certain bacteria and viruses) to activate C1 in the absence of Ab have been described. The isotypes of human Ab that bind C1 are immunoglobulin M (IgM) and IgG, subclasses 1, 2, and 3. IgG subclass 4, IgD, IgE, and IgA do not bind C1. The mechanism of C1 binding and activation, after interaction of Ab with Ag, is unknown. In the case of binding, there may be a distortion in the Ab Fab region such that an interaction with Ag allows the C1q subcomponent access to the CH2 domain (12,13). Another hypothesis is that aggregation of Ig leads to the apposition of multiple C1 binding domains and resultant C1 binding (12,13).

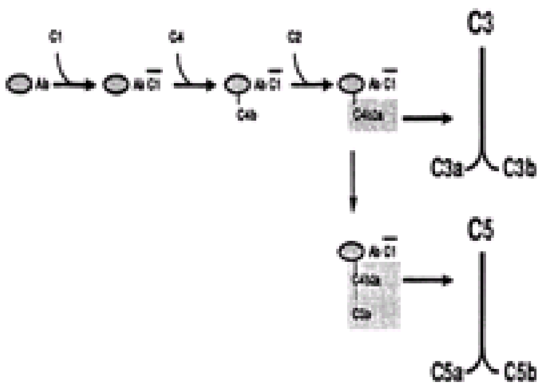

Figure 26.3. Assembly of complement convertases in the classical pathway of complement activation. Ab, antibody of immunoglobulin G (IgG) or IgM class; *circles,* antigenic target. The bimolecular C3 convertase and the trimolecular C5 convertase are *shaded.* These same C3 and C5 convertases are formed by the lectin and classical pathways. C5b continues the cascade by forming the membrane attack complex with C6, C7, C8, and multiples C9s (see Fig. 26.11). (Modified from Volanakis JE. XXXX. Volanakis JE, Frank MM, eds. *The human complement system in health and disease.* New York: Marcel Dekker, 1998, with permission.) Overview of the complement system, pp. 9–32.

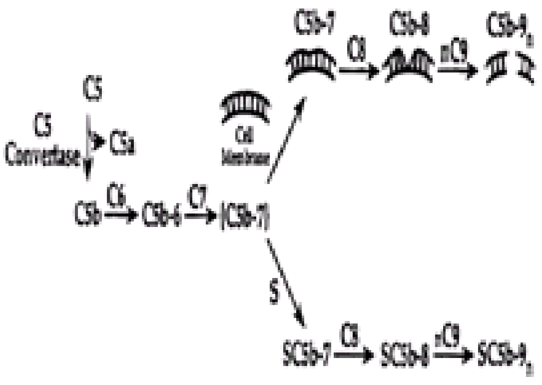

Figure 26.11. Assembly of the membrane attack complex. After the addition of C7 to the C5b-6 complex, a stable interaction with the membrane can be formed. The end result is the formation of lytically active C5b-9 (membrane attack complex) on target cell membranes or the inactive, soluble SC5b-9 complex. N, multiple (5 to 10) C9s join the complex; S, soluble (fluid-phase) complex. (Modified from Plumb M, Sodetz J. Proteins of the membrane attack complex, pp. 119–148. In: Volanakis JE, Frank MM, eds. *The human complement system in health and disease.* New York: Marcel Dekker, 1998, with permission.)

Two molecules of IgG, side by side (a so-called Ab doublet), act cooperatively to bind one molecule of C1. In contrast, a single molecule of IgM, bound to multiple Ag sites, is capable of binding and activating C1. These data point to conformational changes in the Ab molecules as well as cooperative binding of multiple Fc domains needed to form a C1 binding and activating site. A critical angle may be required among the Fab, Fc, and arms of C1 for successful activation to proceed.

The finding that two molecules of IgG side by side are required to bind one molecule of C1 has medical implications (Chapter 57) (14). Thus, sufficient Ag site density on a surface is necessary to allow two molecules of IgG to cluster sufficiently close to bind C1. On many surfaces, thousands of molecules must be deposited before an effective C1 fixing site is formed. The reason that IgG Abs to Rhesus (Rh) Ags, commonly detected in warm Ab (IgG)–mediated hemolytic anemia, do not activate complement efficiently is likely a consequence of the distribution of the Rh Ag on erythrocyte surfaces, rather than an unusual property of the Ab or complement. Alternatively, non–complement-binding Ig may intercalate between complement-binding IgG, thereby preventing effective doublet formation. This situation may occur in the meningococcal Ab response in which IgA can inhibit complement activation by IgG (14).

C1 is a complex macromolecule containing three individual protein subunits held together by calcium ion (Ca^{++}) (12,13). The largest of these subunits, C1q, binds to the Ag-Ab complex. C1q, an 18-chain molecule with six copies each of three A, B, and C chains, has a central core with six radiating, fibrillar arms (Fig. 26.4). The amino-terminal end of each arm is a triple-helical structure similar to collagen, and the carboxy-terminal end forms a globular or podlike domain. These structures form an ionic bond with the CH2 domain of IgG or IgM. By binding to multiple IgGs, C1q cross-links IgG bound to Ag and thereby stabilizes the Ag-Ab complex.

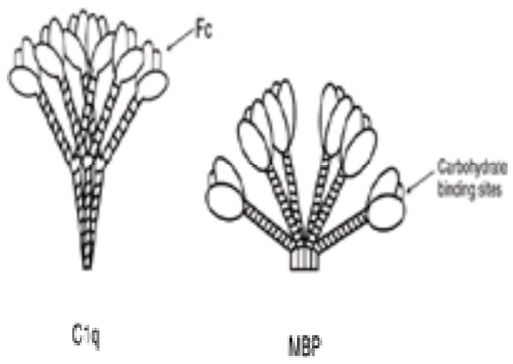

Figure 26.4. Molecular models of C1q and mannose-binding protein (MBP). The tuliplike structure protein of C1q consists of six major chains. The collagenlike sequences (shown by *cross-hatching*) adopt a triple-helical structure. Three highly homologous chains make up each of the six arms and give rise to three parts of each head. The C1$\bar{r}$ and C1$\bar{s}$ binding sites are located in the collagen regions, whereas the binding sites for the Fc regions of IgG and IgM are in the globular heads. A side view of the hexameric form of human serum MBP is shown in the panel on the **right.** In contrast to C1q, the three chains in each monomeric subunit are identical. Each head of MBP contains three C-type lectin domains. (Modified from Reid K. In: Volanakis JE, Frank MM, eds. *The human complement system in health and disease.* New York: Marcel Dekker, 1998, with permission.) Clay and mannose; binding lectin, pp. 33–48.

Associated with C1q in the presence of Ca^{++} are two chains of C1r and two chains of C1s, bound as a tetramer to the central core of the C1q. In unactivated C1, C1r and C1s are proenzyme serine esterases. Binding of C1q to the Ag-Ab presumably leads to distortion of the structure such that, in an unknown way, C1r is activated, and this, in turn, activates C1s. During activation, the two 85,000-d C1r and C1s chains undergo cleavage to a 28,000-d light chain and a 57,000-d heavy chain. The chains remain attached because of disulfide bonds. The enzymatic site on the C1$\bar{s}$ light chains cleaves the next two proteins in the complement cascade, C4 and C2.

Certain materials bind and activate C1 without the requirement for Ab binding to Ag (12). For example, monosodium urate crystals activate C1 in the absence of Ab and likely account for some of the inflammatory response in gout. Similarly, certain viral envelope proteins and bacterial surfaces bind and activate C1 in the absence of Ab. Moreover, complexes of polyions such as heparin and protamine can also activate C1. C-reactive protein (CRP), an acute-phase reactant, rises strikingly at times of inflammation (15). CRP, a lectin that binds to certain carbohydrates and phospholipids, attaches to the capsule of pneumococci and initiates the CP attack on the organism's surface. This protein, like many of the CP-initiating proteins, is a multimer, in this case featuring five identical subunits in cyclic symmetry. On one face of each subunit is a Ca^{++} containing the phosphocholine binding site and on the opposite face a cleft that contains the C1q binding site. CRP binds through multiple low-affinity interactions and then interacts with C1q to initiate the CP. Lectin-mediated activation is considered further in discussion of the mannan-binding lectin pathway.

C1 INHIBITION

C1$\bar{r}$ and C1$\bar{s}$ are regulated by the C1 inhibitor (C1-INH) (Table 26.4) (16,17 and 18). This protein binds stoichiometrically to the activated protease on each of the light chains of C1r and C1s and destroys their enzymatic activity. On binding of the inhibitor to C1, C1$\bar{r}$ and C1$\bar{s}$ are released into the fluid phase in the form of two C1r-C1s:$(C1\text{-}INH)_2$ complexes, whereas C1q remains attached to the Ab. This protease-antiprotease complex is highly stable and may be measured in plasma as a guide to C1 activation.

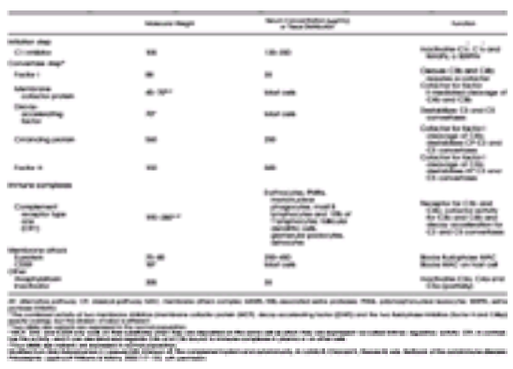

TABLE 26.4. Complement-Regulatory Proteins

The C1-INH is a member of the family of plasma inhibitory proteins called *serine protease inhibitors* (serpins) (16). Serpins provide a bait sequence that mimics the active site of substrate. When C1$\bar{r}$ or C1$\bar{s}$ cleaves the protease inhibitor at the bait sequence, a new functional site is revealed on the protease inhibitor that binds covalently to and thereby destroys the protease. In patients with hereditary angioedema, one of the two structural genes encoding for the C1-INH produces a nonfunctioning protein or no product. In this disease, patients are unable to control the activated C1 complex adequately (Chapter 30). The presence of the C1-INH has *no* influence on the activation of the CP by immune complexes. C1-INH is responsible for preventing fluid-phase activation and for degrading C1 after complement activation has occurred.

Binding and Activation of C4

The C1$\bar{s}$ subcomponent of C1 cleaves the next protein in the reaction sequence, C4. C4 is composed of three disulfide-linked chains (a, b, g) with molecular weights of 93,000, 75,000, and 33,000 d, respectively. On interaction with C1$\bar{s}$, C4 is cleaved with release of a 9,000-d C4a fragment from the amino-terminal of the a-chain. The larger C4b fragment couples covalently through an ester or amide linkage to a constituent of the cell membrane and then continues the cascade (Fig. 26.5). This remarkable ability to transfer from the fluid phase to a surface is the consequence of the action of a labile thioester bond and is essentially a nonreversible reaction. In association with C4 cleavage to C4a and C4b, C4b undergoes a major change in shape, and the internal thioester bond is broken. The reactive carbonyl species thus is immediately attached to a hydroxyl or amino group on the target of attack or becomes hydrolyzed.

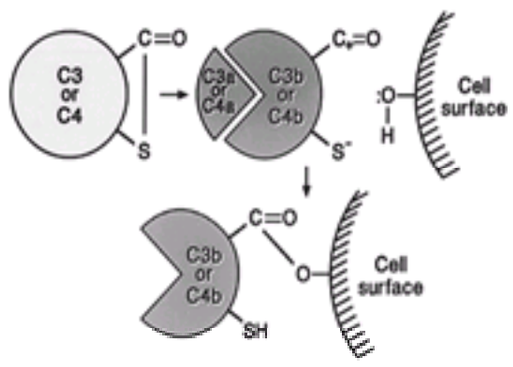

Figure 26.5. The thioester bond of C4 and C3. The activation of the thioester bond in C3 and C4 and its condensation with a hydroxyl group (formation of an ester bond). Amino groups on the target can also be engaged producing an amide linkage. (Modified from Hughes-Jones NE. The Classical Pathway, pp. 21–44. In: Ross GD, ed. *Immunobiology of the complement system: an introduction for research and clinical medicine.* Orlando, FL: Academic Press, 1986, with permission.)

Two C4A and C4B alleles code for C4 and give rise to four C4 genes in most persons (17). The proteins differ by as few as five amino acids in the a-chain. C4A tends to form amide bonds with targets, whereas C4B tends to form ester bonds. These two C4 alleles are associated with two human E blood group Ags, Chido and Rogers. The Chido and Rogers Ags are located in the C4d (thioester bond site) and are derived from plasma C4 (18,19).

Multiple C4 molecules are cleaved by C1, yet approximately 10% actually couple (the remainder are lost into the fluid phase) in a cluster about the Ag (where Ab is bound) site. Nevertheless, in this amplification process, each C1 fixed by Ab is amplified many times. For example, 10 to 20 C4s were bound per C1 in one well-studied example (20).

C4b deposited on a target is an opsonin, recognized by complement receptor type 1 (CR1), and thus is able to bind to a specific complement receptor, CR1, a process termed immune adherence. Further, certain viruses are neutralized by the deposition of multiple C4bs on their surface, and this prevents their binding to suitable host cells. The liberated C4a fragment is known as an anaphylatoxin and has weak proinflammatory activity. It is inactivated by the anaphylatoxin inhibitor (Table 26.4). C4b is inactivated in the fluid phase by the plasma regulator known as C4 binding protein (C4bp) and on self-tissue by membrane cofactor protein (MCP, CD46) (see later).

Binding and Activation of C2

C2 follows C4 in the CP cascade. This 105,000-d protein binds to C4b in the presence of magnesium ion (Mg^{++}). Once bound to C4b, C2 is cleaved efficiently by the C1s̄ subcomponent of C1, into two fragments, a small fragment C2b (34,000 d) and a large fragment C2a (74,000 d) (Fig. 26.3). The latter remains bound to C4b to form a new enzyme complex, the C3 convertase or C3 splitting enzyme. The enzymatic (catalytic domain) site resides on the C2a portion (a serine protease), and the C4b portion anchors the enzyme complex to the target. This bimolecular enzyme complex is unstable and decays spontaneously, with release of the C2a in an inactive form into the fluid phase surrounding the cell. The C4b is covalently bound to the cell surface and can accept another C2, which, in the presence of active bound C1, is then cleaved to reform the C3 convertase.

Regulation of the Classical Pathway C3 Convertase

The ability of C4b to bind C2 and to form a C3 cleaving enzyme is under strict regulatory control. C4b in the fluid phase is rapidly bound by the C4 binding protein (C4bp), which is a cofactor for a plasma serine protease factor I to cleave C4b (Table 26.4). After cleavage by factor I, the 45,000-d C4d and 170,000-d C4c fragments are rapidly cleared from the circulation. Further, C4bp binds C4b in the C3 convertase and, in so doing, displaces C2a (decay-accelerating activity), thereby destroying convertase activity. Like C1-INH, however, C4bp has no influence on CP activation on a suitable target.

Decay-accelerating factor (DAF or CD55) is a widely expressed GPI-linked membrane protein. DAF accelerates decay of the C4b2a enzyme (just like C4bp) and prevents this complex from forming (Fig. 26.6). DAF monitors host cells to dissociate convertases that form on the same cell in which DAF is expressed. DAF is one member of a group of GPI-linked proteins that are absent from erythrocyte membranes in patients with paroxysmal nocturnal hemoglobinuria (21,22). MCP is a widely expressed regulator that has cofactor activity for C4b bound to *self-tissue.* It patrols host cells and tissues and inactivates C4b. MCP acts intrinsically in that it only interacts with C4b attached to the same surface on which it is expressed. MCP serves as a cofactor (like C4bp) for factor I, and the cleavage fragments produced are as noted earlier. The C4d fragment remains covalently bound to the host cell (an immunologic scar). Thus, most cells of the body express DAF and MCP that function synergistically to prevent formation of the CP C3 convertase on host tissue (23).

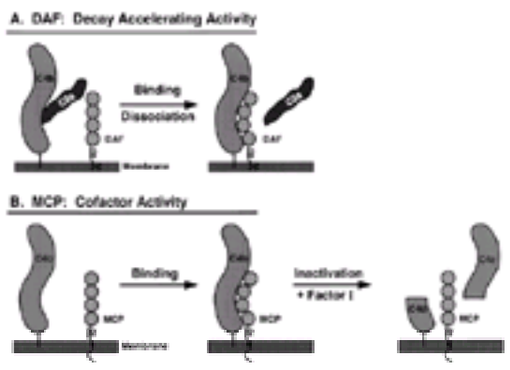

Figure 26.6. The classical pathway C3 convertase is shown. Decay-accelerating factor (DAF) displaces the protease, C2a, from C4b, and this C2a cannot rebind. To prevent C4b from interacting with a newly formed C2a, C4b is cleaved by membrane cofactor protein (MCP). The residual C4d has no known biologic activity. Classical pathway C5 convertase can be similarly inactivated. Moreover, AP C3 and C5 convertases are also disassembled in an identical fashion by DAF and MCP, except C3b is cleaved to iC3b rather than to C3dg.

CR1, a membrane-bound protein receptor for C4b and C3b, has both decay-accelerating activity for CP C3 convertase and cofactor activity for C4b (Table 26.4). This receptor is primarily expressed on peripheral blood cells including granulocytes, monocytes, B lymphocytes, approximately 15% of T lymphocytes, and erythrocytes of primates (see later). These activities likely serve to dampen complement activation by C4b- and C3b-bearing immune complexes and prepare them for transfer to immunocompetent cells in the spleen and lymph nodes.

MANNOSE OR MANNAN-BINDING LECTIN PATHWAY

A series of plasma, complement-activating, protein lectins (also known as collectins) have been defined that play a major role in innate immunity (24,25,26 and 27). The two best studied are CRP (discussed earlier) and mannan-binding lectin (MBL). Like C1q, MBL has a triple-helical “collagenlike” arms; however, instead of the arms terminating in an Ig Fc binding region, a lectin region binds to repeating polysaccharides on surfaces such as occur on microorganisms (Fig. 26.4). The polypeptide chains of MBL form oligomers, from dimers to hexamers. MBL attaches to the terminus of polymeric carbohydrate chains (mannose>GlcNAc>fucose>glucose). MBL, on interaction with an appropriate polysaccharide, binds to and activates one of three serine proteases with which it circulates in plasma, termed MBL-associated serine proteases 1, 2, 3 or MASP 1, MASP 2 and MASP 3. These serine proteases have many structural and functional similarities to C1r and C1s including Ca^{++} dependency and overall size and domain organization. On activation, MASP 2 cleaves C4 and C2, initiating the CP, just as C1 cleaves C4 and C2 (Fig. 26.2 and Fig. 26.3). The MBL pathway can be looked at as another means of activating the CP, but with its own initial proteases. MASP 1 and MASP 2, like C1r and C1s, are inactivated by the C1-INH.

The relationship of MASP 1 with complement activation is less clear. Evidence indicates that MASP 1 bypasses the early steps of the CP to cleave and activate C3 directly. Other studies suggest that MASP 1 activates MASP 2. MASP 3 has been described, and its function is still being investigated. This pathway was discovered in the 1990s, and much remains to be learned about the activation and regulation of its proteases.

C3 AND THE ALTERNATIVE PATHWAY

As discussed previously, CP C3 convertase (C4b2a) is responsible for binding and cleavage of the next component in the cascade, C3 (Fig. 26.3 and Fig. 26.7). C3, present in serum in the highest concentration of any component (approximately 1.2 mg/mL), is central to the function of the system (28). The major goal of the complement system is to deposit large quantities of clustered C3b on a target. For this reason, pathways converge at the step of C3 activation, and the steps up to C3 activation are characterized by an amplification process. Because the steps leading to the formation of AP C3 convertase mimic closely those of the CP, we now consider the AP in some detail.

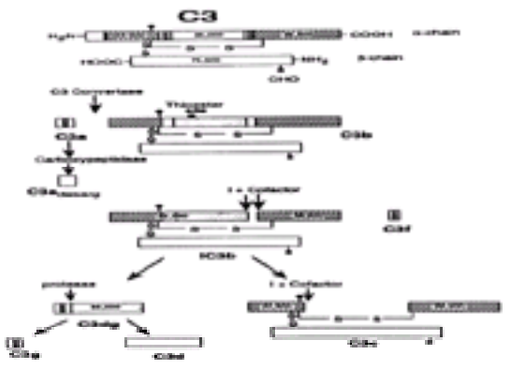

Figure 26.7. Activation and degradation of C3. The cleavage sites are indicated by *arrows.* Only disulfide bridges relevant to the degradation pattern are shown. The cleavages of C3b to iC3b by factor I require a cofactor. CR1, factor H, or membrane cofactor protein can mediate this function. Further cleavage of iC3b to C3dg by factor I is mediated by CR1. Several plasma proteases such as kininogen, trypsinlike enzymes, and others can cleave C3dg to C3d and C3g. The fragment bearing the thioester (C3b, iC3b, C3dg, or C3d) remains attached to the target. (Modified from Lambris J, and Sahu A. The Chemistry and Biology of C3, C4, and C5, pp. 83–118 (Chap. 5). In: Volanakis JE, Frank MM, eds. *The human complement system in health and disease.* New York: Marcel Dekker, 1998, with permission.)

The existence of a second pathway of complement activation was first suggested in 1954 by reports by Pillemer (29), who was interested in defense mechanisms in the unimmunized host (innate immunity). They reasoned that the components of the CP would be useful for protecting the host against infection once Ab had formed, but they thought that there must be a mechanism for defense against microbial invasion that was active before the host had time to form Ab. To explore this question, these investigators examined, in a remarkable series of experiments, the interaction with serum of an insoluble yeast particulate polysaccharide called zymosan. They discovered a factor that did not appear to be Ab but could activate complement. They named this protein properdin (from *perdere,* Latin for to destroy). Various cofactors were required for zymosan to remove this protein from serum, including a heat-labile factor and an ammonia-sensitive factor. Moreover, properdin-depleted serum had altered biologic activity in general. For example, it no longer sustained the lysis of many types of microbes *(in the absence of Ab),* or lysed the erythrocytes of patients with paroxysmal nocturnal hemoglobinuria, or neutralized certain viruses.

During the next two decades, the concepts of properdin and an AP of complement activation fell into disrepute. It was assumed that the experiments performed by Pillemer and associates reflected the depletion from serum of IgM (so-called natural Ab) antizymosan Ab that was required for complement activation. Restoration of this Ab to depleted serum would restore its complement-activating properties. Thus, properdin was thought to be a special type of Ab that was present in low titer in normal serum. The only remaining question was why absorbed serum failed to lyse a *variety* of microorganisms. If the antiyeast (zymosan) Ab cross-reacted with multiple types of microbes and cells, the failure of the absorbed Ab to lyse the microbes and cells would be explained. Later work proved conclusively that this line of reasoning was incorrect, and, during the late 1960s and 1970s, the theories of Pillemer (29), Muller-Eberhard & Schreiber (30) and colleagues were resurrected and reexamined (30). Series of proteins, similar to the early proteins of the CP, were rediscovered that constituted the AP.

Factor D

Factor D is a 24,000-d single-chain serine protease that cleaves factor B of the AP, analogous to $C1\bar{s}$ cleaving of C2 (Fig. 26.8). No evidence of activation exists for this protein, and it appears to function as a serine protease in its native state. However, it can only cleave factor B if factor B is bound to C3b. This protein is identical to a control protein in fat cells, adipsin (31).

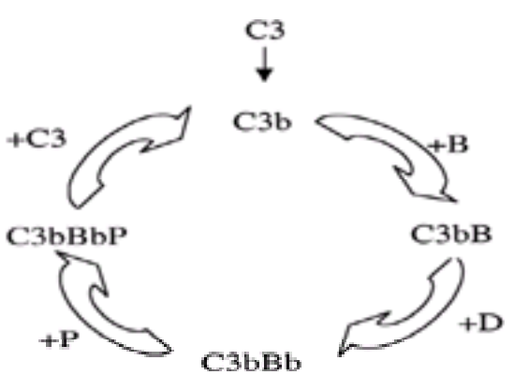

Figure 26.8. Feedback or amplification loop of the alternative pathway. If C3b is deposited on a target by the classical pathway or the lectin pathway, it then can engage the alternative pathway components shown here to generate more C3b. C3bBbP is the physiologic C3 convertase of the alternative pathway. The reaction cascade is anchored to the target by C3b. Factor D (a serine protease) cleaves factor B but only if it is bound to C3b. Properdin stabilizes the enzyme complex. The liberated Ba fragment is not shown.

Factor B

Factor B and C2 are approximately 30% homologous serine proteases, having arisen by gene duplication. As with C2, the catalytic activity is on the larger fragment of factor B (Bb) and requires Mg^{++}, like its C2 equivalent in the CP. Factor B is cleaved by factor D when it is bound to C3b, the C4b equivalent of the AP (discussed in the next section).

C3b: C4b Equivalent Protein of the Alternative Pathway

Having found a protein analogous to C1 (factor D) and one analogous to C2 (factor B), investigators believed that an AP protein analogous to C4 would also be discovered. In fact, such a protein was described during the initial studies of Pillemer (29). He defined a protein that, like C4, was sensitive to ammonia, did not require metal ions to act, and was necessary for complement activation to proceed. After a prolonged and difficult search, the protein analogous to C4 in the AP was shown actually to be C3. However, native C3 does not function in this capacity, and an understanding of the structure and function of C3 is required before continuing the discussion of the AP.

STRUCTURE AND FUNCTION OF C3

C3 is a two-chain glycoprotein with an a-chain of 110,000 d and a b-chain of 75,000 d (Fig. 26.7) (28). Within the a-chain of C3, as in the a-chain of C4, is an internal thioester bond formed between a cysteinyl and a glutamyl, just three amino acids apart (Fig. 26.5). The thioester bond between these two amino acids is highly reactive chemically and is easily attacked by nucleophiles. In the native protein, this linkage is buried within a hydrophobic pocket. If the thioester is hydrolyzed, C3 undergoes a conformational change. It then has about 60 microseconds for the reactive carbonyl group to participate in a transacylation reaction. If not, it interacts with H_2O to form $C3(H_2O)$. As such, it is no longer cleavable by AP or CP C3 convertase or able to bind covalently to cellular targets and thus has no hemolytic activity. However, the conformationally altered C3 [iC3 or $C3(H_2O)$] can interact with factor B in the presence of Mg^{++} to form a complex; in other words, it acts like cleaved C3 (i.e., C3b) (Fig. 26.8). Factor B bound to C3b or $C3(H_2O)$ can be cleaved by D to form the large fragment Bb. The complex of altered C3 [$C3(H_2O)$] or C3b with Bb, as with the complex of C4b with C2a, is an enzyme capable of cleaving native C3. This is AP C3 convertase.

Additional molecules of native C3 (with an intact thioester) are cleaved into two fragments by either CP or AP C3 convertase. The smaller 8,900-d fragment is called C3a, and the larger 185,000-d fragment is termed C3b. When C3 is so cleaved, the thioester bond is exposed. It can interact directly with an acceptor to form an ester or amide bond. The particle-bound or fluid-phase C3b, with its open thioester loop, can bind fresh factor B. Thus, two forms of C3, $C3(H_2O)$ and C3b, can act like C4b of the CP. Both bind factor B in the presence of Mg^{++} and, in the presence of a suitable factor B cleaving enzyme (factor D), the factor B is cleaved to form a C3 cleaving enzyme just as C4b binds C2 in the presence of Mg^{++} and the C2 is cleaved by C1 to form a C3 cleaving enzyme. Both $C3(H_2O)$ and C3b, which have bound

factor B, participate in AP convertase. The convertase formed interacts with native C3 (feedback loop) to lead to further deposition of C3b on the activating surface (Fig. 26.8).

As mentioned, the C3 internal thioester loop undergoes slow hydrolysis (30). The hydrolyzed molecule can bind factor B to initiate the AP. The generation of altered C3 is slow but constant. This slow hydrolytic step is likely responsible for the effects originally observed by Pillemer and colleagues. When an AP-activating substance such as zymosan is added to plasma in the absence of Ab, it is exposed to native C3. The internal thioester of the native C3 undergoes slow, spontaneous scission to yield altered C3 that can interact with B and D to form a C3 cleaving enzyme. A portion of the C3b generated by this enzymatic activity may bind to the activating surface, thus initiating and propagating complement binding to the target. The requirement for spontaneous hydrolysis of native C3 for initiation of the AP explains why this pathway requires high concentrations of serum and is relatively slow to activate. In these characteristics, it differs from the CP, which is efficiently and rapidly activated by Ab, even in dilute serum.

Properdin

To complete this discussion of the AP, we must discuss Pillemer's original protein, properdin. Properdin contains two to four 53,000-d subunits, held together by noncovalent interactions. Its function is to stabilize the AP C3 convertase by decreasing the rate of decay of $C3(H_2O)Bb$ or C3bBb. By stabilizing this enzyme, it allows continued activation of the AP (Fig. 26.8). Therefore, the key protein originally described by Pillemer and associates, properdin, is not central to AP activation scheme *per se,* but it is critical to “successful” activation by preventing rapid decay of AP convertase. In fact, without properdin, rarely, if ever, is the AP capable of depositing clusters of C3b on a target.

C3 Nephritic Factor

Under certain pathologic circumstances, an Ab is formed that recognizes C3bBb (32). This Ab, termed C3 nephritic factor (C3NeF), occurs at times in patients with systemic lupus erythematosus or partial lipodystrophy and more frequently in patients with membranoproliferative glomerulonephritis. The behavior of C3NeF is similar to that of properdin in that it stabilizes AP convertase. Such stabilization permits the convertase to remain (excessively so) in its active state, thereby allowing continued C3 cleavage. Thus, patients with C3NeF have markedly low serum C3 levels and a depleted AP system.

Function of Antibody in Alternative Pathway Activation

As is apparent from the reaction scheme, specific Ab to an Ag is not a requirement for AP activation. Nevertheless, Abs of many classes (IgA, IgG, IgM, IgE) facilitate AP activation (33). F(ab)'2 fragments of Ab trigger AP activation, in contrast to the CP, in which the Fc fragment is required. The mechanism of this effect is not clear. C3b bound to IgG resists degradation by factors H and I (34,35), so stabilization of C3b by IgG may explain part of its ability to augment AP activation. Other possibilities include alteration of physical or chemical properties of Ags by exposing or covering various chemical groups that make the Ags better acceptors for C3b. The heterodimer containing one or two molecules of C3b and one molecule of IgG has potent biologic effects, acting as a superlysin and a superopsonin (35). IgG is a preferred acceptor for C3b, so IgG-C3b complexes readily form at sites of CP activation.

The binding of C3b to a particle after C3 cleavage by either CP or AP convertase is inefficient (20). Many molecules of C3 are cleaved to C3b by each convertase, but only up to 10% of the C3bs successfully bind covalently to the particle surface. Those C3b molecules that do not bind are inactivated in the fluid phase by control proteins, namely, factor H in concert with factor I (as shown for another cofactor protein in Fig. 26.6 and Fig. 26.7).

Biologic Activity Associated with C3 Activation

As mentioned, the C3 convertases cleave native C3 into C3a and C3b (Fig. 26.7). The smaller C3a fragment is an 8,900-d peptide that is cleaved from the amino-terminal of the a-chain. C3a is a potent anaphylatoxin and binds to its receptor to produce cell activation phenomena such as histamine release from mast cells. The larger 185,000-d cleavage fragment, C3b, has many important biologic activities after it combines covalently with Ag surfaces. In addition to its ability to activate the AP and to form part of the C5 convertases (see later), C3b and its principal decay fragments comprise one of the two major opsonins (IgG being the other) of serum. Microbes or other surfaces coated with opsonins are more easily ingested by phagocytic cells bearing receptors for these ligands. Because this is a vital host defense activity and the most important function of the complement cascade, we next discuss the complement receptors that interact with C3 fragments.

COMPLEMENT RECEPTORS

The receptors and regulators of C4 and C3 are a family of closely related proteins (36,37 and 38) (Table 26.3 and Table 26.4). The regulator of complement activation (RCA) gene cluster is located on chromosome 1q 3.2 and consists of six proteins with related structural features (Fig. 26.9). C4bp and factor H are two plasma regulators, whereas DAF and MCP are two membrane regulators (Fig. 26.6). They have the same profile of regulatory activity, although the division of labor is slightly different. The other two members of this tight gene cluster are receptors and are discussed later.

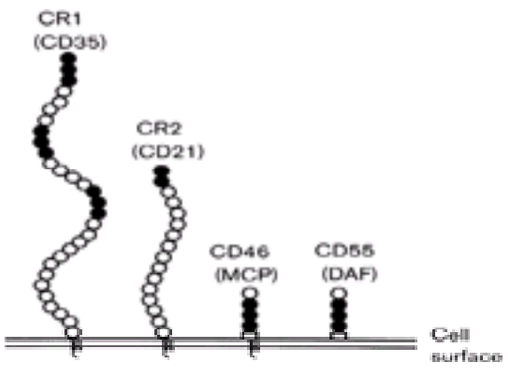

Figure 26.9. The structure of human complement membrane regulators and receptors in the regulator of complement activation family. The *circles* represent the approximately 60 amino acid repeating modules that are a prominent feature of the extramembranous portion of these proteins and contains the ligand-binding domains *(filled circles). Filled circles* indicate domains required for complement regulation and/or for binding of complement components. The *open boxes* at the juxtamembranous segment of CD46 and CD55 represent serine/threonine–rich regions that are extensively *O*-glycosylated. DAF, decay-accelerating factor; MCP, membrane cofactor protein. DAF is linked by a glycophospholipid, whereas CR1, CR2, and MCP are type 1 transmembrane proteins. (Modified from Lindahl G, Sjobring U, Johnsson E, et al. Human complement regulators: a major target for pathogenic organisms. *Curr Opin Immunol* 2000;12:44–51, with permission.)

CR1

CR1 binds C4b/C3b-bearing immune complexes (37,39,40 and 41). CR1 is a rodlike, 220,000-d (most common allelic form) protein whose extracellular domain is composed of 30 linked repeating modules known as short consensus repeats (SCRs) or complement control protein (CCP) repeats (Fig. 26.9). Twenty-eight of the 30 CCPs are grouped into 4 long homologous repeat (LHR) structures, each containing 7 repeating modules, that arose by duplication of a basic 7 CCP unit. CR1 has 3 binding sites for C4b and 2 binding sites for C3b. In addition to immune adherence (binding of C3b- and C4b-bearing immune complexes), CR1 also possesses cofactor activity for C4b and C3b and decay-accelerating activity for the C3 and C5 convertases. Cleavage of C3b to C3bi and then to C3dg or C3d is important for the proper handling and disposal of Ags (Fig. 26.7).

To facilitate further processing, these two C3b-derived products (i.e., iC3b and C3dg) can interact with other receptors (CR2, CR3, CR4) (see later). CR1, by interacting with C4b and C3b, also promotes the disassociation of CP and AP C3 and C5 convertases by displacing the C2a and factor Bb catalytic domains from the convertase. By this mechanism, CR1 may prevent unnecessary and undesirable complement activation by immune complexes.

The biologic activity of CR1 has been examined on phagocytes (39,40). CR1 is expressed on the cell membrane, but more is located on the membrane of endocytic vesicles. On cell activation, cytoplasmic CR1 is transported to the cell surface, thus leading to a severalfold increase in CR1 expression. Binding of C3b-coated particulate Ags, such as a C3b-coated erythrocyte, promotes adhesion efficiently but ingestion poorly. A second signal is required to initiate the phagocytic process. This second signal can be provided by IgG binding to the phagocyte Fc receptor, by a carbohydrate such as occurs on a bacterial surface binding to its lectin receptor, or by exposure of the phagocytic cell to the appropriate cytokines (Chapter 10). If a C3-coated Ag is bound to CR1 and then is endocytosed, it is sorted from the

endocytic vacuole and is transported into a phagocytic vacuole, where it is digested.

Erythrocytes express 100 to 1,000 CR1 per cell, the average number (approximately 300) being an inherited characteristic (41). If immune complexes form in the circulation, they may activate complement and may lead to deposition of C4b and C3b. The complexes bearing sufficient C4b or C3b attach to cells expressing CR1. Numerically, the largest pool in the blood of CR1-expressing cells is erythrocytes. Complexes bound to erythrocytes are effectively removed from the circulation (presumably to prevent deposition in tissue sites such as the renal glomerulus). Erythrocytes bearing immune complexes traverse the sinusoids of the liver and spleen, where they come into close contact with fixed phagocytes (41,42,43 and 44). Phagocytes, which express CR1, CR3, and Fcg receptors, effect a transfer of the immune complexes to their surface. The erythrocytes then leave the liver and spleen freed of their complexes and ready for another round of immune complex binding and transfer. This transfer may be simply an increased affinity for the multiple receptors on macrophages, but there is also evidence for proteolytic cleavage of CR1 near its transmembrane domain. In addition to preventing deposition of immune complexes in undesirable locations, Ags in the immune complex are delivered to the lymphoid system for processing and an immune response.

CR1 of B lymphocytes and FDCs functions in the localization and processing of Ag that is bound by Ab and complement. Triggering CR1 on B lymphocytes induces lymphokine release (45). C3b receptors are also expressed on the surface of the epithelial cells of the human glomerulus (46). In patients with glomerulonephritis who have deposition of C3 fragments in the kidney, the C3b receptors are either occupied or partially destroyed and lose their activity. How this occupation of C3b receptors on glomerular cells relates to the development of glomerulonephritis and whether the receptors ordinarily play a protective role in the kidney are still unclear.

As discussed in Chapter 57, the function of complement receptors and the concepts of first and second signals controlling phagocytosis are important for understanding the pathophysiology of diseases such as immune-mediated hemolytic anemias. In summary, in both *in vitro* and *in vivo* studies, particles coated with C3b are more easily ingested by phagocytes, but C3b is usually not a sufficient stimulus to initiate the phagocytic process. The phagocyte commonly requires one of several additional signals to proceed to ingestion of the membrane-bound particle.

CR2

The second complement receptor to be described, CR2, binds the complement degradation fragments iC3b and especially C3dg and C3d (47,48,49 and 50). This receptor is present on most B lymphocytes and FDCs but is not present on granulocytes, monocytes, or macrophages. Coligation of CR2 with the B-cell Ag receptor decreases the threshold for B-cell activation by approximately 100-fold (51,52). Further, the presence of C3 fragments such as C3d on an Ag increases its antigenicity many times (perhaps up to 10,000-fold) (52). It accomplishes this first by facilitating Ag localization and then by serving as a coreceptor for B-cell signaling through the Ag receptor. CR2 is also the receptor for the Epstein-Barr virus on B cells. The virus codes for a 350,000-d protein with a short amino acid sequence that mimics C3d and mediates binding to the CR2-expressing cell (53).

Factors H and I

Factor H is a 150,000-d plasma protein that consists entirely of 20 CCP repeating modules common to other members of the RCA class (54). It binds to C3b and possesses decay-accelerating activity for C3b-bearing convertases and cofactor activity for C3b. Factor I is a 90,000-d glycoprotein that consists of two disulfide-linked chains of 50,000 and 38,000 d. It is a serine protease that converts C3b to iC3b (Fig. 26.7). Factor I requires a cofactor protein such as factor H, MCP, or CR1. These cofactors are thought to induce a conformational change in C3b that exposes a cryptic site and thereby allows it to be cleaved by factor I. After cleavage by factor I, the cofactor is released from the complex. The cleaved C3b, known as iC3b, cannot bind factor B and therefore does not participate in the AP activation cascade. The catalytic domain of factor I is on the 38,000-d chain. The enzyme is an unusual serine protease because it is not inhibited by diisopropylfluorophosphate, soybean trypsin inhibitor, or other common inhibitors of this class of proteases.

In the common situation, C3b, attached to the surface of a foreign AP activator, binds factor B, which is then cleaved by factor D to initiate the AP (Fig. 26.8). Conversely, if C3b is bound to non-AP activator, factor H may preferentially bind and may thereby inhibit further AP function. When the AP cannot be efficiently activated on a foreign target, the surface has usually been modified to inhibit complement activation, and one mechanism for this is that it promotes factor H binding (54,55).

The chemical nature of the interaction that confers protected site status to Ag-bound C3b is unknown (54,55). In some cases, sialic acid, a charged sugar on many cell surfaces, is of key importance to this interaction. For example, sheep erythrocytes are not activators of the human AP. C3b deposited on these cells is rapidly inactivated by factors H and I. If the cells are treated with neuraminidase, which releases sialic acid, deposited C3b no longer rapidly interacts with factors H and I. Such cells, even if not sensitized with Ab, are rapidly lysed by AP activation. The strains of *Escherichia coli* and group B streptococci, which are dangerous pathogens especially for the newborn, contain sialic acid in their capsules and are poor activators of the AP. Similarly, *Treponema pallidum* has a sialic acid–rich outer coat. In other situations, microbes may escape complement activation by synthesizing their own complement regulators or by coating themselves with the host's own inhibitors (Table 26.5). To summarize, the most critical factor in allowing the AP to activate on a target is the absence of membrane regulatory proteins (in contrast to self-tissue); however, microbes have evolved mechanisms to inhibit AP by modifying their surfaces.

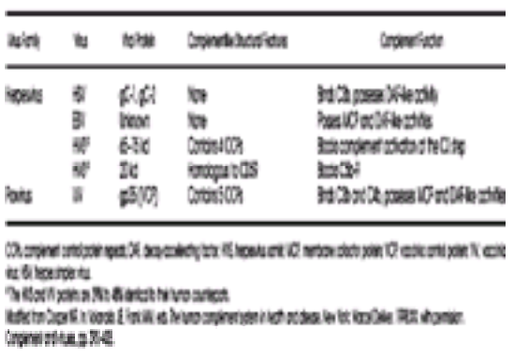

TABLE 26.5. Viral Gene Products Possessing Complement-Regulatory Functions

CR3 and CR4

Although unable to interact with the proteins of the AP, iC3b is of critical importance to host defense. Two receptors for iC3b (CR3 and CR4) are expressed on phagocytic cells. The receptors are two-chain proteins with a-chains of 165,000 and 150,000 d, respectively; both have an identical b-chain of 95,000 d. CR3 and CR4 are members of the b integrin protein family (56). The a-chain confers receptor specificity, whereas the b-chain directs the receptor into the proper configuration on the cell membrane. CR3 is expressed by phagocytes and there also exists an intracellular pool. Polymorphonuclear leukocyte activation induces its upregulation by inducing fusion of the CR3-containing vesicles with the outer cell membrane. A second signal for antigens coated with iC3b efficiently triggers ingestion. After complement activation, Ags become rapidly coated with clusters of C3b, many of which are then converted to iC3b and C3dg (see later). In this way, multiple receptors can be engaged to facilitate microbial destruction and Ag processing.

C3DG AND C3D

iC3b is converted by CR1 and factor I (cofactor activity) to C3dg (Fig. 26.7). Certain proteases, such as neutrophil elastase, can then cleave C3dg to C3d. Both C3dg and C3d interact with CR2 on FDCs and B lymphocytes. On B lymphocytes, CR2 serves as a coreceptor for the B-cell Ag receptor (47,48). On FDCs, CR2 facilitates Ag localization (49,50).

In summary, C3 is a central component of the complement system. The presence of C3b is required for AP activation and engagement of the feedback loop. C3 degradation fragments and IgG are the two major opsonins in blood and play an important role in immune adherence, Ag processing, and phagocytosis. Not surprisingly, the activation and degradation of C3 are under exquisite control. Limited cleavage to iC3b and C3dg is important in mediating phagocytosis and Ag clearance. C3b is also the entry to membrane attack complex (MAC), as part of the enzyme complex that cleaves C5. The components before C3 in the CP, lectin pathway, and AP function primarily as an amplification mechanism to produce clusters of C3b on a target.

Cobra Venom Factor

Since the beginning of the twentieth century, investigators have known that a protein in the venom of Egyptian and Asiatic cobras is capable of activating the complement system. Most animals including humans can be depleted of complement by injecting cobra venom factor (CVF). CVF is a cobra C3b homolog produced by glandular tissue in the venom site that functions like mammalian C3b (57). It differs, however, from mammalian C3b in that it is not efficiently *inactivated* by human regulatory proteins such as factors H and I; therefore, it continues to interact with AP components until the system is exhausted. Thus, CVF produces an AP convertase that cleaves C3 but cannot be properly regulated.

C5 CONVERTASES AND ANAPHYLATOXINS

The attachment of C3b to either CP or AP C3 convertase converts this enzyme to a trimeric complex capable of binding and cleaving C5 (Fig. 26.3 and Fig. 26.10). In the case of CP convertase, considerable evidence points to a preferred acceptor site on C4b for this C3b. C5 is cleaved by the C5 convertases into an 11,000-d fragment (C5a) and a large 190,000-d fragment (C5b) (see next section). C5a has anaphylatoxic activity and causes mast cells to degranulate and, further, is a potent chemotactic factor for phagocytic cells (58,59). C5a, on binding to its receptor on phagocytic cells, causes upregulation of CR1 and CR2, aggregation of neutrophils, and adherence of neutrophils to the surface of endothelial cells. Patients undergoing renal hemodialysis or cardiac bypass procedures may experience profound pulmonary dysfunction because the membranes activate the AP and thereby induce the generation of C5a (60). C5a causes neutrophil aggregation, and the neutrophil aggregates embolize to the lung.

Convertase	Classical or Lectin Pathway	Alternative Pathway
C3	C4bC2a	C3bBbP
C5	C3b / C4bC2a	C3b / C3bBbP

Figure 26.10. C3 and C5 convertases. C4b or C3b anchors the enzyme to the target. The catalytic domains are the serine proteases C2a and Bb. The C3 convertase becomes a C5 convertase when a C3b attaches to a preferred acceptor site on C4b or C3b. Properdin (P) stabilizes the alternative pathway convertases.

Another important biologic consequence of C5a generation is the directed migration of cells, particularly neutrophils, monocytes, and macrophages. When C5a interacts with these cells, it not only alters their membranes to induce adherence but also profoundly alters their migratory properties. The cells migrate along a concentration gradient to the site of complement activation. C5a plays a major role in the local response at sites of bacterial invasion and tissue injury (see later).

C5a is the most potent of the three complement-derived anaphylatoxins that cause mast cell degranulation (58). As with the anaphylatoxins mentioned earlier, C4a and C3a, the activity of C5a is regulated by carboxypeptidase N or Y, which cleaves an essential terminal arginine. Although these des-arg anaphylatoxins lose much of their anaphylatoxin activity, C5a des-arg, unlike the inactivated C3a, retains considerable chemotactic and neutrophil-activating activity. Evidence suggests that part of the effect of C5a des-arg results from its ability to bind to a cofactor, probably vitamin D binding protein in plasma, and, in this form, to mediate chemotaxis (61).

MEMBRANE ATTACK COMPLEX: FORMATION AND CONTROL

C5b is the initiating component of the MAC (Fig. 26.11 and Fig. 26.12). C5b is unstable and rapidly loses activity. Stability is conferred by the presence of C6, a C5b binding component that follows C5 in the cascade. In the presence of the next component in the sequence, C7, a C5b67 complex is formed. This complex is highly hydrophobic, and, if it is formed near the surface of a cell or bacterium with a lipid bilayer, it tends to associate with and insert into the lipid bilayer. The association is not covalent like C4b and C3b binding, but the proteins firmly attach to form a stable complex in the lipid bilayer through hydrophobic interactions. C8 and C9 interact with the membrane-bound C5b67, perturb the membrane, and produce lysis of some pathogens. If formed in the plasma at a distance from a lipid bilayer, C5b67 interacts with a plasma molecule termed S protein and is inactivated. The C5b67S-protein complex can interact with C8 and C9 but is unable to induce cell damage.

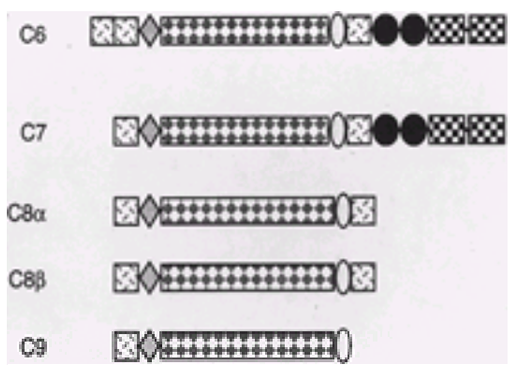

Figure 26.12. Modular structure of terminal pathway components. The structures become smaller from C6 to C9. From amino-terminal to carboxy-terminal, the proteins consist of one or two thrombospondin repeats, a single low-density lipoprotein receptor class A repeat, membrane attack complex (MAC) proteins or perforinlike segment, one epidermal growth factor–like repeat, another thrombospondin repeat, two complement control protein repeats, and last, in C6 and C7, two factor I/MAC modules. (From Morley BJ, Walport MJ. *The complement facts book.* San Diego: Academic Press, 2000, with permission.)

The molecular basis for the lytic activity of C5b-C9 continues to be intensely studied (62,63). C5b, C6, C7, C8, and multiple C9s form a macromolecular complex that resembles a cylinder, as visualized by electron microscopy. The complex has a hydrophobic outer surface and a hydrophilic central core. It tends to orient perpendicular to and within the lipid bilayer of the cell. The complex allows the free passage of water and small ions through the central hydrophilic channel, thus placing the inside and outside of the cell in communication. The cell cannot maintain its osmotic equilibrium, and it swells and lyses. In most cases, binding of C5b, C6, C7, and C8 is sufficient to cause a slow lysis of targets, including erythrocytes and some bacteria. C9 increases the rate of hemolysis. Purified C9 polymerizes when it is incubated in free solution to form a cylindric complex. It is believed that a small channel is formed in the cell membrane when C8 binds to the C5b67 complex. Multiple C9 molecules bind to the C5b678 complex. The function of C9 appears to be to bind and polymerize, thereby enlarging the pore and rapidly causing cell lysis. Although lysis of cells is emphasized in the foregoing comments, MAC insertion also produces cellular responses in many cell types in which lysis does not occur (64,65 and 66).

Even at the level of transmembrane lesion formation, the system is under considerable regulatory control. Investigators have long known that complement activation is less efficient in damaging host cells than in damaging cells from most other species. This capability, called homologous restriction, results from the presence of MAC inhibitor, CD59 (36,37 and 38). This GPI-linked membrane protein binds C8 and C9 and thereby inhibits their proper insertion into the lipid protein bilayer. Homologous restriction reflects the finding that CD59 is optimally designed to inhibit its own C8 and C9, not that of distantly related species.

COMPLEMENT IN THE INNATE AND ADAPTIVE IMMUNE RESPONSE

In 1974, Pepys reported that injection of CVF into mice to destroy normal plasma complement activity attenuated the animal's immune response (67). Klaus observed that CVF-treated mice did not generate memory B cells (68). In multiple studies, C4- or C2-deficient animals and humans did not respond efficiently to intravenous

administration of a phage Ag (51,69,70 and 71). Although producing IgM Ab, they did *not* show the normal class switch from IgM to IgG Ab or demonstrate immunologic memory on reexposure to the Ag. CR2 fused to the Fc region of IgG by molecular engineering techniques competes with cellular CR2 for C3 binding (71). By this interaction, it suppresses the Ab response to T-dependent Ags and inhibits normal isotype switching. Attachment of C3d to an Ag increases its immunogenicity by several logs and appears to serve as nature's adjuvant (52). By this mechanism, complement instructs the adaptive immune system to respond to certain Ags (Fig. 26.13). To summarize, C3d on the Ag surface instructs adaptive immunity. It links innate to adaptive immunity, amplifies the immune response, and facilitates the switch from an IgM to an IgG Ab, especially to T-cell–dependent Ags.

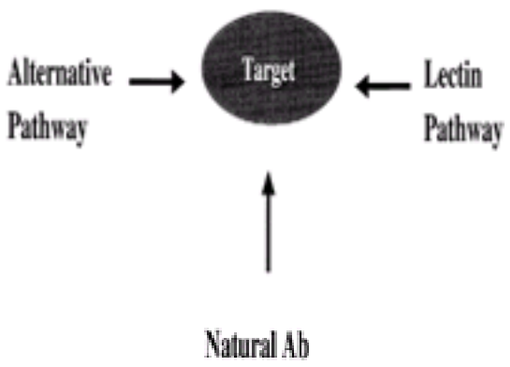

Figure 26.13. Activation of the complement system in innate immunity.

HOST DEFENSE FUNCTIONS OF COMPLEMENT IN CONTROL OF INFECTIOUS AGENTS

As discussed earlier, complement plays a key role in innate immunity. Whether by the AP, lectin pathway, or natural Ab and the CP, complement fragments are deposited on membranes of infectious agents, and the liberated fragments generate an inflammatory response at the site of contact. These events, in addition, provide instructions to the adaptive immune response, and once a specific Ab response is developed, complement is a major effector arm of Ab-mediated events.

Membrane Modification

DIRECT LYSIS

Complement forms membrane pores in susceptible bacteria and enveloped viruses (62,63). Although the exact mechanism of microbial killing is not known, in the case of susceptible gram-negative bacteria some evidence indicates that the formation of a lytic lesion triggers metabolic processes that, in turn, cause death. For complement to kill a bacterium, the organism must be in log-phase growth and not in stationary phase. Bacteria have developed mechanisms of avoiding complement-induced death. Gram-positive bacteria contain a thick peptidoglycan layer in the periplasmic space that precludes penetration by C5b-9 to the cytoplasmic membrane. Many pathogenic gram-negative organisms avoid complement lysis, an important prerequisite of spread in the circulation. For example, long-chain lipopolysaccharide appears to facilitate binding of active complement components far from the bacterial surface to avoid lysis. Numerous bacterial surface proteins also inactivate complement proteins or block their binding to preclude effective lesion formation. *Neisseria* species particularly require direct lysis for control because patients with late complement and AP deficiencies are at risk of disseminated meningococcal and gonococcal infections.

OPSONIZATION

Specific complement fragments, namely, C4b and C3b, deposit on an organism's surface, where they facilitate phagocytosis by interacting with specific receptors to immobilize the organism at the phagocyte surface. These fragments and their limited degradation products are critical for the host to control microbes. C3-deficient children develop a clinical syndrome of recurrent pyogenic infections, analogous to children with hypogammaglobulinemia and children lacking b integrins on their phagocytes (leukocyte adhesion defect), who also have frequent infections (Chapter 30).

Inflammation

Receptors for proinflammatory complement-derived peptides, C3a and C5a, signal the cell to induce movement (chemotaxis) or other cell activation phenomena. At one time, investigators believed that C3a and C5a receptors were largely restricted to granulocytes, monocytes, and mast cells (58,59). We now know that these receptors are much more widely expressed, including on endothelial cells and many types of epithelial cells (72,73). The cloning of C3a and C5a receptors and the preparation of gene-targeted mice lacking these receptors will allow a more definitive dissection of cell activation phenomenon mediated by C3a and C5a and of the role of these anaphylatoxins in health and disease.

EVASION OF COMPLEMENT BY MICROORGANISMS

In addition to the preceding examples, some microorganisms (including bacteria, viruses, fungi, and parasites) synthesize or acquire proteins that mimic the action of complement regulatory proteins (74,75 and 76) (Table 26.5). These virulence factors facilitate dissociation and degradation of active complement enzymes deposited on the surface of the organisms or bind components so they are not available to cause damage. Particularly noteworthy examples are the vaccinia CCP (77) and related proteins of other poxviruses and gC1 and gC2 of herpes simplex viruses (78). They possess cofactor and decay-accelerating activity, analogous to that of the host's own regulatory proteins. In some cases, the organism uses complement components or receptors to enter a host cell. Tuberculous and leprosy bacilli, *Leishmania,* and *Legionella* use limited complement deposited on their surface to attach themselves to phagocyte complement receptors and thereby to gain entrance (79) (Table 26.6). Mycobacteria have even been reported to synthesize a lipid that substitutes for C2a in the C3 convertase to facilitate further complement activation on their surface (80).

RCA Protein	Microorganism	Ligand in Microorganism
Membrane RCA protein		
CR2 (CD21)	EBV	gp350/220
MCP (CD46)	MV	Hemagglutinin
	Streptococcus pyogenes	M5 protein
	Neisseria gonorrhoeae	Pili
	Neisseria meningitidis	Pili
	Herpesvirus 6	Unknown
DAF (CD55)	*E. coli*	O-like antigens
	Picornavirus: Echovirus 7	Capsid
	Coxsackievirus A21	Capsid
Fluid-phase RCA protein		
C4BP	*Streptococcus pyogenes*	Some M proteins
	Bordetella pertussis	Unknown
Factor H	*Neisseria gonorrhoeae*	Porin
	Streptococcus pyogenes	Some M proteins
	Neisseria gonorrhoeae	LOS or porin
	Streptococcus pneumoniae	Unknown
	Human immunodeficiency virus type 1	gp41, gp120

DAF, decay-accelerating factor; EBV, Epstein-Barr virus; LOS, lipooligosaccharide; MCP, membrane cofactor protein; MV, measles virus.
[a] The I (Ig) -like binding domains of these proteins are composed of complement control protein (CCP) repeats and there is overlap (CR2 and EBV, CD46 and measles, and DAF and *Escherichia coli* or echovirus) between the physiologic ligands and pathogen binding sites.
Modified from Lindahl G, Stalhammar-Carlemalm M, Areschoug T: Surface protein virulence factors of Gram-positive pathogens: interaction and subversion of the human immune system. In Fischetti VA, Novick RP, Ferretti JJ, Portnoy DA, Rood JI, eds: Gram-Positive Pathogens, 2nd ed. Washington, DC: ASM Press, 2006, pp 478–496.

TABLE 26.6. Interactions Between RCA Proteins and Microorganisms[a]

BIOSYNTHESIS OF COMPLEMENT PROTEINS

Studies of the synthesis of complement proteins have proceeded largely *in vitro* in cell cultures and in established cell lines and, to a much lesser extent, *in vivo* in animals and humans. However, analysis of the polymorphic variants of complement plasma proteins after orthotopic liver transplantation indicates that they became largely those of the donor. Except for properdin (leukocytes) and C7 (granulocytes), components of the activation cascades and plasma regulators are synthesized in the liver (4). Nevertheless, peripheral blood monocytes, endothelial cells, tissue macrophages, fibroblasts, keratinocytes, and many types of epithelial cell types synthesize many different complement components and regulators. Synthesis at local sites is likely important for initiating an inflammatory response. Complement components are present in body fluids, in concentrations ranging from a few to 50% of that in serum. Especially low levels of complement proteins are found in

cerebrospinal fluid and bronchial alveolar lavage (BAL). Presumably, an extensive inflammatory reaction may be detrimental to normal organ function. On breakdown of the blood–brain or capillary–alveolar barrier, plasma proteins flood in and promote inflammation.

A major feature of the regulation of expression of many complement proteins in plasma relates to their being acute-phase proteins. Thus, under the direction of cytokines such as interleukin-1, interleukin-6, tumor necrosis factor-a, and others, complement protein synthesis may increase up to severalfold. These and other aspects relative to transcriptional control of complement proteins have been reviewed (81).

COMPLEMENT IN OTHER SPECIES

This chapter is specifically written to describe the human complement system. In general, the activating system is nearly identical for primates and other mammals as well as for birds, reptiles, and bony fishes. However, there seems to be more variation among receptors and regulators, probably because, as noted earlier, they have become the target of pathogens. Among mammals, components, inhibitors, and receptors can usually be substituted, one for the other (e.g., guinea pig for human and vice versa), but one-way or two-way incompatibilities have been noted. In general, the more closely related are the species, the more likely it is that the components will be compatible.

Some interesting differences between human and other species have been characterized, as follows:

1. Mouse complement is less stable (for unknown reasons) and less lytic; the lytic aspect is in part related to the inability to form an efficient C5 convertase except through the AP (82).
2. In the mouse, sex-limited protein (Slp) is a C4 homolog (approximately 90% identical) that has some interesting regulatory features and likely has functional activity (83).
3. There is tissue-specific expression of smaller size variants of CR1 on erythrocytes of many primates other than humans; this may relate to susceptibility to malarial infections (74).
4. In the mouse, CR1 and CR2 are expressed by a single gene with only the amino-terminal one-fourth of CR1 attached to the full-length CR2 gene (84).
5. In the rat and mouse, MCP is expressed predominantly in the testis (on the inner acrosomal membrane of spermatozoa), whereas in other tissues, a protein known as Crry, which is more closely related to CR1, is widely expressed and possesses the regulatory activity of MCP and DAF (84,85).
6. In New World primates, the first CCP repeat of MCP is spliced out, possibly related to the finding that repeats 1 and 2 are required for measles virus binding; in addition, MCP is expressed on most primate erythrocytes but not on human erythrocytes (74).
7. In the sand bass, a regulatory protein is expressed with structural and functional features of both C4bp and factor H, a finding suggesting that it is a precursor of the mammalian forms (86).

C FIXATION REACTIONS

Shortly after the discovery of complement, investigators recognized that the interaction of Ag and Ab was detectable by its effect of lowering complement titers. Thus, when Ag-Ab complexes are formed in the presence of fresh serum, the complement titer of the fresh serum falls, and the complement is said to have been fixed by the Ag-Ab complex. This test has been valuable, particularly in the study of infectious diseases, because it is sensitive, and neither the Ag nor the Ab needs to be available in purified form. Clearly, however, anything that lowers the complement titer of fresh serum is detected as an Ag-Ab complex. In most cases, this test has been replaced by enzyme-linked immunosorbent assay, flow cytometry, Western blotting, and related tests that often employ purified Ags and monoclonal antibodies to create greater specificity.

CLEARANCE OF DEAD, DAMAGED, AND APOPTOTIC CELLS AND OTHER CELLULAR DEBRIS

The complement system likely plays an important role in facilitating the removal of damaged cells (87,88). Natural antibodies, lectins, and the AP recognize altered surface characteristics of injured cells and, through opsonization, promote their efficient and safe removal (Fig. 26.13). Such a system may have evolved to promote clearance of nonviable or poorly viable tissue, especially traumatized skin and apoptotic cells. If this sytem fails, such as could happen in C1q or C4 deficiency, the individual may be predisposed to develop autoantibodies (87). Ischemia-reperfusion injury is likely to be a related situation (88). In this case, complement activation has been clearly shown to mediate damage of viable (but at risk) tissue surrounding a myocardial infarction.

IMMUNE COMPLEX HANDLING AND COMPLEMENT

The complement system is important for the processing and clearance of immune complexes (41,42,43 and 44). As immune complexes form, activation of the CP leads to C3b deposition that, in turn, prevents the immune complex from precipitating in a vessel wall or tissue site (so-called maintenance of immune complex solubility). The deposition of C3b on the Ab and Ag may reduce the ability of Ab to cross-link and therefore precipitate the immune complex. Even preformed immune complexes can be solubilized by exposure to fresh serum. The soluble immune complex, bearing clusters of C3b, then becomes bound to peripheral blood cells, especially erythrocytes. This phenomenon is called immune adherence. Erythrocytes possess more than 80% of the CR1 in blood and serve as a taxi or shuttle, taking the immune complexes to liver and spleen, where they are dissociated from the erythrocytes. Most immune complexes are destroyed in liver or spleen Ags. This transfer of immune complex from the erythrocyte to tissue macrophages may be mediated by simple affinity differences (multiple types of receptors with higher affinity for C3 fragments and IgG than CR1 on erythrocytes) and also by a proteolytic cleavage event that occurs near the stalk of CR1-bearing immune complexes. The erythrocytes then return to the circulation, minus a few of their receptors, for another round of immune adherence and immune clearance. This handling system for immune complexes evolved to keep the complexes from depositing in undesirable locations such as the kidney. Based on the foregoing discussion, it is apparent how this immune complex clearance mechanism could fail: (a) CP deficiency up to and including C3, (b) complement receptor deficiency, (c) synthesis of a non-CP fixing Ab such as IgG subclass 4 or IgA, and (d) hepatic dysfunction or after splenectomy.

COMPLEMENT IN THE IMMUNE RESPONSE

Investigators have known since the 1970s that complement depletion by cobra venom protein (see section on *in vivo* models) inhibits the immune response to a variety of T-dependent Ags (51,68,89,90). This is, perhaps, most strikingly demonstrated with the fX-174 bacteriophage in which animals deficient in C4, C2, or C3 have a weak IgM response, limited or no isotype switching, and poor immunologic memory (91). Further, Ab to CR2 decreases immune responses to T-dependent and T-independent Ags. B cells express CR1 and CR2 as well as B-cell Ag receptors. Complement binding to an Ag leads to C3dg on the Ag surface that can interact with CR2. An Ag with multiple C3dg peptides bound to its surface has a far higher affinity for the B-cell receptor because it binds the cells at multiple receptor sites (B-cell receptor or Ag receptor plus the possibility of multiple complement receptors). Thus, investigators have shown that C3d bound to Ag in model systems can increase antigenicity 100- to 10,000-fold (51,52,92). Moreover, Ag retention in germinal centers by FDCs is far more efficient when C3 fragments are bound to the Ag (93). This likely leads to continuous Ag presentation, driving the formation of Ag-specific B cells and memory cells. CR2 tends to associate on the B-cell surface with CD19, CD81, and Leu-13 (92). Aggregation of CD19 augments B-cell triggering and Ag with multiple CR2s may aggregate these accessory molecules to promote activation of B cells (47,48). Triggering of complement receptors may also induce the surface expression of cofactor molecules that facilitate the immune response. Finally, Ag with bound complement may promote B-cell and FDC interactions.

Animals with a targeted gene deletion of complement receptor CR1/CR2 have a decreased response to Ag and a failure to show normal isotype switching (49,50). Mice with the B cells lacking CR1/CR2, but with these same receptors present on FDCs, have poor initial responses to Ag and a failure to class switch (93). However, if the situation is reversed (FDCs lack CR1/CR2 but B cells are normal), then poor long-term responses and a lack of immunologic memory are noted (93).

The data, therefore, are overwhelming that complement plays a major role in augmenting the immune response and in instructing adaptive immunity. Further, C4-deficient mice and guinea pigs tend to make autoantibodies, and C4 deficiency on a predisposing genetic background makes the autoimmune disease more severe (91,94,95). Investigators have shown that C4-deficient mice, but not C3-deficient or CR1/CR2 knock-out mice, fail to induce normal tolerance to certain model Ags (94). Thus, the early steps in the CP may be important in allowing tolerance, but how this works and why C3 does not appear to be a factor are still unknown. That persons who are deficient in C1q and C4 have a strong tendency to develop autoimmune disease goes along with a failure to develop tolerance (96,97). Perhaps intimately related are reports that C1q binds to apoptotic cells to facilitate their ingestion and destruction (97). If this proves important, C1q deficiency could therefore lead to failure to handle apoptotic cells properly and could allow self-Ags to be presented to Ag-presenting cells, with a consequent autoimmune response.

ANIMAL MODELS OF DISEASE

Many *in vivo* models have been established to examine the consequences of complement activation (95). In general, these models have explored the effect of complement activation (a) in mediating tissue damage in diseases featuring immune effector mechanisms, (b) in producing inflammation in more general terms, or (c) in enhancing the afferent limb of the immune response.

Deficient and Normal Animal Models

Colonies of mice deficient in C4, C3, and factor B or C receptors and regulators have been developed using the technology of homologous recombination (70). Even before these knock-out mice were available, guinea pigs deficient in C4 or C2 or with extremely low levels of C3, rats and rabbits deficient in C6, dogs deficient in C3, and pigs deficient in factor H had been characterized (95). Further, investigators discovered in the 1960s that many strains of inbred mice were deficient in C5. Experiments with all these species clearly indicated the double-edged aspects of the complement system. Thus, compared with sufficient mice, C5-deficient animals were approximately 100-fold *more* susceptible to being killed by pneumococci but approximately 100-fold less sensitive to auto-Ab–mediated tissue injury (95).

Normal animals have been compared with animals treated with cobra venom protein that had low to undetectable AP and C5-C9 values in many studies. These studies have been informative and have been corroborated by the gene-targeted animals. CVF is a strong immunogen in most species, and, after 3 to 6 days, an immune response on the part of the recipient animals usually leads to neutralization and elimination of the protein. Thus, in contrast to experiments with gene-targeted animals, these were short-term studies.

Results of research emphasize that it is essential to separate the effects of IgG Ab working through the myriad Fc receptors on phagocytes and B cells from those induced by the various complement proteins (98,99,100 and 101). Thus, for example, it has generally been believed that the Arthus reaction, an immunopathologic inflammatory reaction caused by the formation of Ag-Ab complexes in tissue, is mediated to a great extent by local complement activation. The immigration of neutrophils in this process is thought to be caused primarily by the local formation of C5a. This concept was challenged when it became possible to generate mice by homologous recombination with C3 deficiency as well as with FcgRI and FcgRIII deficiency. Investigators reported that IgG FcgRIII was required for Arthus reaction, but not complement (98). Careful studies have shown that this is model specific, with FcgRIII playing a central role in the Arthus reaction in the skin of mice (98), but complement being of critical importance in immune complex–mediated peritonitis in mice (99) and in immune complex–mediated lung disease in rats (100). Complement is also of major importance in the immune complex–mediated skin disease of guinea pigs and rats (101). Thus, the species, experimental conditions, and genetic backgrounds are of critical importance.

Investigators have generally believed that complement activation occurring during the formation of immune complexes in serum sickness is an important factor of renal damage and vasculitis. Data obtained in rabbit models and studies of humans support that conclusion, although the evidence is indirect (95,101,102). Serum sickness is generally considered to be an excellent model of systemic lupus erythematosus.

A useful model of complement-dependent cell and tissue lysis is that of Forssman shock (95,103). Forssman Ag is a lipopolysaccharide widely distributed in nature. Animals that are Forssman negative treat this Ag as highly foreign and develop a vigorous immune response. Sheep are a Forssman-positive species, and sheep erythrocytes are coated with Forssman Ag. The rabbit is a Forssman-negative species and responds to the injection of sheep erythrocytes with high-titer anti-Forssman Ab. On injection intravenously of this rabbit Ab into guinea pigs, a Forssman-positive species, the Ab travels from the vein into the lung, where it causes massive damage that is CP dependent, with alveolar capillary fluid leakage and hemorrhage. Phagocytes are not important in this cataclysmic reaction in which death occurs within a few minutes, but the lytic activities of complement appear to be essential. This model has been used, for example, to test the effect of complement inhibitors agents in preventing tissue damage (103).

Pigs with factor H deficiency die rapidly of progressive membranous glomerulonephritis resulting from unopposed activation and abnormal regulation of the AP (104,105). Large quantities of C3 fragments are deposited in the glomerulus. A deficiency in factor H has been implicated in hemolytic-anemia syndrome, especially in the familial forms in newborn humans (105).

Animal models have demonstrated alternative methods of complement activation (106,107,108 and 109). Thus, there clearly exists a mechanism for Ag-Ab complexes to activate C1 and to bypass either C4 or C2 of the CP to recruit components of the AP and to cause damage. The mechanism that bypasses C4 is clearly less efficient than that bypassing C2. Under ordinary circumstances, it would appear that these bypass mechanisms are not used. Investigators believe that these animal models, particularly those in mice in which sophisticated genetic manipulations of the immune system and the complement system are now possible, will provide many additional answers to the function of complement in immunopathologic states.

Gene-Targeted Mice

In the 1990s, C1q, factor B, factor D, factor B/C2, C3, C4, CR1/CR2, C5aR, DAF, and Crry were all deleted by targeted insertional mutagenesis (70). Except for Crry mice (see the section on reproduction later), which is an embryonic lethal phenotype, the deficient mice developed normally. C1q, C4, C2, C3, and CR1/CR2 mice demonstrated substantial defects in T-cell–dependent immune responses and had the expected reduction in immune complex clearance. The C1q-deficient mice (depending on the background strain) had enhanced humoral immunity and glomerulonephritis (lupuslike picture) with problems in clearance of apoptotic bodies (96,97). For many of the strains with defects in the CP or AP, defective clearance of bacteria and viruses was shown on challenge. The C5aR-deficient mice had a decrease in inflammatory cell infiltrates. These mice started to be developed in the mid-1990s, and over the next decade they will be used to clarify the role of complement in host defense against infection, in the immune response, and in autoimmunity.

RESISTANCE TO LYSIS

Many cell types are relatively resistant to lysis by homologous complement. This “resistance” is, in part, attributable to regulatory proteins, especially CD59. In addition, active metabolic processes have been identified that eliminate the MAC from the cell membrane. For example, MAC protein complexes may accumulate in clathrin-coated pits, may be endocytosed, and eventually may shed through vesicle formation (64,65). In the last process, a temperature of 37°C, Ca^{++} flux, and activation of kinases, phospholipases, and adenylate cyclases have been implicated. Several variations on these intracellular activation pathways and on the shedding process have been described, depending on the cell type investigated.

In several model systems, the first complement-mediated attack on a cell confers resistance to a second. The responses to MAC presumably protect the cells' integrity and alter the cells' physiology to better it to meet a stress situation more effectively. Some of these responses include the synthesis of arachidonic acid and oxygen metabolites (in phagocytes), mediator secretion, and expression of procoagulant properties through secretion of von Willebrand factor, tissue factor, and adherence promoters. In general, these responses can be viewed as self-protective, occurring in response to a danger signal, that is, MAC assault on membrane integrity. Finally, experimental evidence implicates MAC-mediated disease in conditions featuring complement activation such as rheumatoid arthritis, lupus, and several other immune-mediated glomeruli processes, and even in demyelinating syndromes. The availability of specific inhibitors such as the monoclonal Ab to C5 should facilitate our understanding of the role of C3b deposition as opposed to MAC in causing tissue damage in conditions featuring complement activation.

REPRODUCTION

Complement components, especially C3, are prominent in the secretions of reproductive organs, and, in some cases such as the rat, they represent the dominant secreted proteins of the uterus (110,111). Rat uterus is also responsive to estrogen. MCP and DAF are located on the inner acrosomal membrane of spermatozoa. DAF, CD59, and MCP are also present in seminal fluid, in which a substantial fraction is attached to prostasomes (112). Probably, in most locations, these membrane regulatory proteins in the reproductive tract are performing the same check on complement activation as they do elsewhere. Conversely, the inner acrosomal membrane location is also consistent with a more specific role such as in gamete binding through C3 and its receptors (113). DAF, MCP, and CD59 are abundantly expressed in the placenta and trophoblast cells early in fetal development. The importance of these regulatory proteins in placental protection was most dramatically shown by knocking out the DAF/MCP equivalent protein, Crry, in the mouse (85). This phenotype was lethal with embryonic death before day 10. Examination of the developing placental tissue demonstrated an inflammatory lesion with prominent C3 deposition. The phenotype was rescued by crossing these Crry-deficient mice with C3 knock-out mice.

CLOSING COMMENTS

By the 1970s, the attitude of the general immunologic community was that there just was not much left to be learned about the complement system. In part, this was because, as a result of advances in protein chemistry, the 20 or so proteins of the CP and AP had been purified, and their place in the activation cascade had been firmly established. It was also buttressed by a perception that complement did not play much of a role in the immune response, because it was primarily an effector system. However, the identification and characterization in the 1980s of at least 10 novel receptor and regulatory proteins began a renaissance of interest in the field that continues to the present. In particular, complement is now recognized to be an important identifier of foreignness and to play an instructive role in the adaptive immune response. Cellular, reproductive, and transplantation immunologists, biotechnology companies, and clinicians have come back into the field as they begin to recognize this expanded role for the complement system. Research on the complement system has been reawakened, there is much more to learn, and the future is bright for “a simple little proteolytic cascade” (114).

Chapter References

The initial eight references are comprehensive discussions of the complement system and are excellent initial sources for further information. The other references are primarily selected to provide a highly focused review or represent more recent developments.

27 ARACHIDONIC ACID PATHWAYS

John F. Penrose, M.D., and K. Frank Austen, M.D.

Arachidonic acid pathways produce the eicosanoids, bioactive lipid derivatives that include prostanoids, leukotrienes, and lipoxins. Whereas other 20-carbon fatty acids may act as substrate for the eicosanoids, arachidonic acid is the most common fatty acid found in the sn-2 position of mammalian cell membrane phospholipids and is thus the major precursor of eicosanoids. Two major enzyme pathways catalyze different oxygenation functions of arachidonic acid to form the major classes of eicosanoids. Endoperoxide synthases (cyclooxygenases) form the intermediates for prostanoid biosynthesis, and lipoxygenases provide the intermediates for the formation of leukotrienes and lipoxins. Although all these lipid families are generally described as mediators of inflammation, their physiologic actions are directed to functions of both an autocrine and a paracrine nature.

This chapter reviews the current knowledge of the effects of the prostaglandins and leukotrienes in innate (inflammatory) and adaptive immunity. The characteristics of the genes, cDNA, and encoded proteins involved in eicosanoid biosynthesis, metabolism, and receptors are presented, and the phenotypic changes incurred as a result of gene manipulation of these molecules are addressed.

PREDOMINANT BIOLOGIC EFFECTS OF EICOSANOIDS

Eicosanoid functions are wide ranging and are frequently counterregulatory; however, pharmacologic analyses and antagonist studies in pathobiologic states have provided insight into some specific roles. At the cellular level, eicosanoid actions pertinent to physiologic and pathobiologic functions include ion channel activation (1,2 and 3), neural transmission, hormone release (4,5,6,7 and 8), cellular activation (9), adhesion (10), and structural remodeling (11,12 and 13). At the tissue and organ levels, homeostatic functions of the eicosanoids include regulation of sleep cycles, maintenance of gastric mucosa, vascular tone, blood clotting, ovulation and parturition, and immune responses (14,15,16,17,18,19 and 20) (Table 27.1). Studies with gene-manipulated mice have attempted to elucidate eicosanoid effects in the animal, but some concerns exist. First, in transgenic mice, protein expression leading to mediator generation at various sites may not represent a normal distribution. Second, in targeted gene disruption, a technique that seems particularly elegant, the absence of recognized phenotypes requires the imposition of pathobiologic stimuli to uncover a consequence of the defect, which is then rationalized in terms of some physiologic function. Clearly, the *in vitro* regulation and actions of lipid mediators cannot necessarily be extrapolated to *in vivo* situations. Hence, only the dominant inflammatory effects of eicosanoids and their presence in inflammatory conditions as determined by pharmacologic administration and gene-manipulation studies are briefly considered.

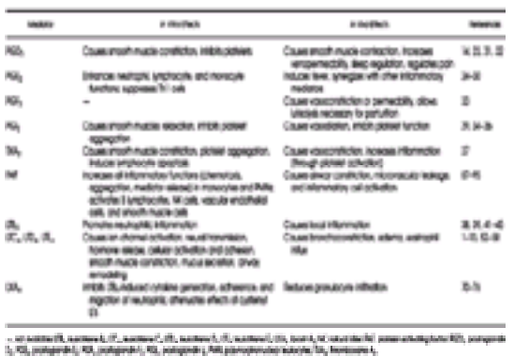

TABLE 27.1. *in Vitro* and *in Vivo* Effects of Eicosanoids

Prostaglandin D_2 (PGD_2), an important mediator of allergic responses, is synthesized by antigen-presenting cells and T-helper lymphocytes of the Th2 phenotype (21), and it is the major constitutive and inducible cyclooxygenase product of hematopoietic mast cells (22). PGD_2 constricts smooth muscle and thereby increases vascular permeability and reduces airway flow (23), regulates nociception, inhibits platelet aggregation, and induces sleep (14). PGD_2 is converted to 9a,11b-PGF_2 or to the J series of prostanoids, such as PGJ_2, d12-PGJ_2, and 15-deoxy-d12,14-PGJ_2. PGE_2 is notable for its biologic effects, which can be proinflammatory or antiinflammatory *in vitro.* Direct effects of PGE_2 on neutrophils *in vitro* are antiinflammatory, diminishing superoxide generation and leukotriene generation (24). In monocytes, PGE_2 impairs cytokine production, chemotactic migration, and adherence (25,26). PGE_2 also affects T lymphocytes; it suppresses Th1 cells relative to Th2 cells by lowering the production of interleukin-2 (IL-2) and interferon-g (27). Based on *ex vivo* culture systems, PGE_2 appears to contribute to bony erosions and periarticular osteopenia by stimulating osteoclastic activity and bone resorption and by inhibiting monocyte-induced proliferation of human bone cells (28). *In vivo,* however, there is considerable direct pharmacologic evidence for its proinflammatory potential, depending on the target cell. In the central nervous system, PGE_2 induces fever, and in the peripheral tissues it acts synergistically with other mediators such as bradykinin, C5a, histamine, and leukotriene B_4 (LTB_4) to cause typical features of early inflammation, including venopermeability and hyperalgesia (29,30) (Table 27.1).

PGF_2 functions as a potent bronchoconstricting agent in human airways; however, it appears to act minimally as a vascular agent in human skin (31,32). PGF_2 also appears to have a critical role in luteolysis, and failure of parturition is a dominant feature in mice lacking the PGF_2 receptor, as described later (33) (Table 27.1). PGI_2 induces smooth muscle vasodilatation and has an antiaggregatory effect on platelets, an effect counterregulated by the potent vasoconstrictor effects of PGF_2 and thromboxane A_2 (TXA_2) (34,35 and 36). The role of TXA_2 in cardiovascular physiology at the levels of both vascular endothelial cells and platelets balances the vasodilating and platelet-inhibiting effects of PGI_2. In addition to the hemostatic effect of TXA_2, there is enhancement of local inflammation because aggregating platelets release a variety of mediators. TXA_2 may also play a role in normal immune function in that it induces apoptosis of immature thymocytes *in vitro* (37) (Table 27.1).

The most notable effects of the dihydroxy leukotriene, LTB_4, based on *in vitro* and *in vivo* pharmacologic assays, are proinflammatory, including adhesion and directed migration of human neutrophils (38). On promoting chemotaxis, LTB_4 autoamplifies neutrophilic inflammation by mediating adhesion, migration, and accumulation of additional activated neutrophils and by stimulating degranulation (38,39). LTB_4 and the cysteinyl leukotriene, LTC_4, stimulate the development of bone marrow cells into both myeloid and erythroid progenitors (40). *In vitro* effects of LTB_4 on T cells include upregulation of the expression of the IL-2 receptor-b and cytotoxic activity (41,42). In monocytes, LTB_4 stimulates production of bioactive and immunoreactive IL-6 preferentially over IL-1 (43,44). B lymphocytes respond to LTB_4 with enhanced activation and immunoglobulin production (45). However, 5-lipoxygenase (5-LO), 5-LO–activating protein (FLAP), and LTA_4 hydrolase gene disruptions have no resting phenotypes, whereas each exhibits some attenuation in one or more models of inflammation. Leukotrienes have been implicated, on the basis of their presence and known effects, in inflammatory bowel disease (46), as well as in the skin lesions of psoriasis (47); they are also present in the synovial fluid of patients with gout, rheumatoid arthritis, and osteoarthritis (48,49,50 and 51).

The most dominant known effects of cysteinyl leukotrienes occur in bronchial asthma and relate to constriction of microvascular and airway smooth muscle that

increases venular permeability and attenuates pulmonary function (52,53). Constriction of bronchial smooth muscle in response to cysteinyl leukotriene inhalation, as in asthma, is dose dependent, temporally distinct, and more severe than that caused by histamine and methacholine (53,54). Additional features of asthma mediated by cysteinyl leukotrienes include submucosal edema from increased venular permeability (55), infiltration of eosinophils and lymphocytes (56,57), and changes of remodeling (58). Many of these features caused by leukotrienes are also present in patients with adult respiratory distress syndrome, chronic obstructive pulmonary disease, and neonatal pulmonary hypertension (59,60 and 61). The proinflammatory effects of cysteinyl leukotrienes are abundantly supported by the short-term and long-term clinical efficacy of antileukotriene drugs (62,63,64,65,66,67,68 and 69). Indeed, the relief of airway obstruction experienced by about two thirds of patients with asthma in the first hour after ingestion of these agents reveals a long-term overproduction of these mediators, because the antileukotriene drugs are not intrinsically bronchodilatory (66) (Table 27.1).

Lipoxygenase interaction products or *lipoxins* are formed by the transcellular metabolism of the respective 5- and 12-lipoxygenase-generated lipids. Lipoxins A_4 and B_4 (LXA_4 and LXB_4) function as endogenously produced chalones or "stop" signals that attenuate the effects of proinflammatory leukotrienes. They inhibit both LTB_4 and cytokine generation and the effects of LTB_4 such as adherence and migration of neutrophils and its attendant venopermeability (70,71,72,73,74 and 75). In a rat model of allergen-induced responses, LXA_4 reduces eosinophil trafficking (76) (Table 27.1).

BIOSYNTHESIS OF EICOSANOIDS

Release of Arachidonic Acid from Membrane Phospholipids

The generation of both prostaglandins and leukotrienes begins with an appropriate cell-activation signal that results in the release of arachidonic acid from cell membrane phospholipids through the action of phospholipase A_2 (PLA_2) (Fig. 27.1). Within the large family of PLA_2 isoenzymes, type IV has been established as essential to both the prostanoid and the leukotriene pathways, whereas types IIA and V have been implicated in amplification steps.

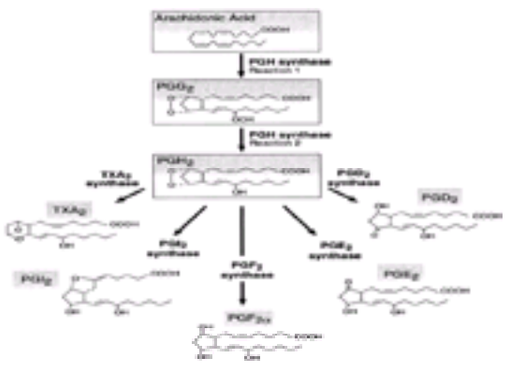

Figure 27.1. Chemical structures and biosynthetic pathways of prostanoids.

At least 16 PLA_2 isozymes exist, differing in molecular weight, subcellular localization, biochemical requirements, and preference for substrate (77). The PLA_2 isozymes have been categorized into 5 families on the basis of homology and structure. The structurally related approximately 14-kd low-molecular-weight enzymes, groups I, II, V, and X, are also referred to as secretory PLA_2 enzymes. These isozymes are characterized by conservation of 12 to 16 cysteine residues and highly homologous catalytic and calcium-binding domains (77). Within this family, group IIA PLA_2 is present in granules of mast cells and platelets, a finding suggesting a downstream extracellular function, compatible with its prominence in inflammatory exudates (78,79,80 and 81). The binding of PLA_2 group IIA and related family members to M-type approximately 180-kd transmembrane PLA_2 receptors implicates a signal transduction function that is not dependent on the catalytic domain (82,83). Bone marrow–derived mast cells from mice with a natural disruption of group IIA PLA_2 can generate cysteinyl leukotrienes and PGD_2 (77), and the extracellular role of group IIA PLA_2 is attributed to receptor-mediated group IV PLA_2-dependent eicosanoid production. Group V PLA_2 is localized to the endoplasmic reticulum and related organelles (84), and it is believed to work in concert with group IV PLA_2 to amplify prostanoid biosynthesis in macrophages and mast cells, possibly by induction of prostaglandin endoperoxide synthase-2 (PGHS-2) (77,83,84 and 85).

Group IV PLA_2, referred to as cytosolic PLA_2 ($cPLA_2$), is relatively specific for arachidonic acid hydrolysis from phospholipids and has no amino acid homology to the group I or group II PLA_2 enzymes. Group IV PLA_2 is located in the cytoplasm of cells in its mature 85-kd form. Cell activation results in micromolar increases of calcium and causes translocation of group IV PLA_2 to the perinuclear membrane and augmented function through membrane-associated protein kinase–dependent serine phosphorylation (86,87). The full-length human cDNA and the deduced amino acid sequence reveal motifs for a calcium (Ca^{++})-dependent lipid-binding domain and a plextrin homology domain that may be involved in the association of $cPLA_2$ with the cell membrane. The gene of group IV $cPLA_2$ is on chromosome 1q25, and the 3.4-kb transcript is widely expressed constitutively but is further inducible with cytokines such as IL-1, tumor necrosis factor, and IL-3 (88).

The SN-1 ether-linked lysophospholipid moiety with the general structure alkylacetyl-glyceryletherphosphorylcholine that remains after the release of the arachidonic acid from cell membrane phospholipids is termed lyso-platelet-activating factor (lyso-PAF). This moiety acts as both a precursor and a metabolite of PAF, a mediator with intrinsic bioactivity, controlled by inactivation through a specific acetylhydrolase (89,90). PAF effects, which include increased chemotaxis, aggregation, superoxide generation, cytokine production, and cytotoxic function in monocytes and also increased leukotriene generation in granulocytes, are transduced through a G protein–coupled serpentine PAF receptor to activate $cPLA_2$ (91,92,93 and 94). Other cells that exhibit increased bioactivity in response to PAF include B lymphocytes, natural killer cells, vascular endothelial cells, and smooth muscle cells (91,92,93,94,95 and 96). At the tissue level, PAF also causes airway constriction, microvascular leakage, and inflammatory cell activation; however, these effects are at least partially mediated through the release of secondary mediators, specifically cysteinyl leukotrienes (97,98 and 99).

The effects of the PAF receptor have been explored in the mouse with both transgenic overexpression and gene disruption. PAF receptor transgenic mice showed a bronchial hyperreactivity to methacholine challenge, which was inhibited by pretreatment with either a thromboxane synthesis inhibitor or a cysteinyl leukotriene antagonist; this finding suggests that both TXA_2 and cysteinyl leukotrienes are involved in the bronchial responses to PAF or cholinergic stimuli (100). Disruption of the PAF receptor gene allowed mice to develop normally and to remain sensitive to bacterial endotoxin. However, systemic anaphylactic symptoms were markedly reduced, a finding clearly showing that PAF plays a dominant role in eliciting anaphylaxis but is not essential for reproduction or endotoxic shock (101).

Prostanoid Generation

The prostaglandins are fatty acid derivatives of 20-carbons in which a five-membered prostane ring separates the olefinic bonds; thromboxanes contain a six-membered ring. The numeric subscript represents the number of carbon-carbon double bonds in the side chains. Most naturally occurring prostaglandins have two aliphatic side-chain bonds, named the a and w chains, known as the "2" series. In diets rich in fish oils, eicosapentaenoic acid gives rise to the "3" series, which, in the case of thromboxane, creates a product with attenuated function relative to the "2" series as assessed by platelet aggregation. The corresponding PGI_3, which is the only other eicosanoid produced in significant amounts, is essentially equally active in platelet aggregation (102). Modifications in the cyclopentane ring result in prostaglandins that are classified from A to I; however, A, B, and C are produced only artificially during procedures of extraction. Prostaglandins G and H share a similar ring structure but differ with the presence at C-15 of either a hydroperoxyl group or a hydroxyl group, respectively (Fig. 27.1).

PROSTAGLANDIN H SYNTHASE-1 AND PROSTAGLANDIN H SYNTHASE-2

The prostaglandin H synthase isozymes, PGHS-1 and PGHS-2, known also as cyclooxygenase-1 and -2, catalyze the two initial reactions in the biosynthesis of the prostanoids (Fig. 27.1, Table 27.2). Arachidonic acid is dioxygenated at positions C-11 and C-15 to form the bicyclic peroxide PGG_2, which, on migration to the peroxidase active site of the PGHS enzyme, is converted to PGH_2. Cell- and tissue-specific terminal enzymes then convert PGH_2 to other cyclic endoperoxides, such as TXA_2 or PGI_2, PGD_2, PGE_2, and PGF_2; the individual effects of these mediators are noted in the preceding section. Prostanoids responsible for many normal homeostatic functions in tissues such as the stomach and kidney are formed through the action of the constitutive PGHS-1 isozyme. In these organs, the cytoprotective effects of prostaglandins provided by PGHS-1 are implicated, and susceptibility to toxic effects from nonselective PGHS inhibitors occurs (103). In contrast, the

generation of prostanoids such as prostacyclin (PGI_2) and PGE_2 in inflammatory responses (104) is attributed to the PGHS-2 isozyme, which is prominently expressed in inflammatory cells such as monocytes, macrophages, synoviocytes, and fibroblasts. PGHS-1 and PGHS-2 are isozymes with 61% overall amino acid identity, each with distinct substrate specificities and binding characteristics, mechanisms of regulation, and tissue expression (Table 27.2). Both isozymes are integral membrane proteins of approximately 68-kd molecular weight, with a subcellular localization in the endoplasmic reticulum and nuclear envelope, although some data suggest that they use distinct lipid pools (105).

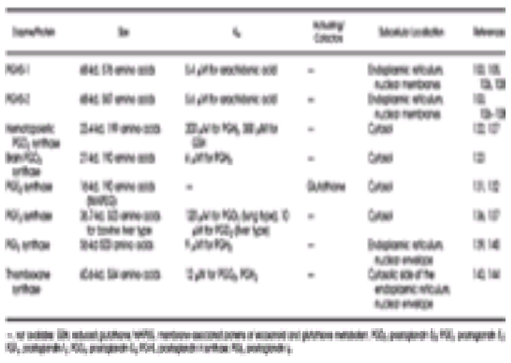

TABLE 27.2. Molecular and Biochemical Characteristics of Prostanoid Biosynthetic Enzymes

The biochemical and structural features of these isozymes are critical for the development of selective drugs to inhibit only the PGHS-2 isozyme, in an effort to avoid toxicity (106,107 and 108). Valeryl salicylate selectively inhibits PGHS-1, whereas compounds such as NS-398, celecoxib, and rofecoxib act selectively on PGHS-2 (109). Crystallographic structure analysis of both isozymes of PGHS reveals Val (instead of Ile) at position 523 in the active site of PGHS-2, as well as a slightly larger active site channel, thereby allowing isozyme discrimination with selective inhibitors (110,111).

The human transcript for PGHS-1 is detected as either 2.8 or 5.2 kb on RNA blot analysis, presumably because of the presence of a canonical polyadenylylation site 0.75 kb downstream from the translation termination codon, a finding suggesting alternative polyadenylylation of the PGHS-1 gene (112). The sequence of the 3'-untranslated region of the PGHS-1 transcripts is highly divergent from that of the human PGHS-2 transcript isoforms, a finding suggesting a distinct function in the regulation of expression at the posttranscriptional and translational levels. PGHS-1 has generally been described as constitutive in all tissues, with only modest increases of inducibility.

The 4.5-kb human PGHS-2 cDNA encodes a polypeptide of 604 amino acids, although various levels of glycosylation affect its approximate 68-kd size, as determined by sodium dodecyl sulfate-polyacrylamide gel electrophoresis. Both PGHS-1 and -2 mRNAs are expressed in human endothelial cells, vascular smooth muscle cells, monocytes, and fibroblasts. However, a high-level induction of the PGHS-2 transcripts by phorbol 12-myristate 13-acetate, lipopolysaccharide, mitogens, inflammatory cytokines, and growth factors suggests a role for PGHS-2 in the inflammatory response; this induction is downregulated by glucocorticoids (113,114,115,116 and 117). Only the PGHS-2 isoform is decreased by glucocorticoids, an effect caused by reduced transcription and mRNA stability (116), characteristic of the family of glucocorticoid-sensitive inflammatory response genes. The PGHS-1 gene is a TATA-less, 22-kb, 11-exon gene on chromosome 9 (118,119), and the PGHS-2 gene is a TATA-containing, 8-kb, 10-exon gene on chromosome 1 (120,121) (Table 27.3).

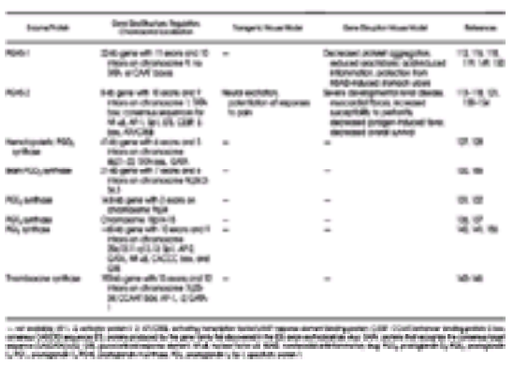

TABLE 27.3. Characteristics of CDNAs/Genes of the Prostanoid Biosynthetic Enzymes

The physiologic effects of the downstream prostanoids from PGH_2 affect all cells, tissues, and organ systems. The presence of biosynthetic enzymes and receptors for the prostanoids is regulated in both positive and negative directions by conditions in a given microenvironment.

PROSTAGLANDIN D_2 SYNTHASE

PGD_2 formation is catalyzed by at least two isozymes of cytosolic PGD_2 synthases, hematopoietic and brain forms, which are clearly distinguished by amino acid composition, catalytic properties, and antigenicity (122,123) (Fig. 27.1, Table 27.2). Hematopoietic PGD_2 is the key enzyme for production of the D and J series of prostanoids in the immune system. Biologically active PGD_2 metabolites can be dehydrated to form d12-PGJ_2, or they can be enzymatically processed by 11-keto-reductase to produce a second prostaglandin, PGF_{2a} (124,125 and 126).

The hematopoietic PGD_2 synthase, a glutathione-dependent, cytosolic isozyme, is found in spleen, mast cells, and antigen-presenting cells, such as dendritic cells, and in Kupffer cells and histiocytes. An 811-bp cDNA encodes this 23.4-kd protein, which has a Michaelis constant (K_m) of 200 µM for PGH_2 and of 300 µM for reduced glutathione (GSH), with a pH optimum of 7.5 (122,127). Crystallization reveals that the enzyme is a s class GSH *S*-transferase (GST) with a unique cleft as the active site that distinguishes it from other members of the GST family and appears to confer specificity for the isomerization from PGH_2 to PGD_2 (127). The 41-kb gene for the hematopoietic isoform of this enzyme is TATA-less, it contains six exons and five introns, and it is localized on chromosome 4q21-22 (128). Although PGD_2 is the dominant prostanoid product in mast cells, it is also produced by monocytes and macrophages (129), and by polarized T cells (21). The hematopoietic form of PGD_2 synthase is inducible in immature mouse mast cells treated with c-*kit* ligand, as demonstrated by enzymatic function and immunoreactive protein (80).

The brain form is a GSH-independent cytosolic member of the lipocalin family (123), with a K_m for PGH_2 of 6 µM at a pH optimum of 9.0. This enzyme is considered to be a dual-function protein; it acts as a PGD_2-producing enzyme and also as a lipophilic ligand-binding protein, with high affinities for retinoids and bile pigments. The 21-kb gene for this isozyme is composed of 7 exons and 6 introns, and it is found on chromosome 9q34.2-34.3 (130) (Table 27.3).

PROSTAGLANDIN E_2 SYNTHASE

PGE_2 formation is catalyzed by PGE_2 synthase. This inducible 16-kd microsomal enzyme is in the newly described family of membrane-associated proteins of eicosanoid and glutathione metabolism (MAPEG) (131) (Fig. 27.1, Table 27.3). PGE_2 synthase possesses a high level of specific activity (250 nmol/min/mg). Expression of PGE_2 synthase mRNA was detected in human placenta, prostate, testis, mammary gland, and bladder; and protein expression is induced severalfold by IL-1b (131). The 14.8-kb gene for human GSH-dependent PGE_2 synthase contains 3 exons and is localized on chromosome 9q34 (132) (Table 27.3). Reporter constructs containing the 5'-flanking region of this gene revealed that the transcript increases transiently in response to IL-1b. This pattern is similar to the effects of IL-1b on PGHS-2 expression, and it implies a transcriptional regulatory basis for the observed coregulation of these enzymes.

The formation of PGE_2 also appears to be catalyzed by 2 isomerases identified as anionic forms of cytosolic GST, which have respective K_m values for arachidonic acid of 147 and 308 µM and maximum velocity (V_{max}) values of 380 and 720 nmol/mg per minute (133,134). PGE_2 is metabolized by oxidation at the C-15 position by 15-hydroxy-prostaglandin dehydrogenase and reduction of the double bond at the C-13 position by d13-reductase. The resultant 13,14-dihydro product has substantially less biologic activity than the parent PGE_2 (135).

PROSTAGLANDIN F_2 SYNTHASE

PGF_2 synthase is a soluble dual-function enzyme that catalyzes the reduction of PGD_2 and PGH_2 and the oxidation of 9a,11b-PGF_2 and PGD_2 (Fig. 27.1, Table 27.2). Although an isozyme of a-hydroxysteroid/dihydrodiol dehydrogenase catalyzes this reaction with a K_m for PGD_2 of 57 µM, at least two specific PGF_2 synthases in the lung and the liver have K_m values of 120 µM and 10 µM for PGD_2, respectively (136,137). A cDNA for PGF_2 synthase cloned from human lung encoded a 36.8-kd protein of 324 amino acids. Its gene is localized on chromosome 10p14-15, and its 1133-bp transcript is expressed in peripheral blood lymphocytes and lung tissue. A bovine cDNA for the liver-type enzyme consists of a 969-bp encoding a 323-amino acid polypeptide with a molecular mass of 36.7 kd (137).

PROSTACYCLIN SYNTHASE

The generation of PGI_2 can be stimulated by thrombin, by the mechanical stretching of arterial walls, or by the 5-LO–generated eicosanoid, LTC_4 (133). PGI_2 is an unstable molecule, and its hydrolysis in plasma to the inactive 6-keto-PGF_{1a} occurs within minutes. This characteristic, coupled with its low entry rate (0.1 ng/kg/min) into the circulatory system, makes PGI_2 unlikely to act as a circulating antiplatelet agent (124,138). PGI_2 is formed by PGI_2 synthase, a 56-kd member of the P-450 superfamily of enzymes found predominantly in endothelial cells and vascular smooth muscle cells (139) (Fig. 27.1, Table 27.2). PGI_2 synthase cDNA has been cloned from human and bovine libraries, revealing a 1,500-bp open-reading frame encoding for a 500-amino acid polypeptide of approximately 50 kd (140). The PGI_2 gene is on chromosome 20q13.11-q13.13, is approximately 60 kb in length, contains ten exons, and has a promoter region with consensus sequences for specificity protein 1 (Sp1), activator protein-2 (AP-2), proteins that recognize the consensus target sequence (T/A)GATA(A/G)(GATA), nuclear factor-kB (NF-KB), a CACCC box, and a glucocorticoid response element (GRE) (141) (Table 27.3).

THROMBOXANE SYNTHASE

Thromboxane synthase, which provides a six-membered ring product, catalyzes the formation of this intermediate by rearrangement of the endoperoxide structure of PGG_2 followed by incorporation of a single molecule of water (142). TXA_2 synthase is a microsomal cytochrome P-450 (CYP450) family member with 534 amino acids and a molecular mass of 60.6 kd (Fig. 27.1, Table 27.2). From nucleic acid sequences, five potential sites for *N*-glycosylation and a hydrophobic region may serve to anchor it in the endoplasmic reticulum membrane (143). The enzyme has similar K_m values (approximately 12 µM) for PGG_2 and PGH_2, with a pH optimum of 7.5. The human TXA_2 synthase gene consists of 13 exons and 12 introns and is 193 kb in length, the largest P-450 gene isolated (144). A 1.2-kb segment of the 5'-flanking region contains potential binding sites for several transcription factors, AP-1, AP-2, GATA-1, and a CCAAT box, as well as multiple transcription start sites, but neither a typical TATA box nor a typical CAAT box. The human gene for thromboxane synthase is localized to band q33-q34 of chromosome 7 (145,146) (Table 27.3). The thromboxane synthase transcript is widely expressed in human tissues and is particularly abundant in peripheral blood leukocytes, spleen, lung, and liver (145,146).

The effects of TXA_2 are transient, because it is chemically unstable; its approximately 30-second half-life in the plasma makes it a locally acting mediator. Its hydrolytic metabolism to biologically inactive TXB_2, measured in the blood or urine, can be used as an indicator of TXA_2 synthesis (142).

PHENOTYPIC EFFECTS OF GENE MANIPULATION OF PROSTANOID BIOSYNTHETIC ENZYMES

In mice with either gene disruption or overexpression of eicosanoid biosynthetic enzymes (or receptors), the effects on innate and adaptive immunity have not been fully elucidated, and in many instances, only an unexpected or dominant phenotype has been reported. In addition to the possible aberrant tissue expression of products of gene manipulation, the phenotypes expressed from altering the upstream enzymes must be interpreted with caution. In the case of PLA_2 or PGHS, multiple downstream mediators, often with counterregulatory effects, are affected. Disruption of a receptor may create a different phenotype from that produced by interruption of a biosynthetic pathway with multiple products.

Because neither monocyte/macrophages nor bone marrow–derived mast cells from mice with gene disruption for $cPLA_2$ produce prostanoids or leukotrienes, the role of group IV PLA_2 in eicosanoid generation is secure (147,148). The fertility and parturition defects of these animals (as in PGHS gene-disrupted mice) reflect the lack of $cPLA_2$-provided substrate for the critical downstream prostanoid functions. Similarly, the attenuated decrement in pulmonary function and hyperresponsiveness in sensitized and aerosol antigen-challenged $cPLA_2$ gene-disrupted mice (as in 5-LO or FLAP gene-disrupted mice or PGD_2 receptor gene-disrupted mice) implicates pathobiologic eicosanoids dependent on $cPLA_2$ for provision of arachidonic acid for their synthesis (147,148). These mice are also protected from neurologic damage after transient ischemia (148).

In PGHS-1 knock-out mice, one sees the anticipated effects of a reduction in platelet aggregation and inflammation from exogenous arachidonic acid, and failure of parturition (149), almost certainly from depletion of downstream prostanoids. However, these mice are also protected against gastric lesions caused by nonsteroidal antiinflammatory drugs, an observation that seems to contradict the involvement of the prostanoids formed by PGHS-1 in cytoprotection of the gastric mucosa. One explanation for this observation is the compensatory increase in PGHS-2 that occurs in *ex vivo* stimulated cells from these mice (150). PGHS-2 knock-out mice exhibited a decreased response to pyrogens and exogenous arachidonic acid (151,152 and 153), as well as an increased susceptibility to the effects of experimentally induced bacterial peritonitis. These mice also had multiple female reproductive failures that include ovulation, fertilization, implantation, and decidualization (151,152). PGHS-2 gene-disrupted mice also displayed unexpected developmental renal disease and myocardial fibrosis, with decreased overall survival. In studies of the role of PGHS-2 in tumorigenesis, there did appear to be reduced numbers of polyps in mice cross-bred with a mouse strain with hereditary adenomatous polyposis (151,152 and 153). A mouse model of overexpression of PGHS-2 in the central nervous system potentiates the intensity and lethality of excitotoxicity (154).

Only limited data for the terminal enzymes are available, but much information exists about receptor knock-outs, as discussed later. Mice with brain PGD_2 synthase gene disruption have diminished responses to tactile pain as the prominent phenotypic feature (155). PGI_2 synthase overexpression in a transgenic mouse model provided protection from hypoxic pulmonary hypertension and its consequent arteriolar hypertrophy (156).

Leukotriene and Lipoxin Generation

The name *leukotriene* is derived from leukocytes, the cells from which they were originally discovered, and their structural feature of a conjugated triple bond (-triene). The leukotrienes are composed of two major families, the dihydroxy leukotrienes and the cysteinyl leukotrienes. The dihydroxy leukotrienes consist of LTB_4 and its metabolites, and the cysteinyl leukotrienes include LTC_4 and its metabolites, LTD_4 and LTE_4. Just as in the case of the prostanoids, the initial step in the generation of leukotrienes and lipoxins is the enzymatic release of arachidonic acid from cell membrane phospholipids by group IV PLA_2. The first committed step specific to the biosynthesis of leukotriene biosynthesis is through 5-LO, with subsequent conversion to either the dihydroxy or the cysteinyl leukotrienes.

5-LIPOXYGENASE

Arachidonic acid is converted sequentially by 5-LO to 5-hydroperoxyeicosatetraenoic acid (5-HPETE) and by enzymatic dehydration to LTA_4 (157,158 and 159) (Fig. 27.2, Table 27.4). Subcellular assays demonstrated augmented enzyme activity with added phosphatidylcholine, adenosine triphosphate, Ca^{++}, and iron. Although the amino acid sequence motifs within 5-LO reveal no binding domains for ATP or Ca^{++}, site-directed mutagenesis has revealed histidine residues at 368 and 373 that appear integral in the coordination of a catalytically essential iron atom (160,161,162 and 163). Because maximal 5-LO activity is accentuated by hydroperoxides, the enzyme exhibits a biphasic concentration dependence for arachidonic acid, exhibits lag phases, and has rapid turnover inactivation that makes steady-state kinetic values for 5-LO difficult to assess. 5-LO of human leukocytes appears to have a K_m of 10 to 20 µM for arachidonic acid and a V_{max} value of approximately 24 µmol/mg per 5 minutes for HPETE (159) (Table 27.4). In addition to its catalytic function, 5-LO exerts effects in cell remodeling, apparently through interactions of an *src* homology (SH3) domain in the carboxy-terminal of 5-LO with cytoskeletal proteins such as growth factor receptor bound protein-2, actin, and a-actinin (164).

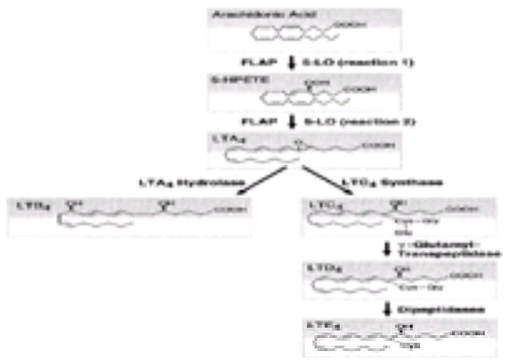

Figure 27.2. Chemical structures and biosynthetic pathways of leukotrienes.

Enzyme/Protein	Size	K_m	Activating/ Cofactor	Subcellular Localization	References
5-lipoxygenase	78-kd, 673 amino acids	10–30 μM for arachidonic acid	Ca^{++}, ATP	Cytosol or nucleoplasm, translocates to perinuclear membranes	157–159, 160–177
5-lipoxygenase-activating protein	18-kd, 161 amino acids	–	–	Perinuclear integral membrane protein	172, 178
LTA_4 hydrolase	70-kd, 610 amino acids	3.5 μM for LTA_4	–	Cytosol	183–185
LTC_4 synthase	18-kd, 150 amino acids	3.5 μM for LTA_4, 1.4 mM for GSH	Mg^{++}	Perinuclear integral membrane protein	183–185

– = not available; ATP = adenosine triphosphate; LTA4 = leukotriene A4; LTC4 = leukotriene C4.

TABLE 27.4. Molecular and Biochemical Characteristics of Leukotriene Biosynthetic Enzymes

In resting cells, 5-LO is localized mainly to the cytosol or nucleoplasm. This localization is cell dependent; in mast cells and basophils, the calcium-dependent movement occurs from the nucleoplasm to the nuclear membrane (165,166 and 167), but in neutrophils, translocation of 5-LO occurs from the cytosol to the nuclear membrane. In neutrophils, this translocation from the cytosolic compartment to the nuclear compartment is associated with increased LTB_4 synthesis, whereas in eosinophils, the similar translocation results in diminished LTC_4 synthesis (167,168). On translocation, 5-LO, in association with a required cofactor, the integral perinuclear protein, FLAP, processes the released arachidonic acid to 5-HPETE and LTA_4 (169,170).

The human 5-LO cDNA encodes a 78-kd protein of 673 amino acids, and the greater than 82-kb, composed of 14 exons and 13 introns, is localized on chromosome 10 (171,172 and 173) (Table 27.4 and Table 27.5). The 5' untranslated region of the 5-LO gene contains a guanosine and cytidine–rich promoter region and lacks TATA and CCAAT motifs. The proximal non–cell-specific promoter element of the 5-LO gene contains a family of alleles in the core promoter characterized by the deletion or addition of consensus Sp1 and early growth response-1 (Egr-1)–binding motifs. Each of the variant alleles binds Sp1 and early growth response-1 (Egr-1) protein, as indicated by electrophoretic mobility shift assays and supershift analyses, and data from reporter assays indicate that these alleles are less effective than the wild-type allele in initiating 5-LO gene transcription (174) (Table 27.5).

Enzyme/Protein	Gene Characteristics	Gene Disruption Mouse Model	References
5-lipoxygenase	>82-kb gene with 14 exons and 13 introns on chromosome 10; 3 tandem Sp1- and Egr-1 sites	Impaired arachidonic acid–induced ear edema, reduced inflammatory cell migration in glycogen and zymosan-induced peritonitis, resistant to platelet-activating factor–induced hypotension, impaired killing of macrophages, and increased lethality in lupus (nzb/w only)	179–184, 214–218
5-lipoxygenase-activating protein	>37-kb gene with 5 exons and 4 introns on chromosome 13q12; modified TMPA box	Blunted inflammatory response to topical arachidonic acid, reduced collagen-induced arthritis, increased resistance to platelet-activating factor–induced shock, and reduced edema in a zymosan-induced model of peritonitis	180, 219, 220
LTA_4 hydrolase	>30-kb gene with 19 exons and 18 introns on chromosome 12q22; TMPA, CAAT-less	Reduced arachidonic acid–induced neutrophil influx and edema, zymosan-induced peritonitis has reduced cellular influx but an intact edematous response	181, 186, 221
LTC_4 synthase	2.5-kb gene with 5 exons and 4 introns on chromosome 5q35; Sp1, cell-specific Hoppel-like factor sites	–	222, 223, 225

– = not available; Egr-1 = early growth response-1; LTA_4 = leukotriene A_4; LTC_4 = leukotriene C_4; Sp1 = specificity protein-1.

TABLE 27.5. Characteristics of CDNAs/Genes of the Leukotriene Biosynthetic Enzymes

Other mammalian lipoxygenases exist in addition to 5-LO. When the products of these lipoxygenases interact, a new family of lipid mediators, the lipoxins, is formed.

12-, 15-, AND 5-LIPOXYGENASE INTERACTION PRODUCTS

The first way in which lipoxins are generated is the neutrophil formation and export of LTA_4, which is then converted by 12-LO in platelets to yield 5S,6R,15S-trihydroxy-7,9,11,13 (E,E,Z,E)-eicosatetraenoic acid (LXA_4) and 5S,14R,15S-trihydroxy-6,8,10,12 (E,Z,E,E)-eicosatetraenoic acid (LXB_4) (175,176) (Fig. 27.3). Alternatively, epithelial cells, monocytes, or eosinophils generate 15S-hydroxyeicosatetraenoic acid (HETE), which is subsequently taken up by neutrophils and is converted to lipoxins by 5-LO. 15R-HETE, which is produced by PGHS-2 after acetylation by aspirin, provides 15-epi LXA_4 (176). Although the lipoxin pathway of human cells has diverged evolutionarily into a two-cell system, lower species such as rainbow trout possess the necessary enzymes to generate both leukotrienes and lipoxins in the same cell in parallel (177).

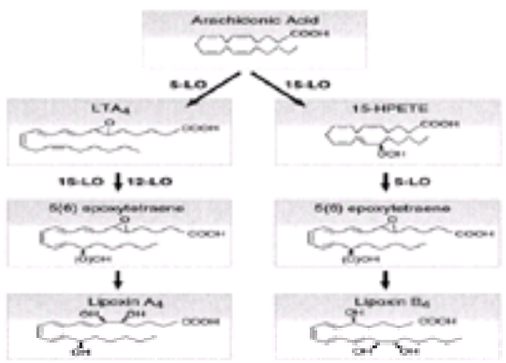

Figure 27.3. Chemical structures and biosynthetic pathways for lipoxins.

5-LIPOXYGENASE–ACTIVATING PROTEIN

FLAP, an 18-kd integral membrane protein of perinuclear membranes, acts in concert with translocated 5-LO to convert released arachidonic acid into 5-HPETE and LTA_4 (178,179) (Fig. 27.2, Table 27.4). FLAP is a 161-amino acid protein with a secondary structure prediction of 3 hydrophobic domains with 2 interspersed hydrophilic loops (179). The carboxy-terminal end of the first loop and the amino-terminal end of the second loop contain amino acid residues responsible for the binding of FLAP-inhibiting drugs. These drugs attenuate cellular leukotriene biosynthesis but not cell-free 5-LO function, which does not require FLAP, a finding implying an effect on intracellular arachidonic acid presentation (180). FLAP has been shown by amino acid sequence and genomic organization to be a member of the MAPEG family of proteins (181). The human FLAP gene is larger than 31 kb, has 5 exons, and is located on chromosome 13q12 (182) (Table 27.5).

LEUKOTRIENE A_4 HYDROLASE

LTA_4 hydrolase, a 70-kd cytosolic metalloenzyme, converts LTA_4 to 5S,12R-(dihydroxy)-6,8,10,14 (Z,E,E,Z)-eicosatetraenoic acid (LTB_4) (Fig. 27.2, Table 27.4). This enzyme requires zinc and contains two overlapping active sites of epoxide hydrolase activity and an aminopeptidase activity; a natural substrate for the latter has not been defined (183,184 and 185). The epoxide hydrolase activity is specific for LTA_4 and, furthermore, is stereospecific for the structure of a 5,6-epoxide with 7,9,11,14 (E,E,Z,Z) double bonds (186). The peptidase activity is activated by chloride ions and, as in the case of 5-LO, is suicide inactivated by the covalent binding of the enzyme to the substrate, LTA_4 (187,188). LTA_4 hydrolase has a K_m value for LTA_4 of 5.8 µM (Table 27.4) and a V_{max} value of 692 nmol/mg per minute for epoxide hydrolase activity (186,187 and 188).

In neutrophils, monocytes and macrophages, and mast cells, 5-LO provides LTA_4 to LTA_4 hydrolase. However, cells such as keratinocytes and type II pneumocytes receive LTA_4 from hematopoietic cells such as polymorphonuclear leukocytes, thus allowing formation of LTB_4 (189,190).

The cDNA of LTA_4 hydrolase encodes a polypeptide of 610 amino acids, and the deduced amino acid sequence shares no significant homology with the nonspecific liver epoxide hydrolase (191). Site-directed mutagenesis studies have revealed that zinc binding depends on histidine 295, histidine 299, and glutamic acid 318; glutamic acid 296 and tyrosine 383 are catalytic residues for the peptidase function; and suicide inactivation by the substrate LTA_4 depends on a tyrosine residue in position 378 (192,193,194 and 195). The human gene for LTA_4 hydrolase is larger than 35 kb, has 19 exons ranging in size from only 24 to 312 nucleotides, and is localized on chromosome 12q22 (196). No definitive consensus sequences for a TATA box are located in the known 5' flanking region, although AP-2 and xenobiotic response elements are present (Table 27.5).

LEUKOTRIENE C_4 SYNTHASE

LTC_4 synthase is an 18-kd integral membrane protein that conjugates GSH to LTA_4 to form the parent cysteinyl leukotriene, 5S-hydroxy-6R-S-glutathionyl-7,9,11,14 (E,E,Z,Z)-eicosatetraenoic acid (LTC_4) (197,198) (Fig. 27.2, Table 27.3). LTC_4 synthase is specific for this enzymatic activity and has no ability to conjugate xenobiotics to GSH. Purified recombinant LTC_4 synthase exhibits K_m values for LTA_4 and GSH of 3.6 µM and 1.6 mM, respectively (Table 27.4), with V_{max} values of 1.3 and 2.7 µmol/mg per minute, respectively (199).

The cDNA for human LTC_4 synthase encodes for a 150-amino acid protein with a secondary structure of 3 hydrophobic domains interspersed by 2 hydrophilic loops (200). Site-directed mutagenesis has suggested that arginine 51 in the first hydrophilic loop is required to open the epoxide by acid catalysis of LTA_4, whereas tyrosine 93 in the second loop provides the thiolate ion by base catalysis of GSH and results in conjugation to form LTC_4 (201). These studies identified additional residues in each loop as being involved in substrate presentation because their mutation increased the K_m without impaired catalytic function (201). The gene for LTC_4 synthase is 2.5 kb and has an intron/exon alignment identical to that of FLAP; however, its chromosomal location is 5q35. This location is distal to the gene cluster for Th2 cytokines (IL-4, IL-5, IL-3, IL-9, and granulocyte-macrophage colony-stimulating factor, which are implicated in allergic and asthmatic inflammation (202). Whereas an SP-1 site and an initiator sequence regulate non–cell-specific function in reporter constructs, upstream motifs for SP-1/-3 and for a Kruppel-like factor govern cell-specific function (203) (Table 27.5).

LTC_4 synthase is also a member of the MAPEG gene family but is distinct in its monospecific function for cysteinyl leukotriene generation. In contrast, FLAP has no known enzymatic function, and the microsomal GSTs possess wider substrate specificities (204,205). Additionally, whereas LTC_4 synthase is expressed in a restricted population of hematopoietic cells including eosinophils, basophils, mast cells, and monocytes and macrophages (206,207,208 and 209), the microsomal GST members are widely distributed, including in cells lacking 5-LO expression, such as those in the liver. This finding implies that the primary function of microsomal GSTs is detoxification, rather than serving as a central source of proinflammatory cysteinyl leukotrienes. Transcellular generation of cysteinyl leukotrienes occurs in platelets and nonhematopoietic cells such as endothelial cells (210), vascular smooth muscle cells (211), synoviocytes (212), and chondrocytes (212,213). Whereas the transcellular conversion of LTA_4 to LTC_4 by platelets occurs by the action of LTC_4 synthase, in the nonhematopoietic cells biosynthesis of LTC_4 appears to occur by microsomal GSTs possessing bifunctional activity (204,205).

PHENOTYPIC EFFECTS OF GENE MANIPULATION OF LEUKOTRIENE BIOSYNTHETIC ENZYMES

Targeted disruption of the 5-LO gene in mice leads to impairment of arachidonic acid–induced ear edema and reduced inflammatory cell migration in glycogen- and zymosan-induced peritonitis (214,215). The shock response to endotoxin remains intact, but these animals are resistant to PAF-induced hypotension, a finding implying a sequential relationship of leukotrienes and PAF (214,215). Although there is no defect in neutrophil recruitment, impaired cellular killing by macrophages appears to be responsible for increased mortality in these mice from *Klebsiella*-induced pneumonia. This particular defect can be restored with the administration of LTB_4 (216).

The role of 5-LO products in the development of the airway reactivity that follows antigen exposure was examined by sensitizing mice lacking 5-LO by intraperitoneal injection of ovalbumin followed by serial exposure to aerosols of ovalbumin. Lung resistance in these challenged mice exhibited an attenuation in methacholine responsiveness and airway eosinophilia (217). A study of 5-LO products in proinflammatory states was undertaken by crossing MRL-lpr/lpr mice, which spontaneously develop autoimmune disease resembling human systemic lupus erythematosus, with 5-LO–deficient mice. The MRL-lpr/lpr mice have sex-related survival differences; female MRL-lpr/lpr mice have significantly higher early mortality rates than males. The mortality rate was higher in male 5-LO–deficient MRL-lpr/lpr mice compared with controls, but not compared with females (218). In male 5-LO–deficient MRL-lpr/lpr mice, renal plasma flow was significantly reduced, although no differences were noted in the severity of renal histopathology, lymphoid hyperplasia, or arthritis. These findings suggest that the presence of 5-LO products confers a survival advantage on male MRL-lpr/lpr mice and that, when 5-LO function is inhibited genetically (or pharmacologically), the gender advantage disappears (218).

Mice with FLAP gene disruption exhibit attenuated responses to inflammatory stimuli similar to those in the 5-LO gene–disrupted mice, including a blunted inflammatory response to topical arachidonic acid, increased resistance to PAF-induced shock, and reduced edema in a zymosan-induced model of peritonitis (219). Additionally, collagen-induced arthritis is significantly reduced in FLAP gene-disrupted mice (220).

Targeted gene disruption of LTA_4 hydrolase in mice ablates only LTB_4 and preserves the cysteinyl leukotrienes (221). Arachidonic acid–induced neutrophil influx and subsequent edema are impaired in these mice, with the vascular edematous response more attenuated than the effects on cellular recruitment. In contrast, with zymosan-induced peritonitis, the reduced cellular influx was not accompanied by any impairment of the edematous response, a finding suggesting that this latter component is an effect solely of the cysteinyl leukotrienes. Furthermore, as in the case of 5-LO and FLAP gene disruption, the mice are resistant to PAF-induced hypotension, a finding suggesting that LTB_4 is the major leukotriene contributing to the hypotension induced by PAF (221).

EICOSANOID RECEPTORS, METABOLISM, AND TRANSPORT

Prostanoid and Platelet-Activating Factor Receptors

Newly generated prostanoids are released by carrier-assisted diffusion to act locally on the cell of origin or on neighboring cells. Two classes of receptors exist to transduce signals for the eicosanoids: the well-characterized G protein–coupled receptor class and the nuclear peroxisome proliferator activator receptors (PPAR) class, which are orphan nuclear receptors acting directly as transcription factors after binding to the appropriate eicosanoid. Thus, in addition to their extracellular functions (Table 27.1), eicosanoids act as intracellular ligands that bind to PPAR-a and PPAR-g to regulate lipid and glucose metabolism, adipocyte differentiation, and inflammatory responses (222,223).

The receptors for prostaglandins are termed P receptors based on the prostanoid to which they bind to transduce a signal; thus, DP, EP, FP, IP, and TP receptors have been classified, including at least four subtypes of EP receptors. These receptors are rhodopsin-type coupling through their respective G proteins to effectors such as adenylate cyclase and phospholipase C (224). Within each of the prostanoid receptors there exists conservation of certain regions, such as in the third and seventh

transmembrane domains and the second extracellular loop. Despite the structural similarities, homology among the prostanoid receptors ranges only from 20% to 30%. The prostanoid receptors have been characterized into three clusters: the relaxant cluster, containing DP, EP2, EP4, and IP; the contractile receptors EP1, FP, and TP; and the inhibitory cluster, containing only EP3 (224) (Table 27.6).

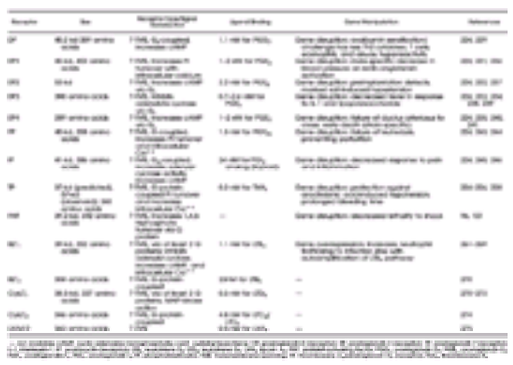

TABLE 27.6. Molecular and Biochemical Characteristics of Eicosanoid Receptors

The TXA_2/PGH_2 (TP) receptor has been isolated from human platelets, and its cDNA and genomic structure have been characterized (225,226) (Table 27.6). This receptor is a 343-amino acid residue, 7-transmembrane domain protein linked to several species of G proteins, and it specifically binds the selective TXA_2 ligand [^{3}H]S-145 with a dissociation constant (K_d) of 0.2 nM. It is encoded by a 3-exon, 15-kb gene on chromosome 19p13.3, containing four potential Sp1 binding promoter sites (226,227). Gene disruption of the TP receptor protects against lethality from arachidonic acid–induced hypotension but it does prolong the bleeding time (228).

The DP receptor is 359 amino acid residues with a predicted molecular mass of 40.2 kd, and it transduces increases in cyclic adenosine monophosphate (cAMP) through G_s protein coupling (Table 27.6). The receptor binds PGD_2 with a K_d of 1.1 nM and shows the highest degree of identity with the IP and EP2 receptors (224,229). Stimulation of the signal transduction pathway of the cloned DP receptor with PGD_2 resulted in elevation of intracellular cAMP and in mobilization of Ca^{++}, but not in generation of inositol 1,4,5-trisphosphate. The DP receptor has limited tissue distribution in humans and is detectable only in retina, brain, small intestine, and lung (224,229). When mice deficient in the DP receptor are sensitized with ovalbumin, the serum concentration of IgE is similar to those in wild-type mice subjected to this model. Aerosol challenge with ovalbumin reveals an attenuation of the markers of a full response, namely, Th2 cytokine concentration in the bronchial fluids, infiltration with T cells and eosinophils into the submucosa of the lung, and appearance of airway hyperresponsiveness to acetylcholine (230).

The human EP receptor subtypes have been cloned (Table 27.6). The EP1 receptor is a 42-kd, 7-transmembrane spanning protein, with a K_d of 1 to 2 nM for PGE_2. Activation of this receptor causes an increase in free intracellular calcium (231). The EP2 receptor is a 53-kd protein with a K_d for PGE_2 of 2.2 nM (Table 27.6); PGE_2 binding is competitively inhibited by misoprostol but not by sulprostone, consistent with the data from mouse EP2. EP2 receptor stimulation increases intracellular cAMP through G_s but fails to transduce a rise in intracellular calcium. As determined by RNA blot analysis, the EP2 receptor is present in lungs, kidneys, pancreas, leukocytes, and immune tissues (232). The EP3 receptor has a k_d of 0.7 to 2.6 nM for PGE_2, but it also binds PGF_{2a}, has a high affinity for sulprostone, and has only an intermediate affinity for misoprostol (233,234). Inhibition of adenylate cyclase occurs through G_s with binding of this receptor, although splice variants transduce differently. The tissue distribution of the EP3 receptor is restricted to the central nervous system, kidney, and pancreas. At least 5 cDNA clones from the human have been detected for the EP3 receptor, and they appear to result from alternate splicing (234). The 5' flanking region of the EP3 receptor possesses a consensus sequence for a classic TATA box. There are no qualitative data for ligand binding for the 289-amino acid EP4 receptor. However, this receptor does transduce increases in cAMP through G_s when bound by PGE_2. It is widely distributed in tissues and is encoded by a 3-exon gene spanning approximately 22 kb, analogous to those of the thromboxane, PGI_2, and PGD_2 receptors (235). The initiation site does not contain a conventional TATA box but contains two CCAAT boxes, Sp1 and AP2 motifs, and motifs consistent with activation by proinflammatory cytokines (235). The EP1, EP3, and EP4 receptors are found on chromosomes 19p13.1, 1p31.2, and 5p13.1, respectively (226).

EP1 receptor-deficient mice have sex-specific changes in blood pressure in that only male mice demonstrate reduced systolic blood pressure with compensatory increases in heart rate and renin-angiotensin activation (236). EP2 receptor-deficient mice are born in small litters because of a preimplantation defect, but their most dramatic phenotype is marked hypertension in response to salt (237). The ablation of the EP3 receptor blunts the fever response to IL-1 and lipopolysaccharide (238,239). Early neonatal death occurs in EP4 receptor gene-disrupted mice because of failure of the ductus arteriosus to close, although this appears in part to be strain specific (240,241). Bone resorption in these mice is also impaired (242).

The FP receptor is a 40-kd 7-transmembrane domain receptor that raises intracellular calcium levels consistent with G protein–coupled transduction (Table 27.6). The K_d for PGF_{2a} is 1.3 nM in the expressed receptor, although mouse studies suggest that this receptor also binds PGD_{2a} (243). The 3-exon gene is located on chromosome 1p31.1 in close proximity to the EP3 gene (224), a finding suggesting evolution by gene duplication. In FP receptor gene-disrupted mice, the inability to transduce the effects of PGF_{2a} prohibited luteolysis, with the consequence that progesterone levels remained elevated, preventing parturition (244).

The PGI_2 (IP) receptor is a 386-amino acid protein with 7-transmembrane domains, a feature that increases free calcium and stimulates adenylate cyclase to raise cAMP; however, it also appears to induce inositol 1,2,5-triphosphate responses, putatively through G_q (Table 27.6). The K_d for PGI_2 is 24 nM in the expressed receptor, and its RNA is abundantly expressed in the luteal cells, aorta, lung, atrium, ventricle, and kidney (245). The 3-exon gene is localized on chromosome 19q13.3 and contains AP-2 sites in its 5' flanking region (224). A gene disruption of the IP receptor revealed the unanticipated effects of PGI_2 as a mediator of pain and inflammation (246).

The PAF receptor is a 342-amino acid polypeptide with a calculated molecular mass of 39.2 kd that possesses 7 putative transmembrane-spanning domains (Table 27.6) (247). Activation of the PAF receptor yields inositol 1,4,5-trisphosphate production through G proteins. PAF receptor mRNA is abundant in leukocytes and heart (247,248), and its intronless gene is localized on chromosome 1 (249). Mice with gene manipulation of the PAF receptor are discussed earlier.

Leukotriene Metabolism

After export from the producing cells, LTB_4 may be metabolized systemically or in the locale of generation. LTB_4 biologic activity is attenuated in neutrophils by serial oxidations of the terminal (C-20) carbon. LTB_4 20-hydroxylase, a microsomal P-450 enzyme, sequentially catalyzes the formation of partially active but unstable intermediates, 20-hydroxy LTB_4 and 20-aldehyde LTB_4 (250,251). The LTB_4 20-hydroxylase cDNA encodes a 60-kd deduced protein of 520 amino acids (252). A 20-aldehyde dehydrogenase converts 20-aldehyde LTB_4 to 20-carboxyl LTB_4 (253), which is functionally inactive. LTB_4 metabolism in keratinocytes occurs by conjugation of LTB_4 to GSH (254). Systemic metabolism of LTB_4 demonstrates b-oxidation (255).

The parent compound of the cysteinyl leukotrienes, LTC_4, either is metabolized to receptor-active products or is inactivated extracellularly. Bioactive derivatives are formed by the sequential removal of glutamic acid by g-glutamyl transpeptidase to form LTD_4, and the cleavage of glycine by dipeptidase to form LTE_4, which is the most stable (256,257). LTE_4 is excreted in the urine directly or after *N*-acetylation. The cysteinyl leukotrienes are locally inactivated in the microenvironment of an inflammatory reaction by hypochlorous acid formed from chloride ions and myeloperoxidase-dependent generation of hydrogen peroxidase. Hypochlorous acid acts at the sulfur bridge to form inactive sulfoxides and then to break the bridge, leaving 6-*trans* diastereoisomers of LTB_4 (258).

Gene disruption of g-glutamyl transpeptidase failed to demonstrate altered leukotriene metabolism; however, the mice displayed glutathionemia and had premature death (259). Membrane-bound dipeptidase gene-disrupted mice retain their ability to form LTE_4, but the dipeptidase cleavage event is not highly selective (260).

Leukotriene and Lipoxin Transport

Specific transporters export LTB_4 and LTC_4 from human granulocytic cells in a temperature-dependent and substrate-specific carrier-mediated process (261,262). The

export of LTB_4 from neutrophils has a Q_{10} value of 3.0 and an energy of activation value of 19.9 kcal/mol; the export of LTC_4 from eosinophils has a Q_{10} value of 3.7 and an energy of activation value of 28 kcal/mol. The transport of LTB_4 exhibits a calculated K_m of 798 pmol/10^7 cells and a V_{max} of 383 pmol/10^7 cells per 20 seconds, whereas K_m and V_{max} values for LTC_4 export are 80 and 38.5 pmol/10^6 cells per minute, respectively (261,262). The LTB_4 carrier export system is distinct from the LTC_4 carrier export system in that no competition for export of LTB_4 occurs when the anionic organic acid transport blocker, probenecid, is present (263). Furthermore, the observation that the export of LTC_4 competes with other GSH conjugates is compatible with a possible role of the adenosine triphosphate–dependent, multidrug resistance–associated protein (264).

LXA_4 is transported into neutrophils by a novel carrier-mediated process that is inducible in human neutrophils and is not present in other hematopoietic cells. At a concentration of 5 nM, uptake of [^{3}H]LXA_4, above that caused by specific binding to receptors, amounted to approximately 0.6 fmol/10^6 cells per minute. This process was specific for LXA_4, was sodium and membrane voltage independent, and exhibited a striking dependence on pH. The LXA_4 carrier did not appear to interact with arachidonic acid, PGE_2, 15(S)-HETE, LTB_4, LTC_4, or LTD_4; it was sensitive to anionic inhibitors, including 3,5-diiodosalicylic acid, pentachlorophenol, and the organomercurial agents mersalyl and *p*-hydroxy-mercuribenzoate (265).

Leukotriene and Lipoxin Receptors

Neutrophils have two different LTB_4 receptors. The high-affinity receptor state, with a K_d of 0.3 nM, transduces the functions of chemotaxis and adhesion; and the low-affinity receptor state, with a K_d of 200 nM, mediates the secretion of granule contents and superoxide generation when it is activated by LTB_4 (266). A cell-surface G protein–coupled receptor for LTB_4 (BLT1) has been cloned and predicts a seven-transmembrane spanning protein of 352 amino acids (267). This receptor is highly expressed in leukocytes and transduces their chemotaxis and chemokinesis. The K_d of this receptor for LTB_4 is 1.1 nM (Table 27.6), and it corresponds to the high-affinity receptor that was biochemically characterized. This receptor increases intracellular calcium and inositol 1,4,5-trisphosphate accumulation with adenylyl cyclase inhibition through both pertussis-sensitive and pertussis-insensitive G proteins (267,268). A transgenic mouse with overexpression of BLT1 has a dramatic increase in neutrophil trafficking to skin microabscesses and lungs after ischemia and reperfusion. BLT2 has 45% amino acid identity to BLT1, has a 23 mN K_d for LTB_4, and is ubiquitously expressed in tissues, whereas BLT1 is leukocyte selective (270).

The cysteinyl leukotrienes mediate their effects through what appear to be at least two distinct receptors. Specific inhibitors of the membrane action of the cysteinyl leukotrienes revealed a receptor for LTD_4/LTE_4 in human lung parenchyma that was blocked, whereas these antagonists were not active against LTC_4 under conditions in which its metabolism to LTD_4/LTE_4 was prevented (271). The former receptor was designated $cysLT_1$, and the latter was $cysLT_2$. A cDNA for the $cysLT_1$ receptor encodes a polypeptide of 337 amino acids with a calculated molecular mass of 38.5 kd (272) (Table 27.6). The transcript for this receptor is widespread, including intestine, heart, spleen, lung, and leukocytes; and within lung, *in situ* hybridization revealed expression in smooth muscle cells and macrophages (272). Pertussis toxin experiments revealed that a $G_{1a/0}$ is the subunit responsible for transduction in the oocyte (272). Previous experiments with the THP-1 monocytic cell line indicated that LTD_4 activates signals through two pathways, with mitogen-activated protein kinase activation using the pertussis toxin–insensitive protein kinase C_a Raf-1 pathway and directed migration transducing through pertussis toxin–sensitive mechanisms (273). $CysLT_2$ has a 38% amino acid identity to $cysLT_1$, has a K_d of 4.8 mN for either LTC_4 or LTD_4, is distributed to lung macrophages and airway smooth muscle as well as to cardiac Purkinje and adrenal medulla cells, and is pharmacologically distinct from $cysLT_1$ in being resistant to the selective $cysLT_1$ antagonists (274).

LXA_4 triggers selective responses with human neutrophils through an inducible, pertussis toxin–sensitive receptor (LXA_4R) with a high-affinity K_d of 0.5 nM (274) (Table 27.6). This receptor in neutrophil membranes is specific, with only LTD_4 competing with LXA_4, with a K_i of 80 nM. In transfection experiments, LXA_4 also stimulated guanosine triphosphatase activity and provoked the pertussis toxin–sensitive release of esterified arachidonic acid, an effect that was also sensitive to pertussis toxin (275).

28 PRIMARY IMMUNODEFICIENCIES OF LYMPHOCYTES

Rebecca H. Buckley, M.D.

Since defects in human host defense were first discovered five decades ago (1,2), more than 95 different primary immunodeficiency disorders have been recognized (3,4). Naturally occurring immune defects also have been described in animals. The study of these human and murine “experiments of nature” and of mice made immunodeficient by inserting mutant genes for selected immune components has provided unique insights into the intricate workings of the immune system (5). Primary immunodeficiency may affect one or more components, including T, B, and natural killer (NK) lymphocytes; phagocytic cells; and complement proteins. This chapter focuses on some but not all of the genetically determined immunodeficiency diseases that affect lymphocytes.

CLINICAL PRESENTATION OF PATIENTS WITH DEFECTS IN LYMPHOCYTE FUNCTION

Primary immunodeficiency diseases are characterized by undue susceptibility to infection, autoimmunity, and an increased risk of malignancy. Patients who have mutations impairing B- or T-lymphocyte function have three major clinical phenotypes: a deficiency of antibody production, a deficiency of cellular immunity, or deficiencies of both. It is important to point out that different molecular defects can manifest with the same clinical phenotype. Conversely, the same molecular defect can sometimes have different clinical presentations. Although the true incidences of these conditions are unknown, it has been estimated that they occur in one of every 10,000 live births (4). Knowledge of the particular infectious agents involved and the anatomic sites most often affected in a given patient can provide clues as to the most likely type of defect. Patients with B-cell defects have recurrent infections with encapsulated bacterial pathogens. In contrast, patients with T-cell defects have problems with opportunistic infections with viral and fungal agents in addition. The latter patients in general begin to fail to thrive shortly after these problems develop. Excessive routine use of antibiotics by primary care physicians has altered the textbook presentation of many of these conditions so that their detection requires not only a high index of suspicion but also extensive knowledge on the part of the physician about their fundamental causes and the various ways they can manifest.

GENETICS OF PRIMARY IMMUNODEFICIENCY

Until the last decade, little insight had been gained into the fundamental problems underlying these conditions. As a result of remarkable advances in human molecular genetics over the past 8 years, however, the abnormal genes have been identified in a rapidly growing number of defects. The genes essential for immune function are distributed throughout the entire genome; however, there is a dominance of X-linked immunodeficiency resulting from hemizygosity in male subjects for the substantial number of X-encoded immune system genes. There is also a high incidence of new mutations in the latter genes. Carriers of X-linked immunodeficiency have skewed X-inactivation in the cell lineage affected, and this can be used diagnostically to assess whether a female relative is a carrier. Within the past 8 years, the molecular bases of five X-linked immunodeficiency disorders have been discovered: X-linked agammaglobulinemia, X-linked immunodeficiency with hyperimmunoglobulin M (hyper-IgM), the Wiskott–Aldrich syndrome, X-linked severe combined immunodeficiency disease (SCID), and X-linked lymphoproliferative disease (Table 28.1) (6).

Chromosomal Location	Disease
Xp11.22	WAS due to WAS protein deficiency[a] (301000)[b]
Xq13.1	X-linked SCID due to common cytokine receptor gamma chain (γ_c) deficiency[a] (308380)[b]
Xq21.3	X-linked agammaglobulinemia due to Btk deficiency[a] (300300)
Xq25	X-linked lymphoproliferative syndrome due to mutation in SLAM-associated protein SH2D1A[a] (308240)
Xq26.3–q27.1	Immunodeficiency with hyper IgM due to CD154 (CD40 ligand) deficiency[a] (308230)[b]

Btk, Bruton tyrosine kinase; IgM, immunoglobulin M; SCID, severe combined immunodeficiency; SLAM, signaling lymphocyte activation molecule; WAS, Wiskott-Aldrich syndrome.
[a] Gene cloned and sequenced, gene product known.
[b] Numbers represent Online Mendelian Inheritance in Man (OMIM) reference numbers, National Library of Medicine.

TABLE 28.1. Abnormal Genes Known To Cause X-Linked Immunodeficiency Involving Lymphocytes

Other chromosomal regions that carry an increased number of immune function genes include 6p, where histocompatibility genes reside, and 5q, where there are many cytokine genes. In the evaluation of patients with suspected immunodeficiency, inquiry into consanguinity is important because those born to parents from genetically restricted populations are at risk for homozygosity for autosomal recessive immunodeficiency disorders. Some autosomal recessive defects for which the molecular bases have been discovered include leukocyte adhesion deficiency type 1 (LAD-1), adenosine deaminase (ADA) deficiency, purine nucleoside phosphorylase (PNP) deficiency, ataxia–telangiectasia, DiGeorge syndrome, major histocompatability complex (MHC) antigen deficiency, z-associated protein-70 (ZAP-70) deficiency, Janus kinase 3 (Jak3) deficiency, and interferon g receptor deficiencies, among others (Table 28.2). Gene-based understanding now allows them to be viewed according to the types of genetically altered molecules involved. It is important for physicians to determine the molecular causes of their patients' defects for purposes of providing genetic counseling, prenatal diagnosis, and possible future correction by gene therapy.

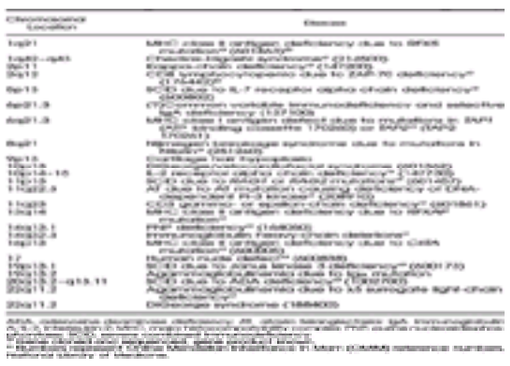

TABLE 28.2. Abnormal Genes Known To Cause Autosomal Immunodeficiency Disorders Involving Lymphocytes

ANTIBODY DEFICIENCY DISORDERS

X-linked Agammaglobulinemia

The clinical problems affecting patients with X-linked agammaglobulinemia (XLA) exemplify the classic phenotype of antibody deficiency. Boys who have deficient immunoglobulin (Ig) and antibody production are protected during the first months of life by maternally transmitted IgG antibodies. Thereafter, they acquire infections with encapsulated organisms, such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus aureus*, and with gram-negative organisms such as *Pseudomonas* species. Chronic fungal infections are not usually present, and *Pneumocystis carinii* pneumonia rarely occurs. Usually, viral infections are handled normally, except those with the hepatitis viruses or with enteroviruses, which can cause persistent meningoencephalitis (with or without a dermatomyositislike picture) (7). Paralysis can result from chronic infection with live attenuated vaccine polioviruses. Infections with echoviruses, coxsackieviruses, adenoviruses (8), and *Ureaplasma urealyticum* (9) have been identified in joint fluids of patients even on immunoglobulin replacement therapy. Concentrations of immunoglobulins of all isotypes are quite low. Circulating B cells are extremely few or absent, tonsils are small, and lymph nodes are rarely palpable, which should facilitate early recognition of this disorder. Thymus architecture is normal, as are the thymus-dependent areas of spleen and lymph nodes. Monthly infusions of intravenous immunoglobulin are life saving.

In 1993, two groups of scientists discovered the mutated gene in XLA, now called the *Bruton tyrosine kinase* (*BTK*) gene (Table 28.1, Fig. 28.1) (10,11). Btk is a member of the Tec family of cytoplasmic protein tyrosine kinases. This kinase appears to be necessary for pre-B-cell expansion and maturation into surface immunoglobulin-expressing B cells, accounting for the lack of circulating B cells (12). It has not been detected in T cells but has been found in myeloid cells (11). The latter could be relevant to the intermittent neutropenia seen in boys with XLA (13,14). To date, more than 300 unique mutations in the human *BTK* gene have been recognized, and there has not been any clear correlation between the location of the mutation and the clinical phenotype (15).

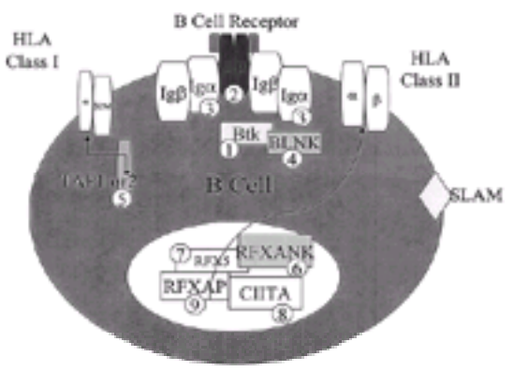

Figure 28.1. Cartoon showing the locations of mutations occurring in B cells in various immunodeficiencies: (1) Bruton tyrosine kinase in X-linked agammaglobulinemia; (2) µ heavy chain; (3) immunoglobulin a; or (4) B-cell linker protein (BLNK) in B-cell-negative, autosomal recessive agammaglobulinemia; (5) transporters of antigenic peptides (TAP-1 or TAP-2) in human leukocyte antigen (HLA) class I antigen deficiency, and HLA class II antigen gene transcription factors: (6) RFX associated protein (RFANK); (7) RFX5; (8) class II transactivator (CIITA); or (9) RFXAP in HLA class II antigen deficiency.

Carriers of XLA can be identified by the finding of nonrandom X chromosome inactivation in their B cells. Prenatal diagnosis of affected or nonaffected male fetuses has also been accomplished by detection of the mutated gene in chorionic villous or amniocentesis samples.

B-Cell Antigen Receptor Gene Deficiencies

These autosomal recessive conditions characterized by a- or hypogammaglobulinemia are caused by mutations in the genes that encode immunoglobulin heavy or light chains or their associated signaling molecules. In µ chain, l5/14.1 (surrogate light chain), Iga (B-cell antigen receptor signaling molecule), and B-cell linker (BLNK, an adapter protein important in B-cell antigen receptor signaling) gene mutations, circulating B cells are also absent (Table 28.1, Fig. 28.1) (16,17,18,19 and 20). Thus, these defects, in which Btk is normal, mimic Bruton agammaglobulinemia clinically and in their absence of B cells. In the case of other heavy-chain gene mutations, deficiencies of individual immunoglobulin classes or subclasses are seen, and circulating B cells are present (21). Mutations in the k-chain gene result in molecules with only l light chains.

Common Variable Immunodeficiency

Common variable immunodeficiency (CVID), also known as *acquired hypogammaglobulinemia*, may appear similar clinically in many respects to XLA (3). The kinds of infections experienced and bacterial etiologic agents involved are generally the same for the two defects. In comparing the two defects further, it is noted that in CVID there is an almost equal sex distribution, generally a later age of onset of infections (which are somewhat less severe), a tendency to autoantibody formation, normal-sized or enlarged tonsils and lymph nodes, and splenomegaly in approximately 25% of affected persons. Lymphoid interstitial pneumonia, pseudolymphoma, amyloidosis, and noncaseating granulomata of the lungs, spleen, skin, and liver also have been seen. There is a 438-fold increase in lymphomas in affected women in the 5th and 6th decades of life (22).

The serum immunoglobulin and antibody deficiencies in CVID may be as profound as in XLA. Despite normal numbers of circulating immunoglobulin-bearing B-lymphocytes and the presence of lymphoid cortical follicles, blood B-lymphocytes from CVID patients do not differentiate into immunoglobulin-producing cells (23,24). From these observations, the defect(s) in this syndrome were postulated to be intrinsic to the B cell (23). In keeping with this are studies showing a lack of protein kinase C activation and translocation to the plasma membrane when CVID B cells are stimulated with phorbol ester or anti-µ (25). However, CVID B cells can be stimulated to both isotype-switch and to synthesize and secrete immunoglobulin when stimulated with anti-CD40 plus interleukin-4 (IL-4) or IL-10 (26,27). T cells and T cell subsets are usually present in normal percentages, but a dominance of gd T cells has been observed in some patients (28) and depressed T-cell function has been reported in others (29,30). In addition, decreased number and function of antigen-specific T cells were noted in CVID patients immunized with keyhole limpet hemocyanin (KLH) (31). One group of CVID patients was reported to have significantly depressed (but not absent) expression of CD40 ligand (CD154) mRNA and surface protein in their activated T-lymphocytes, suggesting that inefficient signaling by poorly expressed CD154 on their T cells could account for failure of their B cells to differentiate (32). Tonsils and lymph nodes are either normal sized or enlarged, and splenomegaly occurs in about 25% of patients with CVID. In addition, there is a tendency to autoantibody formation, and there are now several cases of lupus erythematosus converting to CVID (33). Rarely, CVID has been reported to resolve transiently or permanently when some such patients acquired human immunodeficiency virus (HIV) infection (34).

Because this disorder occurs in first-degree relatives of patients with selective IgA deficiency and some patients with IgA deficiency later became panhypogammaglobulinemic (35), it has long been suspected that these diseases have a common genetic basis (36,37). The high incidences of abnormal immunoglobulin concentrations, autoantibodies, autoimmune disease, and malignancy in families of both types of patients also suggested a shared hereditary influence. This concept is supported by the finding of a high incidence of C4-A gene deletions and C2 rare gene alleles in the class III MHC region in individuals with

either IgA deficiency (38,39) or CVID (40,41), suggesting that there is a susceptibility gene in this region on chromosome 6 (Table 28.2). The abnormal gene has not been identified, however. These studies also have shown that a small number of human leukocyte antigen (HLA) haplotypes are shared by persons affected with CVID and IgA deficiency, with at least one of two particular haplotypes being present in 77% of those affected (41). In one large family with 13 members, two had IgA deficiency and three had CVID (36). All the immunodeficient patients in the family had at least one copy of an MHC haplotype shown to be abnormally frequent in IgA deficiency and CVID: HLA-DQB1 *0201, HLA-DR3, C4B-Sf, C4A-deleted, G11-15, Bf-0.4, C2a, HSP70-7.5, tumor necrosis factor a-5 (TNFa-5), HLA-B8, and HLA-A1 (42). Environmental factors, particularly drugs such as phenytoin, have been suspected as providing the triggers for disease expression in individuals with the permissive genetic background. The prognosis for patients with CVID is reasonably good unless severe autoimmune disease or malignancy develops (22). However, this is a very heterogeneous syndrome, and likely includes some known defects.

Selective IgA Deficiency

An isolated deficiency of serum IgA (i.e., <10 mg/dL) is the most common recognized primary immunodeficiency, with a frequency of 1:333 reported among some blood donors (43,39). This condition has been observed in apparently healthy persons (43), but it also is associated with poor health. As would be expected, infections occur predominantly in the respiratory, gastrointestinal, and urogenital tracts (44). The responsible bacterial agents are essentially the same as in other types of antibody deficiency syndromes. As in CVID, there are frequent occurrences of autoimmune diseases, and there is an increased incidence of malignancy in IgA deficiency (38).

Serum concentrations of other immunoglobulins are usually normal in patients with IgA deficiency, although IgG subclass deficiency has been reported (45) and IgM (usually elevated) may be monomeric. Children with IgA deficiency vaccinated with killed poliovirus intranasally produced local IgM and IgG antibodies. Of the possible causative and important clinical consequences is the presence of antibodies to IgA in the sera of up to 44% of patients with IgA deficiency (43). Some IgA-deficient patients have had severe or fatal anaphylactic reactions after intravenous administration of blood products containing IgA, and anti-IgA antibodies (particularly IgE anti-IgA antibodies) have been implicated (46). For this reason, only normal donor erythrocytes washed five times (in 200-mL volumes) or blood products from other IgA-absent persons should be administered to these patients. Patients with IgA deficiency also frequently have IgG antibodies against cow milk and ruminant serum proteins (47). These antiruminant antibodies often falsely detect “IgA” in immunoassays that use goat (but not rabbit) antisera (44). A high incidence of autoantibodies also has been noted (48).

The basic defect leading to IgA deficiency is unknown. *In vitro* cultures of B cells from some IgA-deficient patients could be stimulated to produce IgA by the combination of anti-CD40 and IL-10; those whose B cells did not produce IgA with these treatments appeared to be more susceptible to infection (49,50). Treatment with dilantin, sulfasalazine (51), d-penicillamine, or gold has been associated with the development of IgA deficiency; the condition also has been known to remit either after discontinuation of dilantin therapy or spontaneously (52,53). IgA deficiency occurs in both male and female patients; in families in whom more than one member is affected, the pattern is that of autosomal dominant inheritance with variable expressivity (36). As already noted, this defect occurs in pedigrees with CVID patients, and some patients with IgA deficiency have gone on to develop CVID (35). Studies suggest that a susceptibility gene for these two defects may reside in the MHC class III region on chromosome 6 as an allelic condition (Table 28.2) (36,37,41,42).

Hyperimmunoglobulin M

The hyper-IgM immunodeficiency syndrome is characterized by extremely low serum IgG, IgA, and IgE concentrations and either a normal or a markedly elevated concentration of polyclonal IgM. Patients with hyper-IgM develop both recurrent pyogenic infections and *P. carinii* pneumonia. There is also an increased frequency of autoimmune disorders and malignancy (3,54,55). Paradoxically, the X-linked form of this condition is not a B cell defect but a T cell defect. Until the T-cell location of the defect was discovered, coexistent neutropenia had been considered a possible explanation for the susceptibility to *P. carinii* pneumonia (3,54).

The abnormal gene in X-linked hyper-IgM was localized to Xq26 (56) and identified by six groups in 1993 (Table 28.1, Fig. 28.2) (57,58,59 and 60). The gene product is a T-cell surface molecule now known as *CD154* (or *CD40 ligand*); it is present primarily on activated $CD4^+$ T cells, and it interacts with CD40 on B cells (61). CD154 is a type II integral membrane glycoprotein with significant sequence homology to TNF (61). Cross linking of CD40 on either normal or X-linked hyper-IgM B cells with a monoclonal antibody to CD40 or with soluble CD154 in the presence of cytokines (IL-2, IL-4, or IL-10) causes the B cells to proliferate and secrete immunoglobulins of various isotypes. Mutations in the gene encoding CD154 result in a lack of B cell signaling by T cells; as a result, the B cells fail to undergo isotype switching and produce only IgM.

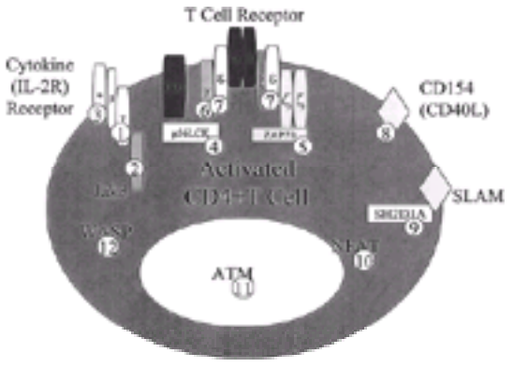

Figure 28.2. Locations of mutations occurring in T cells in various immunodeficiencies: (1) common g chain (gc) shared by multiple cytokine receptors in T^-B^+ natural killer $(NK)^-$ X-linked severe combined immunodeficiency disease X-1 (SCIDX-1); (2) Janus kinase 3 (Jak3) in autosomal recessive $T^-B^+NK^-$ SCID; (3) the chain of the interleukin-2 (IL-2) receptor (CD25) in a lymphoproliferative immunodeficiency syndrome; (4) the tyrosine kinase p56LCK in a SCID-like defect; (5) z-associated protein 70 (ZAP70) in CD8 lymphocytopenia; (6) the g; or (7) e chains of the T-cell receptor complex in CD3 antigen deficiency; (8) the CD40 ligand (CD154) in X-linked hyperimmunoglobulin M (IgM); (9) the adaptor protein SH2DIA in the X-linked lymphoproliferative syndrome; (10) nuclear factor of activated T cells in some T-cell signaling defects; (11) the ataxia telangiectasia mutation; and (12) the Wiskott-Aldrich syndrome protein (WASP).

The lack of cross linking of CD40 also results in failure of the B cells to upregulate CD80 and CD86, important costimulatory molecules that interact with CD28/CTLA4 on T cells (62). The failure of interaction of the molecules of those pathways in the thymus in X-linked hyper-IgM results in defective negative selection of autoreactive thymocytes. Similarly, their lack of interaction extrathymically is postulated to cause defective recognition of tumor cells because of tolerogenic signaling of peripheral T cells. Lymph nodes show only abortive germinal center formation (63).

Many distinct point mutations or deletions in the gene encoding CD154 have been identified (64,65). A highly polymorphic microsatellite dinucleotide (CA) repeat region in the 3' untranslated end of the CD154 gene is useful for detecting carriers and for making a prenatal diagnosis (66).

Numerous examples of autosomal recessively inherited hyper-IgM syndrome (67) indicate that this condition has more than one genetic cause. In such patients, there is an intrinsic B-cell defect; that is, the B cells fail to switch from IgM-secreting to IgG, IgA, or IgE-secreting cells, even when cocultured with monoclonal antibodies to CD40 and cytokines (68). Recently, one defect accounting for non-X-linked hyper-IgM was discovered: mutations in the gene at 12p13 encoding an activation-induced cytidenic deaminase, a messenger RNA editing enzyme (68a).

CELLULAR OR COMBINED IMMUNODEFICIENCIES

DiGeorge Syndrome and the Human Nude Defect

Thymic hypoplasia in the DiGeorge syndrome results from dysmorphogenesis of the third and fourth pharyngeal pouches during early embryogenesis, also leading to hypoplasia or aplasia of the parathyroid glands (3,69). Other structures that form at the same age are also frequently affected, resulting in anomalies of the great vessels (right-sided aortic arch), esophageal atresia, bifid uvula, upper limb malformations (70), congenital heart disease (atrial and ventricular septal defects), a short philtrum of the upper lip, hypertelorism, an antimongoloid slant to the eyes, mandibular hypoplasia, and low-set, often notched ears. There are clinical similarities between the DiGeorge syndrome and the fetal alcohol syndrome (69). Usually, the diagnosis of DiGeorge syndrome is first suggested by the presence of hypocalcemic seizures during the neonatal period. Since the original description of the syndrome, it has become apparent that a variable degree of hypoplasia is more frequent than total aplasia of the thymus and parathyroid glands. Some children have little trouble with life-threatening infections and grow normally; such patients are often referred to as having partial DiGeorge syndrome (71). Those with complete DiGeorge syndrome may resemble patients with SCID in their extreme susceptibility to infections

with opportunistic pathogens (i.e., fungi, viruses and *P. carinii*) and to graft-versus-host disease (GVHD) from nonirradiated blood transfusions.

DiGeorge patients are usually only mildly lymphopenic (71,72); however, the percentage of T cells is variably decreased; as a result, there is a relative increase in the percentage of B cells. B-cell function is impaired only to the extent of needing “helper” T cells. Immunoglobulin concentrations are usually normal, although sometimes IgE is elevated and IgA may be low (71,72). Responses of blood lymphocytes following mitogen stimulation have been absent, reduced, or normal, depending on the degree of thymic deficiency, suggesting that the T-lymphocytes that are present are intrinsically normal (71,72). Thymic tissue, when found, does contain Hassall corpuscles and a normal density of thymocytes; corticomedullary distinction is present. Lymphoid follicles are usually present, but lymph node paracortical areas and thymus-dependent regions of the spleen show variable degrees of depletion.

The DiGeorge syndrome has occurred in both male and female subjects. It is rarely familial, but cases of apparent autosomal dominant inheritance have been reported. Microdeletions of specific DNA sequences from chromosome 22q11.2 (the DiGeorge chromosomal region, or DGCR) have been shown in a majority of patients (73,74 and 75), and polymerase chain reaction (PCR)–based genotyping using microsatellite DNA markers located within the commonly deleted region permits rapid detection of such microdeletions (Table 28.2) (76). Several candidate genes have been identified in this region (74,77,78 and 79). There appears to be an excess of 22q11.2 deletions of maternal origin (80). There are similarities between the DiGeorge syndrome; the velocardiofacial syndrome (VCFS), a condition characterized by craniofacial abnormalities, heart defects, and learning disability) (81); and the conotruncal anomaly face syndrome (CTAFS), which is characterized by congenital heart disease, dysmorphic facies, and cleft palate or hypernasality (82). All three have conotruncal heart defects and 22q deletions. The so-called CATCH 22 syndrome (*c*ardiac, *a*bnormal facies, *t*hymic hypoplasia, *c*left palate, *h*ypocalcemia) includes the broad clinical spectrum of conditions with 22q11.2 deletions. Another deletion associated with DiGeorge and velocardiofacial syndromes has been identified on chromosome 10p13 (Table 28.2) (83,84 and 85).

No immunologic treatment is needed for the partial form. If the patient does not have a severe cardiac lesion, he or she will have few clinical problems, except that some experience seizures and developmental delay. Those with complete DiGeorge syndrome die in infancy unless immune reconstitution can be accomplished.

A clinically similar defect with an entirely different fundamental cause is the human equivalent of the nude mouse (86). In contrast to the DiGeorge anomaly, the defect in nude mice and humans is in their thymic and cutaneous epithelial cells, resulting in hairlessness and a lack of thymic development. The nude phenotype is caused by mutations in a gene on murine chromosome 11 and on human chromosome 17 that encodes a novel winged helix (whn) or fork head domain transcription factor (Table 28.2) (87).

Severe Combined Immunodeficiency

Severe combined immunodeficiency disease is a syndrome of diverse genetic origin characterized by profound deficiencies of T- and B-cell function. In some molecular types, there is also a deficiency of NK cells. In the first few months of life, affected infants have diarrhea and show failure to thrive. Persistent infections with opportunistic organisms, such as *Candida albicans, P. carinii*, varicella, adenovirus, respiratory syncytial virus, parainfluenza 3, cytomegalovirus, Epstein-Barr virus (EBV), and bacille Calmette-Guérin (BCG), lead to death. These infants also lack the ability to reject allografts, leaving them at risk for fatal GVHD (88). This condition is uniformly fatal in the first 2 years of life unless immune reconstitution can be accomplished.

Infants with SCID are lymphopenic; recognition of this characteristic alone can result in early diagnosis, even at birth (89). Their lymphocytes fail to proliferate *in vitro* in response to mitogens, antigens, or allogeneic cells. Serum immunoglobulins and antibodies are diminished to absent. The thymuses are quite small (usually <1 g) and lack thymocytes, corticomedullary distinction, and Hassall corpuscles. Studies have shown that these thymuses are capable of supporting T-cell development when normal stem cells are provided (90). Thymus-dependent areas of the spleen are devoid of lymphocytes, and lymph nodes and tonsils are absent. Flow cytometric studies have shown that there are unique lymphocyte phenotypes for the various genetic forms of SCID. Some have B cells and no NK cells (so-called $T^-B^+NK^-$ SCID), others have no B cells but many NK cells ($T^-B^-NK^+$ SCID), and others have extremely low numbers of all types of lymphocytes ($T^-B^-NK^-$ SCID) (Fig. 28.3) (89,91).

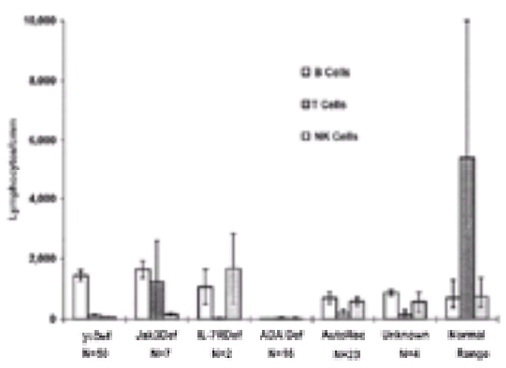

Figure 28.3. Means ± standard error of the mean (SEM) of $CD20^+$ B cells, $CD3^+$ T cells, and $CD16^+$ natural killer (NK) cells at initial presentation of 102 patients with severe combined immunodeficiency disease (SCID), showing the lymphopenia characteristic of all forms of SCID and the different phenotypic characteristics of patients with the various genetic forms of the syndrome compared with mean ± SEM for normal controls.

Enormous strides have been made in identifying the molecular causes of SCID in recent years (Fig. 28.3 and Fig. 28.4) (92,93,94,95,96,97 and 98). An absence of the enzyme ADA was identified in the early 1970s as a cause of SCID, but this defect accounts for only about 15% of patients with SCID (92,89) The gene encoding ADA was mapped to chromosome 20q13.2-q13.11, cloned, and sequenced (Table 28.2). The ADA deficiency caused by mutations in this gene results in marked accumulations of adenosine, 2'-deoxyadenosine and$^{2'}$-O-methyladenosine. The latter directly or indirectly leads to lymphocyte apoptosis. There are certain distinguishing features of ADA deficiency, including multiple skeletal abnormalities of chondroosseous dysplasia on radiographic examination. The latter include flaring of the costochondral junctions and a “bone-in-bone” anomaly in the vertebral bodies. ADA-deficient patients have a more profound lymphopenia than do infants with other types of SCID, with mean absolute lymphocyte counts of less than 500 per mm^3 ($T^-B^-NK^-$ SCID) (89). Milder forms of this condition have been reported, leading to a delayed diagnosis of immunodeficiency even to adulthood (99). The diagnosis should be suspected in any patient with recurrent infections who has severe lymphopenia.

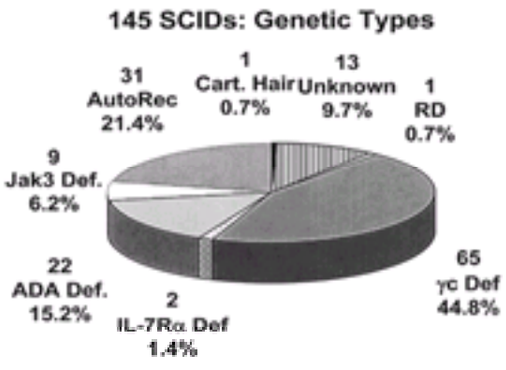

Figure 28.4. Relative frequencies of the different genetic types of severe combined immunodeficiency disease (SCID) among 145 SCID patients seen consecutively by the author over the past three decades. CHH, cartilage hair hypoplasia, a form of dwarfism associated with combined immunodeficiency of varying severity; gene mapped to 9p13 but not cloned as of this writing.

X-linked recessive SCID (SCID-X1) is the most common form of SCID, accounting for about 46% of U.S.cases (Fig. 28.4) (89). The abnormal gene in SCID-X1 was mapped to the Xq13 region and later identified as the gene encoding the common gamma chain (g_c) shared by cell surface receptors for various interleukin molecules (IL-2, IL-4, IL-7, IL-9, and IL-15) (Table 28.1, Fig. 28.2 and Fig. 28.5) (94,100,101). Among the first 136 SCID-X1 patients studied, 95 distinct mutations were identified, resulting in abnormal g_c chains in two thirds of the cases and absent g_c protein in the remainder (102). The finding that the mutated gene results in faulty signaling

through several cytokine receptors explains how T, B, and NK cell types can be affected by a single mutation (Fig. 28.5) (103,93). This was the initial example of $T^-B^+NK^-$ SCID; even though B cells are the dominant lymphocyte type present in the circulation (Fig. 28.3), the B cells do not isotype-switch normally. The single exception to SCID being invariably fatal without marrow transplantation or gene therapy was a patient with SCID-X1 who underwent spontaneous clinical improvement and who was found to have reversion of a documented mutation in the gene encoding g_c, presumably in a T-cell precursor (104).

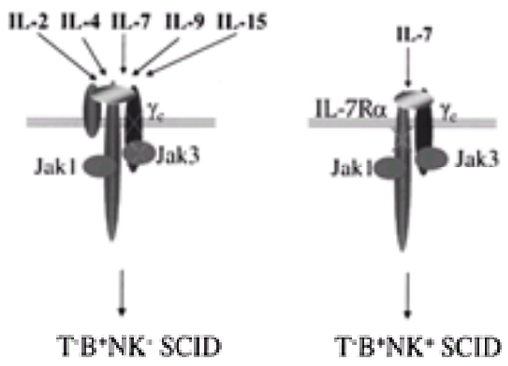

Figure 28.5. Cartoon showing on the left side that Janus kinase 3 (Jak3) is the major signal transducer for the common gamma chain (g_c) shared by multiple cytokine receptors. Mutations in the gene encoding g_c cause SCID-X1 and in the gene encoding Jak3 cause a form of autosomal recessive SCID that mimics SCID-X1 phenotypically. On the right side, it is seen that mutations in the gene encoding the IL-7 receptor a chain also result in another form of autosomal recessive SCID. The latter suggests that the reason for the severe T-cell defect in SCID-X1, and Jak3-deficient SCID is failure to signal through the IL-7 receptor. (Courtesy of Dr. Warren Leonard.) (See Color Figure 28.5.)

Because Jak3 is the only signaling molecule known to be associated with g_c, it was a candidate gene for mutations leading to autosomal recessive $T^-B^+NK^-$ SCID (Fig. 28.5), the identical lymphocyte phenotype seen in SCID-X1 (Fig. 28.3). This proved to be the case, and thus far at least 18 patients who lack Jak3 have been identified (Table 28.2; Fig. 28.4) (89,95,105). Like SCID-X1 patients, they have extremely low NK activity, even after successful marrow transplantation (88,106).

Some of my patients who had previously been shown not to have either g_c or Jak3 deficiency had $T^-B^+NK^+$ SCID (Fig. 28.3). Because mice whose genes for either the a chain of the IL-7 receptor or of IL-7 itself have been mutated are profoundly deficient in T- and B-cell function but have NK function (5), naturally occurring mutations in these genes were sought in human SCID. Mutations in the gene for IL-7Ra on chromosome 5p13 were found in three of my patients (Table 28.2; Fig. 28.4) (97) These findings imply that the T-cell, but not the NK-cell, defect in SCID-X1 and Jak3-deficient SCID results from an inability to signal through the IL-7 receptor (Fig. 28.5).

Infants with SCID due to mutations in recombinase activating genes 1 or 2 (RAG1 or RAG2) fail to rearrange either their T-cell or B-cell antigen receptors and thus have a distinctive lymphocyte phenotype in that they lack both B- and T-lymphocytes and have primarily NK cells in their circulation ($T^-B^-NK^+$ SCID) (Table 28.2) (96). In addition, patients with Omenn's syndrome also have mutations in *RAG1*or *RAG2* genes, resulting in partial and impaired V(D)J recombinational activity (107). Omenn's syndrome is characterized by the development soon after birth of a generalized erythroderma and desquamation, diarrhea, hepatosplenomegaly, hypereosinophilia, and markedly elevated serum IgE levels. The latter are caused by circulating activated, oligoclonal T-lymphocytes that do not respond normally to mitogens or antigens *in vitro* (108,109). Circulating B cells are not found, and lymph node architecture is abnormal due to a lack of germinal centers (110). The condition is fatal unless corrected by bone marrow transplantation.

The most recently discovered molecular defect causing SCID is a mutation in the gene encoding the common leukocyte surface protein CD45 (98). This hematopoietic-cell-specific, transmembrane protein tyrosine phosphatase functions to regulate Src kinases required for T- and B-cell antigen receptor signal transduction. A 2-month-old male infant presented with a clinical picture of SCID and was found to have an extremely low number of T cells but a normal number of B cells. The T cells failed to respond to mitogens, and serum immunoglobulins diminished with time. He was found to have a large deletion at one CD45 allele and a point mutation causing an alteration of the intervening sequence 13-donor splice site at the other (98).

Severe combined immunodeficiency disease is a pediatric emergency (89,88). Nearly all cases could be diagnosed at birth if routine blood counts and manual differentials were done and flow cytometry and T-cell functional studies were performed when lymphocyte counts are below the newborn normal range (i.e., 2,000–11,000/mm^3) (111,89). Marrow transplantation in the neonatal period is highly successful.

Purine Nucleoside Phosphorylase Deficiency

More than 40 patients with combined cellular and humoral deficiencies have been found to have PNP deficiency (112). Although ADA and PNP are both purine salvage pathway enzymes, PNP deficiency does not lead to a combined immunodeficiency that is severe as seen in ADA deficiency. Deaths have occurred from generalized vaccinia, varicella, lymphosarcoma, and GVHD mediated by T cells from nonirradiated allogeneic blood or bone marrow. Two thirds of patients have had neurologic abnormalities ranging from spasticity to mental retardation. One third have developed autoimmune diseases, the most common of which was autoimmune hemolytic anemia. Most patients have normal or elevated concentrations of all serum immunoglobulins. PNP-deficient patients usually have absolute lymphocyte counts less than 500 per mm^3. Analyses of lymphocyte subpopulations with monoclonal antibodies have demonstrated a marked deficiency of T cells but increased numbers of NK cells. T-cell function is low but not absent and is variable with time.

The gene encoding PNP is on chromosome 14q13.1, and it has been cloned and sequenced (Table 28.2). A variety of mutations have been found in the PNP gene in patients with PNP deficiency. Unlike ADA deficiency, serum and urinary uric acid are markedly deficient because PNP is needed to form the urate precursors, hypoxanthine and xanthine. Prenatal diagnosis is possible. This condition is invariably fatal unless immunologic reconstitution can be achieved. Bone marrow transplantation is the treatment of choice but has thus far been successful in only three patients (113,114).

T-Cell Antigen Receptor Gene Deficiencies

These conditions include (a) mutations in the CD3 (cluster of differentiation nomenclature system) g (115) or e (116) chain genes, leading to impaired expression of the T-cell receptor (Table 28.2, Fig. 28.2). Patients have variable susceptibility to infection and autoimmunity. There are few or no circulating CD3+ T cells, poor responses to T-cell mitogens, and variable immunoglobulin and antibody deficiencies.

Wiskott–Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS) is an X-linked syndrome characterized by eczema, thrombocytopenic purpura with small defective platelets, and undue susceptibility to infection (3). During infancy, patients usually have bloody diarrhea or excessive bruising. Atopic dermatitis and recurrent infections with pneumococci and other encapsulated bacteria usually also develop during the first year of life. Later, infections with opportunistic agents, such as *P. carinii* and the herpesviruses, become more problematic. Autoimmune cytopenias and vasculitis are common in those who live beyond infancy. Infections and bleeding are major causes of death, but the most common cause of death is EBV-induced lymphoreticular malignancy.

Immunoglobulin concentrations are variable but near normal (117). Despite normal levels of IgG2, patients with WAS have an impaired humoral immune response to polysaccharide antigens, also evidenced by absence of isohemagglutinins (3). In addition, antibody titers to protein antigens fall with time. There are moderately reduced percentages of CD3-, CD4-, and CD8-bearing T cells, and lymphocyte responses to mitogens are depressed.

The mutated gene responsible for this defect was mapped to Xp11.22–11.23 and isolated in 1994 (Table 28.1) (6). It is highly expressed in lymphocytic and megakaryocyte lineages (6). The gene product, a 501 amino acid proline-rich protein that lacks a hydrophobic transmembrane domain, was designated the Wiskott–Aldrich syndrome protein (WASP) (Fig. 28.2). It binds CDC42H2 and rac, members of the Rho family of GTPases (118). WASP appears to control the assembly of actin filaments required for microvesicle formation downstream of protein kinase C and tyrosine kinase signaling. A large and varied number of mutations in the *WASP* gene have been identified in WAS patients (119). Isolated X-linked thrombocytopenia also is caused by mutations in the *WASP* gene (120). Carriers can be detected by the finding of nonrandom X chromosome inactivation in several hematopoietic cell lineages or by detection of the mutated gene (121). Prenatal diagnosis of WAS also can be made by chorionic villous sampling or amniocentesis. Two families with apparent autosomal inheritance of a clinical phenotype similar to

WAS have been reported (122,123). In another report of a girl with WAS, however, extremely skewed X chromosome inactivation combined with a mutation at the X-linked WASP locus on the active X chromosome to produce typical clinical WAS (124).

Some patients with WAS have had complete corrections of both the platelet and the immunologic abnormalities by HLA-identical sibling or matched unrelated donor bone marrow or cord blood transplants after being conditioned with irradiation or busulfan and cyclophosphamide (114,125,126). Several patients who required splenectomy for uncontrollable bleeding had impressive rises in their platelet counts and have done well clinically while on prophylactic antibiotics and intravenous immunoglobulin (IVIG) infusion (127).

Ataxia Telangiectasia

Ataxia telangiectasia is a complex combined immunodeficiency syndrome with associated neurologic, endocrinologic, hepatic, and cutaneous abnormalities (3,128). The most prominent features are progressive cerebellar ataxia, oculocutaneous telangiectasias, recurrent bacterial sinopulmonary disease, a high incidence of malignancy (129), and variable humoral and cellular immunodeficiency. Fatal varicella occurred in one of my patients, and transfusion-associated GVHD has also been reported (130).

Selective IgA deficiency is found in from 50% to 80% of affected individuals. IgG2 or total IgG may be decreased. *In vitro* tests of lymphocyte function have generally shown moderately depressed proliferative responses to mitogens. The thymus is hypoplastic, exhibits poor organization, and is lacking in Hassall corpuscles.

Cells from patients as well as those of carriers have sensitivity to ionizing radiation, defective DNA repair, and frequent chromosomal abnormalities (128,131). The most common causes of death are lymphoreticular malignancy and progressive neurologic disease (128,129). Adenocarcinoma and other forms of malignancy also have been seen.

The gene that is defective in AT, *ATM,* resides on chromosome 11q22.3 (Table 28.2, Fig. 28.2) (128,132). *ATM* encodes a phosphatidylinositol-3-kinase involved in mitogenic signal transduction, meiotic recombination, and cell cycle control.(133,134)

T-CELL ACTIVATION DEFECTS

T-cell activation defects are those in which there are phenotypically mature T cells present, but the cells fail to proliferate in response to mitogens or antigens.

CD8 Lymphocytopenia or Zeta-associated Protein-70 Deficiency

This condition is due to mutations in a gene on chromosome 2 at position q12 encoding ZAP-70, a non-src family protein tyrosine kinase important in T cell signaling (Table 28.1; Fig. 28.2, and Fig. 28.6) (135,136). ZAP-70 has an essential role in both positive and negative selection in the thymus (137). Patients with this condition may have moderate infections or infections as severe as those in SCID. Eight cases have been reported, and most were in Mennonites (135,136). Affected persons have normal or elevated numbers of circulating $CD4^+$ T-lymphocytes but essentially no $CD8^+$ T cells because of lower availability of compensatory signaling pathways for $CD8^+$ cell development within the thymus. The thymus of one patient exhibited normal architecture; there were normal numbers of double-positive ($CD4^+$ $CD8^+$) thymocytes but an absence of CD8 single positive thymocytes. Circulating $CD4^+$ T cells fail to respond to mitogens or to allogeneic cells *in vitro* or to become cytotoxic cells. By contrast, NK activity, B-cell numbers, and serum immunoglobulin concentrations are normal.

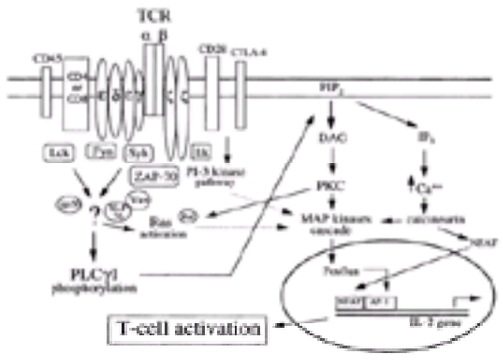

Figure 28.6. T-cell signal transduction pathway. The T-cell receptor (TCR) spans the plasma membrane in association with CD3 and z, CD4 or CD8, CD28 and CD45. Cytoplasmic protein tyrosine kinases (PTK) associated with the TCR are activated on antigen binding to the TCR. These PTK include Lck, Fyn, ZAP-70, and Syk. PTK activation results in the phosphorylation of phospholipase Cg1 and the activation of other signaling molecules. Distal signaling events, including PKC activation and Ca^{2+} mobilization, result in the transcription of genes encoding interleukin-2 (IL-2) and other proteins, culminating in T-cell activation, differentiation, and proliferation. Ionomycin and phorbol myristate acetate (PMA) can be used to mimic distal signaling events. Mutations in the gene encoding z-activating protein-70 (ZAP-70) result in markedly impaired T-cell activation, in addition to abnormal thymic selection resulting in CD8 deficiency. (Modified from Elder ME. Severe combined immunodeficiency due to a defect in the tyrosine kinase ZAP-70. *Pediatr Res* 1996;39:743-748. *Pediatr Res* 31996;39:744, courtesy of Dr. Melissa Elder.)

p56 Lck Deficiency

A 2-month-old male infant who presented with bacterial, viral, and fungal infections was found to be lymphopenic and hypogammaglobulinemic. B and NK cells were present, but there was a low number of $CD4^+$ T cells (138). Mitogen responses were variable. The T cells failed to express the activation marker CD69 when stimulated through the T-cell receptor but did when stimulated with phorbol myristate acetate and a calcium ionophore, suggesting a proximal signaling defect. Molecular studies revealed an alternatively spliced transcript for p56 Lck that lacked the kinase domain (Fig. 28.2 and Fig. 28.6) (138).

GENETIC DEFICIENCIES OF HLA MOLECULES

MHC Class I Deficiency

An isolated deficiency of MHC class I molecules is rare, and the resulting immunodeficiency is milder than in SCID. Class I MHC molecules, normally found on all cells in the body, are absent. There is a deficiency of $CD8^+$ but not of $CD4^+$ T cells. Mutations have been found in two genes within the MHC locus on chromosome 6 that encode the peptide transporter proteins, TAP1 and TAP2 (Table 28.2, Fig. 28.1) (139,140,141,142 and 143). TAP proteins function to transport peptide antigens from the cytoplasm across the Golgi apparatus membrane to join the a chain of MHC class 1 molecules and b microglobulin. The complex then can move to the cell surface; if the assembly of the complex cannot be completed because there is no peptide antigen, the MHC class I complex is destroyed in the cytoplasm (144).

MHC Class II Deficiency

Many persons affected with this autosomal recessive syndrome are of North African descent (145). More than 70 patients have been identified. Affected persons in infancy have persistent diarrhea, often associated with cryptosporidiosis, bacterial pneumonia, *Pneumocystis* infection, septicemia, and viral or monilial infections. Nevertheless, their immunodeficiency is not as severe as in SCID, as evidenced by their failure to develop BCG-osis or GVHD from nonirradiated blood transfusions (145).

Patients who are deficient in MHC class II antigens have a low number of $CD4^+$ T cells but normal or elevated numbers of $CD8^+$ T cells. Lymphopenia is only moderate. The MHC class II antigens, HLA-DP, DQ, and DR, are undetectable on blood B cells and monocytes. The patients have impaired antigen-specific responses caused by the absence of these antigen-presenting molecules. In addition, MHC antigen-deficient B cells fail to stimulate allogeneic cells in mixed leukocyte culture. Lymphocytes respond normally to mitogens but not to antigens. The thymus and other lymphoid organs are severely hypoplastic. The lack of class II molecules results in abnormal thymic selection because recognition of HLA molecules by thymocytes is central to both positive and negative selection. The latter results in circulating $CD4^+$ T cells that have altered CDR3 profiles (146). The associated defects of both B- and T-cell immunity and of HLA expression emphasize the important biologic role for HLA

determinants in effective immune cell cooperation.

Four different molecular defects resulting in impaired expression of MHC class II antigens have been identified (Table 28.2, Fig. 28.1) (147). In one defect, there is a mutation in the gene on chromosome 1q that encodes a protein called RFX 5, a subunit of RFX, a multiprotein complex that binds the X box motif of MHC II promoters (148). A second form is caused by mutations in a gene on chromosome 13q that encodes a second 36-kd subunit of the RFX complex, called RFX-associated protein (RFXAP) (149). The most recently discovered and most common cause of MHC class II defects are mutations in RFANK, the gene encoding a third subunit of RFX (147). In a fourth type, there is a mutation in the gene on chromosome 16p13 that encodes a novel MHC class II transactivator (CIITA), a non-DNA-binding coactivator that controls the cell-type specificity and inducibility of MHC-II expression (150). All these defects cause impairment in the coordinate expression of MHC class II molecules on the surface of B cells and macrophages.

IMMUNODEFICIENCY DISEASES WITH UNIQUE PHENOTYPES

X-linked Lymphoproliferative Disease

X-linked lymphoproliferative disease (XLP) is characterized by failure to eliminate reactive cytotoxic T cells after infection with EBV (151,152). Those affected appear healthy until they experience infectious mononucleosis (151). The mean age of presentation is less than 5 years. The most common form of presentation (75%) is severe mononucleosis, of which 80% of cases are fatal, primarily from extensive liver necrosis caused by activated cytotoxic T cells (151). Most patients surviving the primary infection develop global cellular immune defects, lymphomas, aplastic anemia, and hypogammaglobulinemia. The defective gene in XLP was localized to the Xq26–q27 region and identified as the gene that encodes a T and NK cell adapter protein (Table 28.1, Fig. 28.2) that interferes with the binding to downstream signaling molecules by a high-affinity self-ligand that is present on the surfaces of T and B cells, called signaling lymphocyte activation molecule (SLAM) (153,154 and 155). The adapter protein, called variously *SH2D1A* (the official designation), *SAP* (for SLAM-associated adapter protein), or DSHP (for Duncan syndrome human protein), normally serves to inhibit signal transduction by SLAM so that T cell proliferation does not continue unchecked (151). About half of a small number of patients with XLP given HLA-identical bone marrow transplants are currently surviving without sign of the disease.

Interleukin-2 Receptor a-Chain (CD25) Deficiency

Paradoxically, a mutation in the IL-2 receptor a-chain gene in an infant produced too many, rather than too few, T cells, with extensive infiltrates of the lungs, liver, gut, spleen, lymph nodes and bone (Fig. 28.2) (156). Serum IgG and IgM were elevated, but IgA was low. The infant was lymphopenic, and his T cells responded poorly to anti-CD3, phytohemagglutinin (PHA), and IL-2. This defect and that in XLP are among probably many that are characterized clinically by lymphoproliferation and autoimmunity and are caused by an imbalance of positive and negative signals caused by mutations in genes encoding negative regulatory components.

Hyperimmunoglobulin E Syndrome

The hyper-IgE syndrome is a primary immunodeficiency disorder that was first described in 1972; it is characterized by recurrent staphylococcal abscesses and markedly elevated serum IgE concentrations (157). Those affected have life-long histories of severe recurrent staphylococcal abscesses involving the skin, lungs, joints, and other sites. In addition, there is a unique tendency of these patients to form persistent pneumatoceles following staphylococcal pneumonias. Although usually there is a history of a pruritic dermatitis, it is not typical atopic dermatitis, and respiratory allergic symptoms are usually absent. I noted coarse facial features in the first two patients (157). Hyper-IgE syndrome patients look different from their nonaffected family members. Distinctive facial characteristics were pointed out again by Grimbacher and associates (158). Among the findings reported were a prominent forehead, deep-set eyes, a broad nasal bridge, a wide and fleshy nasal tip, mild prognathism, facial asymmetry, and hemihypertrophy. They also found that the mean nasal interalar distance in these patients was above the 98th percentile ($p < 0.001$). These findings were present in all patients in that study by age 16 years (158). A high incidence of scoliosis also was noted. An interesting observation in that group of patients that had not been previously reported was a 72% incidence of failure or delayed shedding of the primary teeth owing to lack of root resorption (158). This syndrome was mapped to chromosome 4; however, neither the fundamental host defect nor a defective gene has been identified in this condition (159).

TREATMENT

The principal modes of therapy for the primary immunodeficiency disorders include protective isolation, use of antibiotics for the eradication or prevention of bacterial and fungal infections, and attempted replacement of missing humoral or cellular immunologic functions. The complexities of both the immunodeficiency diseases and their treatment emphasize the need for all such patients to be evaluated in centers where detailed studies of immune function can be conducted before therapy is selected or begun.

Antibody Replacement

Regular administration of antibodies in the form of human immune serum globulin (see in later chapter) and judicious use of antibiotics are the only treatments that have proved effective for disorders characterized by antibody deficiency. Patients with agammaglobulinemia, X-linked immunodeficiency with hyper-IgM, antibody deficiency with near-normal immunoglobulins, WAS, all forms of SCID, and any other type of defect in which antibody production is abnormal are candidates for immunoglobulin replacement therapy, most often given as IVIG (160). Anaphylactic reactions caused by IgE antibodies (in the patient) to IgA (in the immunoglobulin preparation) can occur in patients with common variable immunodeficiency who have absent serum IgA (46). All newly diagnosed patients with the latter defect should be screened for anti-IgA antibodies before undergoing IVIG therapy. If such antibodies are detected, IVIG therapy still may be possible by using IVIG containing almost no IgA (Gammagard, Baxter-Hyland, or a similar preparation from the American Red Cross) (160).

Immunoglobulin replacement therapy is contraindicated in patients with selective absence of serum and secretory IgA, owing to the high frequency of anti-IgA antibodies (43,46) and because these patients usually have normal quantities of IgG antibodies (160). IVIG should not be given to infants with transient hypogammaglobulinemia of infancy or to patients with steroid-induced low IgG levels because it could suppress their usually normal innate capacity to form antibodies. There is no indication for the use of gamma globulin therapy in patients with IgG subclass deficiencies unless they have been shown to have a broad defect in antibody-forming capacity, and it is futile to give it to patients with low IgG caused by protein-losing states, such as congenital lymphangiectasia or other protein-losing enteropathies (160).

Thymus Transplantation

The only truly effective therapy for patients with severe forms of cellular immunodeficiency is immunologic reconstitution by means of immunocompetent tissue transplantation (114). Because of variability in the severity of the immunodeficiency in the DiGeorge syndrome, it is difficult to evaluate claimed benefits of fetal thymus transplantation (161,162). Unfractionated HLA-identical sibling bone marrow transplantation was effective in treating three infants with complete DiGeorge syndrome by virtue of adoptive transfer of mature T cells from the donor (163). It is unknown, however, how long that reconstitution will last because they do not have thymi to process stem cells into new T cells. For those infants with complete DiGeorge syndrome who have no HLA-identical siblings, transplantation of unrelated HLA-DR-matched cultured mature thymic epithelial explants is an option. Such transplants have successfully reconstituted the immune function of at least three DiGeorge patients (162).

Enzyme Replacement and Bone Marrow Stem Cell Transplantation

Bone marrow cells from a related donor who is MHC compatible or haploidentical with the recipient are currently the treatment of choice for all other patients with severe cellular immunodeficiency. The only other type of therapy with any efficacy for T-cell deficiency is regular injections of polyethylene glycol-treated bovine adenosine deaminase (PEGADA) for infants with ADA-deficient SCID. Even in those infants, however, bone marrow transplantation remains the treatment of choice because it is more effective and long lasting. PEGADA should not be given unless marrow transplantation has already failed because it will empower the infant's T cells to reject the graft. The major risk to the recipient from transplants of bone marrow or cord blood is GVHD. This risk is much greater if the donation is from a matched unrelated (MUD) adult or cord blood source or if pretransplant chemoablation is given to the recipient. It has been repeatedly shown that pretransplant chemoablation is not necessary to achieve engraftment in SCID patients (88); this also allows the omission of T-cell-toxic drugs like cyclosporine, methotrexate, and steroids in the posttransplant period. The use of the latter drugs defeats the purpose of the transplantation, that is, to achieve immunoreconstitution. The development of techniques to deplete all postthymic T cells from donor marrow has permitted the safe and successful use of haploidentical (half-matched) related bone marrow cells for the correction of SCID for the past 19 years (88,114). Although donor and recipient are only half-matched, rigorous depletion of T cells from the donor marrow also allows the omission of GVHD prophylaxis with cyclosporine and methotrexate. Transplantation of SCID infants in the first 3 months of life with either HLA-identical or HLA-haploidentical related bone marrow stem cells has been shown to offer up to a 96% chance of survival (88). Currently, more than 400 SCID patients worldwide are surviving as a result of successful HLA-identical or -haploidentical bone marrow transplantation (114). Patients with less severe forms of cellular immunodeficiency reject such grafts unless they are given chemoablation before transplantation, and even then there has been a high incidence of resistance to engraftment of T cell-depleted, half-matched marrow cells (164). Several patients with WAS syndrome and other forms of partial cellular immunodeficiency have been treated

successfully with unfractionated HLA-identical related or MUD bone marrow transplants after immunosuppression (114).

Gene Therapy

There is now more optimism than ever that primary immunodeficiency diseases for which the molecular defects have been identified will be correctable by gene therapy. A normal gc-cDNA was successfully transduced into autologous marrow cells of infants with SCID-X1 by retroviral gene transfer, with subsequent full correction of their T and NK cell defects (165). This offers hope that gene therapy eventually will be the treatment of choice for all patients with SCID or other genetically determined immunodeficiency diseases for whom the molecular basis is known. There are still many SCIDs (Fig. 28.4) as well as other types of immunodeficiencies for which the molecular defects have yet to be identified; until then, bone marrow transplantation will remain the treatment of choice (89,88).

29 PHAGOCYTE DISORDERS

Steven M. Holland, M.D., and John I. Gallin, M.D.

The neutrophil is the first line of phagocytic defense (see Chapter 15). In that exalted position, few defects are tolerated for long. Although multiple mechanisms of bacterial killing in the neutrophil have been well described, relatively few defects are associated with a demonstrated deficiency in any one of the components (1). This may be because fundamental defects of this system are lethal; that there may be a level of redundancy of killing that makes defects inapparent, or some reactions are relatively efficient even in the absence of specific enzymes. An example of the latter is myeloperoxidase (MPO) deficiency. Although many people who are deficient in MPO have been identified, the number who are clinically symptomatic is quite small, probably because generation of superoxide and hydrogen peroxide occurs at a superabundant level, killing organisms through pathways not dependent on halogenation. Therefore, it takes relatively extraordinary conditions, such as diabetes mellitus, to bring out the phenotype of this genetic disorder (2). In contrast, chronic granulomatous disease (CGD) is caused by a mutation in any one of four genes of the reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase system, all of which lead to an absence or a severe reduction of hydrogen peroxide generation and a roughly similar clinical condition (3). There have been multiple individual case descriptions of various defects involving neutrophils or their functional systems, but most of these are single case reports and are not well characterized at the pathophysiologic level. We have chosen here to concentrate on the growing handful of relatively well-characterized syndromes. Where they occur in nature, or have been created by humans, we discuss relevant animal models (Table 29.1).

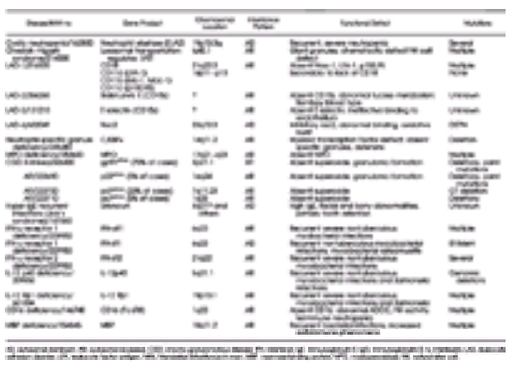

TABLE 29.1. Phagocyte Defects

The incidence of phagocyte defects is formally unknown, but we estimate it to be greater than 1 per 100,000. It is especially important to diagnose phagocyte disorders formally because this leads to specific counseling (e.g., to avoid mulch in CGD), institution of specific therapies [e.g., prophylactic antibiotics and interferon g (IFNg) in CGD], enlistment of other specialists (e.g., dentists for patients with Job syndrome and delayed dental deciduation), and early consideration of bone marrow transplantation [e.g., in leukocyte adhesion disorder (LAD)]. Perhaps more immediately important, the identification of specific phagocyte defects indicates the likely microbiology and therefore leads to appropriate empirical therapy for ongoing infections and will guide the considerations of duration and intensity (Table 29.1).

Symptomatic neutrophil abnormalities fall into several broad categories. They include abnormalities of neutrophil number or production, abnormalities of neutrophil adherence and locomotion, abnormalities of neutrophil granule formation or content, and abnormalities of killing. Several of these syndromes cross the functional categories, share functional defects, and involve abnormalities of nonphagocytic cells as well as phagocytes. A few of these syndromes have been described and characterized at the molecular level. The conditions to be considered in detail are cyclic neutropenia, the Chédiak–Higashi syndrome (CHS), LAD, neutrophil-specific granule deficiency, MPO deficiency, CGD, hyperimmunoglobulin E (HIE) with recurrent infections (HIE or Job syndrome), and defects involving the IFNg and IL-12 receptor pathways (Table 29.2). Although an in-depth discussion of therapeutics is beyond the scope of this chapter, the success of specific agents, notably cytokines, in the treatment of several of these syndromes has shed light on the etiology and pathogenesis of some of these disorders and are discussed herein.

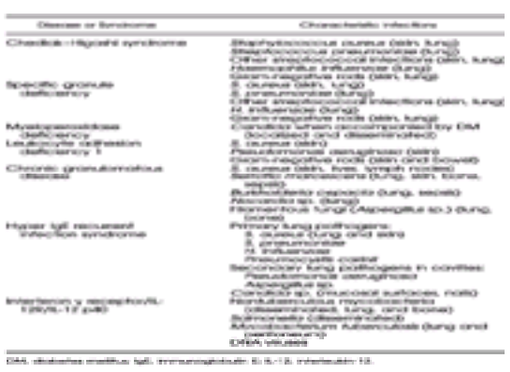

TABLE 29.2. Syndromes and Infections

The clinical presentations of patients with neutrophil disorders share common features. Gingivitis, periodontal disease, and oral ulceration are common in patients with neutrophil dysfunction (4). Cutaneous infections with *Staphylococcus aureus* are recurrent and can be severe. In neutrophil disorders characterized by inadequate inflammation (neutropenia, LAD, CHS, specific granule deficiency), infections can extend locally and subcutaneously with little reaction until marked destruction has taken place. Visceral symptoms, and especially sinopulmonary involvement, are features that help to distinguish neutrophil defects from other syndromes in the differential diagnosis. For instance, patients with HIE experience recurrent pneumonias, whereas patients with atopic dermatitis rarely do. Hepatic abscess is a frequent manifestation of CGD and most often is due to *S. aureus*, an organism rarely encountered at that anatomic site in patients with normal neutrophils. Described abnormalities of neutrophil function are few, and most patients evaluated for the disorders known to date show no defect. Because the management and prognosis of

these diseases vary widely with diagnosis, however, it is critical to search for suspected abnormalities. Updated diagnostic criteria were published (Table 29.2) (5).

As we more fully enter the genomic age of biologic information, we find genes clearly identified as causing disease without understanding their function. The demonstration of a genetic defect is only the first, and in some cases the easiest, step in the march toward understanding diseases, their pathophysiology, and rational therapy.

CYCLIC NEUTROPENIA

Cyclic neutropenia or cyclic hematopoiesis (m/m 162800[1]) is a rare disease occurring in autosomal dominant, spontaneous, and acquired forms. The autosomal dominant form is characterized by regular 21-day oscillations in the levels of blood neutrophils, monocytes, eosinophils, lymphocytes, platelets, and reticulocytes (6). The defect has been identified as being due to point mutations around the active site in ELA2, the gene for neutrophil elastase, one of the components of the neutrophil secondary granules (7). Neutrophil elastase is involved in tissue destruction, presumably to allow neutrophil entry into areas of infection and to allow for neutrophil transit across tissue planes. It is inactivated by a_1-antitrypsin, one of the serpin (serine protease inhibitor) family of proteins. How the loss of normal neutrophil elastase inactivation leads to the phenotype of cyclic neutropenia is still unclear, but presumably the altered neutrophil elastase disrupts the balance of activities in the bone marrow that allow for consistent and constant hematopoiesis. Along these lines, neutrophil elastase has been shown to be a competitive ligand for the binding of CD18/CD11b to intercellular adhesion molecule (ICAM), suggesting that neutrophil elastase may have a crucial role in getting neutrophils off of endothelium once they have adhered (8). The precise role of neutrophil elastase in hematopoiesis is yet to be characterized, however.

Patients usually present in childhood and have recurrent episodes of fever, malaise, mucosal ulcers, and occasionally life-threatening infections associated with periods of neutropenia (<200/µL) (6,9,10). Patients with adult-onset disease have been described with an associated clonal proliferation of large granular lymphocytes (LGL) as well (11,12). Neutrophil number is transiently impaired, but function is normal. Chronic neutropenia as seen in adults has been associated with abnormalities of Fas ligand expression and metabolism (13).

Wright et al. (14) performed bone marrow culture on patient-derived cells in the presence and absence of recombinant human granulocyte-microphage colony-stimulating factor (rhGM-CSF). Numbers of myeloid progenitors (granulocyte-macrophage colony-forming unit [GM-CFU]) were normal to increased and did not vary with cycle time but were markedly hyporesponsive to rhGM-CSF. This relative refractoriness was seen most dramatically in the neutrophil-committed colonies. Mononuclear cells derived from the marrow of patients with cyclic neutropenia and CD34+ progenitor cells also showed abnormally low responses to granulocyte colony-stimulating factor (G-CSF) but not to interleukin (IL)-3 (15).

The gray collie dog has an autosomal recessive condition similar to cyclic neutropenia except that cycling of cell counts occurs every 12 days instead of every 21 days. Bone marrow transplantation can be used to transfer the disease or to cure it in these dogs, confirming the stem cell as the critical component. Treatment of affected gray collies with recombinant human G-CSF (rhG-CSF) increases both peak and nadir neutrophil counts and shortens the frequency of cycling (16). Administration of rhG-CSF to patients has been successful in dramatically decreasing the number of days of neutropenia per month, increasing the peak and nadir polymorphonuclear (PMN) cell counts, shortening the periodicity of the cycle to 14 days from 21 days, and decreasing the symptoms of patients (17,18).

The diagnosis is suspected in children with recurrent stomatitis, gingivitis, cutaneous infections, lymphadenopathy, and fever. The clinical diagnosis can be established only after blood cell counts with differentials are repeated at least three times per week for at least 6 weeks. With the recognition of mutations in neutrophil elastase as the underlying cause of cyclic neutropenia, specific diagnosis requires demonstration of elastase gene mutations. Because this is an autosomal dominant mutation, patients are heterozygous, and mutation detection must be done at the molecular level. In congenital agranulocytosis (the Kostmann syndrome) (19), neutrophil counts are consistently low from birth and show no periodicity. Dale et al. (20) found that not only do patients with cyclic neutropenia have these mutations in neutrophil elastase, but so do most patients with congenital neutropenia; however, the mutations cluster in different areas of the molecule.

Management of the infections in cyclic neutropenia is simplified by the returning neutrophils and need not be as prolonged as in patients whose neutrophils are abundant but dysfunctional. Therapy for cyclic neutropenia is rhG-CSF administered subcutaneously (17). Although rhG-CSF does not eliminate the cycling of cell counts, it does lift the nadirs out of the neutropenic range and thereby prevents infections. Interestingly, rhG-CSF is also the treatment for congenital agranulocytosis (21). Treatment of large granular lymphocyte-associated neutropenia depends on immunosuppression, such as with methotrexate, steroids, or cyclosporine (22).

AUTOIMMUNE NEUTROPENIA

Autoimmune neutropenia is caused by peripheral destruction of neutrophils as a result of granulocyte-specific autoantibodies. Primary autoimmune neutropenia is the most common form of neutropenia seen in infants and young children and is not associated with other systemic immune disorders such as systemic lupus erythematosus (SLE) (23,24). Most patients have mild skin and upper respiratory tract infections, but a small minority may have severe infections such as pneumonia, meningitis, or sepsis. The discovery of primary autoimmune neutropenia may be coincidental because some patients remain asymptomatic despite low neutrophil counts. At diagnosis, most patients have a neutrophil count greater than 500 per microliter. The neutrophil count may transiently increase during a severe infection and return to neutropenic levels following resolution (24,25). Bone marrow examination is normal or shows increased cellularity; maturation arrest may occur, but myeloid precursors reach at least the myelocyte/metamyelocyte stage. Phagocytosed granulocytes may be seen in the bone marrow, indicating that the removal of sensitized granulocytes begins there.

Granulocyte-specific antibodies are found in primary autoimmune neutropenia, but detection may require repeated testing. Granulocyte immunofluorescence testing (GIFT) is one of the most sensitive methods available for the detection of antigranulocyte antibodies (25). The vast majority of these antibodies are immunoglobulin G (IgG), and are most commonly directed at the neutrophil antigen (NA) determinants in FcgRIIIb (CD16), the neutrophil and natural killer (NK) cell surface receptors for immunoglobulin. The NA antigens are recognized in more than 70% of cases of primary autoimmune neutropenia, but in 21% to 28% of cases, the autoantibodies are directed against the leukocyte integrin CD18/CD11b (26). The disease is typically self-limited, with neutropenia disappearing within 1or 2 years. Disappearance of the autoantibodies precedes normalization of neutrophil counts. Symptomatic treatment with antibiotics for infections is usually sufficient. Prophylactic antibiotic treatment should be reserved for those with recurrent infections: Cotrimoxazole, ampicillin, or first-generation oral cephalosporins are the most commonly used. For severe infections and in the setting of emergency surgical interventions, high-dose intravenous immunoglobulin (IVIG), corticosteroids, and rG-CSF are considered; G-CSF is the most effective at increasing the absolute neutrophil count (ANC).

Secondary autoimmune neutropenia can be seen at any age and has a more variable clinical course. It is typically associated with other systemic or autoimmune diseases such as hepatitis, SLE, or Hodgkin disease. Patients are at risk for developing other autoimmune problems, even if these are not evident at diagnosis. The antineutrophil antibodies have pan-FcgRIII specificity and are not specific for the NA. CD18/CD11b antibodies have been detected in a subset of patients with secondary autoimmune neutropenia (24). This neutropenia responds poorly to most therapies (27).

Alloimmune neonatal neutropenia was first described by Lalezari and Bernard (28) and is caused by the transplacental transfer of maternal antibodies against the fetal neutrophil antigens NA1, NA2, and NB1, leading to immune destruction of neonatal neutrophils, as reviewed by Dale (29). These complement activating antineutrophil IgG antibodies can be detected in 1:500 live births. Maternal absence of expression of FcgRIII (CD16) has been reported to be associated with this form of neutropenia in the neonate (30). Antibody-coated neutrophils are removed from the circulation, leaving the neonate neutropenic and at risk for infections. Omphalitis, cellulitis, and pneumonia typically occur within the first 2 weeks of life in the setting of neutropenia. The diagnosis can be made by detection of CD16-directed neutrophil-specific antibodies in maternal serum. Alloimmune neonatal neutropenia responds to G-CSF or high-dose IVIG, but most patients improve without specific treatment in a few weeks to 6 months (31).

CHÉDIAK–HIGASHI SYNDROME

This rare autosomal recessive disorder is characterized by recurrent bacterial infections, partial oculocutaneous albinism, photophobia, nystagmus, and peripheral neuropathy (MIM 214500). Many patients die in childhood from infection. About half of those who survive into adolescence develop an aggressive “lymphoproliferative” phase with diffuse organ infiltration and death. Several patients have lived into adulthood, at which time an aggressive, severe, debilitating peripheral neuropathy is a common feature (32). Pathologically, giant abnormal granules are found in PMN cells, melanocytes, hair, Schwann cells, the central nervous system (CNS), peripheral ganglia, capillary epithelium, renal tubular epithelium, erythroid precursors, fibroblasts, and other granule-containing cells (33) (Fig. 29.1). In neutrophils, the granules are formed mainly by fusion of azurophilic or primary granules to each other and, to a lesser extent, to specific or secondary granules (34). Whereas some features of the CHS cellular phenotype are reversible in cell culture in association with normal cells, granule fusion in CHS cells is not preventable (35). Multiple examples of the CHS phenotype exist in lower animals, making this disease amenable to *in vivo* experimentation.

Figure 29.1. Chédiak–Higashi syndrome. **A:** Polymorphonuclear leukocyte from a patient with Chédiak–Higashi syndrome. The grant granules are easily appreciated. Unfused granules are visible in the cytoplasm as well. **B:** A light microscope view of hair from a patient with Chédiak–Higashi syndrome is shown on the left. Clumps of pigment are seen irregularly distributed in the hair shaft as a result of giant melanosomes. **Right panel:** A normal hair with evenly distributed pigment for comparison.

The syndrome was described in 1943 by Beguez Cesar (36), in 1948 by Steinbrink (37), in 1952 by Chédiak (38), and in 1954 by Higashi (39). It was Sato (40) who identified the cases of Chédiak and Higashi as being one and the same entity and created the eponym Chédiak–Higashi syndrome. Using two-color immunofluorescence in peripheral blood and bone marrow, Rausch et al. (34) showed that in CHS, primary granules are normal in appearance after genesis during the promyelocyte stage, but they are abnormal in cellular distribution. With progressive maturation, primary granules condense into giant abnormal bodies with a few unfused normal primary granules nearby. At the myelocyte stage, genesis of normal-appearing secondary granules occurs. A few secondary granules fuse with the giant lysosomes, giving rise to double staining of the giant lysosomes. By the time of neutrophil maturation, essentially no unfused primary granules remain, and almost all remaining granules are secondary granules. These findings reflect a generalized abnormality of neutrophil granules affecting the earlier arising primary granules more severely and the later arising secondary granules less. The relative deficiency of primary granules and their associated functions may account in part for the abnormal bactericidal activity in CHS cells and the propensity for infection in patients with CHS.

Bone marrow aspirates and biopsy specimens show normal cellularity or hypercellularity despite peripheral neutropenia (32). Normal circulating granulocyte half-life, poor responses to stimuli of bone marrow release, and elevated serum lysozyme levels all indicate that the neutropenia associated with CHS is due to increased intramedullary destruction of PMN cells (41). Chemotaxis to a variety of stimuli and accumulation onto Rebuck skin windows are delayed and diminished in CHS (42). The *in vitro* chemotactic defect may be in part an artifact of interference by the giant lysosome with the ability of the PMN cell to traverse the filter that is frequently used (43). Rates of phagocytosis by CHS cells are increased over normal, but levels of some primary granule enzymes are below normal (44), leading to a decrease in bactericidal activity (45). Resting glucose oxidation and stimulated oxygen consumption are supranormal (45). The discrepancy in killing between CHS and normal phagocytes is most apparent in the first 20 minutes after ingestion and is more marked for *S. aureus* than for streptococci or gram-negative rods; candida-killing activity is normal (45).

Natural killer cell activity has been shown to be deficient in CHS patients. Antitumor NK activity is absent in patients with CHS, but binding of NK cells to tumor targets is normal (46,47). Despite extremely low lymphocytic antibody-mediated cellular cytotoxicity (ADCC), neutrophil and monocyte ADCCs are intact (48). CHS cells stain normally for the NK antigen HNK-1, which is present in higher density than normal (49). In keeping with the kinetic abnormalities observed in the bactericidal activity of CHS neutrophils, Targan and Oseas (50) coined the term *lazy NK cell of Chédiak–Higashi syndrome* to describe the restoration of NK function to CHS cells after prolonged exposures or incubations. Exposure of CHS NK cells to targets for four times longer than normal resulted in 10- to 100-fold increases in the rates of CHS NK cell lysis. Incubation with IFN-a at a high concentration resulted in an increase in lytic activity after 24 hours. CHS NK cells also were able to release normal amounts of soluble cytotoxic factors after 24 hours of target contact. Holcombe et al. (51) demonstrated elevated levels of g-d cells in CHS patients and were able to clone one such line and show it to be fully capable of tumor lysis, thus confirming the presence of a functional lytic mechanism in these cells. CHS cells have a quantitative defect in their killing of both intracellular and extracellular targets, which is most apparent when examined at early time points.

Features of CHS include CNS and peripheral nervous system (PNS) involvement with peripheral neuropathy, myopathy, autonomic dysfunction, and leptomeningeal involvement (33). Lymphohistiocytic infiltration of axons and myelin sheaths occurs in patients with peripheral neuropathy and in ganglia in patients with autonomic neuropathy. Melanin granules seen in the neurons of the substantia nigra are large, irregular, and clumped. These aggregates of melanosomes seem to increase in size and number with age. Low intelligence was noted in some series (32).

The accelerated phase of CHS is a diffuse lymphohistiocytic infiltrative process associated with adenopathy, organomegaly, and pancytopenia in about 85% of patients (32,52). Most of these abnormalities respond to therapy with vincristine and prednisone. Ascorbate is not protective against the accelerated phase (53). Similarities of the accelerated phase to hemophagocytic syndromes associated with defects of the granule protein perforin suggest that the underlying cause of this lymphoproliferative process may be due to the abnormal granule maturation and mobilization in CHS. In addition, abnormal presentation of the cytotoxic T-lymphocyte-associated antigen-4 (CTLA-4; CD152) may be important in the evolution of the lymphoproliferative disease (54). Bejaoui et al. (55) reported 18 episodes of accelerated phase in 11 patients. Treatment with etoposide (VP-16), steroids, and intrathecal methotrexate induced remission in seven of seven patients. Compatible bone marrow transplantation induced apparent cure in all three patients so treated, whereas all other patients eventually relapsed and died.

The protein defect in CHS has been identified as *lysosomal trafficking regulator* (*LYST*), encoded by the gene CHS1 located at 1q42 in humans (56,57 and 58). This gene was positionally cloned in the mouse, and mutations in it have been found to cause CHS-like syndromes in rodents, cattle, and humans. The gene is clearly involved in endosomal trafficking and various aspects of surface molecule display, but the mechanisms by which *LYST* works, and therefore the mechanisms of disease, remain elusive (59).

Many mammalian mutants have the pigmentary dilution characteristic of CHS. These include mink (60), cattle (61), mice (62), killer whales (63), cats (64), blue foxes (65), silver foxes (66), and rats (67). The *beige* mouse has been used extensively as a model for the neutrophil dysfunction of CHS (68). NK cell defects in the *beige* mouse closely resemble those in the human (69,70).

Diagnosis of CHS is made easily by inspecting the peripheral smear for giant lysosomes or microscopic examination of hair for characteristic melanin clumps. Management of CHS is challenging. The small numbers of patients followed at any one center have made design and execution of therapeutic trials difficult. Aggressive diagnosis and treatment of infections are of paramount importance. As in other diseases of defective neutrophil function, the extent of infection is often underestimated by clinical history and examination. This is the result of defective chemotaxis and bacterial killing. Prophylaxis with cloxacillin did not seem to have any significant role in reducing infections in four patients studied at the National Institutes of Health (NIH) (71).

The role of ascorbate has been difficult to clarify. Boxer et al. (72) showed improvement in *in vitro* parameters after *in vivo* administration of ascorbate to an 11-month-old girl with CHS. They found improvements in bactericidal activity, granule release, chemotaxis, and cyclic nucleotide levels. Weening et al. (73) also found improvements in bactericidal activity, chemotaxis, degranulation, and clinical course in a patient treated with ascorbate. Gallin et al. (74) found a slight improvement in the survival of lethally challenged *beige* mice with ascorbate therapy, but could demonstrate no benefit in two patients. The benefit of ascorbate is unreliable, but it is virtually without toxicity.

Bone marrow transplantation has been successful in several patients with CHS and should be pursued when appropriate donors are available (55,75). Although this cures the immunodeficiency and the accelerated phase, it does not alter the progressive neuropathy that is seen in many long-term survivors.

LEUKOCYTE ADHESION DEFICIENCY

Leukocyte adhesion to endothelium, other leukocytes, and bacteria is a critical step in the ability of leukocytes to communicate, travel, inflame, and fight infection. These processes are mediated by several sets of molecules on the leukocytes and the endothelium, critical among which are the integrins and selectins (see Chapter 15). Defects in either of these two intercellular adhesion pathways can lead to somewhat overlapping clinical phenotypes (76). In addition, transduction of the signal from the receptor on the leukocyte surface to structural proteins in the leukocyte permitting movement is dependent on the intracellular molecule *rac2* (77).

Type 1

Type 1 LAD (LAD 1; MIM 116920) is an autosomal recessive disorder that involves the leukocyte integrins, the molecules required for leukocyte adherence to endothelium, other leukocytes, and bacteria (78,79,80,81 and 82). Each of the leukocyte integrins is a heterodimer with a common b chain, CD18 (see Chapter 15). The a–b heterodimers of the integrin family include CD11a/CD18 [lymphocyte function antigen (LFA-1)], CD11b/CD18 (Mac-1 or CR-3), and CD11c/CD18 (p150,95, or

CR-4) (83). CD18 is a 95-kd protein expressed on phagocytes, monocytes, macrophages, and lymphocytes and is obligatory for expression of the respective a chains (84). The CD18 gene is located at chromosome 21q22.3, whereas the a chain genes, CD11a–c, are all located at chromosome 16p11–p13.1, presumably the result of a distant gene duplication event (85). The dysfunctional and nonfunctional mutations of CD18 are clearly multiple and fall into at least five categories (86). To date, no autosomal dominant mutations have been described.

Deficiency of CD18 leads to a corresponding deficiency of the complexes LFA-1, Mac-1, and p150,95 and resulting abnormalities of cellular adhesion (87). These abnormalities are predictable from the basic defect. Patients with LAD-1 have chronic leukocytosis, in part due to the inability of neutrophils to adhere to endothelium through the integrin pathways. Other marginated pools, such as those mediated by selectins and in the lung, mediated in part by the narrow capillaries there, are still likely to be intact. The poor inflammatory response leads to recurrent infections. Since 1974, patients who have recurrent life-threatening bacterial infections, chronic leukocytosis, and delayed and impaired wound healing in the setting of neutrophils defective in chemotaxis and phagocytosis have been described (88,89). Crowley et al. (90) proposed that this abnormality was due to a defect in cellular adhesion. By the mid-1980s, it was appreciated that these patients were all defective in the high-molecular-weight proteins LFA-1, Mac-1, and p150,95 (87,91). Kishimoto et al. (86) subsequently showed that all three molecules exist as a–b heterodimers in association with a common b chain, CD18, which is the defective moiety in LAD.

Type 1 LAD falls into two broad categories, severe and moderate, depending on the degree of CD18 deficiency (87,91). Patients with severe deficiency (<0.5%) of normal protein expression have characteristic delayed umbilical stump separation, umbilical stump infection, persistent leukocytosis in the absence of active infection (>15,000/µL), and severe, destructive periodontitis with associated loss of dentition and alveolar bone. Recurrent infections of the skin, upper and lower airways, bowel, perirectal area, and septicemia are common and usually due to *S. aureus* or gram-negative rods, most notably *Pseudomonas* species. Infections tend to be necrotizing and may progress to ulceration but demonstrate an almost complete absence of neutrophil invasion on histopathology. Aggressive medical management with antibiotics and prompt surgery when indicated are requisite. In the absence of therapy directed at correction of the severe defect, such as bone marrow transplantation or perhaps gene therapy in the future, death before age 2 is common (87,91).

Patients with the moderate form of disease (3%–10% of normal expression) tend to have normal umbilical stump separation, to be diagnosed later in life, and less commonly have life-threatening infections. Leukocytosis is still the rule, as is delayed wound healing and periodontal disease. These patients are less ill and tend to live beyond childhood, but several deaths of young adults from infection have been reported (87,91). Hogg et al. (92) identified a patient with relatively high-level expression of CD18 and its associated complexes but a lack of function resulting from a mutation in the activation domain. Therefore, expression of CD18 alone is not adequate to exclude LAD-1.

Laboratory findings in general reflect the clinical differences between severe and moderate phenotypes of the disease, with the severe form showing more profound deficiencies. Abnormalities include grossly defective granulocyte and mononuclear cell mobilization into Rebuck skin windows *in vivo* and diminished neutrophil migration in response to the bacterial chemoattractant formyl-methionine-leucine-phenylalanine (fMLF) *in vitro*, despite normal numbers of fMLP receptors (87,91). These laboratory abnormalities are demonstrated *in vivo* in histologic sections of infected tissues, showing the presence of some mononuclear cells but extremely low numbers of invading neutrophils. Adherence of granulocytes from patients to glass, plastic, nylon wool, and to other LAD granulocytes is greatly reduced and is not stimulated by exposure to fMLF or phorbol myristate acetate (PMA) (87,91) (Fig. 29.2). The absence of CD18 leads to the absence of Mac-1 (also known as the iC3b receptor, CR3). It is therefore expected and observed that complement-mediated phagocytosis is severely impaired, whereas IgG-mediated phagocytosis is normal. Although viral infections are not usually special problems in LAD, antibody-dependent cell-mediated cytotoxicity (ADCC) by cells from patients is also diminished. Oxidative metabolism in response to PMA or calcium ionophore is normal in granulocytes from patients as measured by nitroblue tetrazolium (NBT) reduction or chemiluminescence. Primary and secondary granule release in response to PMA or chemoattractants is normal in LAD cells, whereas the response after zymosan particle ingestion is depressed (87,91).

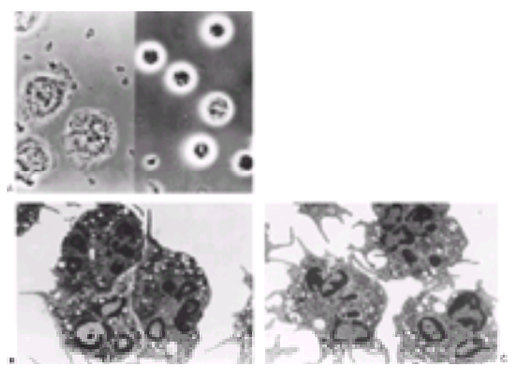

Figure 29.2. Leukocyte adhesion deficiency (LAD) type 1. **A:** Normal neutrophil adhesion to plastic is seen in the **left panel;** note the flat, spread-out cells with cytoplasmic projections. **Right panel** shows LAD-1 cells; note the rounded, refractile, unattached cells, which are characteristic of the adhesion-defective cells of LAD. **B:** Normal neutrophils change shape and clump when stimulated with formyl peptide. **C:** LAD-1 cells change shape but fail to clump in response to the same stimuli.

Animal models of LAD in the dog (93) and mouse (94,95) are currently described. Since 1975, the canine form of this disease has been described at least twice in Irish setters. They have the characteristics of human LAD with neutrophil dysfunction, leukocytosis, and frequent infections. Bovine LAD (BLAD) (96) is a more recently recognized homolog of LAD. The artificial insemination of cows with sperm from a particularly prolific bull, *Osborndale Ivanhoe*, and his progeny led to the current rate of about 14% of American bulls and 6% of American cows being heterozygous for the BLAD gene defect. The BLAD mutation is at nucleotide 383 and results in the change of amino acid 128 from aspartic acid to glycine (D128G). The affected calves have gingivitis, periodontitis, tooth loss, mild diarrhea, and poor growth. Most affected calves die within the first year of life. CD18 expression on neutrophils was less than 2%, and the neutrophil count was more than 47,000 per microliter (normal cow, about 4000/µl) (96).

The diagnosis of LAD1 is established through a thorough history, with special attention to depressed inflammation in the neonatal period, delayed umbilical stump separation, and recurrent infections. A dental history is helpful because most of these patients have severe problems with gingivitis, periodontal disease with tooth loss, and alveolar bone erosion. Wounds often heal abnormally, leaving atrophic, paper-thin scars. The diagnosis is confirmed by fluorescent-activated cell sorting (FACS) which shows reduction or absence of CD18, CD11a, CD11b, and CD11c. Therapy to date has consisted of bone marrow transplantation, when available, for severely affected patients. Engraftment has occurred in most of the few patients reported (91,97). Moderate disease is usually managed by scrupulous attention to infections with surgical débridement and drainage when necessary. Prophylactic antibiotics and cytokine administration, although they may have theoretic merit, have not been studied in a prospective manner. Wilson et al. (98) reported correction of this defect in immortalized patient B cells with a retroviral vector carrying the CD18 gene. Gene therapy may offer the long-term benefits for this disease (99). Animal-model systems should facilitate the next series of gene correction experiments as well as make exploration of other therapeutic approaches possible.

Because neutrophil adhesion is clearly important in the mediation of certain aspects of inflammation, especially in the ischemia–reperfusion period, study of this receptor system is important for understanding the role of neutrophils in inflammation and provides an important site for potential modulation (100).

Type 2

In LAD type 2 (LAD 2; MIM 266265), neutrophil adherence to endothelial cells is defective, on the basis of the absence of the sialyl-Lewis X antigen (CD15s) on the neutrophil surface, which is the binding site for E- and P-selectins (101) (see Chapter 15). The reported patients were products of consanguineous marriages and had neutrophilia; recurrent pulmonary, periodontal, and cutaneous infections; abnormal chemotaxis; mental retardation; short stature; distinctive facies; and the Bombay (hh) blood phenotype (101,102). The underlying defect is autosomal recessive and appears to be in fucose metabolism. This defect in fucosylation has much broader implications than neutrophil function alone (102,103). Despite this apparently severe defect, the infection susceptibility phenotype appears to moderate over time and to present very little problem in adolescence (104).

Type 3

DeLisser et al. (105) recently reported a child with a history of *Pseudomonas* omphalitis, recurrent otitis, and urinary and severe soft tissue infections who had impairment of pus formation and neutropenia. They found normal CD18 and CD15s expression but no E-selectin on endothelium; however, the sequence of the E-selectin cDNA was normal and E-selectin levels in the circulation were twice normal, suggesting that there may be a problem in E-selectin tethering or secretion. The neutropenia is somewhat difficult to explain, but it did respond to G-CSF therapy. This child had lost a full sibling to *in utero* infection but has two normal half-siblings,

leaving the pattern of inheritance unclear.

Type 4

Ambruso et al. (106) described a child with failure of umbilical cord separation at 5 weeks and a perirectal abscess who had neutrophilia but normal CD18 and CD15s levels. They showed that this child had an autosomal dominant mutation in *Rac2*, the predominant *rac* molecule in the neutrophil. This defect led to failure of coupling of the CD18 ligation signal to cellular actin, thereby disrupting the ability of the cell to respond to a variety of stimuli. In addition, *Rac* is needed for superoxide production, degranulation, and chemotaxis, all of which were severely defective in this child. A mouse model of *Rac2* deficiency predicted a similar phenotype (77). This mouse model shows abnormalities in T-helper cell-1 (Th1) activation as well, indicating a critical role for *Rac2* in activation of interferon gamma secretion and Th1 differentiation (107).

NEUTROPHIL-SPECIFIC GRANULE DEFICIENCY

Neutrophil-specific (secondary) granule deficiency (MIM 245480) is a rare, heterogeneous, autosomal recessive disease characterized by the profound reduction or absence of neutrophil-specific granules and their contents (108,109). Associated abnormalities in the few patients reported include bilobed or trilobed notched neutrophil nuclei, mononuclear eosinophils, and absence of some primary granule proteins.

In 1974, Strauss et al. reported a boy with recurrent bacterial infections without sepsis whose neutrophils had nuclear structural abnormalities and appeared to be without specific granules. Nuclei were predominantly bilobed with rare trilobar forms, and eosinophils were mononuclear. Platelet function and results of chromosomal analysis were normal. Specific granules appeared late in neutrophil ontogeny and were few in number and abnormal in shape. Rebuck skin window studies showed no accumulation of PMN or mononuclear cells over 24 hours, and neutrophil migration *in vitro* was markedly diminished. Staphylococcicidal activity was reduced as a result of inadequate phagocytosis, but candidacidal activity was normal. NBT reduction and superoxide production were normal. This was the first report of a selective defect in secondary granules (109). Four subsequent patients have been described, and all share the cardinal features of this boy's syndrome: paucity or absence of neutrophil-specific granules, predominantly bilobed neutrophil nuclei (pseudo-Pelger–Huët anomaly), and increased susceptibility to infections (108,110,111 and 112). Where measured, the cell surface–volume ratio was elevated in specific granule deficiency cells, consistent with either augmentation of plasma membrane surface by premature discharge of specific granules or immaturity (108,113).

The specific granule protein lactoferrin is diminished or absent in these patients' neutrophils (109,113,114). In one patient, despite the low total amount of neutrophil lactoferrin, the percent released in response to stimulation was normal (113). The defective production of lactoferrin is relatively tissue specific. Studies of bone marrow show no lactoferrin protein and extremely low levels of messenger RNA (mRNA) (114). In contrast, lactoferrin protein was more abundant than normal in nasal secretions. The existence of only one lactoferrin gene and the presence of grossly normal copies of it in the affected patients confirmed that the expression of lactoferrin was tissue specific and raised the possibility of a transcriptional factor defect underlying the host of defects seen in specific granule deficiency (114).

Interesting differences between some of these patients suggest that it is not a single entity but perhaps a variety of defects along a pathway that have a final common expression. The patient described by Gallin et al. (108) had no eosinophils detected on visual inspection of peripheral blood or bone marrow smear and delayed disaggregation following stimulation. Subsequently, however, it was shown that cells staining positive for eosinophil peroxidase were present in normal numbers despite the absence of classic eosinophils on smear, and they increased markedly with GM-CSF therapy (115). The patient described by Strauss et al. (109) and Boxer et al. (113) had normal numbers of eosinophils and increased disaggregation. The patient first reported by Gallin et al. (108) developed joint hyperextensibility as a child and diffuse osteopenia and severe aortic regurgitation as an adult.

Other granule contents also are affected in specific granule deficiency. The primary (azurophil) granule products, defensins, are low or absent (116), as is the tertiary granule product, gelatinase (117). Although normal platelet function was noted in the patient reported by Strauss et al. (109), abnormalities of hemostasis were associated with reduced levels of platelet-associated, high-molecular-weight von Willebrand factor and reduced levels of platelet fibrinogen and fibronectin in the patient reported by Parker et al. (118). These anomalies indicate a defect in platelet a granules as well as in the primary, secondary, and tertiary granules. Eosinophil granules also are affected in specific granule deficiency (115). Sibling deaths at early ages, consanguineous marriages in parents of patients, and occurrence of the syndrome in females have led to the assumption of an autosomal recessive pattern of inheritance for specific granule deficiency.

The recognition that the mouse deficient in the CCAAT/enhancer binding protein e (C/EBPe) had a clinical phenotype similar to that of specific granule deficiency prompted our investigation of the human C/EBPe locus in the case reported by Gallin et al. (108). A homozygous, autosomal recessive, disabling mutation was found in C/EBPe, located at 14q11.2 (119). Therefore, at least one case of specific granule deficiency is due to C/EBPe deficiency, confirming the prediction that a transcription factor defect underlies specific granule deficiency, thereby uniting the defects in primary, secondary, tertiary, and platelet a granule contents. Two subsequent cases examined do not have mutations in C/EBPe, suggesting that this may be a genetically heterogeneous disease (Lekstrom-Himes, Gallin, and Casanova, unpublished observations).

The diagnosis of specific granule deficiency (SGD) rests on clinical suspicion bolstered by careful inspection of the peripheral smear (Fig. 29.3). Nuclear morphology is abnormal in both PMN cells and eosinophils with bilobed or trilobed PMN cells and mononuclear eosinophils. In some cases, eosinophils may not be detectable on routine smears. Demonstration of absent or low specific granule contents helps confirm the diagnosis. Electron microscopy shows absent peroxidase-negative granules in some patients and empty peroxidase-negative granules in others. Management is complicated by these patients' impaired inflammatory response and impaired killing of some intracellular organisms. Gram-positive cocci are the most common offenders but not exclusively so. As in other patients with defective inflammatory responses, clinical examination often understates the extent of infection. Aggressive diagnosis of infection, prolonged and intensive therapy, and early use of surgical excision and débridement are necessary. Although the C/EBPe gene is responsible for at least one case of SGD, other cases of this immunodeficiency may reflect defects at other sites along this pathway of early myeloid maturation (120).

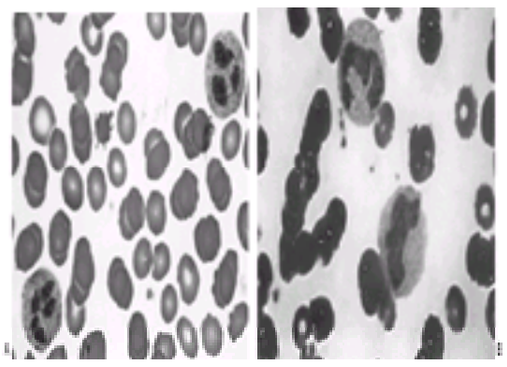

Figure 29.3. Neutrophil-specific granule deficiency. **A:** Wright's stain of normal neutrophils shows granularity of the cytoplasm and well-defined lobulations of the nucleus. **B:** Cells from a patient with neutrophil-specific granule deficiency show a pale cytoplasm with poorly defined nuclear lobulations. Note that the patient's cells are larger than the normal neutrophils. This is easily appreciated if red blood cells are used in comparison.

MYELOPEROXIDASE DEFICIENCY

Also called *verdoperoxidase*, MPO is the heme binding protein that makes pus green. It catalyzes the marriage of hydrogen peroxidase and halide ion into hypohalous acid. In neutrophils, this results in hypochlorous acid or bleach; in eosinophils this results in hypobromous acid. MPO is synthesized and packaged into azurophil granules only during the promyelocyte phase of neutrophil development. From the mature neutrophil, it is released either into the phagosome or into the extracellular space (2). The complementary DNA (cDNA) for MPO has been cloned and the gene localized to 17q21.3–q23 (121,122). The presence or absence of MPO is affected in certain hematologic malignancies and may serve as a tumor marker (123).

Myeloperoxidase is synthesized as an 89-kd precursor molecule that is cleaved to 59-kd and 13-kd moieties in the prelysosomal compartment. The mature enzyme complex, which consists of two heavy and two light chains of MPO, migrates at about 150 kd under nonreducing conditions. Individuals homozygous for myeloperoxidase deficiency are completely deficient in the mature MPO protein product, whereas heterozygotes have half the normal amount of normal MPO in their neutrophils (124) (MIM 254600). Some deficient patients have detectable precursor without mature protein (124), and others have detectable mRNA for MPO but no detectable protein (125). Nauseef (126) demonstrated at least two separate defects in five unrelated patients with MPO deficiency, by protein, mRNA, and genomic

analysis. The most common defect affects the arginine at 569, usually converted to tryptophan (127).

With the advent of automated cytochemical systems for determining differential counts of peripheral blood cells in the late 1970s, MPO deficiency was transformed from the status of a rare syndrome (15 reported cases in the literature) to the most common genetic defect of neutrophils, at 1 in 2,000 persons (2,124). Most patients are entirely asymptomatic and are found only incidentally or through family screening (128). Of the MPO-deficient patients who had difficulty, most were infected with *Candida* organisms (2). Most of these patients also had diabetes mellitus, suggesting that further compromise of host defense exacerbates the phenotype of MPO deficiency.

Neutrophil function is affected by MPO deficiency in a variety of ways. The respiratory burst in MPO-deficient PMNs is prolonged, resulting in exaggerated amounts of superoxide (129). Phagocytosis is normal to increased in MPO-deficient PMNs, whereas bactericidal activity is somewhat slower than normal. Killing of *Aspergillus* conidia by MPO-deficient PMNs is retarded, whereas the combination of MPO-deficient PMNs with CGD PMNs (see later), which are unable to generate hydrogen peroxide but do produce MPO, results in normal killing of *A.* conidia (130). Candidacidal activity is markedly defective against the more pathogenic *Candida* species such as *C. albicans, C. krusei*, and *C. tropicalis*. In contrast, candidacidal activity is preserved against the less pathogenic *C. parapsilosis* (2). This is quite remarkable in view of the rare occurrence of *Candida* infections in MPO-deficient persons.

CHRONIC GRANULOMATOUS DISEASE

This genetically heterogeneous disease is characterized by recurrent life-threatening infections with bacteria and fungi and dysregulated granuloma formation (MIM 306400, 233690, 233700, 233710). CGD is caused by a defect in the NADPH oxidase, which is responsible for the respiratory burst and the generation of superoxide (see Chapter 15). The functional NADPH oxidase is a six-protein complex. In the basal state, it exists as two components: a membrane-bound complex embedded in the walls of secondary granules, and distinct cytosolic components (3). The granule membrane contains the heme and flavin-binding cytochrome b_{558}, which is composed of a 91-kd glycosylated a chain (gp91^{phox}) and a 22-kd b chain (p22^{phox}). The cytosolic components are p47^{phox}, p67^{phox}, p40^{phox} and *rac*. All these components are necessary for the generation of superoxide except p40^{phox}, which is thought to have a regulatory role. On cell activation, the cytosolic components translocate to the cytochrome in the membrane, resulting in an active NADPH oxidase. Pathologic mutations causing CGD in all the required components have been documented (131,132 and 133). The inability to generate superoxide leads to a failure to make the reactive oxygen species hydrogen peroxide and hydroxyl radical. This defect in turn manifests as defective microbial killing and recurrent infections with catalase-positive bacteria and fungi. No spontaneous animal models exist, but homologous recombinants to inactivate gp91^{phox} and p47^{phox} have been created (134,135). *In vitro* techniques are advanced in terms of both cell-free systems and functional cell lines.

The disease was first described by Janeway et al. (136) and by Berendes et al. (137) and Landing and Shirkey (138), but it was not well characterized until 1959 (139). Several cases and cohorts in male subjects were described over the ensuing years, suggesting an X-linked pattern of inheritance (140). The demonstration of cases in three sisters in 1968 led to the recognition of autosomal recessive forms of CGD as well (141). Subsequently, each of the genes required for mounting the respiratory burst has been cloned, sequenced, and localized.

In a classic display of positional cloning or reverse genetics, Royer-Pokora et al. (142) cloned the gene encoding gp91^{phox} by a subtraction hybridization strategy from a boy with an interstitial deletion of Xp21. This led to the description of several mutations in this gene, most of which result in a failure to produce protein (143). The gp91^{phox} promoter element is quite unusual and shows unique phagocyte-specific regulation (144). Failure to produce either member of the cytochrome heterodimer prevents expression of the other (145,146). There are cytochrome-positive cases described in which a defective gp91^{phox} is expressed (143,147,148).

Chronic granulomatous disease is characterized by a host of different mutations in the different genes. The most common gene affected, accounting for about 70% of U.S. cases, is the X-linked gp91^{phox} (149). Defects include those that result in reduced or absent specific mRNA, normal mRNA amount without protein, immunoreactive protein without function, and immunoreactive but profoundly hypofunctional protein (3). One corollary of an X-linked gene is that lyonization of the gene occurs in females. Heavy lyonization of the functional gene resulting in female patients with the X-linked form of CGD has been reported (143). Defects in p47^{phox} account for about 25% of cases (147,149). Most p47^{phox}-deficient patients who have been examined molecularly have at least one allele that has a deletion of a GT couplet at the first intron–exon boundary, leading to improper splicing (150). This common mutation is due to the conversion with a highly homologous p47^{phox} pseudogene (151). There was a suggestion of autosomal dominant transmission in one family, but molecular analysis confirmed only the recessive GT deletion. The GT deletion allele is fairly common in the normal population, about 1:2,000 (S.J. Chanock, personal communication). Deficiency of p67^{phox} was documented in relatively few patients and accounts for fewer than 5% of cases (3,149). Mutations of the b chain of the cytochrome, p22^{phox}, account for the remaining fewer than 5% of cases (3,149). Comprehensive reviews of mutations in CGD have been published (131,152).

Homologous genes for the NADPH oxidase system have been described and characterized to different extents in several species. The mouse NADPH oxidase genes are highly conserved compared with those of humans (153,154). The biochemical and functional dissection of the defect in CGD led to an impressive body of information about the role of both oxidative and nonoxidative mechanisms in bacterial and fungal killing. Quie et al. (155) first noted normal phagocytosis associated with a defect in intracellular killing of bacteria in CGD. Baehner and Nathan (156) developed a quantitative assay using NBT to detect patients and carriers with CGD. This assay was modified and simplified by Ochs and Igo (157) to essentially the NBT slide test that is used today for detection of both patients and carriers of CGD. In an elegant and classic paper, Klebanoff and White (158) showed that CGD cells were able to halogenate bacteria that produced hydrogen peroxide but they could kill organisms that produced catalase. This demonstrated that the defect in CGD cells was at the level of production of hydrogen peroxide and that mechanisms distal to that in the bactericidal pathway, most notably MPO, were intact. Recognition of this defect provided the pathophysiologic explanation for the clinical observation that patients with CGD are subject to infections almost exclusively with catalase producing organisms. Organisms that produce and do not degrade hydrogen peroxide supply the substrate for the formation of hypohalous acid. Other functional defects have been observed in CGD cells, including abnormal membrane potentials in response to PMA or fMLF stimulation, abnormal ADCC, and reduced tubulin tyrosinolation (159). Another corollary of an inability to form superoxide is the failure to oxidize NADPH. In this event, there is no mechanism to regenerate the NADP+, which is the terminal electron acceptor for the hexose monophosphate (HMP) shunt. Therefore, HMP activity is also defective in CGD cells.

Clinically, CGD is quite variable, ranging in time of presentation from infancy to late adulthood, with the most patients diagnosed as toddlers and young children; however, a significant number of patients are diagnosed in later childhood or adulthood (149). Children with CGD tend to be short and small for their age, a finding that may cause anxiety to patients, parents, and physicians. This may be in part due to chronic or recurrent infections or to some other aspect of defective oxidase function. Children with CGD tend to achieve the height predicted by their parents' heights. Bone and chronologic ages are most disparate in early childhood but achieve equivalence in late adolescence (160). It is not uncommon for children with CGD to continue growing into their early twenties.

In the absence of the NADPH oxidase, other host defense genes may be left with more discernible roles. Foster et al. (161) examined assorted host defense genes in patients who have CGD and showed a striking influence of polymorphisms in myeloperoxidase and FcgRIII on the occurrence of gastrointestinal complications and an effect of polymorphisms in mannose binding lectin on the development of autoimmune disorders.

The frequent infections are pulmonary, cutaneous, lymphatic, and hepatic. Osteomyelitis, perianal abscess, and gingivitis are also common (3,149). The microbiology of the infections of CGD is remarkable for its relative specificity. The overwhelming majority of infections in CGD are due to only five organisms: *S. aureus, Burkholderia cepacia, Serratia marcescens, Nocardia,* and *Aspergillus* species. Whereas the typical liver abscess in the immunologically normal patient involves enteric organisms and is liquid and easily drainable, the liver abscesses encountered in CGD are dense, caseous, and staphylococcal. This dense, undrainable abscess material is the reason that surgery is needed in almost all cases of CGD liver abscess. In the preprophylaxis era, most lung, skin, and bone infections were staphylococcal. Now, however, in the setting of trimethoprim-sulfamethoxazole (TMP-SMX) prophylaxis, staphylococcal infections are essentially confined to the liver and lymph nodes. Bacterial infections with the gram-negative organisms listed here are most commonly pneumonia and cellulitis. Bacteremia is uncommon, but when it occurs is due to *B. cepacia, S. marcescens*, or one of the gram-negative rods that inhabits warm, brackish water, *Chromobacter violaceum*. Bacterial and *Nocardia* infections in CGD tend to be symptomatic and associated with elevated erythrocyte sedimentation rates and may be associated with elevated leukocyte counts. Normal values and no symptoms offer scant reassurance that a patient is not significantly infected.

Aspergillus species and some of the rarer fungi such as *Exophiala dermatitidis* (162) and *Paecilomyces* species (163) are encountered in CGD. Fungal infections are now the leading cause of mortality in CGD (149). Bony involvement can occur by direct extension in the case of *Aspergillus* and other fungi. *A. nidulans* is an organism virtually exclusive in its occurrence in CGD. It carries a much higher rate of osteomyelitis than other fungi, and a much higher rate of mortality than *A. fumigatus* or other fungi (164,165). Involvement of the vertebral bodies with fungus, typically by direct extension from the adjacent infected lung, is a grave finding. The advent of antibiotic prophylaxis has altered the frequency of infections in CGD and reduced the frequency of staphylococcal infections in particular (149). The rate of fungal infections in CGD is lower than that for bacterial infections and apparently has not changed in the setting of prophylactic antibiotics (166).

The gastrointestinal and genitourinary tracts are frequently involved in CGD, sometimes as the site of the presenting complaint, sometimes asymptomatically. Ament and Ochs (167) described the clinical manifestations and laboratory and pathologic findings of gastrointestinal involvement in CGD. They noted frequent malabsorption, intrinsic factor-unresponsive vitamin B12 deficiency, abundant lipid-pigmented histiocytes in small-bowel biopsy specimens, and pigmented histiocytes and granulomas in rectal biopsy specimens. These findings were present in both autosomal and X-linked patients. Esophageal, jejunal, ileal, cecal, rectal, and perirectal involvement

with granulomas often mimicking Crohn disease have been described (168,169,170,171,172 and 173). Gastric outlet obstruction is an especially common manifestation and may be the initial presentation of CGD (174,175 and 176). In a comprehensive review of the genitourinary manifestations of CGD, Walther et al. (177) found that 38% of patients had some kind of urologic event. These included bladder granulomas, ureteral obstruction, and urinary tract infection. All patients with granulomas of the bladder or stricture of the ureter had defects of the membrane component of the NADPH oxidase; eight had gp91^{phox} defects, and one had a p22^{phox} defect. A previous report showed this same case bias in favor of membrane component defects (178). Steroid therapy in combination with antibiotics is quite effective and surprisingly well tolerated when used for resolution of obstructive lesions (Fig. 29.4). Several reports and many anecdotes confirm the benefit of steroids given at about 1 mg per kilogram for a brief initial period and then tapered to a low dose on alternate days (178,179,180 and 181). Prolonged low-dose maintenance is often necessary.

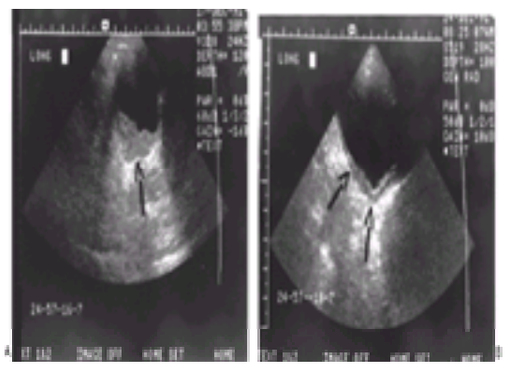

Figure 29.4. Obstructive granulomatous cystitis lesions in chronic granulomatous disease (CGD). **A:** Dysuria and hydronephrosis caused by granulomatous cystitis led to evaluation of this 2½-year-old boy with X-linked CGD. The bladder wall is thickened and irregular. The arrow indicates the bladder wall. Granuloma formation is seen between the bladder wall and the bladder lumen (*black*). **B:** After 1 week of corticosteroid treatment, the boy's symptoms were gone. The bladder wall diminished in thickness.

Cutaneous inflammatory responses are often dysregulated in CGD such that patients with membrane component defects may form exuberant granulomas and granulation tissue (182). This can manifest as wound dehiscence or delayed wound healing. Male CGD patients had an abnormal persistence of PMN cells in Rebuck skin windows compared with female CGD patients and normal subjects. This suggested a defect in “turnoff” of the acute inflammatory response in CGD (182). This abnormal persistence of PMN cells was normalized in one patient who was receiving white blood cell transfusions simultaneously. Blepharokeratoconjunctivitis, pannus formation, and stable chorioretinal scars also have been associated with CGD (183,184). The scars rarely involve the macula, but further study is needed to determine how often these lesions are sight threatening.

The X-linked carrier state for gp91^{phox} is not entirely silent. Lyonization of the X chromosome leads to two populations of phagocytes in carriers. One population has normal oxidase function and is detected as NBT reducing or DHR oxidizing; the other population, which has inactivated the normal X chromosome and has only the defective one functioning, is unable to produce superoxide (Fig. 29.5). Therefore, carriers give a characteristic mosaic pattern on oxidative testing. Discoid lupus erythematosuslike lesions, aphthous ulcers, and photosensitive rashes have been seen in female relatives of gp91^{phox}-deficient patients and screening of patients with discoid lupus erythematosus has detected unsuspected CGD carriers (185,186). The ease of determining which X chromosome is inactivated in a given phagocytic cell has been used to determine the presumed number of stem cells (exceeding 400 cells) necessary to support human hematopoiesis (187). Characteristic infections usually are not seen in female carriers until the normal cells fall below 10% (143,149). Several cases of extreme lyonization of the X chromosome carrying the functional gp91^{phox} have been reported, leading to the rare appearance of X-linked CGD in female patients. This is due to skewed random inactivation in some cases but may be due to selected mutations in the gene controlling X chromosome inactivation, *XIST*, in others. We have had an otherwise healthy highly lyonized X-linked carrier present with *Serratia* lymphadenitis as levels of her normal neutrophils fell below 10% (Malech and Holland, unpublished). Other investigators noted progressive decline in the number of normal neutrophils in some lyonized X-linked carriers over time, leading to the occurrence of CGD-type infections later in life (J. Roesler, personal communication).

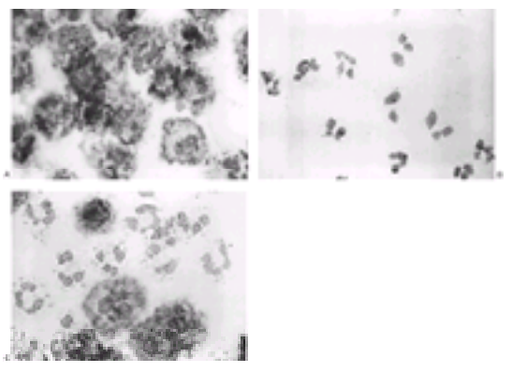

Figure 29.5. Nitroblue tetrazolium (NBT) reduction by purified neutrophils following stimulation with phorbol ester and calcium ionophore.**A:.** NBT is reduced by all stimulated normal neutrophils yielding a blue–black deposition. **B:.** Neutrophils from a patient with chronic granulomatous disease (CGD) fail to reduce NBT and retain a clear cytoplasm. **C:** Neutrophils from an X-linked carrier of CGD show two populations of cells (mosaicism), normal NBT-reducing (blackened), and affected non-NBT-reducing (clear) neutrophils. The presence of an NBT mosaic pattern in the neutrophils of a mother of a CGD patient confirms the X-linked form of CGD.

Advances in recent years drastically altered the morbidity and mortality rates in patients with CGD. Prophylactic TMP-SMX reduces the frequency of major infections from about once every year to once every 3.5 years (159). In addition, prophylactic TMP-SMX changes the type and site of serious infections in patients with CGD to fewer staphylococcal and skin infections (188) but no increase in the frequency of serious fungal infections (166). Ketoconazole is ineffective at preventing *Aspergillus* infection (189), but itraconazole prevents fungal infections in CGD (Gallin, unpublished). In a longitudinal analysis of 47 patients, Muoy et al. (189) found an 8-year survival rate of 70.5% for children born before 1978 and 92.9% percent for those born later. More recently, Winkelstein et al. (149) showed that the mortality rate is about 5% per year for the X-linked form of the disease and 2% per year for the autosomal recessive varieties. The largest causes of mortality are *Aspergillus* pneumonia, followed by *B. cepacia* pneumonia or sepsis.

Treatment of infections in CGD must be aggressive and prolonged for preservation of end-organ integrity and survival. In severe infections, leukocyte transfusions are often used, although the efficacy is anecdotal. The principle is that the deficient product in CGD cells, superoxide, is highly diffusible, such that supplementation of defective cells with a few normal cells leads to complementation of the defective pathway and reconstituted bacterial and fungal killing (190). Therefore, benefits accrue to granulocyte transfusions, even though the overall number of peripheral blood leukocytes is not significantly altered. The number of infused granulocytes averages about 10^9 to 10^{10} per transfusion. Buescher and Gallin (191) showed transfused phagocyte penetration into and persistence in pulmonary secretions in a patient with *Nocardia* pneumonia. Using NBT reduction, they were able to detect transfused neutrophils in peripheral blood for up to 1 hour after transfusion, but they detected normal monocyte derived cells up to 5 days in sputum. At 2 days after transfusion, half of the NBT-positive cells in sputum were monocytes. Emmendorffer et al. (192) conducted a similar study in a boy with *Aspergillus* pneumonia using FACS analysis for p22^{phox} in peripheral blood and pulmonary secretions. Although it is common practice to irradiate white blood cells before transfusion to prevent graft-versus-host disease (GVHD) in the recipient, this reduces the bactericidal activity, growth, and survivability of both neutrophils and monocytes in the transfused product (193,194). CGD patients have no defect in lymphocytic immunity, and there have been no reports of GVHD in recipients of unirradiated leukocytes who have CGD.

In 1983, IFN-g was unequivocally identified as the lymphokine responsible for enhanced HMP activity and hydrogen peroxide generation in macrophages (195). Ezekowitz et al. (196) and Sechler et al. (197) showed that IFN-g could produce some of these same effects *in vitro* in cells from patients with an X-linked variant of CGD. When IFN-g was administered to patients, Sechler et al. (197) and Ezekowitz et al. (198) found similar augmentation of bactericidal activity and superoxide production. In some patients, this was concomitant with an increase in gp91^{phox} levels. The augmentation of superoxide production in neutrophils was demonstrable for several weeks, suggesting that IFN-g was working at the progenitor cell level as well as on more differentiated cells (199). A large multinational, multicenter, placebo-controlled study proved a marked clinical benefit for patients receiving IFN-g. Recipients had 70% fewer and less severe infections than did placebo-treated patients. These benefits held true regardless of inheritance pattern of CGD, sex, or use of prophylactic antibiotics. Interestingly, no significant difference could be

detected in terms of *in vitro* superoxide generation, bactericidal activity, or cytochrome$_b$levels (200) although IFN-g was able to augment neutrophil activity against *Aspergillus* conidia (130).

Bone marrow transplantation leading to stable chimerism was successfully performed in a patient with CGD (201). The patient remained infection free despite having only 15% to 20% of his cells derived from the donor. Ozsahin et al. (202) performed successful bone marrow transplantation on a child with CGD and active incurable *Aspergillus* infection. More recently, Horwitz et al. (203) performed low-intensity ablation (mini–bone marrow transplantation) from HLA-identical siblings into CGD patients. This approach may be promising for patients with HLA-matched relatives. Clinical trials of p47^{phox} gene therapy showed prolonged marking of cells in the periphery for several months, but clinical benefit has not been shown because of the low numbers of corrected cells in the circulation (< 0.01%) (204).

Diagnosis of CGD is made by assays for superoxide production. These include direct measurement of superoxide production, ferricytochrome *c* reduction, chemiluminescence, NBT reduction, or dihydrorhodamine oxidation (DHR). Currently, we prefer the lattermost assay because of its relative ease of use and the ability to distinguish X-linked from autosomal patterns on the flow cytometry assay (205,206). Immunoblot, flow cytometry, or molecular techniques can be used to determine the specific genotype. The history will usually suggest whether a patient has autosomal recessive or X-linked disease, based on sex, age of presentation, and severity. The subtype of CGD is important since AR CGD has a better prognosis than X-linked disease (149). Glucose 6-phosphate dehydrogenase (G6PD) deficiency may mimic certain aspects of the neutrophil dysfunction of CGD, such as the decreased respiratory burst and increased susceptibility to bacterial infections (207). G6PD deficiency is most often associated with some degree of hemolytic anemia, whereas CGD is not.

The index of suspicion should be raised by severe or recurrent infections in children, especially those involving pulmonary or hepatic parenchyma. Infections with unusual organisms such as *B. cepacia, S. marcescens, Chromobacterium violaceum, Nocardia,* or *Aspergillus* species should initiate a search for CGD in patients of any age without other predisposing factors. Granulomatous events such as gastrointestinal or genitourinary obstruction likewise are suggestive of the diagnosis. Management of the infections in CGD must be extremely aggressive. Patients often fail to display symptoms commensurate with the extent of their disease and may present for care late in the course of infection. The erythrocyte sedimentation rate (ESR) is the most sensitive laboratory test to monitor the presence of ongoing infection; a newly elevated ESR should provoke active concern. The importance of a microbiologic diagnosis cannot be overemphasized because the differential diagnosis for infection in these patients includes bacteria, higher bacteria, fungi, and granulomatous processes.

Bronchoscopy, transthoracic needle biopsy, and thoracotomy should be first-line diagnostic procedures, not procedures of last resort. Hepatic abscesses are usually staphylococcal and require open excavation, débridement, and drainage. In occasional cases, percutaneous catheter placement has been successful, but because of the consistency of the lesions, it cannot be routinely recommended. Intralesional instillation of granulocytes has been used and may be helpful in particularly difficult cases (208). Therapy for infections in CGD should be intravenous and prolonged by using more than one agent. The reduction in mortality and morbidity rates seen in recent years is attributable to the recognition and following of these principles. The next generation of advances in molecular and genetic therapeutics should make these therapeutic guidelines obsolete.

HYPERIMMUNOGLOBULIN E AND RECURRENT INFECTION SYNDROME (JOB SYNDROME)

The rare autosomal dominant disorder HIE (MIM 147060) is characterized by recurrent infections, typically of the lower respiratory system and skin, eczema, extremely elevated levels of IgE, eosinophilia, and abnormalities of the connective tissue, skeleton, and dentition. Most patients have facial abnormalities, including ocular hypertelorism; a prominent, protruding, triangular mandible; and a broad, somewhat bulbous nose (209,210,211 and 212). Failure of primary dental deciduation, leading either to failure of secondary dentition eruption or retention of both sets of teeth, is common (212,213). Many patients also have abnormalities of bone formation and metabolism, which may result in fractures, severe scoliosis, kyphosis and short stature, and craniosynostosis (212,214,215,216,217 and 218). HIE occurs spontaneously in all racial and ethnic groups and in many cases is transmitted as an autosomal dominant trait (209,212,219,220 and 221).

This syndrome was first described by Davis et al. (222) in two red-haired, fair-skinned girls who had frequent sinopulmonary infections, severe dermatitis, and recurrent staphylococcal skin infections that were remarkable for their lack of surrounding warmth, erythema, or tenderness. These “cold” abscesses harkened these investigators back to the biblical figure Job, who as part of a celestial wager between God and Satan, was afflicted with boils over his entire body. The syndrome was further defined and clarified by Buckley et al. (223), who noted similar infectious problems in two boys with severe dermatitis, characteristic facies, and elevated IgE levels. Subsequent studies demonstrated abnormalities of the phagocytic, T-cell, and B-cell arms of the immune system (224). Recently, we showed the complex multisystem nature of this disease and documented its effects on skin, bone, teeth, lung, immunity, and infection susceptibility (212). These abnormalities suggested aberrant regulation of some cell or molecule common to all these tissues, such as the monocyte and its derivatives.

Several features of the syndrome have been considered central enough to be of potential etiologic significance. IgE is greatly elevated at most points in the life of patients with HIE (209,210,212). Elevation of IgE was noted in the cord blood of a child born to a mother with HIE, and the child subsequently developed HIE herself (220). Because IgE does not cross the placenta, this must reflect a rate of endogenous synthesis of IgE before exposure of the newborn to the outside world, which suggests that IgE dysregulation is part of the primary problem, not entirely a response to exposure to specific extrauterine environmental stimuli. Although these findings suggest an important role for IgE in the genesis of HIE, it is unclear whether it is a central one. A few patients have been observed to drop their IgE levels below 2,000 IU per milliliter as they get older (212) and yet retain their high susceptibility to infection. Studies by Buckley and Becker (209) showed that unstimulated B cells from HIE patients had maximal *in vitro* rates of IgE synthesis that could not be augmented by exposure to pokeweed mitogen. In contrast, coculture of patient B cells with normal mononuclear cells resulted in significant reductions of IgE synthesis. Geha et al. (225) examined T-cell subsets in children with HIE and found a relative deficiency of CD8+ T cells compared with normals. They also noted a deficit of concanavalin A-inducible suppressor cell activity. *In vitro* IgE synthesis by HIE B cells was greatly reduced by coculture with parental, partially human leukocyte antigen (HLA)-matched lymphocytes. Lymphocyte fractionation identified the IgE-suppressive properties to the CD8+ subset. These data suggest that the abnormality of IgE in HIE lies in the regulation of IgE synthesis, not in the synthesis of IgE *per se*. Dreskin et al. (226) showed that IgE catabolism was also defective in HIE, providing another mechanism for the hyper IgE aspect of the disease.

Interferon-g specifically inhibits the IgE-enhancing activity of a concanavalin A-stimulated T_H cell line supernatant (227) and inhibits the effect of IL-4 on cell expansion and induction of DNA synthesis (228). In HIE patients, there appears to be a reduction in lymphocytes producing either IFN-g or tumor necrosis factor-a (TNF-a) (229). Synthesis of IL-2 and IL-4 appear to be normal, however. A correlation between elevated *in vitro* IgE synthesis and diminished IFN-g production in T cells has been found in HIE patients (229). Vercelli et al. (230) were unable to confirm *in vitro* modulation of IgE synthesis by IFN-g and suggested that T-cell-independent mechanisms of IgE regulation were possible. King et al. (231) examined effects of IFN-g on HIE peripheral blood mononuclear cell IgE production *in vitro* and gave subcutaneous IFN-g to five patients with HIE for 2 to 6 weeks. They found that IFN-g was able to suppress spontaneous IgE production *in vitro* in most patients. This effect was also seen in patients when peripheral blood mononuclear cells were isolated and assayed for spontaneous IgE production before and after IFN-g administration. Serum IgE levels fell in two of five patients treated, one of whom received 0.05 mg/m^2 and the other received 0.1 mg/m^2. Serum IgE levels eventually returned to their previous high levels in both patients. The other three patients experienced no decline in serum IgE. No patient was noted to have any clinical change as a result of the brief course of IFN-g administration.

Grimbacher et al. (212) confirmed autosomal dominant transmission in seven families extending over several generations with variable penetrance. The rate of spontaneous occurrence is unknown, but sporadic cases account for at least half of those recognized so far. The disease in several of the families described by Grimbacher et al. (232) is linked to proximal chromosome 4q. Attention was directed to this region of the genome by a patient with HIE and a ring chromosome involving 4q (232). In several families with autosomal dominant inheritance, the disease is not linked to 4q, suggesting that at least two genetically distinct types of autosomal dominant HIE exist. There may also be autosomal recessive forms of HIE, as suggested by several consanguineous kindreds in which there are multiple affected persons (Grimbacher and Beloradsky, personal communication). Therefore, HIE is likely a complex autosomal disorder with both dominant and recessive forms.

The clinical manifestations of HIE are distinct. Patients usually present within the first days to months of life with severe eczema. Other early infections include mucocutaneous candidiasis and severe diaper rash. Sinus or pulmonary infections, predominantly with *S. aureus* or *Hemophilus influenzae*, are common. Postinflammatory pneumatoceles often are noted early in life. Otitis media and externa are common. Infections occur less frequently in bone and joints and infrequently in the liver, kidneys, and the gastrointestinal tract. Documented sepsis is rare. Deep-tissue infections are frequently extensions of cutaneous or dental infections, such as paronychia or apical abscesses.

Other pathogens that have been recovered include *Aspergillus* species, *Pseudomonas aeruginosa, Streptococcus pneumoniae*, group A streptococci, *Cryptococcus neoformans*, and *C. albicans*. Lung abscesses with empyema require thoracotomy (Fig. 29.6). Although some patients with HIE may have years of relatively low disease activity, the average frequency of infections that required therapy was calculated by Donabedian and Gallin (210) to be 1 every 3.6 months. The incidence of major infections in this same group (requiring intravenous antibiotics or an inpatient surgical procedure) was about 1 per year. The life expectancy of these patients has not been formally determined. Although several patients have survived into adulthood and middle age, there is often severe pulmonary destruction. Cerebrovascular events (strokes, reversible ischemic neurologic deficits, unidentified bright objects/T2 hyperintensities on magnetic resonance imaging (MRI) scanning, carotid artery aneurysms) have been seen in an unusually high number of our patients (unpublished observations). Neoplasms, including Hodgkin disease (233), histiocytic lymphoma of the brain in a 10-year-old girl (234), carcinoma of the tongue, nodular sclerosing Hodgkin disease, and Barrett esophagus (Holland, Puck, and Gallin, unpublished observations) also have occurred in HIE patients.

Figure 29.6. Pulmonary disease in hyperimmunoglobulin E (HIE) and recurrent infection syndrome (HIE or Job). **A:** Computed tomography reveals a staphylococcal left lower-lobe lung abscess in a 19-year-old patient (*arrow*). Central bronchiectasis from previous infections is present in the right lung. **B:** Six months after chest tube drainage and antibiotics in the same patient, pneumatoceles persist (left lower-lobe pneumatocele indicated by*arrow*).

Frequent occurrence of bony abnormalities has been noted in HIE. Osteoporosis of the spine and long bones with thin metaphyseal cortices was found in several patients (217). Brestel et al. (214) found osteogenesis imperfecta tarda of the “slender” type in a young girl with HIE. Of the nine patients reported by Geha and Leung (211), five had experienced at least one bone fracture. Of the six patients they tested by single-photon absorptiometry, all showed reduction in bone density. Likewise, the frequency of pathologic fractures in the population reported by Grimbacher et al. (212) was 58%. Although the general mechanism for these abnormalities is unknown, Leung et al. (235) demonstrated increased *in vitro* bone resorption by monocytes from patients with HIE. They also showed that monocytes from patients had substantially elevated rates of spontaneous prostaglandin (PG) E_2 release compared with cells from controls. This increased rate of bone resorption was normalized *in vitro* with indomethacin and *in vivo* with aspirin. Craniosynostosis has been documented in four male patients with HIE (215,218), yielding a rate much greater than what would be expected for the coincidence of one uncommon and one very rare disease.

The characteristic facies that are so often associated with the syndrome may reflect the same underlying abnormality of bony or soft tissue metabolism. The facies of HIE can develop later in life, as evidenced by two patients, described by Donabedian and Gallin (210), who did not have HIE facies at the time of publication but subsequently developed them. We noted the rate of characteristic facies to be 100% for patients over the age of 16 years (213,233). Prominent clubbing is also common. Unique to HIE is the failure of primary teeth to deciduate, leading to retained primary teeth and unerupted secondaries.

The laboratory findings in HIE cover a broad spectrum. The syndrome is defined by marked elevations of IgE (>2,000 IU/mL), with levels of more than 50,000 IU per milliliter reported (209). IgE levels fell below 2,000 IU per milliliter, close or into the normal range in 20% of the patients followed at the NIH. Therefore, although a high IgE level is part of the diagnostic criteria for HIE, authentic cases may lack this particular feature at the later stages of the disease. The catabolism of IgE is abnormally reduced in both HIE and atopic dermatitis, contributing further to the elevated levels of IgE seen in these syndromes (227).

The tropism of the IgE in HIE has been a source of great interest. A high proportion of the IgE in HIE binds to *S. aureus* and *C. albicans* (236). The lack of similar binding activity in other patients infected frequently with *S. aureus* indicates that this abnormality is host, and not organism, driven. Elevated anti-*S. aureus* IgE is thought to be specific for HIE and can help in the discrimination of this syndrome from severe atopic dermatitis with high IgE levels. HIE patients have normal levels of anti-*S. aureus* IgG and modestly elevated levels of anti-*S. aureus* IgM. In contrast, serum anti-*S. aureus* IgA is depressed in patients with HIE compared with normal control subjects and patients with other types of immune defects (237). Total salivary IgA is also reduced. Quinti et al. (238) reported high-molecular-size (>900,000 Da) immune complexes composed of IgG anti-IgE Fc. Buckley and Becker (209) found low antibody titers to diphtheria and tetanus, with only 1 of 11 patients who received booster inoculations responding. *In vitro* responses to the mitogens phytohemagglutinin, concanavalin A, and PWM have been essentially normal. In contrast, responses to *Candida* and tetanus have been low or absent. Some HIE patients also showed a defect in mixed lymphocyte culture proliferation to intrafamilial but not unrelated mononuclear cells. There is no clear HLA association with HIE (209,210).

White blood cell counts are typically in the normal range but have been reported to range from 60,000 to 1,700 per microliter (209,210). Chronic leukopenia with borderline neutropenia has been observed in several patients (210). Mild to moderate eosinophilia is the rule, although occasional patients do not show this. There is no correlation between IgE levels and degree of eosinophilia or clinical disease (212). There is a slight enrichment of eosinophils in drainage from sites of infection, such as abscesses. ESRs tend to be elevated. Complement levels have been normal when studied. Elevated levels of urinary histamine have been reported in some patients and correlate with the extent of the eczematoid dermatitis (226).

Chemotaxis is abnormal in this syndrome at least some of the time in most of the patients. The failure to demonstrate a consistent chemotactic defect even in the same patient over time suggests that this finding is not a central part of the syndrome. Even when present, the defect is not so severe as in well-defined disorders with defects in chemotaxis. A 61-kd protein inhibitor of chemotactic activity has been described as being produced by lymphocytes from HIE patients (210). The role of this protein in the fleeting chemotactic defect of this disorder remains unknown.

Mucocutaneous candidiasis with involvement of mouth, vagina, intertriginous areas, fingernails, and toenails affects about 50% of patients with HIE (210,212,233). Despite this enormous *Candida* burden, lymphocytes have depressed proliferative responses to *Candida in vitro* (209). A remarkable feature of the patient with HIE is the enormous infectious burden with which he or she may present. By the time the patient admits to illness, there is usually nothing subtle about the diagnosis. Indeed, one of the most difficult problems in the long-term management of HIE is the fact that even in the presence of obvious auscultatory and radiographic evidence of pneumonia, patients continue to feel well and may be unwilling to submit to a prolonged course of therapy. As in most of medicine, the firm establishment of a microbiologic diagnosis cannot be overemphasized. Bronchoscopy can be especially helpful in this regard and may help to mobilize secretions. Lung abscess is not uncommon and may require thoracotomy for adequate drainage. High-dose intravenous antibiotics for a prolonged course are required for eradication of infection and to prevent bronchopleural fistula formation and bronchiectasis. Empirical acute coverage should consider *S. aureus, H. influenzae,* and *S. pneumoniae*. The former two organisms account for most acute infections. Colonization of pneumatoceles and bronchiectatic lung with *P. aeruginosa* and *Aspergillus* species can be especially problematic. Cases of esophageal and colonic cryptococcosis have been reported (239,240).

The role of prophylactic antibiotics has not been rigorously investigated in this setting, but there is general consensus for their use. Most investigators direct coverage at *S. aureus* with a synthetic penicillin. The use of oral antifungals, such as ketoconazole or fluconazole, has made an enormous difference in the prevalence and severity of mucocutaneous candidiasis. The role for immune modulators is undefined. Levamisole was tried in a double-blind placebo-controlled trial, which showed an increase in infectious complications in the treatment arm (241). Patients with a severe condition have received plasmapheresis with apparently dramatic, if short-lived, results (242).

The differential diagnosis from atopic dermatitis can be difficult, and indeed the two are often confused when IgE levels are elevated. Points that rule in favor of HIE include an IgE level above 2,000 IU per milliliter and a history of or sequelae of severe deep tissue infections such as pneumatoceles, scoliosis, hyperextensibilty, and failure of primary dental deciduation. Although IgE levels in atopic dermatitis can be extremely high, those patients are usually not affected with deep tissue infections, do not have the associated skeletal and soft tissue anomalies seen in HIE, and do not have the classic facies. A scoring system has been devised to aid in the formal diagnosis of HIE patients (232).

MONOCYTE/MACROPHAGE DEFECTS

Interferong Production and Receptor Deficiencies

The mononuclear phagocyte is critical in defense against virulent and avirulent environmental pathogens alike, among them mycobacteria, as shown by patients with defects affecting this limb of host defense. The most glaring susceptibility recognized in these patients so far is to nontuberculous mycobacteria and the low virulence vaccine, bacille Calmette–Guérin.

Mycobacteria infect macrophages leading to the production of IL-12. This stimulates T cells and NK cells through the IL-12 receptor (IL-12R) to produce IFNg, which then acts through its receptor (IFNGR) on macrophages to upregulate genes and activities. IFNg increases the killing of mycobacteria, the upregulation of IL-12, and the production of TNFa.

Iterferon g binds to the ligand-binding chain, IFNgR1, as a homodimer, leading to receptor dimerization. Following dimerization of IFNgR1, the “signal transducing”

chains, IFNgR2, join the receptor complex. IFNgR1 and IFNgR2 are constitutively associated with their respective Janus kinases, Jak1 and Jak2. Mutual transphosphorylation of the Jaks leads to tyrosine phosphorylation of the intracellular domain of IFNgR1 at tyrosine 457. Y457 is the docking site for latent cytosolic signal transducer and activator of transcription-1 (STAT1). STAT1 phosphorylation leads to homodimerization of STAT1P, which then translocates to the nucleus and upregulates the transcription of IFNa-regulated genes. Patients with defects in the IFNg receptors, the IL-12 receptor b1, and IL-12 p40 were identified through their susceptibility to mycobacteria as well as *Salmonella* and some viruses (243) (Fig 29.7).

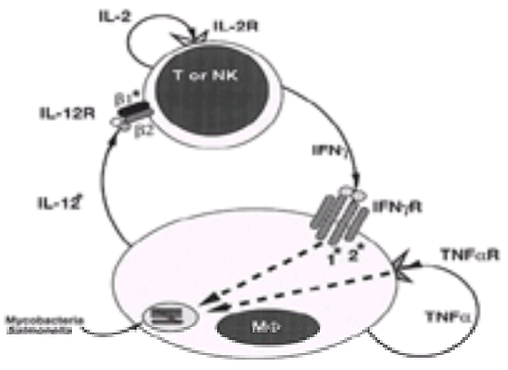

Figure 29.7. Cytokine interactions between mycobacteria-laden macrophages and responding T or natural killer (NK) cells. Macrophage-produced interleukin-12 (IL-12) leads to T-cell production of IL-2, interferon g (IFNg), tumor necrosis factor a (TNF-a), and granulocyte macrophage–colony-stimulating factor (GM-CSF), IFNg and GM-CSF stimulate macrophages to produce TNF-a and kill intracellular mycobacteria through mechanisms not yet characterized. Both IFNg and TNF-a drive the production of IL-12. Asterisks indicate genes in which specific mutations have been identified, as mentioned in the text.

There are several levels of defect in the IFNgR. Mutations in both IFNgR chains have been identified and characterized. Autosomal recessive complete IFNgR1- or IFNgR2-deficient patients tend to develop mycobacterial disease in infancy or early childhood, leading to death or severe disease requiring continuous antibiotics. In countries administering BCG vaccination, these children present with disseminated BCG. These patients typically fail to form well-circumscribed tuberculoid granulomas (244). Although this genetic defect has been associated predominantly with mycobacteria and *Salmonella*, the recognized phenotype has been expanded to include increased susceptibility to a number of viruses such as cytomegalovirus, respiratory syncytial virus, varicella, parainfluenza virus (245), as well as the opportunistic pathogen *Listeria monocytogenes* (246). These patients' cells, both myeloid and somatic, cannot respond to IFNg or signal through the IFNgR. Partial defects in both IFNgR1 and IFNgR2 have been described in which IFNg signal transduction is impaired by 2 to 3 logs, but it is not abolished (247,248). These patients tend to present later in life with more circumscribed disease and to be curable with antibiotics, with or without added IFNg. The autosomal recessive mutations have been in the extracellular domain and lead either to complete loss of protein expression, partial deficiency, or nonbinding but normally expressed receptors due to loss of critical epitopes (249).

Even more common than the autosomal recessive forms of IFNgR defects is the autosomal dominant form of IFNgR1 deficiency (243,250). In this defect, the mutation is in the intracellular domain just beyond the transmembrane segment. This common 4-base-pair deletion leads to a frame shift and premature truncation of the IFNgR1 before the Jak1 and STAT1 binding sites. In addition, the receptor recycling domain is removed, severely impairing the normal removal and recycling of the receptor from the cell surface. Therefore, displayed on the cell's surface is an overabundance of the extracellular domain of IFNgR1. This truncated receptor's IFNg binding is largely preserved, leading to sequestration of IFNg onto impotent receptors as well as the engagement of IFNgR2 molecules. This autosomal dominant mutation occurs relatively frequently as a result of mispairing of DNA at a mutational hotspot around base 818 of the IFNgR1 (250). These patients tend to present later in childhood with circumscribed disease that is antibiotic responsive. In all North American cases identified so far, the children have gone on to develop mycobacterial osteomyelitis. These cases are IFNg responsive and are well controlled by a combination of antimycobacterials and IFNg. The duration of therapy should be prolonged, but the precise duration is undefined. These patients are susceptible to other infections as well, including histoplasmosis and herpes viruses (243).

Interleukin-12 Receptor b1 Mutations

Patients with disseminated nontuberculous mycobacterial (NTM) and *Salmonella* infections in the setting of IL-12 unresponsiveness have been identified in Europe and Turkey. These cases have been due to mutations in the IL-12 receptor b1 (IL-12Rb1) chain (251,252). The genetic lesions are in the extracellular domains of the IL-12Rb1, leading to premature stop codons. All reported patients with IL-12Rb1 mutation show an autosomal recessive inheritance pattern, and heterozygous carriers are clinically healthy with normal IL-12 signaling and IFN-g production. Patients lack cell surface expression of IL-12Rb1 on T and NK cells as detected by FACS. As a result of defective IL-12R signaling, IFNg is not produced by T cells and NK cells. These patients develop severe, recurrent, disseminated *Salmonella* and NTM infections or progressive BCG infection following vaccination. Granulomata are well contained and well organized.

Interferong therapy may provide increased benefit, especially in patients for whom antimycobacterials alone have been incompletely successful. Recombinant IL-12 is being studied in those for whom IFNg is not effective and whose IL-12R is somewhat responsive, perhaps through novel, parallel pathways.

INTERLEUKIN-12P40 DEFICIENCY

The reported patient with IL-12p40 deficiency had disseminated BCG infection and *S. enteritidis* sepsis (253). The mutation was a homozygous autosomal recessive deletion leading to a loss of two exons of IL-12p40. Neither the IL-12p40 subunit nor the IL-12p70 heterodimer was detectable. The patient's lymphocytes secreted IFNg at a reduced capacity, which could be corrected with recombinant IL-12 *in vitro*.

This is a milder clinical phenotype than complete IFNgR1 or IFNgR2 deficiencies because residual, IL-12-independent IFN-g secretion pathways persist, as reflected in this patient's capacity to form organized granulomas.

DEFECTS IN PATTERN RECOGNITION MOLECULES

All organisms encounter other organisms as a matter of daily life, and as such they need to have ways to reject, kill, or contain them immediately that are not dependent on the generation of delayed, specific responses. Innate or natural immunity is the term applied to the panoply of these mechanisms that recognize certain general patterns in the molecules of invading organisms and respond to them on the basis of general and not specific structures (254). The acute-phase response is composed of the early inflammatory responses initiated by ligation of these pattern recognition molecules. The types of cytokine and cellular responses elicited during the acute-phase response then set the stage for the development of the specific or adaptive response mediated by B cells and T cells (255,256). These molecules include the endotoxin-binding molecules of the *Toll* family, CD14, mannose-binding proteins, C-reactive protein, serum amyloid A, complement, integrins, and many others. In addition, Fc receptors are relatively nonspecific receptors that bind classes of host molecules (antibody) that are bound to invading organisms or antigens. The acute-phase response should be seen as the opening salvo in the concerted host response to potential infection. Failure to mount any of this effort correctly may lead to severe infections or blunted responses. The association of autoimmunity with these defects (e.g., complement deficiencies) (257) suggests that these pathways are important in many ways as yet not well understood.

Endotoxin Signaling Pathway

Recognition and response to bacterial lipopolysaccharides (LPS) or endotoxin and other bacterial antigens are critical components of the host defense armamentarium and occur via *Toll*-like receptors and their downstream signaling pathway (258). Only one patient has been identified with a defect in the phagocyte LPS/IL-1 pathway (259); however, her clinical history underscores the importance of this pathway. During her first 15 years of life, she developed 13 life-threatening infections, including two episodes of *S. pneumoniae* meningitis, endophthalmitis, otitis media, cellulitis, septic shock, and a *Clostridium septicum* infection requiring disarticulation of her leg at the hip. All episodes were characterized by minimal to no febrile response. Following experimental challenge with intravenous LPS, she failed to develop fever or neutrophilia and expressed little to no TNFa, G-CSF, or IL-8, compared with normal volunteers. The precise defect remains elusive because the sequences of the patient's genes that encode many of the known components of the LPS/IL-1 pathway appear normal (J. Blanco, A. MedDev, D. Kuhns, S. Vogel, and J. Gallin, unpublished observations). Analysis of these and other signaling molecules involved in this shared pathway is currently ongoing. This condition is consistent with a defect in the *Toll* pathway, which is involved in mediating the binding and response to endotoxin and similar bacterial products (260,261).

Mannose-binding Molecules

Mannose-binding protein is synthesized as a monomer in the liver, but it forms a trimer, which in turn forms multimers of trimers, up to hexamers of trimers. This molecule binds a wide spectrum of gram-positive and -negative bacteria, mycobacteria, fungi, viruses, parasites, and protozoa. Once the mannose-binding protein complex has bound its target, it serves to activate complement by substituting for C1q and to enhance phagocytosis through the C1q receptor, as reviewed by Fraser et al. (262). Polymorphisms and mutations have been identified in the mannose-binding protein (MIM 154545). There are significant population differences in specific alleles, but their functional effect is uncertain (263). Case reports of increased susceptibility to *Neisseria meningitidis* infection (264), as well as more generalized susceptibility to infections (265), suggest that under certain circumstances, mannose-binding protein defects may be important. Garred et al. (266) examined the rates of different mannose-binding protein alleles in patients with cystic fibrosis and correlated that with infection history and survival. They showed a striking association between variant mannose-binding protein alleles and reduced survival, *P. aeruginosa* infection, and *B. cepacia* infection.

The macrophage has many surface binding molecules or lectins that mediate interaction with a variety of pathogens as well as host molecules in various states (267). The best characterized of these is the mannose receptor. The mannose receptor molecule is expressed on macrophages and some lymphatic endothelia. It binds to glycoproteins, especially those with high mannose contents. These molecules may be pathogen associated, such as those on the surface of yeasts and fungi, or they may be host associated, such as cathepsin D. The receptor can circulate in a cleaved form as well (268). Ligation of the mannose receptor initiates several activities of the macrophage, including phagocytosis, inflammatory cytokine production, and generation of reactive oxygen species, as reviewed in Linehan et al. (267). There are discrepancies between mouse and human macrophage mannose receptor-induced activities that may reflect true species differences or differences in activation and developmental states of the cells used. Koziel et al. (269) showed downregulation of the mannose receptor on the surface of alveolar macrophages in patients with *Pneumocystis carinii* and human immunodeficiency virus infection with low $CD4^+$ T lymphocytes.

FcgRIIIb (CD16) Deficiencies

The molecule that makes up two of the major neutrophil antigens, NA1 and NA2, is CD16, the Fcg receptor III (FcgRIII) (270). It binds IgG and, through mechanisms still not entirely clear, induces signaling including calcium flux, granule fusion, and respiratory burst activity. Mutations in CD16 (MIM 146740) leading to CD16 null granulocytes (NA null granulocytes) were first recognized as the basis of isoimmune neonatal neutropenia. Mothers who are deficient in CD16 develop antibody against fetally expressed CD16, leading to a transient neutropenia in the newborn (30,271). Subsequently, it was appreciated that there is a somewhat higher than expected incidence of recurrent bacterial infections in individuals with CD16 deficiency (270). Biron et al. (272) reported a patient with CD16 and NK cell deficiency and severe herpes virus infections. de Vries et al. (273) identified a child with bacterial and viral infections who had a dysfunctional mutation in CD16. Autoimmune phenomena, including Hashimoto thyroiditis and SLE also have been associated with CD16 deficiency (274).

CONCLUSIONS

Detection of neutrophil disorders is fundamentally dependent on a high index of suspicion based on history, physical findings, or suggestive microbiology. All the syndromes discussed in this chapter are capable of certain and specific diagnoses, which carry great importance as to therapy and prognosis. With the exception of MPO deficiency, which is largely clinically silent, the intrinsic functional neutrophil disorders share several key features. The extent of infection is grossly underestimated by clinical assessment. Computed tomography is valuable in examining lungs and livers damaged by recurrent, destructive infections. Recommended therapy that is adequate for normal hosts is associated with high rates of relapse in patients with impaired host defense. High-dose, prolonged, preferably intravenous therapy is indicated. Patients and their families must be educated as to the importance of early diagnosis and treatment.

Characterization of neutrophil defects of clinical importance has come a long way since the first description of abnormal neutrophils by Beguez Cesar in 1943. The features of neutrophil function that have proved most informative are still quite few, however. Superoxide production, chemotaxis, bacterial killing, degranulation, and granule contents have been the staples. Facility in describing and examining newly recognized features of phagocyte function, such as cytokine production and response and phagocyte-endothelial cell interaction, should greatly augment the detail and complexity of the picture we can paint in the future.

30 Complement In Disease: Inherited And Acquired Complement Deficiencies

John P. Atkinson, M.D., and Michael M. Frank, M.D.

As discussed in Chapter 26, complement (C)-mediated host defense processes include two basic mechanisms: first, alteration of microbial membranes by opsonization and lysis; second, promotion of the inflammatory response through cell activation. Complement proteins are being increasingly recognized for their important role in linking innate and adaptive immunity, particularly relative to antigen processing and the development of autoimmunity.

Often, in disease states, the C system functions normally but has been activated by an aberrant immune response. For example, if an autoantibody is formed to a basement membrane protein and activates C (Goodpasture's syndrome), it damages the lung and kidney, which express the targeted antigen. In this setting, C is functioning normally but acts as a misguided bullet. Measurement of the C system's overall activity and its individual proteins can serve as a guide in the diagnosis and, more commonly, to monitor a patient's response to therapy. The inherited deficiencies of C-pathway components, receptors, and inhibitors, although rare, are instructive in teaching about normal C function.

INCIDENCE OF INHERITED COMPLEMENT DEFICIENCY SYNDROMES

Genetic deficiencies in C proteins are rare but instructive anomalies [reviewed in (1)]. In an extensive review of all reported cases up to 1984, only 244 individuals were documented with genetically controlled total deficiency (2). In 1991, 521 cases of inherited component or inhibitor deficiencies, excluding cases of hereditary angioedema, were reported (3). An exception is mannan-binding lectin (MBL) deficiency, wherein some studies homozygous deficiency may be present in as many as 3% of the population (4) and heterozygosity in as many as 30% of the population. This is important because, unlike other complement deficiencies in which heterozygous persons have one third to one half normal level, heterozygous MBL-deficient persons may have 10% of the normal level. Moreover, additional genetically controlled transcription-controlling defects may lead to low MBL levels. The prevalence of inherited C deficiency, excluding MBL deficiency in the general population, is estimated at 0.03%. C2 deficiency is most common in the white population, that is, in 0.009% to 0.010% of normal individuals (4,5). Although total C4 deficiency is rare, the incidence of heterozygosity for one of the four C4 genes is high, approaching 40% (4). C9 deficiency, common among a subset of the Japanese population, is present in ~0.1% of the normal population (4,6,7).

In populations defined by certain disease entities, the incidence of C-component deficiencies is much higher. In rheumatologic disorders, such as systemic lupus erythematosus (SLE), the incidence of C2 deficiency in the white population may approach 1.0% (8). The terminal component C deficiencies in patients with *recurrent*, *disseminated*, neisserial infections, especially meningococcal, have been estimated to be as high as 20%. Although one study demonstrated a 15% incidence of late-component deficiency in patients with even a single meningococcal infection, usual estimates are 5% to 10% (3).

GENETICS OF COMPLEMENT PROTEINS

In Chapter 26, Table 26.2 lists chromosomal location, chain structure, and plasma concentration of each of the C proteins. Many genetic polymorphisms also have been reported. In most cases, these allotypic variants show autosomal codominant inheritance and function normally.

The C proteins C4, C2, and factor B are referred to as *class III gene products* because they are encoded by genes within the major histocompatibility complex (MHC) on chromosome 6 in humans. C4 is encoded at two separate closely linked loci, and its two highly homologous gene products possess subtle differences in their binding to substrates. Because of their proximity to class I and II genes (see Chapter 3, Chapter 26), linkage of C4, C2, and factor B allelic variants with particular histocompatibility phenotypes has been noted. Given the location of these C genes, the association of deficiency in these proteins with autoimmune disorders is notable (9,10 and 11).

COMPLEMENT DEFICIENCIES

As reviewed in Chapter 26, the major pathways of C activation merge at the level of C3 and the later steps of C activation are common to all pathways. The alternative pathway (AP) acts as a first line of defense against invading organisms and functions in the absence of specific antibody. The lectin pathway and the classical pathway (CP) [via natural antibodies (Ab)] allow more specific activation of C in the nonimmune host and provide a measure of recognition to the innate antimicrobial response. In the immune individual, the CP serves as a major effector arm of humoral immunity. Given the presence of an intact AP, the absence of one of the early CP proteins does not usually predispose to overwhelming infection; however, some patients with C1, C4, or C2 deficiency have had serious infectious complications (2,3). Because the early components of the AP and MBL pathways and C3 are critical for control of microorganisms, patients with deficiencies in these components often have infectious disease problems (2,3). This increase in susceptibility to infections is predictable. The surprise in the analysis of inherited C deficiencies is the association of early CP component deficiency with autoimmunity, especially SLE. These results imply an important role for C in immune complex handling and immunoregulation. Finally, a deficiency of a regulatory protein commonly results in excessive activation of the system and a disease process related to a secondary deficiency (C3 in factor H or I deficiency) of a component or liberation of activators to produce a pathologic event [i.e., hereditary angioedema (HAE)].

DEFICIENCIES IN CLASSICAL PATHWAY COMPONENTS

C1 Deficiency

Patients who lack each of the C1 subunits (C1q, C1r, C1s) (Table 30.1) and combined C1r and C1s deficiencies have been identified (2,3). C1q deficiency is the most common of this group. These persons usually produce no identifiable C1q, although the synthesis of a dysfunctional protein has been noted in several families and, when found, is almost always present with SLE (12,13 and 14). SLE in C-deficient persons has some features that are distinct from that of lupus in the general population. For the former group, the age of onset is usually earlier and the male-to-female ratio is more nearly equal. Also, the frequency of renal disease and antinuclear antibodies, especially anti-DNA and ANA, are lower and occasionally absent, although the frequency of the anti-Ro Ab is increased. There is an increased susceptibility to viral and bacterial infections, but it is not nearly as pronounced as in C3 deficiency.

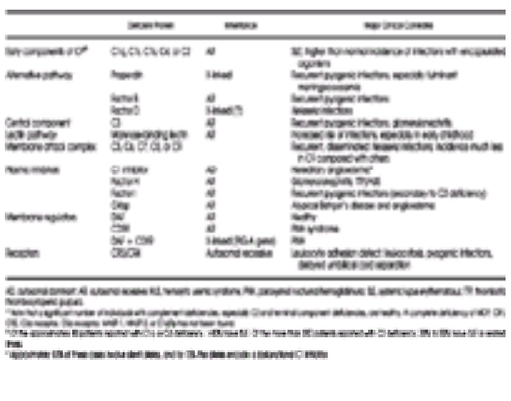

TABLE 30.1. Inherited Complement Protein-Deficiency States[a]

A depressed level of C1q occurs in patients with hypogammaglobulinemia (15). The synthetic rate of C1q is normal; in the presence of reduced immunoglobulin (Ig) concentrations, however, removal of C1q from the intravascular pool is accelerated. Administration of Ig restores the C1q levels to normal.

Antibodies to C1q are found in 15% to 30% of SLE patients and correlate with hypocomplementemia, renal disease, anti-DNA Abs and a poorer prognosis. The Abs are of the IgG class and tend to fluctuate with the course of the disease. Abs to C1q also can be present in patients with the hypocomplementemic urticarial vasculitis syndrome (HUVS MIM C1q deficiency 120790; cis deficiency 216950; cis deficiency 120580).*

C4 Deficiency

There are two separate C4 loci in a 55-kb region of the human MHC that give rise to two protein products: C4A and C4B. Although highly homologous, C4A and C4B differ in molecular weight, electrophoretic mobility, hemolytic efficiency, and types of covalent bonds formed (4). Multiple allelic variants exist for both C4A and C4B. Thus, most persons possess four genes that code for C4, and they may be heterozygous at either or both of the two loci, yielding up to four C4 variants in a given plasma. A deficiency-resulting allele at either C4 locus is termed *Q0* (*quantity zero*) for the gene product in question. The frequency of persons who are deficient in 1, 2, or 3 C4 proteins is about 30%, 15%, and 5%, respectively (16).

Among C-component-deficient patients, those completely lacking C1q and C4 (~40 reported of each) have the highest incidence (80%–90%) of SLE or closely related syndromes (2,3,8,9,12). Infections have been documented in three homozygous C4-deficient patients, one of whom died as a result of disseminated herpes simplex and cytomegalovirus infections (2,3). The absence of either C4A or C4B also is associated with the development of autoimmune disease (3,8,17,18). The relative risk of SLE is increased 16.6-fold for white persons who are homozygous for C4AQ0 and the presence of even a single copy of the C4AQ0 correlates with an increased risk of SLE in both whites and blacks (14,17,18). A portion of this increased risk may be related to the autoimmune diathesis of the human leukocyte antigen (HLA)-B8, -DR3 haplotype with which the C4AQ0 allele is in linkage disequilibrium. The C4AQ0 allele, however, appears to represent an independent risk factor for SLE because, even in the setting of other MHC haplotypes (a situation observed in blacks and in Asians), the incidence of lupus is increased in C4A deficiency (14,16,17 and 18). Other diseases reportedly associated with silent alleles at one or both C4 loci include Graves disease, insulin-dependent diabetes mellitus, Sjögren's syndrome, subacute sclerosing panencephalitis, and chronic active hepatitis (MIM C4 deficiency 120810).

C2 Deficiency

The incidence of C2 deficiency is about 1:10,000 (1% frequency of null allele) in persons of European descent. Many of these persons appear to have a normally functioning immune system. Autoimmune disorders and, less commonly, infections are observed with increased frequency in C2-deficient patients (1,2 and 3,8,9). Infectious complications, including pneumonia, bacteremia, and meningitis, are generally caused by pyogenic bacteria that require opsonization and phagocytosis for eradication. Autoimmune or rheumatic diseases have been reported to occur in 30% to 50% of C2-deficient individuals (1,2 and 3,8). The most common disorder is SLE. C2-deficient individuals tend to be characterized by early age of onset, photosensitivity, modest antinuclear Ab titers but elevated Ab titers to Ro, and relatively mild renal involvement. As in heterozygous C4 deficiency, an increased risk for the development of autoimmune disorders has been reported with heterozygous C2 deficiency (14,17,18). Type 1 deficiency is due to a 28-base-pair gene deletion that leads to aberrant RNA splicing and the deletion of exon 6. In type 2 deficiency, the gene is transcribed, but for unknown reasons, the protein is not secreted (14,19). C2 deficiency sometimes is associated with below-normal factor B levels; this appears to be an acquired defect (2,3,5,19). Two C2-deficient patients with relatively treatment-refractory SLE have had remission of their disease in association with plasma transfusions (MIM C2 deficiency 217000) (18).

IMMUNOREGULATION, ANTIBODY RESPONSES, AND COMPLEMENT DEFICIENCY

Autoimmune disease is the most prominent manifestation of early C-component deficiencies of the CP. The underlying mechanisms are not clear but may include aberrant immune complex handling, increased susceptibility to unusual (especially viral) infections, linkage of C deficiency producing alleles to other disease susceptibility genes inside or outside the MHC, and immunoregulatory defects in the immune response. Numerous spontaneously arising animal models of CP C deficiency, especially C4- and C2-deficient guinea pigs, demonstrate serologic abnormalities (such as rheumatoid factors) suggestive of autoimmunity, but these animals are in good health otherwise (20). In addition, animals deficient in C4, C2, or C3 have repeatedly shown impaired antibody responses to prototypical test antigens and, in particular, failure of isotype switching from IgM to IgG. These abnormalities are correctable by infusion of the missing component (21). Similar abnormalities in Ab responses have been documented in CP-deficient humans (21). C1q, C4, C3, and CR1/CR2 knockout mice have further established a critical role for C in the development of normal immune response, especially to low levels of T-cell-dependent antigens, and have led to a novel hypothesis to explain the association with autoimmunity (14,22,23). The role of complement in the induction of tolerance to self is unclear, but there is a breakdown of tolerance induction in several complement-deficient mouse models, which should allow further dissection of this phenomenon.

DEFICIENCIES IN ALTERNATIVE PATHWAY COMPONENTS

Properdin Deficiency

Properdin deficiency and possibly factor D deficiency are the two C-component deficiency states that demonstrate sex-linked inheritance (2,3,19). The deficiency often comes to medical attention because of fulminant meningococcal infections (2,3). This is in contrast to the late component deficiencies, which tend to have recurrent but less severe neisserial infections. Female carriers also appear to be at greater risk for overwhelming meningococcal infection (2,3). In type 1 properdin deficiency, the most common, the gene defect is such that there is no protein product secreted. In type 2 deficiency, a single gene defect leads to normal plasma levels of a nonfunctioning protein. A type 3 deficiency has been described in which patients have normal levels of a protein that retains some but not all of the functions of properdin (OMIM Properdin deficiency 312060) (24).

Factor D Deficiency

Partial factor D deficiency has been reported in three families. One family had adult twin sisters, both of whom suffered from recurrent upper and lower respiratory tract infections and unexplained infertility. Family studies failed to provide data to suggest a mode of inheritance (3). One person with a complete deficiency suffered from recurrent *Neisseria* infections. X-linked mode of inheritance was suggested, but the location of the factor D gene has not been determined (OMIM factor deficiency

12940).

Factor B Deficiency

There is only one report in abstract form of a 6-year-old white boy with functional factor B deficiency. Meningococcemia was the initial manifestation, and the patient had no alternative pathway hemolytic activity and appeared to be missing epitopes on factor B as identified by specific monoclonal antibodies (MIM factor B deficiency 138470) (25).

C3 Deficiency

Given the central role of C3 in both C activation pathways and the multiple biologic roles that C3 fragments subserve, it is not surprising that C3 deficiency has severe consequences. For example, no homozygous C3-deficient patient thus far reported has been disease free. Also, the molecular basis of human C3 deficiency is specific for each of the six kindreds, indicating that most represent new mutations. This probably reflects the fact that, until the use of antibiotics, patients died before reaching reproductive age. Infectious complications, predominately pyogenic in nature, including meningitis, bacteremia, pneumonia, urinary tract infections, and peritonitis, occur frequently and recurrently (2,3,19). *Streptococcus pneumoniae* and *Neisseria meningitidis* have been the major pathogens reported. In addition, SLE, vasculitic syndromes, and glomerulonephritis have been documented in 15% to 21% of C3-deficient patients (2,3,19). Some patients have detectable, albeit extremely low, amounts of C3 in plasma. Mononuclear phagocytes from such persons synthesize reduced but readily measurable amounts of C3 *in vivo* (19). Other patients have no detectable protein. The genetic defects have included mutations leading to stop codons, major gene deletions, or a failure to secrete an abnormal protein (MIM C3 deficiency 120700) (26).

DEFICIENCIES OF MANNOSE-BINDING LECTIN

Three point mutations of the MBL gene in exon 1 are common, leading to substitutions at codons 54, 57, or 52. MBL contains three identical polypeptide chains, and these substitutions lead to the formation of chains that do not interact normally. Thus, persons with mutations of both MBL alleles have undetectable or extremely low levels of MBL. They constitute about 3% to 5% of the population. Individuals with one normal and one abnormal allele have one sixth to one eighth the normal functional level of MBL and constitute as many as 30% of the population. In addition, mutations in the promotor region of the gene can lead to low levels of protein synthesis. In a number of studies, MBL deficiency has been reported to lead to infection, particularly in neonates and infants (27). Even heterozygous persons appear to be at risk. In a recent study of older children with cystic fibrosis, those who were homozygous deficient for MBL or heterozygous-deficient had a more rapid progression of their lung disease and a shorter life span (28).

The situation with regard to the development of autoimmunity is more complex and less clear. For example, it is reported that patients with rheumatoid arthritis who are either heterozygous or homozygous for MBL deficiency have earlier onset of disease but less rapid progression of their disease (29). Perhaps MBL deficiency predisposes to the development of rheumatoid arthritis. It is known that rheumatoid arthritis is associated with the synthesis of IgG with abnormal glycosylation. It is hypothesized that such IgG can interact with MBL, activate complement, and further promote joint destruction. Presently, there is enormous interest in MBL, and further work will help decide the role of the MBL in acute and chronic infection and in the inflammation that accompanies autoimmune disease (MIM Mannose-Binding Lectin 154545).

DEFICIENCIES OF TERMINAL COMPONENTS

Lysis by terminal C components is important as a host defense mechanism against gram-negative organisms, especially *Neisseria* species. The risk of neisserial infections in a patient with a late component deficiency may be increased as much as 10,000 times above that of the general population (2,3). Patients lacking C5, C6, C7, or C8 present a relatively homogeneous clinical picture with recurrent episodes of meningococcemia, meningococcal meningitis, or disseminated gonococcal infection. More than 50% of such patients reported have had significant neisserial infections (2,3). In addition, other infectious complications, including brucellosis, toxoplasmosis, chronic pyelonephritis, and pneumonia, have been reported. Of the patients with terminal component deficiencies, 11% had autoimmune disorders (often SLE-like syndromes or Raynaud phenomenon) without infectious complications (2,3).

C8 deficiency is particularly interesting. C8 is a three-chain molecule with a, b, and g chains. The genetic locus encoding for the b chain is separate from the locus coding for the a and g chains (19). Thus, two general types of C8 deficiency are recognized: C8b deficiency and C8a-g deficiency. Whereas all reported C8b-deficient patients are white, those with a C8a-g deficiency have been largely black or Hispanic (2,3). A mixture of serum from a-g and b-chain-deficient patients permits the reassembly of functional C8 and restores C activity. A dysfunctional b chain variant has also been described (3,19).

Densen and Ross and colleagues (2,3) pointed out several issues regarding disseminated Neisserial infections in patients with late component deficiency. Perhaps the most striking is that, although the relapse (6.3%) and recurrence rates (45%) of infection in these individuals are considerably higher than those in the normal population (0.6% and 0%, respectively), the mortality rate (2.9%) is lower than that in the normal population (19%). Moreover, fulminant onset of meningococcal disease is not characteristic of patients with late-component deficiency (unlike properdin-deficient patients), and most such individuals have had prodromal symptoms. Two other unusual aspects are an increase in the incidence of infection with serogroup Y organisms and a higher median age at onset of the first infection. It is interesting to speculate about possible reasons for these differences. Although C-mediated bactericidal activity is clearly important in dealing with these organisms, other mechanisms contribute to host defense. Given these figures, it is apparent that patients with terminal-component deficiency acquire systemic Neisserial infections readily, but are capable of at least partial containment of the organisms, presumably via phagocytic cells. In older persons, specific Ab is probably present as a result of previous exposure to these or related organisms, which provides an additional measure of protection. It is striking that the pattern of serum resistance seen in isolates from patients with terminal component deficiency exactly parallels that seen in *Neisseria* isolated from C-sufficient individuals with systemic disease. Thus, terminal component deficiency does not simply confer pathogenicity on a broad spectrum of innocuous *Neisseria* strains that otherwise would have been killed by serum lytic activity (MIM C5 deficiency 120900; deficiency 217050; C7 deficiency 217079; C8 deficiency 120950 X chain 1290 R class; C9 deficiency 120940) (3).

Because killing of some bacteria may occur in the absence of C9, albeit slowly, it has been suggested that C9 deficiency may be of little consequence. Many patients reported to date have not had infectious complications (30). In Japan, screening studies have shown that C9 deficiency is the most common C deficiency, with a gene frequency of approximately 3.5% in some regions, and is present in a relatively large number of individuals (6,7). Initial reports indicated that C9 deficiency occurs with identical frequency in healthy blood donors and in hospitalized populations; however, more carefully controlled studies indicated that there is a higher than expected incidence of meningococcal infection in persons with C9 deficiency (31). There are also reports in the American literature of patients with C9 deficiency who developed meningococcal meningitis (3). Mim C5 deficiency 120900; deficiency 217050; C7 deficiency 217079; C8 deficiency 120950 × chain, 290 R class; C9 deficiency 120940.

DEFICIENCIES IN REGULATORY PROTEINS

Inherited C1 Inhibitor Deficiency: Hereditary Angioedema

Hereditary angioedema is inherited as an autosomal dominant trait (32,33 and 34). The product of one normal C1 inhibitor gene is not sufficient to maintain homeostasis and regulate the various protease functions. Also, there is considerable evidence for a negative feedback by the abnormal gene product on synthesis of the normal gene. For these reasons, plasma levels are below a critical threshold and symptoms result. These patients experienced recurrent attacks of nonpainful, nonpruritic, and nonerythematous swelling of the extremities, face, trunk, lining of abdominal viscera, and, most critically, the upper airway. Bowel wall edema commonly presents as small bowel obstruction syndrome with bouts of colicky abdominal pain, nausea, and vomiting. It should not be confused with an acute abdomen because of the absence of fever, leukocytosis, and clear signs of peritoneal irritation (32,33). Angioedema typically subsides by 48 to 72 hours. The episodes occur spontaneously or, in about half the cases, in response to trauma, such as dental manipulation or pressure. Psychological stress may precipitate attacks in some individuals.

The biochemical mediator(s) of angioedema have not been definitively elucidated. C1-INH is an important regulator not only of C1r and C1s but also of Hageman factor and its enzymatically active fragments as well as clotting factor XIIa, plasma kallikrein, and plasmin (34). Thus, the mediators responsible for angioedema could arise from the C, coagulation, fibrinolysis, kinin-generating system, or a combination of these. There are two principal schools of thought about the mediator of the angioedema. In HAE, unregulated activation of the classical C pathway leads to the excessive formation of C2 fragments (33,35). Some believe that one of these fragments, following interaction with plasmin, is further cleaved into small peptides that induce angioedema. Others proposed that uncontrolled activation of the kinin-generating pathway leads to the formation of bradykinin and that this peptide causes the edema (33). Evidence exists to support both positions, but neither is entirely satisfactory. The quantity of C2 peptide that can be generated seems insufficient for the massive edema sometimes seen. Bradykinin injections cause pain, yet pain is not present (except with intestinal episodes where small bowel obstruction has taken place). Although fluid-phase C consumption is chronic in HAE, acute alterations of both prekallikrein and high-molecular-weight kininogen can be detected in temporal relation to swelling attacks (34). Whereas the activation of C1 is unregulated, the multiplicity of control mechanisms at the levels of C4 and C2 prevents substantial C3 cleavage. Thus, patients with HAE manifest depletion of the early CP components (C4 and C2), but C1, C3, AP, and terminal components are normal (32,33).

Patients with HAE are not at increased risk for infection. Detailed studies, however, suggested that, analogous to the effects of deficiencies in the CP components, patients with HAE have an immunoregulatory abnormality and are probably at increased risk for developing autoimmune disorders such as SLE, Sjören's syndrome, Crohn's disease, and scleroderma (36).

About 85% of HAE patients have one normal and one abnormal C1-INH gene (type 1) that produces no detectable protein (34,37). The remaining 15% have one normal and one gene that codes for a functionless inhibitor (type 2). Thus, in such patients C1-INH antigen levels are in the normal or high range, and functional testing is required if HAE is a strong diagnostic consideration. In these individuals, of course, C4 and C2 levels are low, as in type 1.

The C1-INH gene maps to chromosome 11 in humans and contains eight exons (34,37) as well as a large number of Alu repeat sequences (particularly in the region 3' and 5' to exons 4 and 7, respectively). More than 50 different mutations leading to deficiency or dysfunction have been described. The Alu sequences may be hot spots for unequal crossovers. In analysis of a large number of HAE kindreds with the type 1 abnormality, deletions and, in some cases, duplications of a part of the C1-INH gene, often in the Alu repeat rich regions, have been noted. Kindreds with point mutations are also common. About 20% to 30% do not have a positive family history, and most represent new mutations.

The C1-INH is a *ser*ine *p*rotease *in*hibitor (serpin). It presents a bait sequence to the protease for cleavage. On cleavage of the inhibitor, a reactive site is exposed to the enzyme to be inhibited. The inhibitor then covalently attaches to the active site of the serine protease to cause irreversible inhibition. The usual cleavage point is between Arg 444 and Thr 445. Most type 2 abnormalities represent point mutations that affect the amino acids at or around the active site of the inhibitor, leading to the synthesis of an inhibitor with negligible or absent function.

Angioedema tends to be infrequent and mild before but accelerates in frequency and severity at puberty. Attacks usually are unprovoked but may be precipitated by local trauma, emotional stress, or, in a few patients, menses. The attack frequency varies widely (several times a week to several times a year) from patient to patient, with rare individuals possessing the biochemical defect but having no attacks. This angioedema does not respond to epinephrine, antihistamines, or glucocorticoids, the mainstays of treatment of allergic angioedema (33,38). Laryngeal swelling necessitates careful monitoring in a facility where endotracheal intubation or a tracheostomy can be performed. FFP can be given to persons in nonemergency situations to prevent attacks, for example, and to preoperative patients, particularly those undergoing dental surgery (39). The usual dose of fresh frozen plasma (FFP) is 2 units, an amount that has been used extensively and has proved effective. Infusion of purified C1-INH reliably terminates attacks (34), but this protein is not yet available in the United States. FFP is not usually given in life-threatening situations because it supplies substrate for the various mediator enzymes as well as the C1-INH, and swelling may at times become more severe before it improves.

Long-term prophylactic therapy is used to treat patients with frequent attacks or those with recurrent life-threatening attacks (33,38). Patients respond to impeded, acetylated artificial androgens with increased levels of C1-INH. This is not a direct effect on the promoter of the C1-INH gene, and the mechanism of this response is unknown, although several cytokines also can increase the synthesis of the C1-INH. With such treatment, C1-INH levels partially correct, as do serum levels of C4 and C2. Concomitantly, there is a marked amelioration of symptoms. Adverse effects of long-term androgen therapy include virilization, weight gain, myalgias, headache, microscopic hematuria, abnormal liver-function tests, anxiety, altered libido, and nausea (34). Although the list of side effects is long, they usually do not present major problems. In the rare patient for whom androgens are ineffective or for whom drug toxicity is a problem, the plasmin inhibitor e-aminocaproic acid has been found to be effective (33,38). Its mechanism of action is unknown, and there is no change in the C profile. Antifibrinolytic therapy may potentially be complicated by thrombotic episodes and often is accompanied by myalgias, with or without elevation of muscle enzymes. With each of these agents, there is a high degree of patient-to-patient variation in dosage, and the lowest dose that controls symptoms is chosen. Women are often treated with danazol, an impeded androgen that has few masculinizing side effects, and other attenuated androgens, such as stanozolol are used as well. The usual dosage of danazol is 200 to 600 mg daily or stanozolol 2 to 6 mg daily. Men often are treated with the less expensive but more androgenic agents, such as methyltestosterone at a dose of 10 to 30 mg daily orally (MIM hereditary angioedema 106100, with normal levels of protein 300268).

Acquired C1-inhibitor Deficiency

Low levels of C1q, lack of a family history, later age of onset, and association with other conditions, particularly malignancies, distinguish these patients from those with the hereditary form of C1-INH deficiency (34). Acquired C1-INH deficiency may be associated with lymphoproliferative disorders and in most cases represents development of an autoantibody that binds to and neutralizes the C1-INH (34). Individual patients have been treated successfully with androgens, antifibrinolytic agents, glucocorticoids, and cytotoxic agents, but a uniform, effective approach to therapy is not available.

Factor I Deficiency

Factor I, in the presence of a cofactor protein, cleaves C3b. Cleaved C3b (iC3b) is no longer active in the sense that it cannot react with factor B to form a C3 convertase. Thus, factor I prevents unrestrained activation of the AP by C3b. The absence of factor I will lead to unrestrained consumption of C3 secondary to accelerated spontaneous AP turnover. Patients with factor I deficiency are clinically similar to those with C3 deficiency in that their C3 is low to barely detectable. They suffer from recurrent infections with pyogenic organisms, including meningococcal meningitis (2,3). Some individuals have had glomerulonephritis with lupuslike illness. Infusion of factor I corrects the C3 abnormality and normalizes C levels (19), but its long-term clinical usefulness is not clear (MIM factor I deficiency 217030).

C4b-Binding Protein (C4BP)

There is only one reported case with C4BP, and this patient had a syndrome resembling Behçet's and angioedema (40).

Factor H Deficiency

Like factor I deficiency, these persons cannot regulate C3b and therefore have excessive AP turnover (2,3,19). They usually present with glomerular-based kidney disease. Because of the abnormality in C3 regulation, these patients have low plasma levels of C3 and a high incidence of infection, especially neisserial meningitis. Other patients have more problems with glomerulonephritis. A strain of Yorkshire pigs deficient in factor H develops renal failure a few weeks after birth (41). The kidney lesion is membranous glomerulonephritis, and large C3 fragments are deposited in the glomeruli. Familial deficiency of factor H in humans has been associated with thrombotic thrombocytopenia purpura/hemolytic uremic syndrome (42,43). In one series, the infants at birth manifested severe hemolytic uremic syndrome, and the condition was often rapidly fatal. The association of hemolytic uremic syndrome and factor H abnormalities is being examined in a number of laboratories, and patients with low C3 should have their factor H examined (MIM factor H deficiency 134370).

DEFICIENCIES IN CELL SURFACE COMPLEMENT REGULATORY PROTEINS AND RECEPTORS

CR1 Deficiency

In patients with SLE, as well as in patients with other immunologically mediated diseases featuring immune complexes, such as Sjögren's syndrome, human immunodeficiency virus (HIV), and autoimmune hemolytic anemia, the quantity of CR1 expressed on E is below normal (44). The magnitude of the decrease in CR1 correlates with disease activity and returns to normal as disease activity subsides. As for the role of this partial deficiency in the pathogenesis of SLE, it has been speculated that soluble immune complex handling may be altered when levels of CR1 on the blood cells are low; this can lead to the deposition of immune complexes in organs where their presence is undesirable, such as the kidney (45). No report has been made of a patient with a total deficiency of CR1 or CR2; however, persons with fewer than 50 copies of CR1/E are healthy (46,47). These individuals have normal numbers of CR1 on phagocytes and B-lymphocytes. The copy number of CR1 expressed per E is under genetic control. Despite early reports indicating that persons with a low copy number have a predisposition to development of SLE, such an association has not been confirmed (48).

CR3/CR4 Deficiency

CR3/CR4 are receptors for C3bi and are members of the family of b_2 integrins (4,49). The latter family is composed of four members: CR3, lymphocyte function antigen (LFA)-1, p150,95 or CR4, and a_Db_2, each possessing a common b subunit. Patients with a b_2 integrin deficiency suffer from recurrent severe pyogenic infections and have defects in multiple neutrophil and mononuclear phagocyte microbicidal and adhesive functions. Lymphocyte functions related to adhesion also are impaired, especially cytotoxic activity. The clinical correlates of these *in vivo* findings are delayed separation of the umbilical cord, persistent leukocytosis, recurrent pyogenic infections (particularly of the skin and mucous membranes), and aggressive periodontal disease. Two phenotypic variants have been identified on the basis of the severity of the recurrent infections. These appear to correlate with reduced (in the moderate phenotype) versus absent (in the severe phenotype) CR3 expression (4,49,50). The biochemical basis of this disorder is an inability to synthesize the chromosome 21-encoded b subunit, resulting in failure of these cellular adhesion proteins to insert into cell membranes (see Chapter 15). There is one report of an a-subunit defect in a patient with SLE (MIM leukocyte adhesion defect 116920) (51).

CD59

In the single case of isolated, complete deficiency of this glycolipid attached inhibitor of C8 and C9 insertion into membrane-bound MAC, the initial manifestation was the syndrome of paroxysmal nocturnal hemoglobinuria, including hemolytic and thrombotic complications (see later) (52,53).

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired hematopoietic stem cell disorder characterized by chronic intravascular hemolysis and propensity to thrombosis [reviewed in (54,55)]. It exemplifies the critical role of membrane regulatory proteins in C homeostasis. The clinical manifestations of PNH are due to the absence of multiple proteins, all of which are attached to the membrane by a glycosylphosphatidylinositol (GPI) anchor. This lipid anchor presumably allows for rapid lateral movement of regulatory proteins in the plane of the membrane. This anchor consists of, in order, phosphatidylinositol, *N*-glucosamine, three mannoses, and an ethanolamine. Posttranslationally, the ethanolamine is linked through an amide bond to the carboxyl amino acid of the protein. The fully formed anchor is attached en bloc to the protein in the endoplasmic reticulum (56). This “pigtail,” or so-called “greasy foot,” is not synthesized because of a somatic stem cell mutation in a gene (Pig A) on the X-chromosome responsible for the initial step in its biosynthesis. As a result, the proteins are translated but cannot be attached to the membrane, and all hematopoietic cells derived from this stem cell possess this defect. Thus, GPI-linked C-inhibitory proteins CD59 and CD55 are absent from cells. CD59 was described already. CD55 inhibits the C3 and C5 convertases.

In the absence of CD55 and CD59, more C complexes than normal are added to the E membrane, resulting in lysis when even small amounts of C are activated. Human E, in contrast to most all other cell types, do not express a third C-membrane regulatory protein, MCP or CD46. Consequently, PNH E is devoid of membrane regulators, and the outcome is chronic hemolysis. On platelets that also lack GPI-linked proteins, the addition of polymeric C9 results in the generation of procoagulant vesicles, which may account for the marked tendency to thrombosis in this disease.

Other immunologically relevant proteins deficient on hematopoietic cells in PNH include the FcgIIIa receptor, CD58 (LFA-3), and CD14 (plasma endotoxin-binding protein) (57). Surprisingly, the lack of these moieties results in minimal or no immune deficiency in PNH, and these patients are not highly susceptible to infections. Current evidence indicates that it is the ability of PNH stem cells to survive in bone marrow injury syndromes compared with normal stem cells that accounts for their preferential appearance in PNH (50%–70% of the time PNH arises in an aplastic marrow) (54). Various other proteins are also missing, including several receptors (urokinase receptor, folate receptor), enzymes (acetylcholinesterase, leukocyte alkaline phosphatase), and several proteins of unknown function. Presumably, the deficiency of one or more of these GPI-linked proteins provides a survival advantage to stem cells in the setting of marrow injury (54).

The diagnosis of PNH is no longer made by demonstration that Es have an unusual susceptibility to C lysis but is established by the demonstration of the absence or reduction by fluorescence-activated cell sorter (FACS) analysis of proteins bearing GPI-anchors on hematopoietic cells. CD59 is often the protein monitored and it tends to be lacking on a greater percentage of leukocytes than E.

MANAGEMENT OF THE INHERITED COMPLEMENT DEFICIENCIES

In most clinical situations, it is the management of the complications (infections and autoimmune syndromes) that dominates the clinical picture. Little attention has been paid to correcting the C defect. Plasma infusion treatment has been attempted in a few patients. In several cases, the transient reversal of clinical or biochemical abnormalities has been of sufficient magnitude and duration to suggest the clinical usefulness of plasma infusion in the setting of acute infectious diseases (1,14,58). Because the *in vivo* half-life of most C proteins is short, however, plasma therapy requires evaluation on a case-by-case basis. For a variety of reasons, including inconvenience, possible sensitization to the replaced protein, and the attendant risks of plasma infusions, this approach usually is not recommended for long-term therapy.

Two patients with C2 deficiency have had successful resolution of a relatively refractory lupus syndrome by long-term infusion of plasma. Vaccination with polyvalent meningococcal and pneumococcal vaccines has been recommended (3) for many C-deficient patients, especially those with properdin and C5-8 deficiency. Chronic administration of prophylactic antibiotics also has been suggested and has, in some patients, reduced the incidence of infections (1,3). Given the past failure of penicillin in the prophylaxis of meningococcal disease, this approach may have only limited usefulness in persons who are deficient in terminal components (3). Although a considerable number of C-deficient individuals may be clinically well or have primarily autoimmune syndromes, infection, usually bacterial, accounts for substantial morbidity and mortality rates. A persistently high index of suspicion for infection is thus appropriate in the long-term management of all patients deficient in C components. Therapy of rheumatologic or other autoimmune conditions in C-deficient persons has not been studied extensively but does not appear to differ from optimal treatment of the same syndromes in C-sufficient patients. The influence of replacement therapy (for example, aggressive androgen therapy to achieve normalization of C4 and C2 levels in HAE) on autoimmune disorders in this population has not been assessed in a controlled manner.

EVALUATION OF HYPOCOMPLEMENTEMIA

General Principles

To develop a differential diagnosis of hypocomplementemia in the clinical setting (Table 30.2), the pathophysiology of C activation and the factors that influence the level of the circulating proteins must be considered. The proteins that constitute components of the C cascade generally circulate in a functionally inactive form. Activation of the C sequence leads to utilization of components. The resulting level is the sum of the rates of synthesis, activation, and degradation. Consequently, blood levels may be normal in situations in which C is activated, such as in most infectious diseases and many autoimmune diseases. In pneumococcal pneumonia, C activation occurs at the site of infection, but the magnitude of this localized process is more than balanced by the acute-phase response-mediated increase in C3 synthesis.

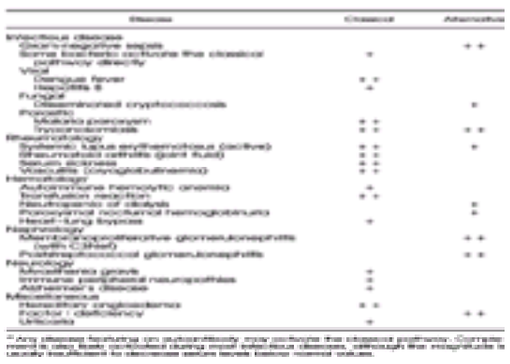

TABLE 30.2. Pathway Primarily Activated By Disease States[a]

Certain cytotoxic, opsonic, and ischemic-reperfusion injury syndromes are associated with minimal lowering of the C titer, even though C is involved in mediating the damage. Thus, in hemolytic anemias, transfusion reactions and PNH C mediates cellular destruction but serum titer is usually within the normal range. In strokes, heart attacks, and burns, C deposition occurs at sites of tissue damage, but serum levels are normal.

The various body compartments may be isolated from one another with respect to transport of C components. Although C is activated in the joint space of patients with rheumatoid arthritis, this activation usually is not reflected in an abnormality in serum C. The blood–brain barrier prevents access of the C proteins to the brain, except in inflammatory states; again, the compartmentalization of these rather large protein components makes it unlikely that the serum titer will be lowered. These data point out that an excess of C is present, which is more than sufficient to carry out its functions related to host defense and clearing dead and dying tissue. To decrease levels substantially usually requires pathologic situations featuring excessive amounts of, for example, immune complexes and chronicity.

The presence of depressed levels of several components of the CP or AP implies that C is being activated (59,60). Many factors can activate the C cascade, but depressed component levels are most commonly associated with the presence of circulating immune complexes, such as in SLE. Proteolytic enzymes released from

dying cells, from phagocytic cells during phagocytosis, and from metabolizing bacteria all may activate the C sequence.

The C cascades may be activated by certain polyanions, such as heparin or heparin protamine complexes, or the surface of uric acid crystals, or C-reactive protein binding to its substrate on the C-polysaccharide of pneumococci. Various exogenous factors, such as the dialysis membrane in an artificial kidney and heart–lung bypass machines, activate C via the AP. Antigen-antibody complexes of many classes, including IgA and IgE, also activate the AP, although, in general, large quantities of complexes are required. Many infectious organisms interact directly with the proteins of the AP and mediate depressed levels of C components.

If a depression in the level of a component is found either by antigenic analysis or by measurement of CH_{50} titer, the first question to ask is whether the finding represents the absence or depression of one or more components of the pathway. Some diseases, such as HAE, activate C4 and C2 but go no farther in the activation sequence. In HAE, C4BP binds to the C4b that is generated to prevent further activation. Other disease processes stop with the activation of C3 or C5. Therefore, it is not surprising to observe lowered titers of several, but not all, components of a pathway. As an example, it has been reported that many patients with membranoproliferative glomerulonephritis have low levels of factor B and low levels of properdin (60). In contrast, most patients with poststreptococcal glomerulonephritis have extremely low levels of properdin but relatively normal levels of factor B. The reasons for this difference in the amount of activation of components of a pathway are unknown. Nevertheless, both situations clearly point to AP activation.

In summary, if a single component is lowered, it is reasonable to question whether the patient has a genetically controlled deficiency. Studies of family members may be in order. If several components of a pathway are lowered, a reasonable supposition is that C is being activated. When hypocomplementemia is associated with a fall in titer of several components, it is often possible to determine whether the classical or AP is the major pathway being activated; this in turn may suggest certain diagnoses and rule out others.

Assays

Antigenic analyses are useful in following patients with ongoing C activation (Table 30.3). For example, monitoring the levels of C3 or C4 by this assay is of value in evaluating disease activity in patients with SLE. In general, a fall in C4 or C3 levels indicates a worsening of the active disease process and an increase with therapy serves as a guide to resolution. Because C3 and C4 activation products are rapidly cleared from the circulation, antigenic analysis of this type provides reasonable information about the functional level of the protein under study.

Method	Use	Comments
CH_{50} or THC	Good screen for complement deficiency or gross activation of classical (CP) pathway	Functional assay—requires appropriate sample handling
AH_{50}	Good screen for complement deficiency or gross activation of alternative pathway	Functional assay—requires appropriate sample handling
Antigenic (ELISA, immunodiffusion, nephelometry)	Standard for C3, C4, factor B, C1-inhibitor, and MBL determinations	Widely available, easy to perform, reliable, inexpensive
Antigenic or hemolytic assay of individual components	Further define a suspected deficiency	Samples usually sent to reference laboratory for complement assay
Activation fragments C3a C5a Bb C1-INH–$C1_2C_2$ C3b-H (neoantigen)	Very low positive with normal complement levels	Expensive, sample collection important; commercial kits often for these assays; more sensitive than ordinary levels
C1-inhibitor function	Clinical picture consistent with HAE but C1-inhibitor levels by antigenic assay are normal or elevated	15% of HAE patients have normal or elevated levels of a nonfunctional protein
Immunofluorescence	Demonstration of complement activation fragments in tissue	$C1_q$, C4, and C3 are most commonly studied in kidney and skin biopsies
Antiglobulin testing	Demonstration of C3 fragments on erythrocytes	Used fragment detected is C3d

AH_{50}, alternative pathway equivalent of THC; CH_{50} or THC, total hemolytic assay for classic pathway; ELISA, enzyme-linked immunosorbent assay; HAE, hereditary angioedema; MBL, mannose-binding lectin.

TABLE 30.3. Assays for Complement Activation in Human Disease

The most commonly used parameter for functional analysis of C activity is the total serum hemolytic C (CH_{50}) or total hemolytic C (THC) titer (Table 30.3). This test, which examines the ability of fresh serum to lyse antibody sensitized sheep erythrocytes, reflects activity of all components, C1 through C9, of the CP. In a genetically controlled total deficiency of any one except C9, the CH_{50} titer approaches zero. A comparable assay, AP CH, measures the functional capability of the AP. Usually, these tests are used on a one-time basis to screen patients for deficiency states. These assays, however, are not particularly sensitive to C activation, generally requiring more than 50% depletion of a component before it will register.

The examination of freshly obtained ethylenediamine-tetraacetic acid (EDTA) plasma (to block C activation in association with clotting, reduced temperatures, or storage) provides a method of determining whether there is ongoing C activation *in vivo* (61,62). The identification of increased levels of cleavage/activation fragments of C3, C1-INH, factor B, and C5 suggests activation of C, even in the absence of lowered C titers (59).

Antisera have been prepared that recognize neoantigens that develop during C activation (Table 30.3). For example, poly-C9 does not exist in native plasma but may be found in patients with complement activation. Antibodies to poly-C9 can be fluoresceinated and incubated with tissue sections from patients with various autoimmune diseases. Antibody to the neoantigens brightly stains glomeruli in patients with glomerulonephritis, suggesting that the C5b-9 lytic complex has formed on the basement membrane of the glomerulus. Similarly, such antibodies stain the dermal–epidermal junction of SLE patients in whom skin lesions are present but are absent where there are no skin lesions. This is in contrast to antisera to C3 that in SLE typically stain the dermal–epidermal junction in both pathologic and nonpathologic areas.

Other antisera monitor specific components or cleavage fragments. For example, in Alzheimer's disease, C1q, C4d, and C3d are deposited in plaques, indicating CP activation. These can be identified with antisera. Other tests are based on enzyme-linked immunosorbent assays (ELISAs), which that can detect activation of the CP or AP in plasma. The ELISA detects the presence of (a) complexes between C1s and C1-INH as evidence of CP activation, (b) complexes between properdin and C3 as evidence of AP activation, and (c) the neoantigen associated with the formation as evidence of formation of membrane attack complex (59). As little as 1% of C activation via the AP can be detected by the ELISA.

Interpretation of Hypocomplementemia

The components of the C sequence are usually considered in groups (59,60): (a) the CP, with its early components C1, C4, and C2; (b) the components of the AP, factor D, factor B, and properdin; (c) C3; and (d) the membrane attack complex, C5 through C9. If the CP is extensively activated as in SLE, utilization of the components C1, C4, C2, and C3 through C9 outstrips synthesis, resulting in a lowering of their titers. If the AP is substantially activated, titers of factor B, properdin, C3, and C5 through C9 (see Chapter 26, Fig. 26.2) will be decreased.

It is therefore useful to study a serum sample for its levels of C4 (a component of the CP) and C3 (a component of both pathways). These proteins can be easily, accurately, and inexpensively measured in serum or plasma. If C4 and C3 are low, as often is the case in patients with lupus, it can be surmised that the classical CP has been activated. In contrast, if C4 is normal in the setting of low C3, as is often the case in membranoproliferative glomerulonephritis, it can be surmised that the AP plays the primary role in C activation. Measurement of factor B levels also can be utilized to confirm such interpretations. In some patients with SLE and glomerulonephritis, a decrease in synthesis of C3 as well as an increase in utilization contribute to the low C3 levels. The reasons for this are still not clear, but C-degradation products may feed back to regulate the rate of synthesis of C proteins. The C proteins themselves turn over rapidly, about 2% per hour or about 50% per day, even in the resting state. Patients who are deficient in plasma regulatory proteins C1-INH, factor H, and factor I excessively turnover complement proteins, resulting in extremely low levels.

Foreign-body Reactions

Foreign materials placed in contact with the bloodstream usually result in activation of AP on the surface of the material [reviewed in (63)]. The two most common clinical situations are kidney dialysis and operations requiring heart–lung bypass. In both cases, by measuring products such as C3a or C5a, C activation can be shown to occur within minutes of exposure. A syndrome of agitation, shortness of breath, and pulmonary edema occurring within the first 30 minutes or so of dialysis was traced to C5a causing neutrophil aggregation and then lodging of these aggregates in lung capillary beds. Subsequently, dialysis membranes have been modified to reduce the intensity of this reaction. In heart–lung bypass, high levels of C5a correlate with longer pump time, ischemic complications, and increased morbidity and mortality. Such reactions are caused by most foreign bodies, but in many situations, blood contact is less because of small surface (intravenous needle or line) or more limited exposure to blood (not in the intravascular space). As exemplified by the dialysis membrane story, surfaces can be designed so as to reduce these reactions.

Ischemia–Reperfusion Injury

Reperfusion of a tissue following transient ischemia leads to complement attack on the still viable but partially damaged zone of tissue that surrounds necrotic tissue [reviewed in (64)]. These situations are common in clinical medicine, occurring to various degrees during myocardial infarctions, strokes, and other arterial thrombotic syndromes. Preservation of the damaged but still viable tissue is of paramount importance in many of these conditions. In animal models, as much as 30% to 50% of ensuing heart-muscle damage can be prevented by blocking C activation. The use of thrombolytics and other means of acutely opening blood vessels provides additional clinical scenarios where C inhibition could be helpful. The mechanism of the C activation in ischemia–reperfusion injury is poorly understood, but the evidence currently favors a CP activation phenomenon versus an inhibitor deficiency condition. Thus, alterations in the surface of ischemic cells may allow natural Abs or (more likely) lectins to bind to the surface and activate the CP. A role for C in the clearance of dead and especially injured (ischemic) tissue may be an important function of C not directly related to infections or immune responses.

This system for clearance of cell debris probably arose to facilitate the healing of cutaneous injury. Rapid removal of damaged tissue likely would limit infectious complications and facilitate wound repair. Of course, this same efficient process might be undesirable in heart or brain tissue. Other conditions that have similarities to these conditions, and where C activation may play a role, include acute respiratory distress syndrome, burns, septic shock, acute pancreatitis, and polytraumatic and multiorgan dysfunction syndromes. As noted, a failure of proper clearance apoptotic cells has been theorized to result in autoimmunity (12,14).

Complement Therapeutics

Currently, no therapy exists that can abrogate undesirable C-mediated cellular and tissue injury in clinical medicine. Two C inhibitors, however, are in clinical trials [reviewed in (65) and (66)]. Ideally, one would like to have an orally administered agent that specifically and temporarily inhibits C activation. Even better would be therapeutics targeting a single pathway or the MAC, depending on what is mediating the tissue damage. Interestingly, both *in vitro* and in experimental animals, intravenous immunoglobulin (IVIG) blocks complement binding to target tissues (discussed in greater detail in the chapter on IVIG).

One compound, sCR1, selectively inhibits the C3 and C5 convertases of all the activation pathways. It accomplishes this task by serving as cofactor for factor-I mediated cleavage of C3b and C4b and accelerates the disassembly of the C3 and C5 convertases. The second agent is a humanized anti-C5 monoclonal antibody (mAb). It binds to C5 and blocks C5 convertase activity of both pathways. Thus, this reagent has no effect on C3 cleavage by the C3 convertases and, therefore, would not inhibit C3b- and C3a-mediated pathologic events. Because many diseases are considered to be mediated by the actions of C3, the mAb to C5 would be of no value. On the other hand, the mAb to C5 would leave C3 reactions intact, and, as a result, the patient would not be as susceptible to infections. Unfortunately, in many clinical situations, we do know the contributions of C3 deposition versus that of MAC formation to a pathologic entity.

There are now more than 70 peer-reviewed publications reporting on the efficacy of sCR1 in inhibiting C activation in disease models in animals (67). Ischemia–reperfusion injury, burn injury, acute respiratory distress syndrome, antibody-mediated autoimmune disease (rheumatic and neurologic), and organ allografts were all ameliorated by sCR1. The data were sufficiently compelling that human trials (phase 1, 2, and 3) have been under way for several years. Reports have indicated no adverse events attributed to the drug and have shown it to be safe and nonimmunogenic and that C inhibition can be achieved. The second agent (anti-C5 mAb) effectively inhibited C5 activation in patients undergoing cardiopulmonary bypass or renal dialysis. There were no adverse effects, and an immune response to the preparation was apparently not observed. This mAb has also been effective, somewhat surprisingly, in several mouse models of immune complex-mediated disease and in several ischemia–reperfusion models. Advantages of this reagent include considerable clinical experience with the use of mAbs, the long half-life of IgG, less expensive production, and lack of immunogenicity. This technology could also be expanded to include a mAb to C2 as well as factor D to block a specific pathway.

Acute, transient C inhibition should be well tolerated, although patients requiring a sustained inhibitor may be at risk for pyogenic infections (sCR1) and *Neisserial* infections (mAb to C5). Potential complications also include exacerbation or development of an autoimmune state.

Xenotransplantation

Hyperacute organ rejection and blood transfusion reactions are two conditions in which sudden, massive, lethal CP activation may occur. Modern blood-banking technology has significantly reduced major transfusion reactions. Similarly, sophisticated tissue typing and other types of pretransplantation testing can limit hyperacute organ rejection. Currently, however, a shortage of transplantable human organs exists. Thus, transplantation of animal organs (i.e., xenotransplantation), is being investigated [reviewed in (68), (69), and (70)]. The major block to such an approach is the ensuing hyperacute rejection of the animal organ mediated by natural Abs and the C system. For example, a pig kidney, if transplanted to primate, survives only a few minutes secondary to a massive attack on the endothelium by natural Abs, which recognize sugars on the pig endothelial cells. These largely IgM Abs activate the CP, producing rapid endothelial damage. Clots soon form at these sites of endothelial damage, causing massive necrosis. To overcome this process, transgenic pigs have been produced that express human membrane C inhibitors. The expression of DAF, CD59, and MCP can ameliorate the hyperacute rejection process, offering hope that eventually xenografting can be a successful alternative approach. The problems of xenosis, especially the concern relative to pig retroviral to human infection, and delayed or vascular graft rejection are issues to be examined. This is reviewed in detail in Chapter 85.

31 LYMPHOCYTIC LYMPHOMAS AND HODGKIN'S DISEASE

Eric H. Westin, M.D., and Dan L. Longo, M.D.

The Hodgkin's and non-Hodgkin's lymphomas are a heterogeneous group of diseases with diverse cytologic, immunologic, and biologic features. These features result in a wide spectrum of clinical presentations and natural histories in treated and untreated patient groups. Information on the biology of the lymphoproliferative disorders continues to increase rapidly as a result of clinical observation, immunologic characterization, cytogenetic analysis, and application of increasingly sophisticated molecular approaches to disease analysis. However, despite our advances in knowledge, the non-Hodgkin's lymphomas in particular are becoming an increasingly important public health problem because of a rapid increase in incidence (5% per year over the last 20 years) for unclear reasons.

The lymphomas are neoplasms of cells of the immune system and generally represent neoplastic clones of cells that in many ways recapitulate specific stages in the normal lymphoid differentiation pathway. In this class of malignancies, however, most cells also acquire genetic abnormalities that are specific to each lymphoma subtype. These genetic changes affect genes of classes that represent both protooncogenes (1) and genes that alter the cell cycle (2) and response of the cell to signals that would normally induce apoptosis (3). In selected cases such as mucosa-associated lymphoid tissue (MALT) lymphomas and lymphomas arising in the immunosuppressed patient, the abnormal immune cell proliferation may not only be due to specific genetic changes within the tumor cell but may also be the result of abnormal immune stimulation or the absence of one or more normal regulatory mechanisms.

A large number of distinct clinicopathologic entities may be considered under the heading of lymphocytic lymphomas and Hodgkin's disease. Table 31.1 lists them according to their cells of origin: B-lymphocyte or T-lymphocyte disorders based on the recent World Health Organization (WHO) adaptation of the Revised European-American Lymphoma Classification scheme (4,5 and 6). The chapter introduces these entities in the context of the normal differentiation of B and T cells and reviews the pathology, clinical features, immunologic features, and treatment issues for the individual diseases that comprise Hodgkin's disease and non-Hodgkin's lymphomas.

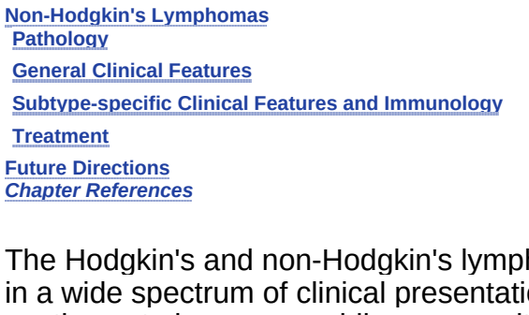

TABLE 31.1. WHO Classification of Lymphoid Neoplasms

ONTOGENY OF B LYMPHOCYTES

A schema for normal B-cell differentiation is depicted in Fig. 31.1 with designation of stages of development that correspond to the WHO classification framework outlined in Table 31.1. The stages of B-cell differentiation have been identified based on data derived from molecular biologic analysis of malignant B cells, an analysis of cell-surface phenotypes using a variety of monoclonal antibodies that detect particular membrane glycoproteins, and certain histochemical staining techniques that determine the presence or absence of intracellular protein products (7,8,9,10,11 and 12).

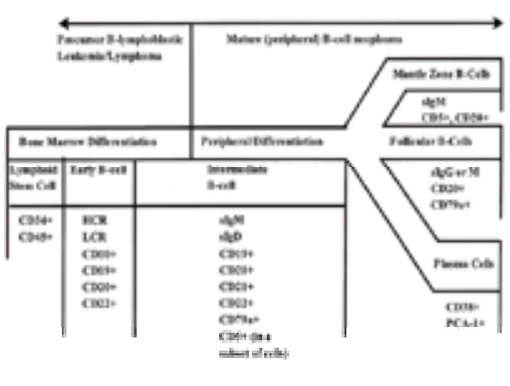

Figure 31.1. B-cell development and lymphoid neoplasms. Normal B-cell differentiation illustrating cells of origin of the B-cell lymphomas. Cell-surface and intracellular markers of B-cell differentiation are given for each discrete stage of development. TdT, terminal deoxynucleotidyl transferase; HCR, heavy-chain rearrangement; LCR, light-chain, k or l, rearrangement; sIg, surface immunoglobulin of indicated subtype (M, D, or G); PCA-1, plasma cell differentiation antigen-1.

Mature B cells usually are identified by the presence of surface immunoglobulin (sIg). The earliest stages of B-cell development can be discerned by detecting the presence of rearranged Ig genes before the expression of their product on the cell surface (10,11 and 12). Ig gene rearrangement is likely the first step in differentiation of cells committed to B-cell differentiation before any expression of B-cell surface markers (11).

As described in detail elsewhere in this book, immunoglobulin molecules are composed of two heavy chains [molecular weight (mol wt), ~50,000] and two light chains (mol wt, ~25,000). There are two types of light chains [k (encoding gene located on chromosome 2) and l (encoding gene located on chromosome 22)] and nine types of heavy chains: four types of g (G_1–G_4), two of a (A_1, A_2), and one each of μ, d, and e (encoding genes all located on chromosome 14). Each heavy and light chain contains a variable region (extensive amino acid sequence variability between immunoglobulin molecules) and a constant region (limited sequence variability). The light and heavy chains are linked by disulfide bonds and aligned so their variable regions are adjacent to one another. This alignment of variable regions forms the antigen-recognition site of the antibody molecule; its unique structural features form a particular set of determinants that can be recognized by other antibodies and are called idiotypes.

Immunoglobulin heavy chains are encoded by four distinct genetic elements: The variable region is encoded by three, the variable (Igh-V), diversity (Igh-D), and joining (Igh-J) elements; the constant region is encoded by one constant (Igh-C) element (11,13). Light chains are devoid of diversity elements and thus comprise three elements, two for the variable region (Igl-V and Igl-J) and one for the constant region (Igl-C).

In the germ line genome (all cells except B cells) the V, D, and J genes are widely separated, and there are numerous forms of each. Once a cell becomes committed to B-cell differentiation, one V and one D gene rearrange to join one J gene, and the intervening genetic material is excised (10,11). The process is termed VDJ joining and results in the production of a unique variable region (11). The newly rearranged VDJ gene is transcribed into a single message along with either an M or D isotype heavy-chain constant gene. On exposure to antigen, another gene rearrangement may occur so that the VDJ gene encoding a particular variable region may be associated with any heavy-chain isotype. The isotype switch usually results from splicing variable region messenger RNA (mRNA) together with constant region mRNA of a different isotype. Similar events occur in light-chain genes (VJ joining) to form its variable region. Because of the mechanics of the gene rearrangements necessary to specify the immunoglobulin variable regions, a particular clone rearranges only one of the two heavy-chain chromosomes and rearranges either its k or its l genes but not both. This process results in allelic exclusion (i.e., a clone expresses only one light-chain isotype). The gene rearrangements result in an altered sequence of DNA on the chromosomes, which in turn produces a molecular signature of a particular clone when the DNA is analyzed by Southern or polymerase chain reaction (PCR) techniques. Using this molecular approach, it has been determined that the overwhelming majority of B-cell malignancies are derived from a single clone, as illustrated by Korsmeyer et al. (14).

Gene rearrangements are the first evidence of commitment to B-cell differentiation. On additional maturation, functional immunoglobulin mRNA is transcribed and translated, leading to detectable cytoplasmic μ heavy chains, a finding that marks the pre–B-cell stage of development (15). When the intracytoplasmic heavy and light chains are assembled and inserted into the plasma membrane, the B cell has achieved an intermediate stage of differentiation. Most B cells go on to express surface IgD as well as IgM, and the resultant cell is the most common circulating B cell. Additional changes can occur on exposure to foreign antigen in the periphery.

Peripheral B cells appear to be divided into two distinct lineages, B-1 cells and B-2 cells. B-1 cells appear first in ontogeny, often express CD5, a pan–T-cell marker on their surface, are distributed in the mantle zones of lymphoid organs, respond to multivalent antigens such as polysaccharides (usually without cognate T-cell help), and do not undergo affinity maturation. Autoantibodies are frequently derived from the B-1 population. B-2 lineage cells are more numerous, do not normally express CD5, and undergo antigen-directed affinity maturation (involving mutations in the antigen-binding site introduced by terminal transferase) and class switch to alternative heavy-chain isotypes in the lymphoid follicle. With further maturation, the cells lose sIgD and sIgM and acquire the sIgG isotype of the antibody they ultimately secrete before terminal differentiation into plasma cells. Plasma cells normally lack sIg.

Monoclonal antibodies that recognize antigens expressed exclusively on B cells have been produced and used to develop models of B-cell differentiation (16). These B-cell–restricted antigens are expressed at certain stages of B-cell differentiation; for example, the CD19 and CD20 antigens appear to span most of B-cell differentiation, with the CD19 antigen appearing earlier. The CD21 antigen is gained and then lost during the middle stages of B-cell development. Maturation to the plasma cell stage coincides with the expression of the plasma cell–associated (PCA-1) antigen (17). Other markers found on certain B cells include Fc receptors, complement receptors, common acute lymphoblastic leukemia antigen (CALLA), CD10, human leukocyte antigen (HLA)-DR antigens, and CD5. These markers are not limited to expression on B cells and may be found on some monocytes, neutrophils, and T lymphocytes. In combination with other B-cell–restricted antigens, they describe a series of discrete stages in B-cell differentiation (Fig. 31.1). In addition, terminal deoxynucleotidyl transferase (TdT) has been found in early B lymphocytes by cytochemical staining techniques.

The role of the cell-surface markers on B cells in their normal physiology is undergoing gradual elucidation. An observation by Fingeroth et al. (18) and Frade et al. (19) implies that certain cell-surface structures may be used by pathogens to target infection, resulting in altered function. They observed that an antibody to the C3d complement receptor on B cells could block B-cell infection by Epstein-Barr virus (EBV). Similar strategies have been used by other viruses such as human immunodeficiency virus (HIV), which targets the CD4 receptor of mature helper T cells.

As depicted in Fig. 31.1 and coupled with the WHO lymphoma classification framework outlined in Table 31.1, most clonal B-cell neoplasms can be linked to at most a small number of discrete stages in B-cell development (16). One may find a degree of heterogeneity among the B-cell acute lymphoblastic leukemia/lymphomas (16,20); however, one does not find diffuse large B-cell non-Hodgkin's lymphomas with the surface phenotype of early B cells, or acute lymphoblastic leukemia cells with the cell-surface phenotype of secretory B cells.

ONTOGENY OF T LYMPHOCYTES

Like B cells, T cells arise from pluripotent marrow stem cells. Unlike B cells, they require a number of adaptations through cell interactions in the thymus, as indicated in Fig. 31.2, which illustrates a number of the steps in T-cell development. T cells have multiple functions, but they specialize, by and large, in the control of the broad spectrum of cell-mediated immunity (21,22). Marrow cells destined to become thymocytes (lymphoid stem cells) express CD71 (transferrin receptor) and CD38 antigens along with CD7. These primitive T-cell precursors account for ~10% of the total thymocyte population and are localized predominantly in the thymic cortex. With further maturation, they lose CD71, acquire CD1, and concurrently express CD4, CD8, and CD38. These cells are functionally immature, constitute 70% to 80% of the thymocyte population, and are nearly exclusively found in the cortex (21,22). The cells then move to the medulla, lose CD1, acquire CD3 (a nonpolymorphic determinant functionally linked to the T-cell antigen receptor), and lose either CD4 or CD8 expression but not both. Such CD3, CD4-positive and CD3, CD8-positive T cells are functionally mature and migrate from the thymus to the periphery. In general, cells expressing the CD4 antigen function as helper or inducer lymphocytes and recognize foreign antigens on cells bearing the class II major histocompatibility complex (MHC) antigens (HLA-DR antigens), and those expressing CD8 function as cytotoxic or suppressor cells and recognize foreign antigens on cells bearing class I MHC antigens (HLA-A, B, C). TdT is present in thymocytes but is not detectable in cells leaving the thymus.

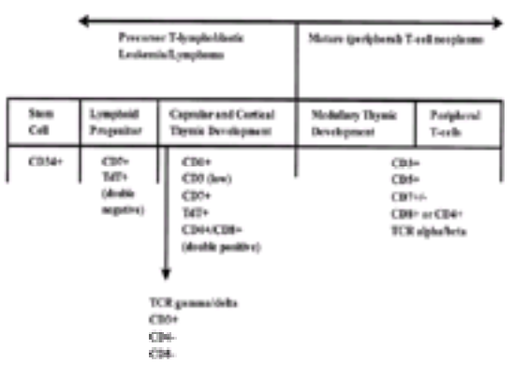

Figure 31.2. Normal T-cell development and lymphoid neoplasms. T-cell differentiation illustrating cells of origin of the T-cell lymphomas. Cell-surface and intracellular markers of T-cell differentiation are given for each discrete stage of development. TdT, terminal deoxynucleotidyl transferase; TCR, T-cell receptor with mature ab or gd receptor expressing T-cells.

Four genes encoding the T-cell antigen receptor have been identified: a, b, g, and d (23,24,25,26 and 27). The antigen receptor is composed of two glycoprotein chains, an ab (the most common) or gd pair, noncovalently associated with the CD3 complex. These paired chains are responsible for antigen recognition. T-cell receptor heterodimers are encoded by rearranged gene segments comprising V, D, J, and C segments, analogous to those encoding the antigen-binding variable domains of immunoglobulins (24,27). Three variable regions corresponding to complementarity-determining regions (CDRs 1–3) have been described, and the V, D, and J gene segments recombine in a developing T-cell to produce a contiguous V(D)J exon, which is spliced together with the C region at the level of RNA. Diversity is further increased by the addition of variable numbers of nucleotides at the V, D, J, and J-C junctions. T-cell receptor gene rearrangements, as with immunoglobulin gene rearrangements, can be used as the signature of a particular T-cell clone and its progeny.

Figure 31.2 depicts T-cell ontogeny and identifies discrete stages of development that correspond with current lymphoma classification (Table 31.1). In a proportion of malignancies of more mature phenotype, for example, mycosis fungoides and T-cell prolymphocytic leukemia (TCL-1 oncogene activation by juxtaposition with a T-cell receptor gene, $CD2^+$, $CD3^+$ and $CD4^+$ or $CD8^+$) and large granular lymphocytic leukemia ($CD3^+CD8^+$ T-cell or $CD56^+$ $CD3^-$ NK cell of origin), the malignant cells can retain a semblance of immune function that may contribute to the clinical picture (28,29,30,31,32 and 33).

In general, T-cell malignancies are considerably less common than B-cell malignancies. A noteworthy exception was found in Japan, where about two thirds of all lymphoproliferative disorders are of T-cell origin, primarily because of the prevalence of human T-cell lymphotropic virus type I (HTLV-I) in the Kagoshima prefecture at

the southern tip of Japan (34). However, given the epidemic increase in HTLV-I infection worldwide, frequency of this subset of T-cell malignancies may increase rapidly in affected populations over the next 10 years along with other HTLV-I–associated diseases (35).

HODGKIN'S DISEASE

First described in 1830 by Thomas Hodgkin (36), ~8,000 new cases are diagnosed every year in the United States with classic and lymphocyte-predominant Hodgkin's disease. Unlike the non-Hodgkin's lymphomas, the incidence of Hodgkin's disease has remained relatively constant over the last 20 years at 2.9 per 100,000 population. The etiology of Hodgkin's disease remains largely unknown, although epidemiologic and clinical features of classic Hodgkin's disease suggested an infectious etiology, with the EBV among others being a potential candidate (37,38,39 and 40). The disease is nearly 100-fold more common in identical twins of affected individuals than in the general population, implying some genetic contribution. There are no strong predisposing factors, although the disease appears to occur with increased incidence in woodworkers, persons who have had tonsillectomy and appendectomy, and those with certain HLA genotypes. In children, it appears that the incidence of Hodgkin's disease is increased in groups with a higher level of education (39,41). Patients with Hodgkin's disease have cellular immune defects (42), at least some of which may precede the development of the disease (43). However, the relation of this finding to disease development is unclear.

Pathology

The malignant cell in Hodgkin's disease is the Reed-Sternberg cell (44,45). It is a large cell with two or more nuclei, each of which has a single nucleolus (thus the “owl's eyes” appearance). Unlike most malignancies, this characteristic malignant cell represents only a small fraction of the cells that compose the masses palpated by the physician. Lymph nodes involved with Hodgkin's disease contain predominantly normal lymphocytes, plasma cells, eosinophils, and fibrous stroma, with only a small percentage of the cells being the malignant Reed-Sternberg cell. Although Reed-Sternberg cells must be seen to make the diagnosis of Hodgkin's disease, their presence is not pathognomonic (44,46). They also may be seen in occasional patients with infectious mononucleosis and breast cancer.

In the current WHO classification of Hodgkin's lymphoma (Table 31.1) (4), two major subtypes of Hodgkin's disease are recognized: nodular lymphocyte predominant and classic Hodgkin's disease are considered distinct entities. In both major groups, the malignant cell has been shown to be a B cell. In classic Hodgkin's disease, the direct precursor cell may be the germinal center B cell with markers including CD30 and 40 with $CD20^{+/-}$. In the lymphocyte-predominant form of Hodgkin's disease, the malignant cells express CD19, CD20, and CD22 (46,47 and 48). The Reed-Sternberg cell variants seen in this entity also are called popcorn cells because of the nuclear contour (46). Within classic Hodgkin's disease, four subtypes are currently recognized: nodular sclerosis, lymphocyte-rich classic Hodgkin's disease, mixed cellularity Hodgkin's disease, and lymphocyte depletion Hodgkin's disease (Table 31.1). In general, the natural history of lymphocyte-predominant Hodgkin's disease is more indolent than that of classic Hodgkin's. However, with ongoing advances in treatment, it is not clear that histologic type is an important prognostic factor (49,50).

Clinical Features

Hodgkin's disease is predominantly a disease of lymph nodes with direct contiguous spread from one lymph node group to another (51,52). When only one site is involved, overwhelmingly it is the left supraclavicular nodes (53). Most patients have an asymptomatic swelling in the neck. Approximately 10% of patients first notice inguinal or axillary adenopathy. The adenopathy is most often painless, unless the growth of the node is rapid. Up to 20% of patients notice pain in the enlarged lymph node on ingesting alcoholic beverages, perhaps because of alcohol-induced eosinophil degranulation. Constitutional symptoms of weight loss (10% of body weight), fevers, and night sweats occur in ~40% of patients. A classic clinical sign in Hodgkin's disease is the Pel-Ebstein fever, cyclic bouts of high fever, each lasting a week or two, separated by afebrile periods of similar duration. When fever occurs, it usually peaks in the evening and falls precipitously in the early morning hours, resulting in drenching night sweats. However, continuous fever is not infrequent. These symptoms, called B symptoms, are more common in patients with advanced stages of disease. Pruritus also is a common complaint of patients with Hodgkin's disease, but it is not a B symptom.

As noted, the spread of Hodgkin's disease is to contiguous lymph node–bearing groups (52). Thus when the left cervical region is involved, the abdominal nodes are rarely involved without concomitant mediastinal disease. Another predictable feature of the disease is that the liver is never involved unless the spleen also is involved. Within the abdominal cavity, the spleen is the most common site of disease. Thus pattern of spread is predictable, and in general, the prognosis is related to the number of sites of disease. Because of the need to standardize the therapeutic approach to patients with Hodgkin's disease, the patterns of spread of the disease were used to formulate the staging classification shown in Table 31.2 (54). This staging system, known as the Ann Arbor classification, has been the basis for treatment decisions for more than 30 years. The increased use of computed tomography (CT) and a greater appreciation of the effect of tumor burden on the outcome of Hodgkin's disease have led to minor revisions of this system in the form of the Cotswolds modifications (55). The revised staging classification recommends that CT be included as the procedure for evaluating intrathoracic and infradiaphragmatic lymph nodes, that the criteria for clinical involvement of the spleen and liver be modified to include focal defects, that liver-function abnormalities be ignored, and that the suffix “X” be used to designate bulky disease. In addition, stage III is subdivided to reflect upper versus lower abdominal lymph node involvement, and patients with residual radiographic abnormalities are given the designation CR_u for unconfirmed complete response, although the value of this latter change is questionable (56,57). Treatment is based on stage of disease. Thus once a histologic diagnosis is made, the stage of disease must be assessed.

Stage	Criteria
I	Involvement of a single lymph node region, or a single structure such as the spleen
II	Involvement of two or more lymph node regions or structures on the same side of the diaphragm
III	Involvement of lymph node regions or structures on both sides of the diaphragm with subdivisions including III₁ Involvement limited to spleen, splenic hilar nodes, celiac nodes and portal nodes III₂ Involvement including paraaortic, mesenteric, and iliac nodes in addition to upper abdominal nodes
IV	Extranodal involvement beyond E including any involvement of liver or bone marrow
Staging Modifiers	
A	Absence of constitutional symptoms of fevers, night sweats, or weight loss
B	Unexplained fever (>38°C), night sweats, or loss of 10% of body weight within 6 mo
X	Bulky disease (nodal mass >10 cm in diameter or a mediastinal mass >1/3 the transverse chest diameter at T_5–T_6)
E	Localized solitary extralymphatic tissue involvement (excluding bone marrow and liver) or extralymphatic direct extension from an involved nodal site or a single discrete geminal site to a regional lymph node site (e.g., IE)

[a] Modified Ann Arbor staging system for Hodgkin's disease.

TABLE 31.2. Staging Classification for Hodgkin's Disease[a]

A number of nonspecific laboratory abnormalities are found in patients with Hodgkin's disease, including an elevated white blood cell count, an elevated erythrocyte sedimentation rate due to an increased fibrinogen level, and elevation of a number of acute-phase reactants including ceruloplasmin (58). However, the most important information for staging patients comes from the sequential use of physical examination, chest roentgenography, CT scanning, lymphangiography, and in selected cases, exploratory laparotomy with splenectomy and multiple lymph node sampling in addition to liver and bone marrow biopsies. CT scans can be thought of as complementary to lymphangiograms, although use of lymphangiography has steadily decreased. Lymphangiography is more sensitive than CT in detecting retroperitoneal adenopathy because it can detect nodes with distorted architecture as well as enlarged nodes. Conversely, CT can visualize celiac, splenic, portal, and mesenteric nodes, which are not readily visualized with lymphangiography (59,60). Thoracic CT is frequently uninformative if plain chest radiographs appear normal (61).

Ninety percent of patients with Hodgkin's disease have clinical stage I or II disease after physical examination and chest radiography. The rest have advanced stages of disease. One third of the patients with early-stage disease are found to have more advanced disease after lymphangiography. Among the 60% of patients still thought to have clinical early-stage disease after lymphangiography, one third are found to have advanced disease on exploratory laparotomy. The probability of finding intraabdominal disease at laparotomy is 50% for patients with B symptoms and 25% for those without B symptoms. When sequential staging evaluation was performed on patients with Hodgkin's disease, 40% had early-stage, and 60% had advanced-stage disease. One of the most difficult areas in the staging of patients with Hodgkin's disease relates to the need to evaluate intraabdominal disease in patients with supradiaphragmatic adenopathy and negative findings on a lymphangiogram. However, this is becoming less critical to outcome, as lower-dose combined modality therapy has come into increasingly frequent use in patients with early-stage Hodgkin's disease.

It is discouraging that noninvasive measures are so insensitive in evaluating involvement of the spleen, the most common intraabdominal site for Hodgkin's disease. Because the spleen has no afferent lymphatics, spleen involvement implies hematogenous spread of disease. Only about two thirds of palpably enlarged spleens are histologically involved with Hodgkin's disease, and one third of normal-size spleens contain Hodgkin's disease, yet removal of the spleen is associated with an increased risk of infection.

The need for staging laparotomy is based on the desire to use radiation therapy alone as the form of treatment. If chemotherapy is used either alone or as a component of treatment, the need to pathologically define intraabdominal disease is removed. It was hoped that one could pick patients with an exceedingly low risk of

having intraabdominal disease on the basis of clinical features. One retrospective study identified women with clinical stage I disease, women younger than 27 years with only two or three sites of disease, clinical stage I patients with only mediastinal disease, and clinical stage I men with either lymphocyte predominance or follicular histologic forms of Hodgkin's disease as patients with a low risk of intraabdominal involvement (62). However, when these criteria were used to treat patients with radiation therapy alone without surgical staging, disease-free survival was compromised. Thus shortcuts in staging are not recommended if radiation therapy alone is to be used as the treatment. However, patients with stage IA disease above the level of the clavicles are at very low risk of having disease below the diaphragm (63). Radiation therapy alone can be safely applied to these patients without compromising treatment outcome.

Immunologic Features

As recently reviewed by Stein and Hummel (48,64) as well as by Chan (47), the cellular origin of the malignant cell in classic Hodgkin's disease and lymphocyte-predominant Hodgkin's disease has been shown with increasing consistency to be of B-cell origin. Reed-Sternberg cells in classic Hodgkin's disease frequently express B-cell markers that include CD30, CD40, and in some cases, CD20. When CD20 is expressed, the Reed-Sternberg cells contain clonally rearranged immunoglobulin genes, clearly placing them in the B-cell lineage depicted in Fig. 31.1. The popcorn Reed-Sternberg cells in lymphocyte-predominant Hodgkin's disease are more clearly B cell in origin, expressing CD20 uniformly but also expressing the epithelial membrane antigen (EMA), which is not known to be expressed at any stage in normal B-cell development.

Although monoclonal antibody panels have failed to prove a single cell type of origin in all cases of Hodgkin's disease, it is now possible in nearly all cases to use certain antibodies to distinguish Hodgkin's disease from other nonneoplastic sources of adenopathy (65,66 and 67). Hodgkin's disease cells nearly always express CD30 (Ki-1, Hefi-1; originally made against the L428 cell line) (68,69) and CD15.

Several investigators also have examined the spectrum of cytokines released by Hodgkin's disease–derived cell lines (70,71). Indeed, the occurrence of B symptoms, sclerosis, and eosinophilia may be characteristic of a tumor containing cytokine-producing cells. Interleukin 6 (IL-6) (72) and IL-9 (73) secretion has been demonstrated in both cultured and primary Hodgkin's tissues. In addition, the transcripts and corresponding proteins for granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-1a (but not -b), IL-3, IL-5, IL-6, IL-8, tumor necrosis factor (TNF)-a and -b, and transforming growth factor (TGF)-b have been detected in cytoplasmic RNA and culture supernatant obtained from two Hodgkin's disease–derived cell lines (71,74).

It has been known since Dorothy Reed's initial observation in 1902 that the immune system in patients with Hodgkin's disease is not normal (45). She found that patients with Hodgkin's disease were anergic to tuberculin on skin testing. Many studies that attempted to shed light on the meaning and mechanism of the immune defects have now been reported. These are mentioned here but are also summarized in greater depth in the review by Poppema et al. (42). Hodgkin's disease patients have poor delayed-type hypersensitivity responses to new and recall antigens (75). Lymphocyte proliferative responses to mitogens and auto-MHC and allo-MHC antigens are depressed (76,77). Some evidence from a study of twins suggests that the immune defect may precede the development of Hodgkin's disease (43). The degree of decreased T-cell response loosely parallels the stage of disease. Impaired responsiveness of T cells to IL-2 has been observed, and T cells from Hodgkin's disease patients appear to be defective in their production of IL-2 in response to mitogenic stimuli as well (78,79). It is interesting that these defects persist after the successful treatment of Hodgkin's disease (80,81). It is unclear if this impaired T-cell function is related to the pathogenesis of Hodgkin's disease, although a number of investigators have proposed hypotheses, most of which are not testable. However, despite a growing literature on immune defects in Hodgkin's disease, for the vast majority of patients, the T-cell defects in Hodgkin's disease appear to have no permanent or serious sequelae.

Treatment

Although the treatment of choice for patients with true early-stage Hodgkin's disease (stages I and II) was radiation therapy, which results in long-term disease-free survival in £80% of patients (82), increasing knowledge of late effects from radiation (83) and a variety of effective alternative approaches have lead to the current situation; there is no single standard approach to treatment in stage I and II patients (49). If radiation therapy is used as a single-modality approach to early Hodgkin's disease, then precise radiation techniques must be used to obtain optimal results. These techniques include pretreatment simulation, the use of megavoltage photon beams, the contouring of large radiation fields to the patient's anatomy with shielding of the heart and lungs, the administration of a tumoricidal dose in equal amounts from anterior and posterior ports, and verification that the diseased area is encompassed within the field (84). Most of these patients will require staging laparotomy with its attendant acute surgical risks (15% serious morbidity) and life-long increased risk of bacterial infection, particularly from pneumococci.

Studies have increasingly shown combination chemotherapy to yield at least equivalent outcomes in early-stage Hodgkin's disease. This, in addition to providing curative therapy, obviates the need for staging laparotomy and splenectomy. Radiation therapy alone is reserved with increasing frequency to patients with supraclavicular stage IA Hodgkin's disease only. An early study from the National Cancer Institute (63) compared chemotherapy directly using MOPP (nitrogen mustard, vincristine, procarbazine, and prednisone) versus radiation therapy in stage I to IIA Hodgkin's disease. Disease-free survival from this trial favored chemotherapy alone, with a projected 92% 10-year survival compared with 76% for radiation therapy alone. Currently this, and other regimens such as ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) (85,86), have been increasingly incorporated either as single-modality therapy in stage I and II Hodgkin's disease or combined with radiation therapy in cases with either massive mediastinal disease or persistent disease after completion of chemotherapy (86,87). ABVD in particular is an attractive regimen in early-stage Hodgkin's disease because of a lower incidence of gonadal damage (88), although pulmonary toxicity from bleomycin remains a significant problem with or without the combination of radiation therapy to the chest as a part of treatment. Overall, the increased long-term risks associated with combined-modality therapy are substantial, and generally, the advantage of combined-modality therapy in disease-free survival is mitigated by the increased late toxicity of this approach, with the exception of selected patients. As such, treatments combining limited chemotherapy with lower-dose radiation therapy should be considered with caution as a routine treatment approach until long-term follow-up is available documenting a reduced rate of late fatal complications.

The mediastinum is involved in ~70% of patients with Hodgkin's disease, and massively involved in ~25%. Residual mediastinal abnormalities persist in the majority of patients with massive mediastinal disease after treatment; the larger the original mass, the higher the likelihood of abnormality (56,89). Such persistent radiologic abnormalities do not necessarily represent persistent Hodgkin's disease. Gallium and positron emission tomography (PET) scans should show no uptake at the completion of therapy. Radiographic abnormalities that are stable and gallium or PET negative after radiotherapy or chemotherapy should be managed conservatively. An enlarging mass in the anterior mediastinum during the first 6 months after treatment can represent a regenerating thymus and pose a diagnostic problem (90). Gallium and PET scanning cannot distinguish recurrent Hodgkin's disease from regenerating thymus. Needle biopsy is necessary to make the diagnosis; the presence of CD4/CD8 double-positive thymocytes diagnoses normal thymus.

Combination chemotherapy alone is the treatment of choice for patients with advanced stage IIIA to IVB Hodgkin's disease. Any number of regimens appear to be roughly equivalent in their efficacy, inducing complete responses in 70% to 90% of patients with advanced-stage disease. These regimens ultimately result in cures in 65% to 75% of all patients with advanced-stage disease. The question of whether alternating or hybrid eight-drug regimens are superior to standard four-drug regimens remains controversial. Studies addressing this question have yielded conflicting results, but in general, rates of complete remission and relapse, as well as disease-free and overall survival rates are similar for the four- and eight-drug regimens. Currently, ABVD remains the most frequently chosen standard for treatment of advanced Hodgkin's disease, with some data to support its superiority over MOPP in treatment outcome (91) and in late complications from therapy (92).

Recent efforts to improve treatment outcomes have involved the development of new combination chemotherapy programs. Stanford V, a regimen using short-course chemotherapy with radiation to previous sites of disease, has completed a pilot trial indicating potential promise (93) and is currently undergoing testing against ABVD in Intergroup trials in advanced-stage Hodgkin's disease. Another regimen, BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone) also has completed trials in Germany and shows great promise in direct comparison with ABVD (94). Autologous bone marrow transplant and, in selected circumstances, allogeneic transplant also is a promising option in patients with either refractory or relapsed Hodgkin's disease (95,96 and 97), although it is important to note that patients relapsing after a long remission (more than 12 months) often retain chemotherapy sensitivity to standard regimens, although remission duration is considerably shortened.

NON-HODGKIN'S LYMPHOMAS

The non-Hodgkin's lymphomas are a heterogeneous group of diseases ranging from aggressive and rapidly fatal tumors to slow-growing indolent diseases, some of which may need essentially no therapy for many years (20). Although the etiology is unknown and can only be partly accounted for by the increased average age of the population in addition to occupational and environmental risk factors (98,99), the incidence of this group of neoplasms has continued to increase at a rate approaching 5% per year for the last 20 years. These lymphomas are neoplasms of the immune system (Fig. 31.1 and Fig. 31.2 along with Table 31.1). A wealth of information continues to evolve from clinical observation, immunologic phenotyping, cytogenetic analysis, and the application of recombinant DNA technology, leading to improved understanding of this group of diseases and their classification, behavior, and treatment.

Despite progress, the etiology is known in fewer than 1% of the 50,000 new cases of lymphoma diagnosed every year. For example, adult T-cell leukemia (ATL), endemic to Japan and the Caribbean and sporadically seen in the United States, is caused by HTLV-I (100,101,102,103 and 104). Many primary lymphomas of the central nervous system (CNS), aggressive lymphomas accompanying immunosuppressive therapy, and African Burkitt's lymphoma are likely caused by the EBV (105,106,107 and 108). A number of other conditions have been demonstrated to predispose individuals to lymphoproliferative disorders (Table 31.3). Most of these

conditions are associated with some form of immunodeficiency or hyperreactivity as a common denominator.

Immunosuppressive therapy to prevent heart or kidney transplant rejection
Wiscott-Aldrich syndrome
Ataxia-telangiectasia syndrome
Klinefelter's syndrome
Lymphomatoid granulomatosis
Chediak-Higashi syndrome
Common variable immunodeficiency disease
Sjogren's syndrome
Rheumatoid arthritis
Systemic lupus erythematosus
Acquired immunodeficiency syndrome
Acquired hypogammaglobulinemia
Swiss-type agammaglobulinemia
Exposure to ionizing radiation
Prolonged phenytoin (Dilantin) therapy

TABLE 31.3. Conditions Predisposing Patients To Non-Hodgkin's Lymphoma

EBV B-cell transformation may be a partial explanation for the lymphomas arising in immunodeficient patients, but there is little evidence suggesting that similar mechanisms can account for most of the lymphomas that occur in patients without apparent predisposing illnesses. It has been said that chronic antigenic stimulation may play a role in the development of lymphomas, on the basis of animal models demonstrating an increased incidence of lymphomas in graft-versus-host disease. Much of the neoplasia in these models appears to be related to the activation of endogenous retroviruses. However, chronic antigenic stimulation is difficult to document in most human lymphoproliferative diseases outside of the marginal zone subtypes.

Cytogenetic abnormalities are common in the non-Hodgkin's lymphomas (Table 31.4). Although the modal chromosome number is near diploid in most cases, banding techniques have detected a variety of structural rearrangements, inversions, and deletions, which have been reviewed extensively (109,110). For the vast majority of rearrangements, the antigen-receptor genes are one component of the translocation, and a normally silent oncogene is the other partner. The translocation thus activates expression of a normally silent transforming gene, and it appears that this occurs at an early developmental stage when the antigen-receptor genes are normally rearranged. It is increasingly clear that these acquired translocations play a critical role in lymphomagenesis, altering genes critical in programmed cell death as well as transcriptional control, control of the cell cycle, and development (110). The single most common abnormality involves a translocation of the bcl-2 gene in the t(14;18)(q32;q21). This translocation is seen in ~85% of patients with follicular lymphoma (111), in £30% of patients with diffuse large B-cell lymphoma, and at lower frequencies in other lymphomas as well. Variant translocations involving bcl-2 between chromosomes 2 and 22 with 18 also are seen (112).

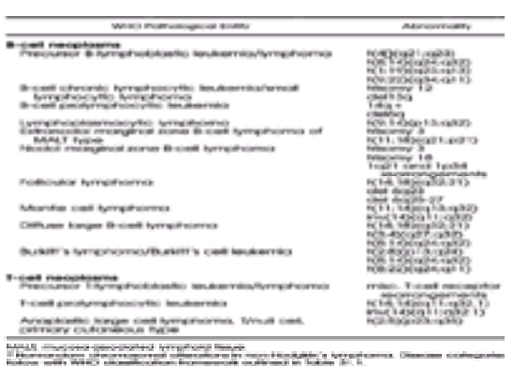

TABLE 31.4. Nonrandom Chromosomal Abnormalities in Non-Hodgkin's Lymphoma and Lymphoid Leukemias[a]

The translocations found in Burkitt's lymphoma are instructive; the distal segment of the long arm of chromosome 8 translocates to chromosome 14 (113,114) in 75% of the cases and to either chromosome 2 (115) or 22 (116) in the remaining 25%. These chromosomes (14, 2, and 22) contain the loci for immunoglobulin heavy chains and k or l light chains, respectively. These translocations are of particular interest because of the apparent integral role played by the cellular oncogene c-*myc* on chromosome 8 (117,118). In Burkitt's lymphoma cell lines with the t(8:14) translocation, the c-*myc*oncogene located on band q24 of chromosome 8 is translocated to the heavy-chain locus on chromosome 14. In the variant translocations t(8:22) and t(2:8), the c-*myc*oncogene stays on chromosome 8, and gene sequences from either the k or l chain loci translocate to 8. These rearrangements can result in the altered transcription of c-*myc* so that it is expressed constitutively at high levels in contrast to the transcriptionally silent normal c-*myc* oncogene on the uninvolved chromosome 8 (119). These translocations also are associated with mutations in conserved coding sequences (120).

Pathology

Between 1832, when Thomas Hodgkin (36) first reported seven patients with tumors of the “absorbent glands,” and 1956, when Henry Rappaport (121) devised his classification of the malignant lymphomas, the diagnosis of lymphoma was difficult, and many disease entities were not classifiable. However, with the development and popularization of the Rappaport scheme, an organized approach to patients with lymphoma became possible. The Rappaport classification grouped the lymphomas based on their pattern of growth (nodular or diffuse) and the degree of differentiation of the predominant malignant cell (well-differentiated lymphocytic, poorly differentiated lymphocytic, histiocytic, or mixed). This classification had several salutary features. It was more reproducible than the previous scheme (122), it was easily learned, and it provided clinicians with prognostic information on the likely clinical course of the patient (123).

In general, patients with diffuse well-differentiated lymphocytic (DWDL), nodular poorly differentiated lymphocytic (NPDL), or nodular mixed lymphocytic/histiocytic (NML) lymphomas followed an indolent course. Those with nodular histiocytic (NHL), diffuse mixed (DML), or diffuse histiocytic (DHL) lymphomas tended to have an aggressive clinical course (123). Clinicians found that they could plan a therapeutic strategy based on the histologic diagnosis. However, the Rappaport scheme was flawed; it did not encompass certain rare cases. The DHL group in particular was heterogeneous and the term histiocytic was in most cases a misnomer (“histiocytes” are usually transformed lymphocytes). With this, a bewildering variety of classifications was proposed in an attempt to improve on the perceived deficiencies.

The continuing controversy over these classification schemes and the difficulty of comparing treatment results from trials using diverse terminology led to the large-scale lymphoma-classification project sponsored by the National Cancer Institute (NCI) (124) and development of a “Working Formulation.” However, ongoing use of the Kiel classification scheme in Europe (125), originally proposed by Lennert et al., continued to lead to confusion in comparison of studies across national boundaries. A subsequent international collaboration resulted first in the Revised European-American Lymphoma Classification scheme (6), and with ongoing work, adaptation of a modified version of this scheme into the recently published WHO classification of hematopoietic and lymphoid tissue malignancies that is shown in Table 31.1 (4,5). This classification amalgamates morphologic, immunologic, genetic, and clinical information to define discrete clinical entities. Based on our growing knowledge of normal B-cell development and the genetics of transformation in lymphoid malignancies, this classification method should lead to increasingly effective and consistent classification of the non-Hodgkin's lymphomas in both retrospective analysis of previous trials and prospective analysis of ongoing clinical treatment trials. It also will need to be gradually modified over time as knowledge based on increasingly sophisticated molecular techniques such as adaptation of microarray technology to analysis of global expression patterns reveals further information permitting subgrouping of lymphomas in clinically and pathologically relevant fashions. This has been demonstrated in the diffuse large B-cell lymphomas (126) and will, without question, be applied to other subgroups of non-Hodgkin's lymphomas in the next several years.

General Clinical Features

Unlike Hodgkin's disease, the clinical patterns of the non-Hodgkin's lymphomas are heterogeneous. The more indolent lymphomas are virtually always associated with asymptomatic lymphadenopathy. Nearly half of patients with indolent lymphoma have liver and bone marrow involvement, and more than 85% of patients have advanced stages of disease. B symptoms are unusual in patients with indolent histologic subtypes. The adenopathy can wax and wane without treatment. The natural history of the more indolent of the non-Hodgkin's lymphomas is quite variable, but in general, the median survival time is 8 to 10 years (127,128). It appears that the natural history becomes progressively shorter as the large-cell component of the follicular lymphoma increases. In addition, the more indolent small cell lymphomas

have a tendency over time to undergo histologic progression from a follicular to a diffuse pattern of growth, and from small cleaved cells to large cells as the predominant malignant cell (129). The actuarial risk appears to be 5% to 10% per year and is not increased by administering therapy during the follicular stage. This tendency to progression is so marked that the overwhelming majority (94%) of patients with indolent lymphoma who die with lymphoma have converted to aggressive histologic subtypes such as diffuse large B-cell lymphoma (130). This histologic progression from indolent to aggressive histology is nearly always a morphologic change in the same malignant B-cell clone (131,132 and 133), although exceptions to this have been noted (133,134,135 and 136). The altered morphology reflects accumulation of genetic damage in genes that affect cell growth (137). Histologic transformation is always accompanied by a change in the natural history of the disease from an indolent to more aggressive behavior (129).

The aggressive subgroups of the non-Hodgkin's lymphomas have a much higher propensity to originate in or to involve extranodal sites such as the bowel, skin, brain, and testes than do the indolent lymphomas. The most common aggressive lymphoma is the diffuse large B-cell lymphoma. The aggressive lymphomas are more likely to produce B symptoms (Table 31.2) and are considered aggressive in natural history because the median survival of such patients untreated is ~8 months (138). The aggressive lymphomas are prone to widespread dissemination and are more likely to involve Waldeyer's ring and epitrochlear nodes than Hodgkin's disease or the indolent lymphomas (139). Liver involvement in more aggressive non-Hodgkin's lymphomas is rare. Despite this, there is a subgroup of patients that present with liver involvement as their primary site of disease in the absence of significant lymphadenopathy (140). Perhaps because of their rapid growth pattern, the aggressive subgroups have been overall more responsive to combination chemotherapy treatment programs than the clinically indolent lymphomas.

Because of the diversity of behavior in individual patients, it is difficult to distinguish the various types of non-Hodgkin's lymphoma on clinical grounds alone. The diagnosis relies on the pathologist's interpretation of biopsy material and, with increasing frequency, the immunologic and genetic characteristics of the lymphoma. The optimal management of individual patients is determined by careful diagnostic studies and assessing the extent of disease by the staging evaluation that is used for patients with Hodgkin's disease with certain modifications. Because only a minority (20%) of patients with non-Hodgkin's lymphomas have localized disease, there are fewer therapeutic implications to the staging of patients. Virtually all patients need treatment with chemotherapy at some point and the major value of the staging evaluation is to define the sites that must be reexamined after therapy to document complete response. Staging laparotomy as performed previously in Hodgkin's disease patients has no role in the routine management of patients with non-Hodgkin's lymphomas; however, because many patients have abdominal signs and symptoms, diagnostic surgical procedures are fairly common. Abdominal and chest CT, in some instances lymphangiography, and bilateral bone marrow biopsies and aspirations are routinely performed. Beyond that, specialized tests are used to pursue an individual patient's symptoms.

Although the Ann Arbor staging system (Table 31.2) is used in most subtypes of non-Hodgkin's lymphomas, it applies poorly to these lymphomas. The difference is largely because Hodgkin's disease spreads contiguously until late in its course, whereas non-Hodgkin's lymphomas disseminate hematogenously early in their course. In fact, with the sensitivity of the fluorescence-activated cell sorter, it has been clear for many years that most patients with non-Hodgkin's lymphomas of all stages have circulating malignant lymphoma cells (141,142,143 and 144). Nevertheless, there are clinical predictors of prognosis. In the clinically indolent lymphomas, B symptoms, advanced age, gender, and tumor bulk are generally considered to have a significant impact on survival (145,146,147,148 and 149). Surrogate measures of tumor bulk such as number of sites of disease, degree of marrow involvement, and lymph node size also are found to predict survival in some series. Other potentially useful staging/prognostic testing may include the serum b_2-microglobulin level, which was reported by investigators at the M.D. Anderson Cancer Center to be the single best prognostic factor and was found to be independent of Ann Arbor stage (150). Ascertainment of TNF-a, and its receptor levels may also provide prognostic information (151).

For the clinically aggressive lymphomas, advanced stage, B symptoms, large gastrointestinal or mediastinal masses, bone marrow involvement, liver involvement, and elevated lactic acid dehydrogenase or b_2-microglobulin levels in the serum are particularly poor prognostic signs (139,152,153,154 and 155). Poor performance status negatively affects the outcome of all lymphomas. Many of these risk factors have been combined into the now standard International Prognostic Index (156). This incorporates features listed in Table 31.5 into a simple scoring system, which divides patients into relevant prognostic groups based on a summed score of one for each category present in a given patient. However, the relevance of this to patients with follicular lymphoma remains somewhat controversial (157,158 and 159), despite application by many research centers.

Factor	Adverse Prognosis
Age	>60
Ann Arbor stage	III or IV
Serum LDH	> Normal
Number of extranodal sites of involvement	≥2
Performance status	>ECOG 2 or equivalent

LDH, lactate dehydrogenase; ECOG, Eastern Cooperative Oncology Group.
From The International Non-Hodgkin's Lymphoma Prognostic Factors Project. A predictive model for aggressive non-Hodgkin's lymphoma. N Engl J Med 1993;329:987–994.

TABLE 31.5. International Prognostic Index for Non-Hodgkin's Lymphoma

In the individual patient, the prognostic index must be combined with information regarding the WHO subtype of lymphoma present to then guide treatment recommendations based on the composite assessment of prognosis.

Subtype-specific Clinical Features and Immunology

Immunologic phenotyping of the lymphomas has in large measure driven our increasing understanding of the heterogeneity of the non-Hodgkin's lymphomas that was not originally predicted by morphologic studies (Fig. 31.1 and Fig. 31.2). The WHO classification framework has become the new international standard for lymphoma subtyping (4,5). Given the variable clinical and immunologic behavior of individual lymphoma variants within the WHO classification of non-Hodgkin's lymphomas (Table 31.1), it is best to consider each subtype separately to more accurately assess the spectrum of immunologic findings and clinical behavior expected within a given subclass. According to the WHO classification, lymphoid malignancies are divided into B-cell disorders, T-cell disorders, and Hodgkin's disease, which has already been discussed. Individual entities within the non-Hodgkin's lymphomas are considered next.

PRECURSOR B-LYMPHOBLASTIC LEUKEMIA/LYMPHOMA (PRECURSOR B-CELL ACUTE LYMPHOBLASTIC LEUKEMIA)

Seventy-five percent of the cases of acute lymphoblastic leukemia occur in children younger than 16 years, and the remaining 25% are roughly evenly distributed throughout the remaining age groups. Eighty percent of childhood leukemias but only 20% of adult leukemias are lymphoblastic in origin (160,161). Of the lymphoblastic lymphomas, only 20% are of B-cell origin. Children with acute leukemia often have the symptoms and signs of bone marrow failure, fever, pallor, petechiae, and easy bruising; adults usually have nonspecific symptoms of malaise, lethargy, fatigue, anorexia, and weight loss (162,163). Hepatosplenomegaly and lymphadenopathy are seen in most adults and children. Tumor cells characteristically express TdT, CD19, CD22, and CD79a and are HLA-DR^+ while not expressing surface or cytoplasmic immunoglobulin (164,165,166,167,168 and 169). Of these, CD79a is the most reliable marker to differentiate the lymphoblastic B- versus T-cell origin of the malignancy. Cytogenetic abnormalities are variable, with presence of the Philadelphia translocation t(9;22) and t(12;22) being of clear prognostic significance (170,171,172,173,174,175 and 176). Dose-intensive therapy offers a high rate of cure, approaching 80% in some studies (163,177).

B-CELL CHRONIC LYMPHOCYTIC LEUKEMIA/SMALL LYMPHOCYTE LYMPHOMA

This malignancy derives from a mature B-cell population (Fig. 31.1) expressing CD5 and usually CD23, with weaker expression of CD20 and CD22 along with surface immunoglobulin. In patients with more than 4,000 circulating malignant cells per µL, the diagnosis is chronic lymphocytic leukemia. In patients with lymphadenopathy and less than 4,000 circulating malignant cells per µL, the diagnosis is small lymphocytic lymphoma. Genetically, trisomy 12 is frequently seen (110). Clinically, the disease increases with age and accounts for 6.7% of cases based on the non-Hodgkin's Lymphoma Classification Project analysis (178,179). Immunologically, the disease is associated with hypogammaglobulinemia. Patients frequently are first seen with or have complications related to infection. Overall, the disease is characterized by an indolent course, with gradual progression over many years depending on stage, and may be associated with autoimmune phenomena including hemolytic anemia and thrombocytopenia (180,181). Although the malignant cells express CD5, about half of the cases express mutated immunoglobulin genes, suggesting that the cells had passed through a lymphoid follicle. Cases with mutated immunoglobulin genes have a more indolent disease than do cases with unmutated immunoglobulin genes (182,183). Staging follows one of two systems in widespread use, that of Rai or the Binet system (184,185). Both are based on assessing of the amount of marrow compromise. No therapy appears curative for patients with systemic disease although the very small subset of patients with localized small lymphocytic lymphoma may be cured with radiotherapy alone. Systemic treatment often is withheld until symptoms demand treatment; alkylating agents

with or without glucocorticoids or single-agent fludarabine are the most widely used agents. Treatment in early stages does not influence survival. Interestingly, ~5% of patients will undergo transformation of their lymphoma/chronic leukemia to a more aggressive phenotype termed Richter syndrome, in which the immunoglobulin gene rearrangements may be identical to or divergent from that of the original indolent leukemia/lymphoma (135,186).

B-CELL PROLYMPHOCYTIC LEUKEMIA

Occasionally, patients with high white blood cell counts have a somewhat larger cell seen on peripheral smear compared with those in chronic lymphocytic leukemia (187). Whereas surface marker studies are similar to that of chronic lymphocytic leukemia, only half of patients will have tumors expressing CD5 and more often express CD22 and generally have strong rather than weak surface immunoglobulin expression (188). Genetically, $14q^{+}$ and $6q^{-}$ defects along with other chromosomal abnormalities and abnormalities in p53 are frequently seen (189,190 and 191). Overall, the clinical course is shorter, with therapy less effective than in chronic lymphocytic leukemia; median survival is only 3 years.

LYMPHOPLASMACYTIC LYMPHOMA

Lymphoplasmacytic lymphoma occurs infrequently, representing only 1% on non-Hodgkin's lymphoma (179). Patients often have the clinical syndrome of Waldenström macroglobulinemia (192,193). Although no consistent cytogenetic abnormality is seen, a t(9;14)(p11;q32) translocation in seen in a subset of patients though t(11;18)(q21;q21) translocations are seen as well (194). The immunophenotype of cells on lymph node or bone marrow biopsy reveals B cells that are CD20 and cytoplasmic immunoglobulin positive and do not express CD3, CD5, CD10, or CD23. Patients have variable symptoms, the most consistent of which are related to macroglobulinemia with hyperviscosity from the monoclonal IgM protein present in the circulation. The course is clinically indolent, with a variety of therapies showing efficacy in the absence of apparent cure, with median survival of 65 months (193,195).

SPLENIC MARGINAL ZONE B-CELL LYMPHOMA (±VILLOUS LYMPHOCYTES)

B-cell lymphomas of this subgroup may have their origin in the marginal zone of B-cell development outside the follicular mantle zone. Cells express surface immunoglobulin (IgM and IgD) along with CD19, CD20, and CD79a (Fig. 31.1) (196,197 and 198). Cells are typically negative for CD5, CD10, and CD23 expression. Chromosome abnormalities are seen involving chromosomes 1, 3, 7, and 8, with complex karyotypes present (199,200). A subset may have specific rearrangements of the *bcl*-1 locus (201). Among the non-Hodgkin's lymphomas, this is a rare variant accounting for only 0.8% of all lymphoma cases (179). Clinically, patients usually have splenomegaly in the absence of lymphadenopathy and may have circulating cells that must be distinguished from other B-cell leukemias with splenomegaly (202,203). Overall the clinical course appears to be indolent (200), although splenectomy is frequently required for either treatment or diagnosis.

HAIRY CELL LEUKEMIA

This is a rare clinical/pathologic malignancy of B-cells that produces splenomegaly and pancytopenia. It typically responds to treatment with 2-chlorodeoxyadenosine with long-term hematologic remission in the majority of patients (204,205 and 206). Morphologically, cells have a characteristic fuzzy or “hairy” cell-surface appearance, leading to the name (207). The malignant cells express CD11c, CD19, CD20, CD22, and CD25 in increased amounts and are found to have tartrate-resistant alkaline phosphatase by immunohistochemistry (208,209). Serum soluble CD25 is a reliable tumor marker (210) with elevations preceding relapse by a median of 8 months (211).

PLASMA CELL MYELOMA/PLASMACYTOMA

For completeness, this is reviewed only briefly here but is covered extensively elsewhere in this text. Histologically, tumors of this subgroup, seen either as isolated masses (plasmacytomas) or as an infiltrating bone marrow process (myeloma), resemble immature plasma cells (212,213). Tumor cells are generally surface immunoglobulin negative and may secrete either IgG, IgA, or light chains alone. In rare cases, IgD or IgE may be the primary immunoglobulin secreted (214,215 and 216). Cells are usually CD19, CD20, and CD22 negative. Clonal rearrangement of the immunoglobulin loci is seen (217). The most frequent genetic changes appear to be related to abnormal immunoglobulin class switch recombinations (218). Aneuploidy is a common cytogenetic finding although translocations also are seen and may have prognostic significance (219,220,221,222,223 and 224). Alterations in *ras* and *Rb* proteins have been found in subsets of patients. Patients may have a concomitant infection with human herpesvirus 8 (HHV-8) (225,226). Patients have abnormalities including paraproteinemia, anemia, thrombocytopenia, renal failure, and hypercalcemia along with isolated or diffuse bony pain symptoms (227,228). Clinical course is variable depending on the presence of negative prognostic findings such as hypercalcemia and renal failure at presentation (229,230). Although cure remains elusive in the majority, patients respond to a variety of aggressive and nonaggressive therapeutic approaches (157,231,232,233 and 234).

EXTRANODAL MARGINAL ZONE B-CELL LYMPHOMA OF MALT TYPE

Extranodal marginal zone lymphomas of MALT type arise most frequently in patients with prolonged lymphoid reactive proliferations (235). The gastric mucosa is the most common site due to infection with *Helicobacter pylori*, and other sites are related to autoimmune disease such as Sjögren syndrome (lacrimal glands) or Hashimoto thyroiditis (thyroid) (236,237 and 238). Lymphomas of this group account for 7.6% of all non-Hodgkin's lymphomas (179). Histologically, these appear uniformly to be proliferations of small to medium-sized lymphocytes. As with the other marginal zone lymphomas, cells typically express pan B-cell antigens including CD19, CD20, and CD79a along with surface immunoglobulin and lack expression of CD5, CD10, and CD23 (239,240 and 241). In cases in which confusion may exist as to the malignant nature of the lymphoid infiltrate, the demonstration of k or l light-chain restriction becomes critical. Genetically, abnormalities with trisomy 3 and the t(11;18)(q21;p21) translocation are seen (242) with less frequent trisomies involving chromosomes 7, 12, and 18. With the most frequent gastric presentation, patients have nonspecific upper gastrointestinal symptoms of pain and/or reflux. Clinically, the disease follows an indolent course (243,244). Nearly all patients have *H. pylori* infection, and its eradication leads to cure in 50% to 65% of cases (240,243,245,246,247 and 248). Surgery, once a critical aspect of treatment, now has a secondary role. Interestingly, eradication of infection with *Borrelia burgdorferi* in patients with marginal zone lymphomas involving the skin has been shown to have similar clinical efficacy, indicating a common theme in pathogenesis and treatment of many of the patients with this general class of lymphoma (249). Patients then require frequent follow-up, and in patients not responding to this treatment, surgery, radiation, and/or chemotherapy may be required, particularly in patients with histologic evidence of transformation to a more clinically aggressive histologic subtype, which occurs in ~5% of cases.

NODAL MARGINAL ZONE B-CELL LYMPHOMA (±MONOCYTOID B CELLS)

B-cell lymphomas of this subgroup (250), as with their splenic counterpart, are thought to have their origin in the marginal zone of B-cell development outside the follicular mantle zone (251,252). Cells express surface immunoglobulin (IgM and IgD) along with CD19, CD20, CD79a, and CD11c (Fig. 31.1) (251,253,254). Cells are typically negative for CD5, CD10, CD23, and CD25 expression and can be differentiated from hairy cell leukemia by the absence of tartrate-resistant acid phosphatase expression. Chromosomal abnormalities with trisomy 3 and 18 are frequent (255). Clinically, this is a relatively rare entity, accounting for only 1.8% of the non-Hodgkin's lymphomas (179). Patients have isolated lymphadenopathy that, like the MALT lymphomas, may be associated with Sjögren syndrome and other autoimmune diseases (256,257,258 and 259). These lymphomas appear to follow an indolent clinical course similar to that for advanced follicular lymphomas, although, because of their rarity, extensive studies of treatment and outcome have not yet been done (260,261).

FOLLICULAR LYMPHOMA

Follicular lymphoma histologically has a nodular or follicular growth pattern without the zones of maturation seen in normal lymphoid follicles. In the WHO classification framework, this group is subdivided into three grades based on the presence of increasing numbers of large cells in which grades I and II are thought to follow an indolent natural history, and grade III (formerly termed follicular large cell lymphoma) follows a more aggressive course. The majority of patients have gradually increasing lymphadenopathy at one or more sites but with frequent involvement of extranodal sites including bone marrow. It is unusual for patients to have B symptoms. After initial diagnosis by lymph node biopsy and staging, up to three fourths of patients will be stage IV (Table 31.2), with only 10% to 15% of patients being stage I (179,262). Although a high percentage of stage I patients appear curable, at this point, cure in patients with more advanced stages has not been unequivocally proven. The majority of patients respond to a spectrum of treatment options discussed in the next section, whereas otherwise following a clinically indolent although relapsing and progressive course measured in years, with average survival of 8 to 10 years from diagnosis (263).

Genetically, the hallmark of follicular lymphoma is the t(14;18)(q32;q21) translocation involving the *bcl*-2 gene, which is centrally involved in control of apoptotic cell death pathways (264,265). The immunophenotype of this group of lymphomas tends to reflect the cell of origin in the B-cell lineage, with surface IgM positivity in addition to expression of CD19, CD20, CD22, and in many cases, CD10, but not CD5 (Fig. 31.1).

MANTLE CELL LYMPHOMA

Patients with mantle cell lymphoma account for £6% of all patients with non-Hodgkin's lymphoma (179). Histologically, neoplastic cell expansion in the mantle zone surrounding lymph node germinal centers occurs, with the cells representing a range of small to medium-sized lymphocytes. Cells of this lymphoma subtype express

not only B-cell markers including CD19, CD20, and CD22 but also CD5. Cells are negative for CD10 expression and usually for CD23 expression as well (266,267 and 268). Cytogenetically, the majority of these lymphomas have the characteristic t(11;14)(q13;q32) translocation (Table 31.4), which deregulates expression of the *bcl*-1 (cyclin D1) gene on chromosome 11 by juxtaposition with the immunoglobulin heavy chain gene on chromosome 14 (269,270 and 271). Because of heterogeneity in the breakpoints, PCR analysis is helpful clinically in only a subset of patients (272), but antibodies that detect increased cyclin D1 expression or PCR analysis of cyclin D1 mRNA levels are very helpful in distinguishing this lymphoma subtype (273,274,275 and 276). Clinically, patients are seen with mantle cell lymphoma at an average age of 60 years, with generalized lymphadenopathy, splenomegaly, and bone marrow involvement being frequent, as is the presence of circulating lymphoma cells (277). At present, no clinical treatment regimens are considered curative, with particular difficulty obtaining clearing of the bone marrow in these patients with or without inclusion of anthracyclines in the treatment regimen (261,268,278). Overall survival is therefore short, with median survival of 3 to 4 years (179,279,280).

DIFFUSE LARGE B-CELL LYMPHOMA

This lymphoma, which is more likely localized than are the other non-Hodgkin's lymphomas, generally is seen with lymphadenopathy. Median age of onset is 64 years, based on analysis done as part of the Non-Hodgkin's Lymphoma Classification Project (179). Patients have a full range of Ann Arbor stages, although involvement of at least one extranodal site is frequent, occurring in £70% of patients. Overall clinical behavior is aggressive in untreated patients, with up to one third of patients having B symptoms and masses more than 10 cm at the time of presentation, with half of patients having an elevated lactate dehydrogenase (LDH) and performance scores on the Eastern Cooperative Oncology Group (ECOG) scale of ³2 (156,281). However, as discussed later, this lymphoma is quite responsive to chemotherapy, with a significant number (40%-50%) of patients cured (282).

Cells from this class of lymphoma generally express an immunophenotype that is $CD20^{+}$ and $CD3^{-}$. Acquired cytogenetic abnormalities are frequent (listed in Table 31.4) and include translocations involving the *bcl*-2, *bcl*-6, and c-*myc* genes (109,110,283,284,285,286,287,288 and 289). Morphologically, the predominant cell is large, with the nucleus at least twice the size of a small lymphocyte, with prominent nucleoli and a basophilic cytoplasm. The diagnosis can be complicated in a subset of patients with the variant T-cell–rich B-cell lymphoma because of the presence on infiltrating normal T lymphocytes (290), which do not otherwise alter prognosis.

MEDIASTINAL LARGE B-CELL LYMPHOMA

As a subset of large cell lymphoma, primary mediastinal large B-cell lymphomas (291,292) account for 13% of these lymphomas (293) and ~2% of all non-Hodgkin's lymphomas (179). Cells express B-cell markers of CD20, CD22, and CD79a, although they do not express either surface or cytoplasmic immunoglobulin (294,295,296 and 297). No characteristic chromosome translocations have been described, in contrast to their diffuse large B-cell lymphoma counterparts, although alterations in 9p and amplification of the *rel* protooncogene have been described (298,299). The disease is rare in patients older than 65 years and typically is seen with respiratory symptoms associated with a large anterior mediastinal mass (300,301,302 and 303). Bone marrow, visceral organ, and lymph node involvement is uncommon. Clinically, the course is aggressive in untreated patients, but this lymphoma has response and cure rates at least as good as and probably better than those for diffuse large B-cell lymphoma, although more aggressive chemotherapeutic regimens beyond CHOP may be required (301,303,304 and 305).

PRIMARY EFFUSION LYMPHOMA

First described in patients infected with HIV and EBV, this form of lymphoma occurs in effusions without associated nodal or extranodal masses (306) and may occur in HIV-negative patients (307). Immunophenotypically, the malignant cell is of B-cell origin. All cases show infection with HHV-8 (307,308 and 309). Rapid progression characterizes the clinical course, with median survival of ~6 months (306) despite treatment.

BURKITT'S LYMPHOMA/BURKITT'S LEUKEMIA

Burkitt's lymphoma was first described by Dennis Burkitt in 1961 (310) as a disease of African children with tumors of facial bones. Endemic regions include equatorial Africa and New Guinea (311,312). In Western countries, Burkitt's lymphoma is the most common childhood lymphoma (35%–45%), although overall incidence as a part of the spectrum of non-Hodgkin's lymphomas is very low (10 of 1,400 cases in a recent review) (179). Histologically, cells grow in a diffuse pattern of medium-sized cells compared with other lymphomas, and in the nonendemic form, patients may have a variety of clinical manifestations (313). The malignant cell is a mature B cell (Fig. 31.1), expressing surface IgM as well as CD19, CD20, CD22, CD79a, and usually CD10. Cells are typically CD5 and CD23 as well as TdT negative (314,315). Chromosomal translocations involving 8q24 (the site of the c-*myc* gene) are universal. Partners in the reciprocal translocations found in Burkitt's lymphoma include all immunoglobulin chain loci. The most frequent translocation is t(8;14)(q24;q32), involving the immunoglobulin heavy-chain gene, whereas k (2p11) and l (22q11) light-chain gene translocations occur in a smaller percentage of cases (113,114,115 and 116). Precise break points vary in endemic (African) versus sporadic Burkitt's lymphoma, with truncation of the first coding exon in sporadic cases. Point mutations also are found in c-*myc* coding sequences similar to those found in the viral transforming *myc* gene seen in the MC29 retrovirus (120,314,316,317). EBV infection is characteristic of endemic Burkitt's lymphoma, although it also occurs with lower frequency in sporadic cases (313,314,318). Inactivation of p53 and deletions in chromosome 6q also are frequent (319).

Because of an extremely high growth fraction within the tumor (nearly 100% based on Ki-67 immunohistochemistry), patients have rapidly progressive masses requiring emergency treatment if life-threatening complications are to be avoided. Patients have a rapid response to chemotherapy with high probability of cure in early-stage and even advanced-disease patients (320,321,322,323 and 324). Staging currently is based on one of two Burkitt's lymphoma-specific staging systems, the St. Jude staging system (325) or the Uganda Cancer Institute staging system (326).

PRECURSOR T-LYMPHOBLASTIC LYMPHOMA/LEUKEMIA (PRECURSOR T-CELL ACUTE LYMPHOBLASTIC LEUKEMIA)

This entity is seen predominantly in adolescent and young adult patients and composes £40% of childhood lymphomas and 15% of acute lymphoblastic leukemias (327). On morphologic grounds, the cells are indistinguishable from their B-cell acute leukemia counterparts. Clinically after a rapidly fatal untreated course, patients can nevertheless achieve remission and cure with aggressive therapy. The transformed cells are generally CD3 and CD7 positive and express TdT and are either CD4/8 double positive or negative, indicating a precursor T-cell origin (Fig. 31.2) (328,329 and 330).

T-CELL PROLYMPHOCYTIC LEUKEMIA

This is a rapidly progressive T-cell lymphoproliferative disorder seen with a high white blood cell count, diffuse adenopathy, and skin lesions. It is characterized by inversions and translocations involving chromosome 14 (Table 31.4), with activation of the *TCL*-1 locus, which is critically involved in genesis of this disorder based on transgenic mouse studies (331,332 and 333). Cells express CD2 and CD3, with the majority expressing CD4 as well, although a subset will express CD8. Poor response to treatment leads to a median survival of only 6 months.

T-CELL GRANULAR LYMPHOCYTIC LEUKEMIA

Clinically, this is a somewhat more chronic leukemia compared with its NK-cell leukemia counterpart, with a spectrum of immune abnormalities including recurrent infections, hepatosplenomegaly, and pancytopenia. Cells have a T-cell phenotype, being $CD3^{+}/CD8^{+}$ (334).

AGGRESSIVE NK-CELL LEUKEMIA

Clinically, this is a rapidly progressive leukemia compared with its T-cell chronic granular lymphocytic counterpart, but with a similar spectrum of immune abnormalities including recurrent infections, hepatosplenomegaly, and pancytopenia. Cells have an NK-cell phenotype, being $CD56^{+}/CD3^{-}$ (334).

ADULT T-CELL LYMPHOMA/LEUKEMIA (HTLV-I^{+})

On epidemiologic and clinical grounds, adult T-cell leukemia was first recognized as a distinct clinical entity in Japan (335,336). Subsequent work identified the first pathogenic human retrovirus, HTLV-I, as the cause, based on initial isolation of this virus coupled with subsequent epidemiologic studies worldwide (337,338,339 and 340). Clinically, this is an aggressive lymphoma (340,341) seen endemically in Japan and the Caribbean. Pathologically, lymph nodes show an infiltrate of T cells of variable size and morphology. However, immunophenotypically, the cells express CD2, CD3, and CD4, but not CD7 or CD8, and have lower than typical CD3/TCR, based on stage of differentiation (Fig. 31.2). The malignant cell is clonal based on TCR-b gene rearrangement and contains a clonal integrated HTLV-I genome.

EXTRANODAL NATURAL KILLER/T-CELL LYMPHOMA, NASAL TYPE

Clinically similar to peripheral T-cell lymphoma, not otherwise specified, diagnosis of this named entity relies on the finding of NK cell–specific antigen CD56 expression in the lymphoma cells that also contain clonal EBV genomes (342,343 and 344). Clinical presentation is generally with an aggressive, destructive, midline facial tumor,

which has a poor prognosis if dissemination has occurred (345,346).

ENTEROPATHY-TYPE T-CELL LYMPHOMA

This lymphoma generally develops late in life in patients with a long-standing history of celiac disease. It is included in the peripheral T-cell lymphoma group with presentation that is predominantly gastrointestinal. Clinically, this entity has or results in intestinal perforation and has a very poor prognosis because of poor response to therapy. Phenotypically, the lymphoma cell is $CD3^+$ but $CD4^-$ and generally $CD8^-$ (347,348).

HEPATOSPLENIC gd T-CELL LYMPHOMA

This is a rare form of T-cell lymphoma involving the TCR-gd rather than TCR-ab subset of T-cells (Fig. 31.2). It affects a young patient group with or without bone marrow involvement and is characterized by an aggressive clinical course with involvement of extranodal sites in the absence of significant lymphadenopathy (349,350). Immunophenotypically cells are CD2 and CD3 positive but do not express CD4, CD5, or CD8 (350).

SUBCUTANEOUS PANNICULITIS-LIKE T-CELL LYMPHOMA

Clinically distinct from other peripheral T-cell neoplasms, this T-cell lymphoma subgroup is characterized by systemic symptoms of fever and fatigue along with subcutaneous nodules, particularly involving the legs, in the absence of nodal and visceral organ involvement. Patients have an aggressive clinical course with poor response to therapy and thus poor overall prognosis (351). Immunophenotypically, cells show a T-cell phenotype ($CD3^+$ and $CD8^+$) along with expression of NK-cell antigens such as CD56 (351,352).

MYCOSIS FUNGOIDES/SÉZARY SYNDROME

Mycosis fungoides/Sézary syndrome accounts for 65% of lymphoma patients with primarily cutaneous manifestations (353,354). The tumor cells are $CD3^+$, and CD4, CD8, and $CD30^-$. Clinical behavior of mycosis fungoides is indolent, with a chronic course in which multiple therapies directed at cutaneous manifestations of the disease are effective but not curative (354). Sézary syndrome, as a leukemic cell variant of mycosis fungoides, is defined as a triad of erythroderma and lymphadenopathy along with circulating lymphoma cells and follows a more aggressive course. Like follicular B-cell lymphoma, cutaneous T-cell lymphoma also can undergo histologic transformation to a more aggressive large cell lymphoma (355,356).

ANAPLASTIC LARGE CELL LYMPHOMA, T/NULL CELL, PRIMARY CUTANEOUS TYPE

This entity, seen with predominantly cutaneous nodules (as opposed to nodal involvement characterizing anaplastic large cell lymphoma, T/null cell, primary systemic type) otherwise has similar histologic and immunophenotypic findings, with the malignant cell showing CD3 and CD30 expression. However, clinically, this is a distinct entity with poorer overall response to therapy and a poor prognosis (357,358 and 359).

PERIPHERAL T-CELL LYMPHOMA, NOT OTHERWISE CHARACTERIZED

On clinical grounds, with presentation as generalized lymphadenopathy in the majority of cases, this form of peripheral T-cell lymphoma cannot be distinguished from its aggressive B-cell counterparts (360). Histologically, nodal architecture is effaced, with lymphocytes of varying sizes. Based on analysis of 1,400 patients (179), this form of peripheral T-cell lymphoma occurs in 3.7% of patients with lymphoma. The only clinical association with a T-cell versus B-cell phenotype is presence of the hemophagocytic syndrome in selected cases of peripheral T-cell lymphoma (361). Distinction relies on immunophenotypic analysis with, in most cases, expression of one or more pan T-cell antigens including CD2, CD3, CD5, and CD7. In up to two thirds of cases, expression of one or more of these surface antigens is lost, and the tumor cells have a phenotype unlike that of any normal T cell. Genetic heterogeneity also is frequent, although clonality can be proven with TCR gene rearrangements, and up to two thirds of patients have a translocation involving the TCR gene (110). When treated like diffuse large B-cell lymphoma, outcome in peripheral T-cell lymphoma is often poorer.

ANGIOIMMUNOBLASTIC T-CELL LYMPHOMA

Previously, patients with this T-cell lymphoma were thought to have an abnormal immune reaction to an unknown stimulus, with diffuse adenopathy, skin rash, fevers, and the laboratory finding of hypergammaglobulinemia. With the understanding that this was indeed a lymphoma, the name has been changed, with the clinical syndrome termed AILD (angioimmunoblastic T-cell lymphoma with dysproteinemia) (362). Immunophenotypically, the transformed cells are CD3 and $CD4^+$ without uniform cytogenetic abnormalities, although trisomy 3 and inversions within chromosome 14 have been detected (363,364), along with the EBV genome (365). Early in the disease, interferon may produce responses; however, advanced disease requires aggressive multiagent chemotherapy (366).

ANAPLASTIC LARGE CELL LYMPHOMA, T/NULL CELL, PRIMARY SYSTEMIC TYPE

Diagnosis of this entity relies on the finding of CD30 expression in the lymphoma cells (367,368). Genetically, this is a distinct subgroup within the peripheral T-cell lymphomas, with chromosome rearrangements involving the anaplastic lymphoma kinase (ALK) gene product in translocations such as t(2;5)(p23;q35) characteristic of this subtype (369,370). There is a bimodal age incidence, with treatment in the pediatric and adult settings leading to a high probability of cure (368,371,372), making this the single most curable entity of the non-Hodgkin's lymphomas.

Treatment

Given the spectrum of entities in the non-Hodgkin's lymphomas with the large differences in their biology and clinical behavior, it is unlikely that any single therapeutic modality or approach will ever have universal utility. Consistent with this, therapeutic approaches at present depend on the specific lymphoma subtype in question. Patients with clinically indolent lymphomas such as small lymphocytic lymphoma/chronic lymphocytic leukemia may require little or no treatment initially, given that randomized clinical trials have shown no improvement in survival with treatment of early-stage disease (373). From this as well as other studies, although purine analogs such as fludarabine and 2-chlorodeoxyadenosine produce higher response rates, there is no difference in overall survival and no apparent cures when compared with watchful waiting and institution of oral chlorambucil with disease progression (373,374). Similar principles are applicable to the treatment of lymphoplasmacytic lymphoma, although newer purine analogs have again showed early promise compared with or as salvage for failure with chlorambucil alone (375,376,377 and 378). In a clinical trials setting in young patients, stem cell transplantation with either auto- or allografting may also produce complete remissions, although cure remains to be proven (379).

As with small lymphocytic lymphoma/chronic lymphocytic leukemia, the indolent follicular lymphomas are considered incurable outside of the unusual setting of patients with limited, stage I or II (Table 31.2) disease, in which radiotherapy or chemotherapy combined with radiation may allow cure (380). However, application of increasingly intensive therapy for remission induction and maintenance, including use of CHOP-like regimens with or without interferon for maintenance (381,382) and use of high-dose radiolabeled anti-CD20 antibodies in the transplant setting (383), have led to prolonged remission even in relapsed and otherwise treatment-refractory patients. New agents such as anti-CD20 (rituximab; Rituxan) alone (384), and purine analogs such as fludarabine, along with anthracyclines such as mitoxantrone and taxanes such as paclitaxol also hold promise for improvement of therapy in the future (385,386). Molecular complete remissions may be achieved in two thirds of patients with advanced-stage follicular lymphoma treated with the FND (fludarabine, mitoxantrone, dexamethasone) regimen alone or incorporating rituximab into each monthly cycle (386). In the grade III (follicular large cell lymphoma), aggressive therapy may, in a significant proportion of patients, offer a chance for cure (387).

Although the approach to treatment of the diffuse large B-cell lymphomas has been directed at cure, considerable evolution in our knowledge of effectiveness of treatment regimens has occurred in the last several years. Multiple iterations of combination chemotherapy regimens have been developed, leading to progressively complex and in some cases, more toxic regimens. Each generation of therapy, developed in the setting of single-arm clinical trials, appeared to give improved outcomes when compared with historic controls. However, with publication of the direct comparison of the early CHOP regimen with m-BACOD, MACOP-B, and ProMACE-CytaBOM, it was asserted that no regimen offered a clear advantage over another in cure rate (although the cure rates were less than half the level reported initially). Thus many consider the CHOP regimen to be the treatment standard because of ease of administration and excellent patient tolerance (388,389 and 390). Contrasting with this, patients with the primary mediastinal variant of large B-cell lymphoma may benefit from more aggressive therapy (293,391). In patients with relapse, high-dose chemotherapy with autologous stem cell support offers a further chance of long-term disease-free survival and cure in chemotherapy-sensitive patients (392,393 and 394). At present, similar approaches are used in the treatment of the peripheral T-cell lymphomas, although, in the case of HTLV-I^+ disease, no standard treatment approach appears effective with patients exhibiting a rapidly progressive course. In contrast, treatment of anaplastic T-cell lymphomas with CHOP or CHOP-like regimens has proven extremely effective.

In mantle cell lymphoma, although cure remains elusive, limited data suggest improvement in survival when anthracycline-containing regimens such as CHOP are

used, although this remains controversial (261,278,395). Certainly, in older patients and patients with poor performance status, use of chlorambucil alone or use of CHOP-like regimens without the anthracycline remain reasonable options. CHOP plus rituximab appears to achieve a higher response rate, but follow-up is still short (396). Only limited work has examined the potential role of high-dose therapy with stem cell support, which, although showing improved complete remission rates, does not appear to lead to cure (397,398). Therefore, outside of the clinical trial setting, dose-intensive therapy with stem cell support cannot be routinely recommended for this patient group.

Extranodal marginal zone B-cell lymphoma of MALT type presents a unique therapeutic problem in oncology, in which conventional approaches using surgery, radiation, and chemotherapy are no longer considered the treatments of choice. In patients with *H. pylori* infection, initial treatment of choice should be treatment with appropriate antibiotics to eradicate the infection (240,243,245,246,247 and 248). Eradication of infection with *B. burgdorferi* in patients with marginal zone lymphomas involving the skin may have similar clinical efficacy (249). Patients then require frequent follow-up, and in patients not responding to this treatment, surgery, radiation, and/or chemotherapy may be required, particularly in patients with histologic evidence of transformation to a more clinically aggressive histologic subtype.

Evolution of treatment of Burkitt's lymphoma, unlike that for diffuse large-cell lymphoma, has continued to show progress. With increasing intensity of therapy and incorporation of multiple agents into therapy, patients with Burkitt's lymphoma now have one of the highest probabilities of cure in even advanced-disease patients (320,321,322,323 and 324) with one of several treatment regimens. This is in contrast to hairy cell leukemia, in which introduction of new purine analogs, particularly 2-chlorodeoxyadenosine, has led to a high probability of cure with a single treatment course (204,205 and 206). Thus, while defying many tenets underlying the application of modern chemotherapy to malignant disease, hairy cell leukemia also highlights the potential importance of introduction of new agents into treatment and the manner in which these agents can radically alter prognosis and outcome in properly selected patient groups.

As with Burkitt's lymphoma, success in treatment of lymphoblastic lymphomas/leukemias has continued to improve. This is due in large measure to the application of acute lymphoblastic leukemia approaches to the therapy of this related lymphoma. Successful regimens combine principles such as use of multiple agents in combination and sequence, including high-dose methotrexate for CNS prophylaxis and concepts such as induction, consolidation, and reinduction with maintenance therapy that has been a part of acute lymphocytic leukemia therapy for decades. Regimens such as the LMT81 protocol and BFM 86 and 90, although complex, result in event-free survival rates that approach 75% to 80%, even in patients with advanced-stage disease (320,399,400 and 401). From these studies, patients that remain in remission for more than 3 years are probably cured.

Thus chemotherapeutic approaches to the treatment of non-Hodgkin's lymphomas continue to undergo evolution. From an immunologic perspective, immune-based therapy has only recently been shown to have promise for incorporation into specific treatment recommendations. Despite continuing controversy, interferon does appear to improve durability of remission in patients with otherwise poor-prognosis follicular lymphomas who are treated with an anthracycline-based chemotherapeutic regimen (402). Interferon in conjunction with high-dose therapy also may have a role in the treatment of plasma cell myeloma/plasmacytoma (403). In the CD20-positive lymphomas, CHOP plus rituximab in a strategy combining conventional chemotherapy with immune-directed therapy also has shown promise in improving overall response rate and potential reduction in relapse rate in the clinically indolent lymphomas (396). Finally, with our rapidly improving abilities to identify tumor antigens, vaccines may play an increasing role in lymphoma therapy although trials are only now beginning in earnest (404,405,406 and 407).

FUTURE DIRECTIONS

It is clear that the understanding of the biology as well as treatment of both Hodgkin's disease and the non-Hodgkin's lymphoma is undergoing a period of rapid evolution. In the case of Hodgkin's disease, work in the clinical arena must now concentrate on reducing long-term treatment-related complications from successful therapy. Whether this will involve increasing use of chemotherapy alone in early-stage disease or combined-modality, limited-dose radiation and chemotherapy to achieve the best long-term results will need to be established from long-term follow-up of recently completed as well as ongoing trials.

In the non-Hodgkin's lymphomas, evolution of both lymphoid biology and therapeutic approaches is likely to continue to be rapid. This is manifested in its simplest form by the rapid evolution in the classification of non-Hodgkin's lymphomas in the last 10 years, with establishment of the recent WHO framework, which, by definition, is a work in progress rather that a fixed scheme (4,408). As increasingly sophisticated molecular approaches are applied to the characterization of both normal lymphoid development and the lymphomas, this is likely to undergo further rapid evolution by application of new technologies to assess gene expression within the heterogeneous large B-cell lymphoma subgroup (126). Elucidation of the etiology of specific lymphoma subtypes also is progressing rapidly. Understanding the role of HHV-8 in multiple myeloma may provide new insights into both the pathogenesis and treatment or prevention of this plasma cell disorder. With the marginal zone lymphomas, further work to identify additional antigenic stimuli of infectious agents such as the recently identified *B. burgdorferi* infection in patients with this lymphoma involving the skin (249) is likely to change both our understanding of pathogenesis and treatment of this group of lymphomas. Progress in “traditional” treatment, although complicated by the broad spectrum of diseases within the non-Hodgkin's lymphomas, also is likely to undergo rapid evolution. Progress in subtypes such as the diffuse large B-cell lymphomas will require the introduction of new agents if significant progress is to be made, whereas in other cases such as the Burkitt's lymphomas, refinements of established regimens may permit significant progress. In addition, the role of immune cell–directed or modulating agents including antibody-based therapies such as anti-CD20 and IL-2 fusion toxins (409), interferon, and DNA- or protein-based vaccines will need to be increasingly incorporated in experimental treatment programs. Clearly, much has been achieved in our understanding of Hodgkin's and non-Hodgkin's lymphomas and their treatment in the last 10 years. However, the next decade should bring even more exciting changes in this understanding.

32 MULTIPLE MYELOMA

Jean-Claude Brouet, M.D., Ph.D., and Jean-Paul Fermand, M.D., Ph.D.

Multiple myeloma (MM) is a malignant disease affecting the most mature cell of the B-cell lineage (i.e., the plasma cell). MM has attracted much attention from both immunologists and oncologists because it represented the first model of a clearly clonal disorder, the monoclonal immunoglobulins (Ig) produced by the malignant plasma cells being an invaluable clonal marker; allowed elucidation of the structure of antibodies; and permitted investigators to gain new insights into the understanding of tumor progression and response to therapy and, more recently, to dissect the role of lymphokine-mediated regulatory circuits in the growth of plasma cells. This fundamental progress has had, however, no discernible effects on the prognosis of MM, which is still a badly disabling malignancy with patients' mean survival time being 20 to 30 months. Present efforts are evaluating the efficacy of high-dose chemotherapy regimens followed by hematopoietic stem cell grafting, with some promising results.

HISTORY

The main clinical and pathologic features of MM were described nearly 150 years ago (85). The term *multiple myeloma* was coined by Rustizky (295) to emphasize the multiple focal bone lesions. In Europe, MM is still called Kahler disease because of the definite description of the disease by Kahler (191). Wright (374) noted that the tumor cells in MM belong to the plasma cell lineage. Finally, the serum protein abnormality was recognized more than 60 years ago (268). The value of L-phenylalanine mustard in the treatment of MM was recognized in 1958 (50).

EPIDEMIOLOGY

Although the incidence and mortality rates of MM have been increasing until recently (107), the disease remains a relatively rare cancer, accounting for 1% of all malignancies in whites and 2% in blacks in the United States (289) as well as in other countries (73,264,346). The average annual incidence rates per 100,000 are 4.7 in men and 3.2 in women for whites. The median age at diagnosis is ~70 years (289).

Apart from exposure to ionizing radiation (220,235,316), no convincing risk factor has been established. Farming occupations have been linked to the occurrence of MM in some studies (53,61,65,145,371). Prolonged exposure to benzene is not a risk factor (42). Special interest focused on the possible role of long-term antigenic stimulation leading to plasma cell dysregulation; the results of most studies, however, were inconclusive (53,88,96,155,205,224,372).

Familial occurrence of MM is well established (54,163,176,228,317); an environmental agent may be implicated, as MM has occurred among spouses (62,193,211). Genetic anticipation may occur in successive generations as observed in other lymphoid malignancies (164).

PATHOGENESIS

Current ideas on the differentiation of normal B cells suggest that they proliferate on antigenic stimulation in the primary and secondary follicles of the lymph nodes, the spleen, and Peyer patches and give rise to rapidly dividing plasmablasts, which circulate and home in bone marrow, where they mature to plasma cells (181,231). Interleukin (IL)-6 plays a major role in the late maturation of B cells (200,352). To what extent this scheme applies to the biology of MM is largely unknown. The phenotype of the vast majority of plasma cells in most patients appears similar to that of their normal counterpart (337), featuring CD38, CD10, CD138 (109), the HM1-24-antigen (252) and plasma cell-associated 1 antigen (PCA-1) molecules (166,180), and, unexpectedly, some antigens associated with other hematopoietic lineages such as myeloid, monocytic, and erythroid markers (127,162,336). A notable exception is the frequent expression of adhesive molecules such as CD11b, CD44, and CD56 (neural cell-adhesion molecules, N-CAM) (3,115,166,219,336,351), the latter mediating homotypic adhesion between cells. Most plasma cells and cell lines express the Fas-Fas ligand (Fas-L) molecules; whereas Fas-L is functional and may protect cells from cytotoxic T cells, Fas triggering does not provoke apoptosis, and mutations in the death domain of Fas have been noted in some patients (214,359). Loss of CD56 occurs in plasma cell leukemias, and expression of CD28 (as noted in a subset of normal plasma cells) may indicate aggressive myeloma (291). Secretion of matrix-degrading enzymes as well as angiogenic mediators may be associated with the progression of disease (349). In patients with inactive or slowly progressive disease, plasma cells are mostly nondividing, whereas in rapidly progressive disease, a variable number of actively proliferating plasmablasts are found. Some of them may give rise to colonies growing in soft agar, which define a myeloma stem cell assay that is highly correlated with the severity of the disease (165). The phenotypic and functional characterization of such stem cells is still elusive. Indeed, one may wonder whether in most cases, the bulk of the nondividing, end-stage, mature plasma cells do not preclude the identification of the important cells whose renewal constantly replenishes the mature pool of tumor cells. Evidence has been provided that some bone marrow atypical B cells ($CD10^+$, $HLA\text{-}DR^+$, surface and cytoplasmic Ig^-) (70) and blood precursors (43) may differentiate *in vitro* in the presence of lymphokines (IL-3 and IL-6) to plasma cells. Of note, cells with a phenotype between that of mature B cells and plasma cells coexist in myeloma bone marrow with typical plasma cells (198,221,303).

Some observations indicate that the clonal disease process also may include immature pre-B cells and mature B cells. Idiotypes are shared by the μ chain synthesized by pre-B cells and the serum monoclonal Ig (206). In different studies, different proportions of blood B cells displayed surface Ig idiotypically related to the serum monoclonal Ig (1,24,223,238,271,308). Genetic studies of these monoclonal populations of B cells yielded contradictory results (37,82,86,186,217); however, several studies unequivocally showed that a very small subset of IgM-producing B cells (1 in 10^4 or 10^5) share with malignant plasma cells the same mutated variable segment (17,45,91). It seems likely that if such B cells do exist, they account for a minority of blood B cells in any case. The significance of myeloma-related pre-B or B cells is unknown because functional studies could not be performed. The establishment of cultured lines derived from these peculiar B cells may help to resolve these issues (160,258).

A major advance in the biology of MM came from studies indicating that the growth of abnormal plasma cells was under the control of several lymphokines. IL-6 plays a key role in the proliferation of plasma cells (352). Initially it was shown that plasma cells produced IL-6 and expressed the surface receptor for this lymphokine and that antibodies to IL-6 inhibited cell proliferation (194). Whereas the latter finding was confirmed in several studies (9,201,245), the nature of the cells producing IL-6 is more debatable. Production of IL-6 by malignant cells was demonstrated only in some patients and in a subset of autonomously growing plasma cell lines (170,255,273). With *in situ* hybridization and immunocytochemistry, IL-6 messenger RNA (mRNA) and protein were detected in all patients with MM or benign monoclonal gammopathy (304). However, bone marrow nonplasmacytic cells (stromal cells, fibroblasts, macrophages) produce huge amounts of IL-6, suggesting that the proliferation of plasma cells was paracrine (273). The hypothesis of autocrine growth, however, holds true for certain plasma cell lines (218). It seems conceivable that the heterogeneity of plasma cell populations on the basis of phenotypes and kinetics in individual patients or from case to case accounts for some of these apparent discrepancies. The major role of IL-6 in the growth of MM also is supported by the antitumor effects of anti-IL-6 antibodies *in vivo* (202). Overproduction of this pleiotropic lymphokine also is responsible for fever in rare patients with fulminant disease and an increase in C-reactive protein (CRP) levels in more than one third of patients with MM (29,227). IL-6 both triggers plasma cell division and enhances plasma cell survival by upregulating *bcl*-XL and *Mcl*-1 (75,280). IL-6 signaling uses both Jak-stat 1,3 and ras–mitogen-activated protein (MAP) kinase pathways (75,250).

Lymphokines using the gp130 transducing chain of the IL-6 receptor (oncostatin M, IL-11, leukemia inhibitory factor, ciliary neurotropic factor) also trigger plasma cell proliferation (248,380). Oncostatin M production may be constitutive or its receptor upregulated by IL-10 (369), which is produced by plasma cells in half of the patients with myeloma (203). Evaluation of the level of cytokine or cytokine receptors in myeloma has no accepted clinical significance (305,330,370).

IL-6 is not the sole lymphokine triggering plasma cell growth. Hematopoietic cytokines [granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-3, IL-5, granulocyte colony-stimulating factor (G-CSF), tumor necrosis factor (TNF), interferon-a (IFN-a)] also may modulate plasma cell proliferation, mostly because they synergize with IL-6 or induce IL-6 production by plasma cells (9,43,189,190,379). These cytokines are now believed to mediate the characteristic increased osteoclastic bone resorption and inhibition of bone formation in MM (31,242). IL-6, TNF, and IL-1 appear to be the most critical factors (30,71,94,195,375). The recent identification of the osteoclast-differentiating factor may shed new light on bone disease in MM.

Some animal models also suggest that IL-6 may be involved in the development of plasma cell tumors. Mouse plasmacytoma growth is IL-6 dependent, and transfection of the IL-6 gene in tumor cells leads to an autocrine growth and increased tumorogenicity (339,360). Furthermore, mice homozygous for a null IL-6 gene are refractory to induction of plasma cell tumors (168). In mice transgenic for the IL-6 gene fused with the Ig heavy-chain enhancer, a massive polyclonal plasmacytosis develops in the C57BL/6 strain (331), and transplantable plasma cell tumors develop in the myeloma-prone BALB/c strain (332). The latter observation suggests that additional factors besides IL-6 are needed for tumor generation. Mouse plasmacytomas invariably carry a rearranged c-*myc* gene (92). Cytogenetic studies in human MM point to a frequent involvement of chromosomes 1 and 14 (14q32 abnormalities), with several and less frequent numeric or structural changes of chromosomes 3, 5, 7, 11, 17, and 18 (78,108,123,152,247,348). The t(11;14), t(8;14), and t(14;18) translocations, which are recurrent in other hematologic malignancies, have been observed in a limited number of patients (246,355). In view of the mouse model, particular attention had been paid to the c-*myc* oncogene. Its expression is frequently high, but identifiable gene rearrangements are rare (149,262,311). Expression of the *bcl*-2 oncogene is a feature of both normal and malignant plasma cells (269). Recent sophisticated techniques using fluorescent *in situ* hybridization, spectral karyotypes, and comparative genomic hybridization demonstrate that chromosomal anomalies exist in the malignant cells of most, if not all, patients with MM (69,84,285,377). Chromosomal translocations involve the heavy-chain locus and the site of the isotype switch region, indicating that the translocation might occur in cells maturing in germinal centers.

Various non-Ig partner chromosomes have been identified, most commonly chromosomes 11q13 and 4p16, and less commonly, chromosomes 8q24, 16q23, and 6p25. Genes expressed because of the translocation code for cyclin D1, the receptor for basic fibroblastic growth factor receptor, c-*myc*, c-*maf* transcription factor, and IFN regulatory factor 4 (79,80 and 81,143,376). Abnormalities of chromosome 13, including monoallelic deletion, carry a poor prognosis and may be associated with transition between benign monoclonal gammopathy and myeloma (15,77). The presence of p53 gene deletion predicts short survival (116). Structural oncogenic modifications of the Ki-*ras* and N-*ras* genes were noted in approximately one third of patients (225,244).

Because the differentiation and maturation of normal B cells are tightly regulated, and because there is frequently a latent period before plasma cell proliferation becomes aggressive, several studies aimed to define immunoregulatory circuits. There is a decrease in T-cell number and an imbalance between T-cell subsets, with evidence of abnormal helper function (216,234,239,272,312). A monoclonal T-cell population (367) and an abnormal distribution of Va and Vb genes expressed by peripheral T cells (185) were noted in a few patients. Three kinds of suppressive cells belonging to the monocytic (57), B- (230), and T-cell (265) lineages were identified. Cytotoxic T cells against autologous plasma cells were noted (261). The actual role of these cell populations in the biology of MM remains speculative. It seems likely that they are responsible for the humoral immune deficiency that is a hallmark of MM. The possibility that monoclonal populations of CD4 and CD8 T cells are specific for idiotopes of myeloma protein may have therapeutic significance (59,281). Efforts are being made to stimulate the immune response to autologous Ig idiotypes by immunization with myeloma protein-loaded dendritic cells (287). In addition, myeloma cells may express other tumor-associated molecules such as MUC1, an underglycosylated epithelial mucin (23), or MAGE-type proteins (350). Transfection of malignant plasma cells with the T-cell costimulatory CD80 molecule allowed the expansion of T cells cytotoxic for autologous plasma cells (336).

In MM, the bone marrow microenvironment is important in supporting the growth of plasma cells. Adhesion of plasma cells to stroma triggers IL-6 secretion (347). These data prompted investigators to search for human herpesvirus 8 (HHV-8) infection because this herpesvirus harbors a viral gene that is homologous to human IL-6. HHV-8 genes were detected by gene amplification and *in situ* hybridization in the adherent nonmalignant cell population from long-term culture of bone marrow from most patients with MM and one fourth of patients with benign monoclonal gammopathy (99). However, no antibodies to HHV-8 are present in patients' sera, and detection of HHV-8 was not reproduced in several laboratories (256,335). The role of HHV-8 in MM pathogenesis therefore remains controversial.

Most symptoms in patients with MM are related to the high tumor cell burden. Determination of the Ig secretion rate by plasma cells, the monoclonal Ig serum level, and the catabolic rate allow a precise estimation of the tumor mass (120,173,297,301,333). Patients become symptomatic when the number of plasma cell tumors reaches an average doubling time of 6 months. The disease is fatal when the number of cells is 1 to 2 × 10^{12} (i.e., 1- to 2-kg tumor mass). In progressive MM, the doubling time of the tumor follows a gompertzian growth curve; back-calculation indicates that the subclinical phase of the disease lasts 1 to 5 years before diagnosis. However, such calculation may be hazardous because it fails to account for latent or smoldering MM or even so-called benign monoclonal gammopathies.

In more than 99% of patients, malignant plasma cells retain the property of secreting Ig molecules; the detection of monoclonal Ig (or light chains) in serum and urine is a frequent mode of diagnosis. However, 80% of patients have an excess of light-chain synthesis and secretion, leading to proteinuria and/or the presence of free light chain in serum, especially when light chains form oligomers (101,172). In 10% of patients, only light chains are secreted; however, in a fair percentage of these patients, heavy chains are synthesized by plasma cells, as shown by immunofluorescence studies (275). In the rare patients in whom no abnormal Ig or Ig chains are detectable in serum and urine, immunofluorescent studies of malignant plasma cells evidence Ig chains (178,275,290). Biosynthetic studies performed in these nonsecretory MMs as well as in light-chain MMs suggest that the Ig chains produced are structurally abnormal and rapidly degraded (276).

The incidence of the secretion of a particular Ig isotype in MM is roughly in accordance with the serum level and with the distribution of plasma cells secreting a given isotype in normal bone marrow. IgG MM is therefore the most common variant (159); it displays a 66% k/l light-chain ratio. Tumor growth is slower than that in IgA, IgD, or light-chain MM. Self-aggregation of IgG3 molecules may induce a hyperviscosity state (72,328). The latter complication occurs more frequently in IgA MM because IgA molecules are uniquely prone to polymerize with a molecular size up to 900,000 d (207). IgD MM represents 1% to 2% of all cases and exhibits special features. More than 90% of patients display IgD with l light chains (147), indicating that the malignant cells may arise from rare germinal center cells with a similar phenotype including a high rate of mutations (10). The serum level of monoclonal IgD is often low, and light-chain proteinuria is constant. Extraosseous localizations (lymph nodes, liver, spleen, nervous system) are frequent (174,184,279), and the prognosis is especially poor (172). IgE MM comprises less than 0.01% of all cases and often is seen with aggressive plasma cell leukemia (124,138,251,294). Of note, ~1% of patients with otherwise typical MM display a serum monoclonal IgM (64,366); in these cases the prognosis and course of the disease are those of MM.

The presence of two or more monoclonal Igs (the most common combination being IgG and IgA) in serum is not very rare (209,278). There is evidence that the cells synthesizing these Igs are clonally related (142,175,266,274,319). In certain lymphoid malignancies such as acute lymphoblastic leukemia or chronic lymphocytic leukemia, a bias in the use of the diverse V_H and V_L families has been noted (177,199,315). No such bias seems to exist in MM; however, individual genes of the V_L1 and V_H3 families may be overrepresented, whereas others such as the V_H4-34 gene, which is often used in chronic lymphoid disorders or autoimmune diseases, are absent (288). Different mutational patterns have been observed in myeloma (no clonal heterogeneity) and benign monoclonal gammopathy (296).

The determination of the antibody activity of monoclonal Ig had been extensively worked out with the hope of gaining insight into the triggering mechanism of the disease (310). Some indirect evidence does exist that antigen may play a role in the development of the malignant clone (309). A patient with acquired immune deficiency developed a myeloma characterized by a monoclonal IgG directed to a viral protein (254). However, most identified antibody activities belong in the groups of natural antibodies, autoantibodies, or antibodies against common pathogens (the most usual is against streptolysin), all of which belong to the repertoire expressed in normal serum IgG (46,97,110,274,381). Some antibody activities may be correlated with unusual clinical symptoms. Patients whose IgG or IgA is directed against IgG cryoprecipitate can develop circulatory impairment (Raynaud phenomenon), skin necrosis of cold-exposed areas, or skin (vascular purpura) and kidney (glomerulonephritis) vasculitis (58). In 5% of patients, although no antibody activity is demonstrable, the monoclonal Ig is also a cryoglobulin. Antibody activity to lipoproteins can induce hyperlipidemia (197); that to transferrin can cause hemochromatosis (90); antibody activity to fibrin monomers or von Willebrand factor can precipitate hemorrhages (90,378); that to platelets can lead to thrombocytopenia (111); and antibody activity to insulin can provoke hypoglycemia (286). A discoloration of hair and nails was observed in a patient whose IgG reacted with flavin (130).

Systemic symptoms may be related to the deposition of Ig chains or fragments in tissues that compromise their function (see Chapter 34 on amyloidosis). Light-chain (and rarely light- and heavy-chain) deposition disease is characterized by deposits of amorphous, nonfibrillar material that is stained by antisera to light chains (66,148). Deposits of k chains occur twice as often as those of l chains. Renal involvement is constant, with light-chain deposits in glomerular and tubular basement membranes sometimes with nodular glomerulosclerosis. Immunofluorescent studies of kidney biopsy specimens allow an easy diagnosis of this complication. Widespread deposition of light chains in heart, liver, vessel walls, and nerves is common and variably affects organ function (146,284,313,345). Biosynthetic studies of the secretion of Ig chains as well as chemical study of the deposits indicate frequent structural abnormalities of the light chains, which may be truncated or polymerized or may feature an unusually high state of glycosylation (67,270,277,340). Of note, the abnormal light chains may not be detectable in serum or urine because of a small tumor mass, increased catabolism, or deposition in tissues. A mouse experimental model indicates that discrete mutation of a *Vk 4* gene led to widespread tissue deposition (196).

CLINICAL AND LABORATORY DIAGNOSIS

The diagnosis of MM may be suspected in a number of clinical settings. Bone pain, nonspecific symptoms such as weakness or weight loss, and laboratory abnormalities (electrophoretic spike, proteinuria, increased sedimentation rate) are common presenting signs. A complication of MM such as bone fracture or tumor, hypercalcemia, renal failure, recurrent infectious process, amyloidosis, and neurologic injury also frequently leads to diagnosis. The detection of serum monoclonal Ig by routine serum electrophoresis in otherwise asymptomatic individuals is increasingly frequent and legitimates an extensive workup. The diagnosis of MM relies on the study of serum and urinary Ig, the search for abnormal bone marrow plasmacytosis, and skeletal lesions.

Identification of Monoclonal Immunoglobulin

Serum electrophoresis detects the clonal Ig as a narrow spike of homogeneously migrating Ig molecules. Immunoelectrophoresis or immunofixation identifies the isotype of light and heavy chains. Special care must be taken not to overlook a small amount of free light chains. Neither normal total protein or electrophoretic fraction levels nor quantitative estimates of the various Ig isotypes eliminate the presence of a monoclonal Ig. Aside from the monoclonal Ig, these studies in most cases show a decrease of polyclonal Ig isotypes. Such hypogammaglobulinemia of recent onset in adults justifies a search for MM. Note that a quantitative nephelometric estimate of the monoclonal Ig is often unreliable and that the value of densitometric tracing of serum electrophoresis is more accurate for the follow-up of the disease.

Sulfosalicylic acid precipitation must be used to detect urinary light chains as a routine, because other tests, and especially the classic heat test, are insensitive to detect a small concentration of light chains. As for serum study, immunoelectrophoresis and immunofixation are needed to identify urinary monoclonal light chains. Study of a 100-fold concentrated urine sample is required before acceptance of the diagnosis of nonsecretory MM. All these tests detect abnormal clonal Ig or light chains in more than 99% of patients with MM.

Hematologic Features

The diagnosis of MM depends on the presence of an increased number of plasma cells, often with atypical features. The cytoplasmic maturity contrasts with the degree of nuclear differentiation (118,154,323). Plasma cells account usually for more than 10% of bone marrow cells. Plasmablasts with a high labeling index are indicative of a poor prognosis (157). In early MM, the malignant infiltrate is often nodular, and several aspirates or a bone marrow biopsy may be useful to ascertain the degree of marrow involvement.

Anemia is present in roughly two thirds of patients with MM, whereas leukopenia and thrombocytopenia are found in less than 15%. A leukoerythroblastic picture indicates massive bone marrow involvement. A small number of plasma cells is detectable in many patients; a leukemic dissemination (plasma cells 2×10^9/L) may be a presenting feature but tends to occur more often at the late stages of the disease. Rouleaux formation is common and related to the presence of the monoclonal Ig, as is the rapid cell sedimentation.

Skeletal Findings

The typical changes of MM are multiple, punched-out, purely osteolytic lesions occurring in hematopoietically active areas (208,362). Frequently, diffuse osteoporosis coexists with these lesions and may be the sole abnormal finding. Rarely, the lesions are osteoblastic (125,215,293), and these patients may have unusual symptoms, especially a peripheral neuropathy (241).

Fewer than 10% of patients harbor a single osteolytic lesion, raising the possibility of a solitary plasmacytoma. This distinction with MM is of great importance because true solitary lesions may be cured with local radiotherapy. The disappearance of a monoclonal Ig, when present, is good evidence for this possibility. However, most patients with ap-parent localized plasmacytomas exhibit new focal lesions or develop MM, sometimes years after treatment of the initial lytic lesion (25,76,105,204,236).

The importance of establishing the occurrence of bone lesions in a patient suspected of having MM may legitimate a bone survey with computed tomographic scanning (167,324) or magnetic resonance imaging (MRI) (140,167). The latter is of considerable value in detecting bone marrow abnormalities and may have a therapeutic impact in patients with asymptomatic, stage I disease (112,233). In contrast, bone scintigraphy does not detect myeloma lesions (27,139,361). These studies are useful to delineate the extent of compressive tumors, especially in patients with neurologic symptoms.

COMPLICATIONS

Patients with MM are exposed to multiple complications related to tumor formation, immune humoral deficiency, and toxicity of light (and rarely heavy) chains.

Neurologic Symptoms

Spinal cord and nerve root compression occurs in nearly 10% of patients with MM (55,320). The malignant plasma cell tumor often originates from a rib or vertebra, invades the spinal canal, and leads to extradural compression. Radicular pain is a frequent early sign. Sensory and motor loss and paraplegia are late symptoms. Emergency evaluation includes spinal cord radiographic studies and MRI, which are useful to assess the extent of tumor and to plan the treatment.

Patients with aggressive MM may have myelomatous meningitis with infiltration of the meninges and presence of plasma cells in the cerebrospinal fluid (232,365).

In fewer than 1% of patients, a sensorimotor polyneuropathy develops. The onset is progressive, and pain and dysesthesias predominate. Patients with peripheral neuropathy exhibit some distinct features: young age, monoclonal Ig with l light chains, osteosclerotic bone lesions (102,104,117), endocrine abnormalities (diabetes, hypertrichosis, gynecomastia), and skin thickening with hyperpigmentation. This constellation of symptoms had been described as the POEMS (polyneuropathy, organomegaly, endocrinopathy, M protein, skin changes) syndrome in Japan (334). Although the pathogenesis of this complication is unknown, it is directly related to the plasma cell tumor because improvement follows treatment, especially irradiation of a solitary plasmacytoma.

Renal Impairment

The most common renal injury is the distinctive cast nephropathy associated with tubulointerstitial inflammation. It is caused by light-chain excretion and occurs in approximately half of patients with MM. The nephrotoxicity of light chains is quite different from patient to patient (169); there is no correlation with the level of light-chain excretion. Studies of the physicochemical characteristics of light chains such as their isoelectric point provide no satisfactory explanation for their toxicity. Animal models of renal toxicity correlate well with clinical findings (325). Development of acute renal failure is often precipitated by dehydration, infection, hypercalcemia, or the fluid restriction needed for radiographic examination with iodinated contrast medium, which is contraindicated in these patients (87). Chronic and acute renal failure due to cast nephropathy may be reversible, at least in part, after rehydration, treatment of the hypercalcemia or infection, and chemotherapy (44,87). Hemodialysis must be considered when the improvement is slow and even when renal failure appears irreversible (60,93,98,187). In selected patients with an excellent response to chemotherapy, successful renal transplantation has been performed (56,93,106,327,363).

The second cause of renal disease is amyloidosis (Chapter 34).

Light (and heavy) chain deposition disease is increasingly recognized, as discussed in the preceding section; it legitimates performance of a renal biopsy when cast nephropathy is not clearly the cause of renal dysfunction. Light-chain proteinuria also has been associated with defects in renal tubular reabsorption, including the adult Fanconi syndrome (103,126,299).

Miscellaneous Complications

The characteristic increased bone resorption in MM patients often leads to hypercalcemia, which is a presenting symptom in one third of symptomatic patients. Hypercalcemia develops in a majority of patients during the course of the disease. It may exacerbate kidney damage, as anorexia, vomiting, polyuria, and drowsiness or coma are usual symptoms that cause dehydration. Some monoclonal Ig may bind calcium ions with increased total Ca^{2+} but normal ionized calcium (182,222,326).

The humoral deficiency of MM favors the development of bacterial infections. Pneumonia due to *Streptococcus pneumoniae* remains the predominant infectious process, although gram-negative organisms, especially *Pseudomonas*, are increasingly isolated in these patients (240).

The hyperviscosity syndrome is actually rare in MM. It occurs mainly in patients with IgG3 or IgA monoclonal Ig; its manifestations (bleeding, impaired vision, ischemic

symptoms) are relieved by plasmapheresis.

Dissemination of plasma cell tumors outside the bones is not rare but occurs mainly in the late stage of MM. Hepatic and splenic infiltrations are usually asymptomatic and may be found at pathologic examination early in the disease. Extraosseous myelomas (or extramedullary plasmacytomas) feature a distinctive natural course, ending in MM in less than 20% of patients (26,204). Most extramedullary plasmacytomas arise in the upper respiratory tract, especially in the nasopharynx and oral cavity (141,192); other visceral localizations include the lungs, lymph nodes, spleen, skin, kidneys, and stomach (2,74,114,192,373). Prognosis of these localized tumors is fairly good, and local treatment yields a cure in 80% of patients. Extraosseous myelomas may arise in different anatomic sites simultaneously; recurrence may occur at various sites or as medullary plasma cell spreading.

PROGNOSIS AND TREATMENT

MM remains a universally fatal malignancy, and limited advances in its treatment have been made since the introduction, in the early 1960s, of alkylating agents (4,40). Median survival time from diagnosis, which was ~6 months before the use of these drugs (257), thereafter reached a median duration of ~3 years (8). Recently additional drug therapies and therapeutic strategies, including bisphosphonates and high-dose cytotoxic regimens supported by hematopoietic stem cell transplantation, have provided some improvement in survival and quality of life of patients with MM (52,243).

Prognostic Factors

The survival time of individual patients with MM is variable, ranging from few months to more than 10 years (5,210). Various prognostic criteria have been proposed to distinguish between patients who might require different therapeutic strategies.

The most useful clinical staging system, proposed by Durie and Salmon in 1975 (118), is based on a combination of data that correlate with the myeloma tumor cell mass (298). The serum and urine monoclonal Ig concentrations, levels of hemoglobin and serum calcium, and the extent of lytic bone lesions allow patients with low, intermediate, and high tumor mass (stages I, II, and III) to be distinguished (118). Patients with relatively normal renal function are designed as A, whereas those with a serum creatinine level more than 20 mg/L are designed as B, to take into account the poor survival rate associated with renal failure. The variability of survival within a given stage led to the development of other prognostic factors, the most powerful of which is the serum b_2-microglobulin (b_2-M) level, which depends on both tumor mass and renal function. Prospective studies have shown that b_2-M levels at diagnosis are the best predictive factor of survival duration; patients with a low value (b_2-M, less than 4 mg/L) have a two- to three-fold increase in life expectancy compared with those with a high level (28,122,158).

The percentage of dividing plasma cells can be determined *in vitro* by incorporation of tritiated thymidine or by a more convenient immunofluorescence technique using monoclonal antibodies that recognize DNA precursor molecules, such as bromodeoxyuridine or nuclear Ki-67 proliferative antigen (158,161). A plasma cell–labeling index (PCLI) of 1% implies a poor prognosis, and in combination with a serum b_2-M level of 4 mg/L and plasmablastic morphology of myeloma cells, the PCLI allows a subclassification of patients into low-, intermediate-, and high-risk groups (158,283). Indirect measures of myeloma cell proliferation include levels of serum cytokines that can stimulate it, such as IL-6 and its agonist, serum soluble IL-6 receptor (29,283). In addition, the serum CRP level can be used as a surrogate marker of serum IL-6 activity, and its combination with the serum b_2-M level may be a useful staging system (32).

A high serum level of lactic dehydrogenase identifies a small group of patients who have aggressive myelomas with features of extraosseous disease (20). Many other prognostic factors have been identified, but the applicability of very few has been demonstrated (283). In contrast, the prognostic importance of cytogenetic abnormalities is now well documented, particularly of abnormalities involving the 11q chromosome, monosomy and deletions of chromosome 13, which are associated with an adverse outcome and with significantly decreased survival time (267,342).

Various means have been proposed to assess bone status in patients with MM, and serum levels of bone markers, such as peptides derived from type I collagen, were reported to be of prognostic value (95). Response to treatment is a major determinant of prognosis and survival (5,210), but drug sensitivity remains difficult to predict. In particular, studying myeloma cells from newly diagnosed patients for the membrane-associated P-glycoprotein linked to multidrug resistance is of limited interest because it is expressed only in 6% of cases (100). Last, the patient's age is an important consideration, as complications of the disease and treatments are life threatening in older patients (137).

Initiation of Therapy, Monoclonal Gammopathy of Unknown Significance

Patients with overt myeloma require specific treatment to relieve discomfort and to prevent complications by reducing myeloma tumor load. Virtually all patients with an asymptomatic myeloma, who are increasingly diagnosed by chance, will require chemotherapy eventually to prevent or control complications. Patients with early disease progression should be treated soon after diagnosis, but there is presently no evidence that prompt treatment provides a survival benefit to others whose disease may remain stable for many years (171). In addition, inappropriate chemotherapy, particularly with alkylating agents, exposes patients to the risk of acute leukemia, the rate of which may reach 17% at 4 years (41,63).

In asymptomatic patients, the presence of any lytic bone lesion on skeletal survey is usually associated with early progression within a year (6). MRI of the thoracic and lumber spine reveals myelomatous lesions in ~40% of patients with normal bone radiographs. In patients with an abnormal MRI pattern, median time to progression is on the order of 2 years, whereas treatment may be delayed safely for many years when the MRI pattern is normal (233,364). The other prognostic factors identifying patients with early disease progression include serum myeloma protein more than 30 g/L, Bence Jones protein excretion (50 mg/day), IgA type, hemoglobin level less than 12 g/dL, and bone marrow plasmacytosis (25%) (6,128,233,364).

Very slowly progressive malignant plasma cell proliferation often cannot be differentiated from monoclonal gammopathy of unknown significance (MGUS), until the patient eventually develops a clinically distinct MM or related disorder. MGUS is usually considered when the serum monoclonal Ig concentration is less than 30 g/L, plasma cells account for less than 5% of bone marrow cells, and monoclonal Ig in urine is absent or less than 1 g/day. These patients must not have bone lesions (including spinal MRI, if performed), anemia, hypercalcemia, and renal failure. MGUS is diagnosed in 63% of patients with monoclonal Ig (212). Its incidence, which is greater among blacks than whites (89), increases with age and is ~3% in white patients older than 70 years (16,89,179,212). Long-term follow-up indicates that 26% of these patients will develop MM or related disorders 2 to 29 years (median, 10 years) after detection of the monoclonal Ig (212). There is presently no reliable marker for differentiating patients with a benign monoclonal Ig from those with incipient MM (48,212,353).

Conventional Chemotherapy

Since its introduction in the 1960s (4,40), the intermittent oral administration of melphalan (L-phenylalanine mustard) and prednisone remains a therapy of reference. Melphalan and prednisone are usually given for 4 days, and courses are repeated at 4- to 6-week intervals. This chemotherapy results in subjective and objective improvement in a majority of patients. Objective changes include a significant decrease in the monoclonal protein concentration, hematologic improvement, and stable bone lesions. A good response is usually considered when there is a 50% or greater reduction in the concentration of the monoclonal Ig (83), as occurs in ~50% to 60% of patients (329). The disappearance of the monoclonal Ig is noted in less than 3% of patients (329), and cure is exceedingly rare (354). In patients who respond, the disease is usually stabilized within the first year of therapy. At any time, the tumor mass size tends to plateau, and continuation, intensification, or diversification of the therapy induces no further cytoreduction (119). When continued, chemotherapy delays the time of relapse but does not offer a significant advantage in survival time (34). Accordingly, suspension of treatment during the plateau phase is advisable. After a mean period of ~20 months, there is usually a relapse, and the overall median survival time of patients does not exceed 3 years (51).

Other alkylating agents, such as cyclophosphamide and, to a lesser extent, carmustine, are effective drugs in MM (237). Patients resistant to one drug may still respond to the other, prompting the introduction, in the early 1970s, of the combined use of these agents (129). In subsequent studies, cycle-specific drugs were tested, and the addition of vincristine was found to improve remission rate and survival duration (300). Thereafter, the potential advantage to using drugs with differing modes of action has promoted regimens that associate vincristine, melphalan, cyclophosphamide (Endoxan), and prednisone, alternated monthly with vincristine, carmustine, prednisone, and doxorubicin (121).

More recently, interest has been demonstrated in the administration of high-dose glucocorticoids, such as dexamethasone, either alone or in combination with vincristine and doxorubicin to relapsing patients or those with refractory disease (18,68,302). As initial treatment, vincristine, doxorubicin, and dexamethasone are not more beneficial to the survival time than are other multidrug regimens (7,8,302).

Randomized studies have compared melphalan/prednisone with combination chemotherapy regimens. In virtually all trials, combination chemotherapy was superior in terms of incidence of remission, but conflicting results have been reported with regard to survival (51,150,156,338). A recent overview of more than 6,600 patients from 27 trials found no significant difference in the mortality rate overall, in poor-risk patients, or in any subgroup, between the two therapeutic options (338). However, current opinion is that patients with symptomatic MM should be treated with combination chemotherapy rather than with melphalan/prednisone in an attempt to relieve

their discomfort more rapidly and more frequently (8,51).

High-dose Therapy

The demonstration that dose escalation of intravenous melphalan can produce high response rates with apparent complete remissions has provided evidence for a dose–response effect of alkylating agents in MM (229,307). To reduce the duration of the drug-induced myelosuppression with its high risks of morbidity and mortality (307), high-dose melphalan has been combined with stem cell transplantation, which, in addition, has allowed the use of more intensive high-dose regimens, even including total body irradiation (19,131,151,183). Allogeneic, syngeneic, or autologous grafts with blood or bone marrow as the source of hematopoietic stem cells have been used to support various marrow-ablative regimens (19,35,131,144,151,183).

In the past 10 years, the concept of dose intensity with hematopoietic stem cell support has modified the treatment of young patients with MM (243). Transplantation from an allogeneic donor may have the advantage over autotransplantation of a potential "graft versus myeloma" effect (226,341,356), but the procedure still has a high rate of related mortality, even when considered in patients younger than 50 years with human leukocyte antigen (HLA)-identical siblings (36,47). Many more patients are candidates for autologous transplantation, which is now usually performed with peripheral blood stem cells (134). Peripheral blood stem cells have many advantages over marrow stem cells, including an easier collection procedure that avoids general anesthesia, the potential to treat a larger number of patients, lower hazard of reinfusion of malignant cells, and shortened duration of marrow aplasia (132).

Phase II studies (133,358) and pair-mate analyses (21) have suggested that high-dose therapy (HDT) with autologous stem cell support is superior to conventional chemotherapy in newly diagnosed patients with MM. This has been confirmed by a randomized clinical trial that demonstrated benefits of HDT as compared with conventional chemotherapy in terms of higher response rate, longer event-free survival, and longer overall survival (11,12). HDT with autotransplantation may allow a median overall survival exceeding 5 years, whether performed early, as first-line therapy, or late, as rescue treatment for refractory or relapsed disease after conventional chemotherapy (135). Early HDT may be preferred because it is associated with a longer time without any chemotherapy (135). In any case, early autologous stem cell collection is critical for the relatively safe conduct of transplants (132,153).

Controversies remain with regard to the upper age limit at which HDT is of greater benefit than conventional chemotherapy (136,63,318). Melphalan with or without total body irradiation is the most common HDT regimen, but no regimen has been proven superior to others. The benefit of further intensification with tandem HDT and transplantations is still controversial (14,22). Attempts at further improvement also have included reduction of tumor cells in reinfused grafts, for example, with positive selection of $CD34^+$ stem cells (306,343,357).

Whatever the HDT protocol, it is unlikely that any patients will be cured after HDT and autotransplantation, emphasizing the need for additional strategies (13,243). Immunologic approaches, such as immunization against idiotypic determinants of the monoclonal Ig, are under investigation to stimulate autologous immunity to myeloma cells and to treat the residual disease, often minimal, that frequently persists after autografting (260,368). Present studies of allogeneic transplantation also aim to reinforce immunologic antitumor effects while decreasing treatment-related mortality rates through, for example, nonmyeloablative conditioning regimens (322).

Bisphosphonates

Bisphosphonates, which are derived from the natural compound pyrophosphate, are potent inhibitors of bone resorption: they reduce osteoclast development, enhance apoptosis of these cells, and reduce production of most bone-resorbing cytokines (292). Currently biphosphonates are the treatment of choice for hypercalcemia in patients with MM, as in other malignant diseases (52). Bisphosphonates also prevent the skeletal complications of MM bone disease (33), especially the second-generation agent pamidronate, which may reduce by half the risk of a new skeletal event (38). Long-term monthly cycles of intravenous pamidronate are of continued benefit, and a survival advantage over chemotherapy alone has been reported for patients receiving salvage chemotherapy and pamidronate (39). Third-generation bisphosphonates, such as zoledronate and ibandronate, which are much more potent than pamidronate, hold the promise of further reducing the skeletal morbidity in patients with MM (33). In addition, other therapeutic agents might derive from the recent characterization of the osteoprotegerin ligand, which appears to play a key role in osteoclast activation in MM (344).

Other Agents

Thalidomide appears to have an emerging role in the treatment of MM. Used alone, in incremental daily doses beginning at 200 mg, it can induce responses, sometimes marked and durable, in ~30% of patients who relapsed, including those after HDT (321). Major toxicities are neurologic (mainly somnolence) and gastrointestinal (constipation). The duration of response, optimal dose, use in combination with chemotherapy, and use in newly diagnosed patients are being investigated. The mechanism of action of thalidomide in MM is currently unclear but may include antiangiogenesis (282,321).

IFN-a may be used in patients with MM either in combination with chemotherapy during the induction phase or as maintenance treatment, but its actual benefit remains controversial. Indeed, IFN-a may prolong relapse-free survival, but the magnitude of the gain does not exceed a few months and does not translate into a clear prolongation of overall survival (213). Benefit appears as more marginal, as it is achieved at the cost of reduced quality of life from frequent adverse effects.

Recent advances in understanding resistance mechanisms to chemotherapy are resulting in the investigation of novel therapies for MM, including P-glycoprotein inhibitors, which increase intracellular drug transport in tumor cells (100). Therapeutic strategies based on the pathophysiologic role of cytokines in myeloma cell growth, such as approaches blocking IL-6 signal transduction, also are being investigated (249).

Supportive Care

In addition to bisphosphonates, prevention for skeletal complications such as fractures of long bones or vertebral collapses and treatment of bone pain may include cimentoplasty, local irradiation, and, more rarely, surgical fixation. Local radiotherapy is the treatment of choice for solitary plasmocytoma (113). Spinal cord compression also should be treated with radiation therapy, combined with high-dose glucocorticoids; surgical decompression is rarely necessary (68,213).

About 50% of MM patients with symptomatic anemia may benefit from recombinant erythropoietin therapy (usually 150 U/kg subcutaneously 3 times weekly) (213,259). In addition to supportive care, most patients with acute renal failure should promptly receive chemotherapy such as vinblastine and dexamethasone (VAD) or high-dose steroids alone (49,213). The benefit of combining plasmapheresis is controversial (188). For patients with irreversible renal failure, hemodialysis or peritoneal dialysis must be initiated (314). When hyperviscosity is suspected, the decision to perform plasmapheresis depends on the symptoms and changes in the ocular fundus, regardless of the serum viscosity level (150).

Many infections occur in the first months after the initiation of chemotherapy, during which antibiotic prophylaxis may be useful (253). Intravenously administered gamma globulin also may be useful but is inconvenient and costly. Patients may receive pneumococcal and influenza vaccination despite a suboptimal antibody response.

Finally, patients with MM need continuing emotional support, with emphasis on the potential benefits of therapy and the prolonged survival of some patients.

33 MACROGLOBULINEMIA

Nancy L. Bartlett, M.D., and Sophia M. Arackal, B.S.

The term macroglobulinemia usually refers to the presence of a serum monoclonal immunoglobulin M (IgM) protein and is not used to describe the polyclonal elevations of IgM associated with infectious or inflammatory conditions. Diseases associated with monoclonal macroglobulinemia include (a) primary or Waldenström's macroglobulinemia (WM), a lymphoplasmacytic lymphoma with distinct clinical features; (b) IgM monoclonal gammopathy of undetermined significance (MGUS), which refers to detection of a monoclonal paraprotein (usually less than 3 g/dL) without any other identifiable disease; and (c) secondary macroglobulinemia, the presence of a monoclonal IgM in association with other malignant neoplasms, including other non-Hodgkin's lymphomas, chronic lymphocytic leukemia, or rarely infectious or inflammatory conditions (1). The distinction between WM and IgM MGUS is somewhat arbitrary, with MGUS progressing to WM in 10% to 30% of patients by 30 years. The distinct clinical presentation of isolated peripheral neuropathy and a serum monoclonal IgM with anti–myelin-associated glycoprotein (MAG) properties is difficult to classify, but may represent a spectrum of the differentiation of MGUS to WM. This chapter describes in detail the epidemiology, clinical and immunologic features, treatment, prognosis, and pathobiology of WM, with mention of MGUS and secondary macroglobulinemia where appropriate.

HISTORICAL FEATURES

In 1944, Jan Waldenström (2) described two patients with a unique clinical syndrome that included oronasal bleeding, mild lymphadenopathy, profound anemia, high serum viscosity, hypoalbuminemia, low fibrinogen, and marked hyperglobulinemia with a globulin fraction that contained “a very large molecule” with a molecular weight of ~1,000,000 (3). In contrast to myeloma, none of these patients had bone marrow plasmacytosis or skeletal lesions. Because these “giant molecules” most closely resembled human antibodies, Waldenström initially suggested this disorder resulted from an immune reaction to an infectious disease of unknown origin, or that inoculation with a virus led to transformation of a human protein into a virus protein.

As serum electrophoresis was performed with increasing frequency, numerous patients were identified with a moderate increase in macroglobulin, but who were otherwise symptomless (4). In 1958, Kappeler et al. (5) maintained that there were two different types of macroglobulinemia, one benign and the other progressive and malignant. By the late 1950s, Waldenström no longer supported his original “immune reaction” hypothesis and proposed that just as myeloma was an unlimited proliferation of one plasma cell clone, macroglobulinemia was a neoplastic disease resulting from unlimited proliferation of lymphocytoid cells “of a special type” (4). This disorder of malignant lymphocytes was termed primary macroglobulinemia or WM, and the Ig designated IgM. In the most recent World Health Organization (WHO) classification of hematologic malignancies and the revised European-American classification of lymphoid neoplasms, WM is classified as a mature B-cell neoplasm and referred to as lymphoplasmacytic or lymphoplasmacytoid lymphoma (6,7).

Skoog and Adams in 1959 (8) and Schwab and Fahey in 1960 (9) suggested that many patients with WM and clinical symptoms attributed to increased serum macroglobulins and elevated serum viscosity might benefit from intensive plasmapheresis. Two patients with WM, severe retinopathy, and congestive heart failure improved markedly and remained asymptomatic with continued plasmapheresis (9). In 1961, Bayrd (10) from the Mayo Clinic reported the first objective responses to the alkylating agent chlorambucil, which remains a mainstay of therapy today. The prognosis of WM has changed little in the last 50 years.

IMMUNOLOGIC HIGHLIGHTS

Like their counterparts in the normal population of Igs, monoclonal Igs have antigen-binding properties, including autoantigen binding (11). Whereas 10% to 15% of patients with WM have autoimmune manifestations such as peripheral neuropathy, Coomb's-positive autoimmune hemolytic anemia (cold agglutinin disease), thrombocytopenia, gastric ulcer with parietal cell autoantibodies, and IgM-cardiolipin syndrome, most patients with WM and an IgM exhibiting autoantibody activity have no clinical manifestations of autoimmune disease (12,13 and 14). The binding patterns of the monoclonal rheumatoid factor (RF) detected in ~15% of patients with WM differ significantly from those of patients with rheumatoid arthritis, perhaps explaining the clinical silence of RF in WM (15,16). In contrast, Varticovski et al. (17) found binding and idiotypic characteristics of the monoclonal IgM in a patient with WM and thrombocytopenia similar to those of a human monoclonal IgM secreted by a hybridoma established from the peripheral blood lymphocytes of a patient with systemic lupus erythematosus and immune thrombocytopenia, and suggested a common origin for autoantibodies in autoimmune diseases and monoclonal gammopathies. Further support for this includes studies of relatives of patients with WM, especially those families with more than one member with WM, which have demonstrated diverse immunologic abnormalities including autoantibodies and abnormal Ig levels, raising the possibility of a common susceptibility gene for WM and autoimmune disorders (18,19).

Immunophenotyping and the high rates of somatic mutation in the Ig heavy-chain (IgH) complementarity-determining regions (CDRs) of tumor cells from patients with WM imply derivation from memory B cells that have undergone antigenic stimulation (20,21). Case reports of cross-reactivity of monoclonal IgM with canary droppings in a bird breeder with WM and of the lipopolysaccharides of *Campylobacter jejuni* in two patients with distinct neurologic manifestations and WM, also suggest a role for antigenic stimulation as the initiating factor in at least a subset of patients with WM (22,23).

Both humoral and cellular immunity are impaired in a subset of patients with WM (24,25,26,27 and 28). The incidence of infectious complications in patients with WM is twice that seen in a control population, but considerably less than in multiple myeloma (25). Hypogammaglobulinemia is present in approximately one third to one half of patients with WM, but levels are less markedly depressed than in multiple myeloma (24,25,28). Most patients with WM exhibit significant impairment of antibody response after immunization with typhoid, diphtheria, and mumps antigens (25). The ratio of CD4 to CD8 T cells is significantly reduced in many patients with WM, because of a decrease in the CD4 subset (26,27). Patients with the highest number of circulating tumor cells had the lowest CD4-to-CD8 ratio, and those with IgM MGUS usually had a normal ratio. More detailed studies of the immune system in patients with WM and IgM MGUS may eventually contribute to our understanding of the mechanism of transformation to more advanced disease. In addition to underlying immune defects in patients with WM, the widespread use of the purine analogs, fludarabine and 2-chlorodeoxyadenosine (2-CdA) to treat this disease, have contributed to the severe immunodeficiency and opportunistic infections seen in some patients (29,30 and 31).

EPIDEMIOLOGY

Currently there are ~1,500 cases of WM reported in the United States each year. The etiology of WM is unknown, but epidemiologic studies have implicated both genetic and environmental factors in a small subset of patients. To clarify the epidemiologic pattern of WM, Groves et al. (32,33) recently evaluated 624 cases of WM reported to 11 population-based cancer registries over a 7-year period. WM is twice as common in men as in women, and rates increase significantly with age, with 0.1 cases per 1 million person-years at risk for those aged 45 years or younger and 16.4 to 36.3 cases per 1 million person-years at risk for those 75 years or older. The rate among black men is half that of white men, in contrast to multiple myeloma, which occurs twice as frequently among blacks.

Genetics

Familial reports of WM are rare, but suggest a genetic component in a small subset of patients, although exposure to a common stimulus cannot be completely ruled out in these cases. After the first two reports of familial WM in 1962, Seligmann (34) studied the sera of 216 close relatives of 65 patients with WM. In seven of the 65 families, there was an asymptomatic monoclonal IgM identified in at least one relative; in 45 of the 65 families, abnormal Ig levels without an “M-component” were noted; and there was an increased incidence of anti-g-globulins in family members younger than 60 compared with normal controls. A more recent case–control study of 65 patients with WM in the Baltimore area showed that cases were more likely than were controls to have a first-degree relative with a history of pneumonia,

diphtheria, rheumatic fever, and diabetes mellitus (18). In addition, laboratory tests of 109 first-degree relatives of these patients demonstrated that close to 40% had diverse immunologic abnormalities.

Blattner et al. (19) reported WM in a father and three offspring, all of whom had the identical human leukocyte antigen (HLA) haplotype A2, B8, and DRw3. Interestingly, multiple family members also had autoantibodies including antithyroid microsomal antibody, antithyroglobulin antibody, and antimyocardial antibody. Whereas the findings in this family favor a chromosomal linkage between the HLA complex and a susceptibility gene for WM and autoimmune disorders, other reported families do not share a common haplotype (35). Additional studies are needed to determine whether the consistent finding of familial immunologic dysfunction in patients with WM is etiologic in the development of WM, or whether both the immunologic dysfunction and WM are secondary to an as-yet-unidentified genetic defect or environmental stimulus.

Ögmundsdóttir et al. (36,37) followed up an Icelandic family with macroglobulinemia and B-cell malignancies for more than 20 years. Of a sibship of seven, one had WM; one, malignant lymphoma; and two, benign monoclonal gammopathy. Increased serum IgM levels were subsequently detected in nine additional family members in three generations. Additional studies of 35 or more family members have shown a significant increase in Ig production after minimal stimulation to pokeweed antigen compared with controls, but no difference in serum levels of interleukin (IL)-4 or alterations in natural killer (NK) cell function, known regulators of B-cell function (36). More recently, these authors have shown that family members with increased Ig production have enhanced B-cell survival, which is associated with increased expression of the programmed cell death–repressor gene, *bcl-2* (37). It is not known whether Bcl-2 overexpression is a primary or secondary phenomenon.

Environmental

Environmental factors are not yet known to play a significant role in the etiology of WM. One case-control study found no association between WM and a variety of occupational exposures including benzene, petroleum, lead, asbestos, and radiation and no significant difference between cases and controls in tobacco or alcohol use (18). Three cases of WM in shoe repairers in Sheffield, England, a catchment area that included only ~20 shoe repairers, suggests an association with leather or rubber dust, alcohol-based dyes, or organic solvents (38). One case of WM in a bird breeder with monoclonal IgM antibody activity to canary droppings also indicates a possible role for antigenic stimulation in some cases, similar to that seen between *Helicobacter pylori* and gastric mucosa-associated lymphoid tissue (MALT) lymphoma (22).

An association between WM and the hepatitis C virus (HCV) has been confirmed in several small studies (39,40,41 and 42). Most show a high rate of HCV antibodies only in the subset of WM with a monoclonal IgM with cryoglobulinemic activity (40,41). However, a report from southern Italy showed an extremely high prevalence of HCV in patients with a variety of B-cell lymphoproliferative disorders (22.4%) and an extraordinarily high rate in WM (61%) (42). Recent reports also suggest a possible association between WM and the hepatitis G virus (HGV) (43,44 and 45). De Rosa et al. (42) proposed that HCV and HGV may be causative in a subset of WM either by producing an early hit in a sequence of oncogenic events or indirectly by causing expansion of lymphoid clones that may subsequently undergo mutational events. Additionally, HCV triggers autoimmunity, and the association between non-Hodgkin's lymphoma (NHL) and autoimmune disorders also suggests this as a possible mechanism (46).

Recently human herpesvirus-8 (HHV-8) DNA has been isolated from the marrow and dendritic cells of some patients with multiple myeloma and WM, although this finding has been questioned by others (47,48 and 49). Interestingly, HHV-8 contains a biologically active homolog to IL-6, an important growth factor for plasma cells (50,51 and 52). In some cases, HHV-8 may play a causative role in the transformation of MGUS to a malignant lymphoproliferative disorder and the propagation of malignant cells (47).

CLINICAL PRESENTATION

Many patients are asymptomatic and are diagnosed during evaluation of an incidental laboratory abnormality such as mild anemia, an elevated serum protein, or hypoalbuminemia. Initially it can be difficult to distinguish between asymptomatic WM and an IgM MGUS (53).

Signs and Symptoms

Dimopoulos et al. (28,54) in a recent review categorized the clinical manifestations of WM according to whether they were related to direct tumor infiltration, to complications of circulating IgM protein, or to deposition of the IgM protein in various tissues. Patients with extensive marrow involvement often have weakness, anorexia, dyspnea, or fatigue secondary to anemia. Patients may report fever, night sweats, or weight loss, most commonly in the late stages of the disease. Abdominal pain or bloating may occur secondary to hepatosplenomegaly (55). Localized bone destruction and severe bone pain occur in fewer than 2% of patients with WM (28,53). There are also rare reports of pulmonary infiltrates with dyspnea or cough, involvement of the stomach or intestine seen as diarrhea and malabsorption, and skin manifestations including urticaria, rash, and paraneoplastic pemphigus (56,57,58,59,60,61 and 62).

When IgM levels greater than 3 to 4 g/dL are present, patients may experience signs and symptoms of hyperviscosity syndrome, most commonly bleeding and ocular, neurologic, and cardiovascular manifestations (54). Hyperviscosity occurs because of the increased concentration of the large, pentameric IgM molecule. Easy bleeding of mucous membranes, most commonly the gums and nose, complaints of blurred or decreased vision, headaches, vertigo, drowsiness, hearing loss, confusion, altered mental status, or seizures should prompt evaluation of serum viscosity. The increased plasma volume associated with macroglobulinemia may lead to congestive heart failure, especially in older patients receiving red cell (RBC) transfusions for anemia.

Approximately 5% of patients with WM will experience symptoms or complications of cryoglobulinemia including arthralgias, acrocyanosis, Raynaud phenomenon, palpable purpura, renal insufficiency, or peripheral neuropathy (54,63,64 and 65). The cryoprecipitate may activate complement and create an immune complex vasculitis resulting in ischemia of skin, nerve, and renal tissues (28). Ten percent of patients with WM have cold agglutinin disease (28). The IgM will react with RBC antigens at temperatures less than 37°C and result in episodic or chronic hemolytic anemia.

Peripheral neuropathy is reported in 5% to 45% of patients with macroglobulinemia and can antedate hematologic symptoms by years (66,67). As discussed in detail later in this chapter, most cases of neuropathy are believed to result from the monoclonal IgM protein binding to a component of myelin or the axolemma (67,68 and 69). Nerve-conduction studies are consistent with a demyelinating neuropathy in most patients (69). Typically, the neuropathy affects the lower extremities first and is slowly progressive, symmetric, and predominantly sensory (67). Patients commonly experience foot numbness, painful paresthesias, imbalance, gait ataxia, and occasionally tremor (68). Neurologic symptoms are more heterogeneous in the subset of patients in whom IgM does not react with any known nerve antigen or has non-MAG specificity (67,68,69 and 70). Pure motor neuropathy has been described (68). Muscle weakness also may result from a humorally mediated immune myopathy (71).

Amyloidosis is a rare complication of macroglobulinemia (72,73). Deposition of polymerized light-chain fragments can result in cardiomyopathy, renal insufficiency, liver dysfunction, autonomic neuropathy with hypotension, impotence and bladder dysfunction, and sensorimotor peripheral neuropathy (72,73).

Physical Findings

Physical examination may reveal lymphadenopathy and hepatosplenomegaly. Findings associated with hyperviscosity syndrome include altered mental status, decreased visual acuity, retinal exudates or hemorrhage, and sausage-linked retinal veins. Neurologic examination in those afflicted with peripheral neuropathy most often reveals sensory loss, hyporeflexia, gait ataxia, and occasionally muscle weakness and tremor.

Laboratory Tests

Serum protein electrophoresis (SPEP) and serum immunofixation are critical for the diagnosis and follow-up of WM (74,75 and 76). An SPEP should be repeated approximately every one to two cycles in patients receiving treatment and every 2 to 4 months during periods of observation. Alternatively, disease activity and effectiveness of therapy can be assessed with serial quantitative IgM levels. IgG and IgA levels are often decreased in patients with WM (53). Urine protein electrophoresis (UPEP) detects the presence of Bence Jones proteins in the majority of patients with WM; however, levels more than 1 g/dL are uncommon (28,53,77). Serum viscosity should be checked in all patients with an IgM monoclonal protein. Elevated serum viscosity occurs most commonly when IgM levels are greater than 4 g/dL, and symptoms of hyperviscosity are rare if viscosity is less than 4 cp (centipoises) (74). Serum should be evaluated for the presence of cryoglobulins in patients with a history of cold sensitivity. Type I cryoglobulins are detected in 10% to 20% of patients with WM, but less than 5% are clinically evident (53,54).

Many patients have a normochromic, normocytic anemia, with the peripheral blood smear showing rouleaux formation. Macroglobulinemia can result in an expanded plasma volume and consequently a factitiously low hemoglobin. Direct measurements of red cell volume may be warranted in patients who are at high risk for transfusion complications because of hypervolemia (78). Episodic or chronic hemolytic anemia can occur when the IgM protein acts as a cold-agglutinin (54). Thrombocytopenia occurs occasionally. All patients with WM have an elevated erythrocyte sedimentation rate. Hyponatremia may result from an inability to excrete water and has been attributed to tumor production of a substance functionally similar to antidiuretic hormone (ADH) in a subset of patients with WM (79).

Hypercalcemia and renal insufficiency are rare. The most common abnormalities of coagulation are a prolonged bleeding time and thrombin time attributed to platelet coating by macroglobulins and binding of Ig to fibrin, respectively (1,80,81).

Pathology

Current classifications of lymphoid malignancies categorize WM as a mature B-cell neoplasm, specifically a lymphoplasmacytic or lymphoplasmacytoid lymphoma (6,7). Morphologically, the malignant cells have eccentric nuclei with paranuclear clearing similar to that of plasma cells, but the nuclear outline is often slightly irregular, and the nuclear chromatin is diffusely arranged (82). Dutcher bodies, intracytoplasmic inclusions due to cytoplasmic Ig, are a classic histologic finding in WM (82). Lymph node and bone marrow biopsies often show a pleomorphic infiltrate composed of small lymphocytes, lymphoplasmacytic lymphocytes, and plasma cells (83). Marrow involvement can have a diffuse, nodular, or nodular/interstitial appearance, and the growth pattern in lymph nodes is often interfollicular (6,83). Increased numbers of mast cells and basophils are seen in affected tissues.

Because other mature B-cell neoplasms including chronic lymphocytic leukemia (CLL), marginal cell, mantle cell, and follicle center cell lymphomas occasionally show maturation to plasmacytoid or plasma cells and contain cytoplasmic Ig, immunophenotyping is often used to differentiate lymphoplasmacytic lymphomas from other B-cell neoplasms (6). Lymphoplasmacytic lymphomas strongly express the B-cell–associated antigens CD19, CD20, CD22, CD79a, and surface IgM, but lack or weakly express IgD, CD5, CD10, CD23, and CD38 (24,84,85 and 86). The immunophenotype may vary because of the pleomorphic cells of WM, with small lymphocytes being strongly positive for surface Ig and negative for CD38, and plasma cells being negative for surface Ig and strongly positive for CD38 (54).

Treatment and Prognosis

WM is incurable with standard therapies. Goals of therapy are to palliate or prevent symptoms and to prolong survival. Therapy often is deferred in asymptomatic patients. Patients observed off therapy must agree to close follow-up, including a history and physical examination, IgM level, and complete blood count (CBC) every 3 to 6 months. The goal is to intervene when the disease appears to be progressing, but before complications of anemia, splenomegaly, or hyperviscosity occur. Although prospective randomized trials comparing immediate with deferred treatment have not been done in WM, there is no evidence in other low-grade lymphoproliferative disorders that immediate treatment of asymptomatic patients prolongs survival (13).

PLASMAPHERESIS

Emergency therapy is needed for signs and symptoms of hyperviscosity. Plasmapheresis rapidly reduces IgM levels and serum viscosity and usually results in marked improvement in symptoms including mental status changes, visual disturbances, and bleeding (9,87). Techniques used to remove IgM paraproteins include centrifugal plasma exchange and membrane plasma filtration. Plasma exchange results in nonselective removal of plasma and requires volume replacement with albumin or fresh frozen plasma. Intensive plasma exchange can result in a transient decrease in platelets, complements, coagulation factors, and gammaglobulins (87,88). However, plasmapheresis stimulates rapid antibody rebound with levels reaching 50% to 80% of preplasmapheresis levels in 48 hours and peaking after 1 to 2 weeks, much faster than the 30 days that would be predicted based on normal synthesis and catabolism rates of IgG (89). Membrane plasma exchange, which selectively removes macromolecules and does not require replacement fluid, was introduced in 1978 and is used commonly in Europe and Japan, but not in the United States (87).

Because the response to plasma exchange is transient, as a single modality it must be repeated every 1 to 4 weeks to maintain an acceptable serum viscosity (90). Consequently, cytotoxic agents are generally given concurrently, and plasmapheresis discontinued after a few weeks or months, if the disease responds. Interestingly, some patients resistant to cytotoxic therapy whose predominant symptoms are related to hyperviscosity without symptomatic organomegaly, lymphadenopathy, or pancytopenia are successfully maintained for months or years on intermittent plasma exchange (90,91). There also are several reports of plasma exchange slowing progression of macroglobulinemia-associated neuropathy (68,87,92).

CHEMOTHERAPY

Historically, first-line treatment for WM has been oral alkylating agents, primarily chlorambucil. IgM levels decrease slowly, and several months of chlorambucil treatment may be required before a documented objective response occurs (93). Daily (0.1 mg/kg/day) and intermittent (3 mg/kg daily for 1 week, every 6 weeks) schedules have equivalent response and survival rates (28,55,93). In a recent randomized trial comparing daily with intermittent therapy, the M-protein or hemoglobin improved in 88% of patients given daily doses and in 68% of patients given intermittent doses, with the onset of response for hemoglobin being 5 to 7 months, and for IgM improvement, 18 to 22 months (93). Complete responses are unusual. Treatment is generally continued for 3 to 6 months after stabilization of IgM levels and restarted when symptoms develop or IgM levels increase above 3 to 4 g/dL. There is no evidence that maintenance therapy improves survival rates, and prolonged exposure to alkylating agents increases the risk of myelodysplasia or secondary leukemia (94,95).

The addition of steroids to chlorambucil does not improve survival or response rates, but may be useful in treating autoimmune hemolytic anemia, cryoglobulinemia, or cold-agglutinin disease associated with WM. Chemotherapy regimens combining alkylating agents with vinca alkaloids, anthracyclines, or nitrosoureas have occasionally shown higher response rates than single-agent alkylators, but none has shown an improvement in survival (28,96,97,98,99 and 100).

More recently, the purine analogs fludarabine and 2-CdA have been tested in WM with encouraging results. Response rates ranged from 33% to 85% in previously untreated patients (29,101,102,103 and 104). Median time to response was ~6 months, with median response durations of 2 to 3 years (29,101). IgM levels can continue to decrease for several months after discontinuing therapy (30). The overall response rate to 2-CdA using a 7-day continuous infusion schedule appears similar to that of a 5-day daily bolus regimen; however, time to response with the continuous infusion was significantly shorter in a nonrandomized comparison (29,103,104). Evaluation of the combination of alkylating agents and purine analogs is under way in many indolent lymphoproliferative disorders, including WM. Weber et al. (105) reported an 89% response rate in 19 previously untreated patients with WM treated with 2-CdA and oral cyclophosphamide.

Both 2-CdA and fludarabine also have been effective in treating disease refractory to alkylating agents, again with reported response rates ranging from 22% to 78% (102,106,107,108,109 and 110). Higher response rates were recorded among patients relapsing off treatment (78%) than in patients who were resistant to first- or second-line treatment, with the worst response rates in those patients who had resistant disease of more than 1-year duration (22%–57%) (109). A randomized multicenter trial compared six cycles of fludarabine with six cycles of CAP (cyclophosphamide, doxorubicin, prednisone) in 92 patients with WM resistant to first-line therapy or in first relapse after alkylating agents (111). Thirteen (28%) patients responded to fludarabine compared with five (11%) patients with CAP (p = .019).

The primary side effects of 2-CdA and fludarabine are myelosuppression and immunosuppression. Myelosuppression is usually moderate, but repetitive courses of these agents can produce cumulative and delayed pancytopenia. Dramatic decreases in $CD4^+$ and $CD8^+$ lymphocytes occur after a single cycle, significantly increasing the risk of opportunistic infections (29,30 and 31). CD8 counts generally recover in 3 to 12 months, but CD4 counts may remain profoundly depressed for more than 2 years after treatment (30). The use of fewer courses of nucleoside analogs may result in less myelosuppression and immunosuppression without significantly decreasing the chance of response (103,112).

The therapeutic potential of high-dose radiochemotherapy and stem cell rescue in multiple myeloma and other low-grade lymphoproliferative disorders has led to clinical evaluation of this approach in a limited number of younger patients with WM. Preliminary results of autologous stem cell transplant in 18 patients showed responses in all patients, but persistent paraproteinemia in the majority. However, as with other indolent B-cell neoplasms, remissions appear to be more durable than with standard therapies (113,114 and 115). Martino et al. (116) described a 34-year-old woman and 39-year-old man with aggressive, refractory WM, who remain in complete remission 3 and 9 years after HLA-identical allogeneic transplants.

BIOLOGIC THERAPY

Use of the anti-CD20 monoclonal antibody, rituximab, is also under study for patients with WM. CD20, a pan-B-cell antigen that does not internalize or shed, is expressed on nearly all lymphoplasmacytoid lymphomas. The mechanism of action of rituximab is not completely understood, but evidence suggests it acts through stimulating both antibody-dependent cytotoxicity and cell-mediated cytotoxicity, as well as perhaps having a direct effect on apoptosis (117). Small series evaluating rituximab in relapsed or refractory WM reported response rates of 23% to 75% (117,118,119 and 120). Most had failed to respond to both purine analogs and alkylators. Responses lasted a median of 6 to 9 months. Treatment with rituximab does not induce cytopenias or cellular immune dysfunction, a distinct advantage over chemotherapy. Studies are ongoing to test the efficacy and synergy of rituximab in combination with chemotherapy.

Another biologic agent, interferon, also has shown some activity in WM. Rotoli et al. (121) reported a partial response in 33% and a minor response in 16% of 36 patients with WM treated with a-interferon, 3 million units (MU) per day for 1 month and then 3 times a week, with most responses occurring after 4 to 6 months of treatment. Doses of a-interferon as low as 1 MU 3 times a week have resulted in decreased IgM levels in 28% of patients and an improvement in hemoglobin in 42% (122). Higher doses are poorly tolerated and not used routinely in indolent B-cell neoplasms. IgM-associated neuropathy also occasionally responds to a-interferon (123).

SPLENECTOMY

Although splenectomy is not usually reported as a treatment for WM, a case report and review of the literature published in 1995 described 14 patients with massive splenomegaly refractory to chemotherapy who underwent splenectomy (124). Three had no response, but in 11 patients, splenectomy resulted in a major decrease or even complete disappearance of the IgM paraprotein. One response lasted 13 years, and another is ongoing at 12 years. The authors hypothesized that the spleen may be a favored site of growth of IgM-producing malignant B cells. Observations in humans and mice, including a permanent decrease in IgM levels and an impaired IgM response to pneumococcal vaccine after splenectomy in humans, and low levels of IgM but normal levels of IgG and IgA in neonatally splenectomized mice, suggest the spleen may provide a special environment for differentiation or homing of normal IgM-producing B lymphocytes (124,125,126,127 and 128).

Prognosis

Most series reported median survivals of ~5 years, with longer survivals for responders (median, 7.7 years) than for nonresponders (median, 2 to 3 years) (28,129). Approximately 20% of patients survive more than 10 years (77,130). Transformation to aggressive lymphomas occurs in a small percentage of patients and is usually fatal (131,132). Approximately 20% of patients with WM die of unrelated causes (28,129).

Because of small patient numbers, few trials have been able to define prognostic factors accurately for patients with WM. In multivariate analyses, age 60 years or older, anemia, male gender, low neutrophil count, weight loss, cryoglobulinemia, elevated serum b_2 microglobulin (sb_2M), and low IgM levels have all been identified as independent poor prognostic variables (110,129,133). Investigators in the Southwest Oncology Group and Eastern Cooperative Oncology Group identified low sb_2M and high IgM levels as favorable predictors of overall survival (OS) and progression free survival (PFS) in 234 patients with WM participating in a clinical trial of fludarabine (111). Three risk groups were identified. A low-risk group with sb_2M less than 4 g/L had a median PFS of 61 months (median OS not yet reached), an intermediate-risk group with sb_2M 4 g/L or greater and IgM 4 g/dL or greater with a median OS of 42 months and PFS 31 months, and a high-risk group with a sb_2M 4 g/L or greater and IgM less than 4 g/dL with OS 26 months and PFS 7 months. The basis for the observation of a relatively favorable prognosis with high IgM is not understood, although the authors hypothesized that this may be associated with more differentiated disease. A second prognostic model based on age, albumin, and total number of cytopenias has also been proposed (134). This model also successfully identified three risk groups with 5-year survival rates of 86%, 61%, and 26%, depending on the number of poor prognostic features.

PATHOBIOLOGY AND IMMUNOPATHOLOGY

The malignant cells of WM are characterized by a postgerminal center phenotype ($CD19^+$, $CD20^+$, $CD5^-$, $CD10^-$, $CD23^-$, IgD^-) and therefore are believed to arise from marginal zone memory B-cells (86). Analysis of the DNA sequences of the IgH CDRs of tumor cells from patients with WM supports this theory (20,21). Somatic hypermutations, which are essential for the affinity maturation of antibody, occur most frequently in IgH CDRs during the generation of memory B cells (21). High rates of somatic mutation were found in most cases of WM, implying derivation from B cells that have undergone antigenic stimulation (20). In normal memory B cells, antigenic stimulation is often accompanied by antibody class switching to IgG. Some investigators proposed WM cells are B cells that carry somatic Ig mutations, but have lost the ability to undergo class switching (20,21,54). Alternatively, the malignant cells of WM may derive from the more recently described subset of IgM-only expressing memory B cells (135,136,137 and 138).

Il-6 has been implicated in the differentiation process of both IgM MGUS and WM (52). Levy et al. (52,139) showed that neutralizing anti–IL-6 antibodies abrogated spontaneous B-cell differentiation and IgM secretion in patients with IgM MGUS, but not those with WM, possibly indicating a two-step pathogenesis for this disease. All *trans*-retinoic acid (RA), a compound known to interfere with IL-6–dependent growth of plasmacytoma cell lines, inhibited *in vitro* differentiation of purified B cells in four of five patients with MGUS, but only in one of five patients with WM (139). RA appeared to inhibit IL-6 secretion by B cells and downregulated the IL-6 receptor on B cells. The absence of RA-mediated regulation of B-cell differentiation in WM, in contrast to MGUS, may represent a step toward malignancy in WM (139). Understanding the mechanism of autonomous IL-6 secretion in WM may have therapeutic implications (139).

Approximately 30% of patients with WM have abnormal karyotypes in tumor cells. However, there is no “common” chromosome change, as described in other lymphomas such as follicular center cell (t14;18), Burkitt (t8;14), or mantle cell (t11;14). Described abnormalities include trisomies or deletions of chromosomes 3, 6, 10, 11, 12, 15, 18, 20, and 21, with some patients having complex karyotypes (84,85,140,141,142 and 143). In other subtypes of lymphoma, overexpression of genes such as *bcl-2* on chromosome 18, *myc* on chromosome 8, and *PAX*-5 on chromosome 9 juxtaposed to the strong promoter elements of IgH on chromosome 14 are thought to contribute to lymphomatogenesis (54,144). Isolated cases with these abnormalities also have been described in WM, but do not explain the pathogenesis of most cases of WM.

In addition to trying to determine how and why WM develops, work continues on understanding the pathologic consequences and mechanisms of injury of monoclonal macroglobulinemia, both circulating IgM and tissue IgM. As discussed briefly in the introduction, the diverse antibody properties of monoclonal IgM account for many of the unique clinical and laboratory features of WM and have been studied in detail. Interestingly, the spectrum of activities of IgM monoclonal components does not reflect the frequency with which various specificities are represented in the total pool of antibody-forming cells (145). This provides further evidence that the monoclonal Ig-producing cells are memory B cells participating in an immune response when they undergo monoclonal proliferation. Given this, it is striking that so many of the observed activities of the monoclonal IgMs fall into the autoantibody class (145). Possible explanations for this increased repertoire of autoantibodies include cross-reactivity of antibodies produced in response to an exogenous antigenic stimulus to self-antigens, or alternatively, that memory B cells with autoantibody activity are more prone to malignant transformation (146).

The first reports of antibody activity of a monoclonal IgM occurred in 1957 with the association of cold-agglutinin disease and high titers of monoclonal IgM (145,147,148 and 149). The protein is usually IgMk, and its most common target is the Ia antigen on RBCs (28,63,64). Rosse et al. (65) suggested that conformational changes occur in RBC membranes at low temperatures, exposing epitopes not accessible to IgM at 37°C. The RBCs may fix complement and agglutinate in colder areas of the circulation, producing Raynaud syndrome, acrocyanosis, livedo reticularis, and episodic or chronic hemolytic anemia (28). The cold agglutinin dissociates in warmer parts of the body, but C3d complement remains on the RBCs, resulting in a positive Coomb's test.

The most studied complication of tissue deposition of monoclonal IgM is that of polyneuropathy seen in 10% or more of patients with WM. Multiple pathogenetic mechanisms have been proposed for these neuropathies, accounting for the diversity of clinical findings. Dimopoulos et al. (54) divided the neuropathies of WM into five subsets: (a) demyelinating polyneuropathy with IgM anti-MAG antibodies; (b) demyelinating polyneuropathies with monoclonal IgM reacting with gangliosides, but not MAG; (c) polyneuropathies with monoclonal IgM nonreactive with known peripheral nerve antigens; (d) cryoglobulinemic neuropathy; and (e) amyloid neuropathy.

In at least half the cases of polyneuropathy in WM, a monoclonal IgMk targeted against the minor carbohydrate epitopes of MAG is identified (150,151). The anti-MAG IgM paraprotein co-reacts with a glycolipid on peripheral nerves, sulfoglucuronyl glycosphingolipid (152). Because MAG is widespread in both central nervous system (CNS) and peripheral nerves, whereas sulfoglucuronyl glycosphingolipid is present only on peripheral nerves, the latter may be the more likely target, given the lack of CNS manifestations in patients with peripheral neuropathy and anti-MAG IgM. Direct immunohistochemical study of peripheral nerve biopsy specimens shows deposition of M protein on myelin sheaths (153). Monaco et al. (154) used direct and indirect immunofluorescence and immunoperoxidase methods to demonstrate colocalization of monoclonal proteins and complement components C1q, C3d, and C5 along myelin sheaths of peripheral nerve fibers, suggesting that demyelination in this disorder may be complement mediated. Terminal complement complex also was detected in myelin sheaths, specifically at sites of separation of myelin lamellae, suggesting that the terminal complex contributes to myelin damage. Inflammatory cells can be seen infiltrating the nerves in some cases of IgM-associated neuropathy. Immunohistochemical staining of these cells shows equal distributions of CD4- and CD8-positive T cells, but no B cells, indicating a possible role for cell-mediated immunologic mechanisms (155).

A number of non-MAG nerve-related antigens also have been implicated in immune-mediated peripheral neuropathy (68). Identified antigens include the gangliosides, complex glycosphingolipids (GM1, GM2, GD1a, GD1b, GT1b, GQ1b, and LM1), sulfatide, and chondroitin sulfate C (66,67,68,69,70,151,152,156,157 and 158). Patients with anti-GD1b and anti–chondroitin sulfate C have a predominantly motor impairment with axonal degeneration (69,159). Patients with anti–chondroitin sulfate C antibodies also often have epidermolysis because of cross-reactivity in the skin (159).

Monoclonal IgMs with antibody activity against gangliosides with disialosyl moieties are associated with chronic ataxic neuropathy and occasionally ophthalmoplegia and RBC cold-agglutinin activity (23,70,160). Willison et al. (160) prepared a human hybridoma secreting an antidisialosyl monoclonal IgM from peripheral blood B cells of an affected patient, and injected the affinity-purified antibody intraperitoneally into mice. Electrophysiologic recordings demonstrated impairment of nerve excitability, confirming the pathophysiologic effects of the antibody. Interestingly, these same authors showed that purified antidisialosyl paraproteins from two affected patients bound not only a wide array of peripheral nerve structures, but also lipopolysaccharides of *Campylobacter jejuni* isolates in all of three cases of Miller Fisher syndrome, a variant of Guillain-Barré syndrome characterized by acute ataxia, areflexia, and ophthalmoplegia (23). Based on these data, Jacobs et al. (23) suggested the following possible pathophysiologic sequence: (a) individuals are infected with *C. jejuni* or other pathogens bearing disialylated gangliosidelike epitopes, (b) a low-level low-affinity IgM response is mounted with insufficient autopathogenic potential to cause an acute postinfectious neuropathy such as Miller Fisher syndrome, (c) transformation from a state of antigen-dependent B-cell proliferation to autonomous B-cell proliferation with the formation of monoclonal IgM, and (d) increase in serum

monoclonal antibody levels to a level at which binding kinetics activate proinflammatory pathways in target membranes. Further clinical evidence to support this hypothesis of prolonged antigenic stimulation as the etiology of some cases of WM includes a description of a canary breeder who developed pulmonary infiltrates, initially thought to be consistent with “breeder's disease,” a hypersensitivity pneumonitis (22). Lack of improvement with steroids and avoidance of canary exposure led to reevaluation of the patient's disease. A serum monoclonal IgM and lymphoplasmacytic infiltrate of the bone marrow confirmed the diagnosis of WM. Purified monoclonal IgM from the patient precipitated canary's droppings, implying antibody activity against some antigen found in the droppings.

As discussed previously, 10% to 15% of patients with WM have a cryoglobulin, but less than 5% have symptoms or complications of cryoglobulinemia. Most are type I cryoglobulins (monoclonal IgM), but occasionally mixed Ig complexes in which monoclonal IgM behaves like an antibody against polyclonal IgG (type II) occur in WM (28,53). The mechanism of cryoprecipitation is not well understood, but most clinical manifestations are thought to be related to the physicochemical properties of the cryoprecipitate. However, the cryoprecipitate also may activate complement sequences, resulting in an immune complex vasculitis with ischemia of the skin, nerves, and renal tissues (28).

FUTURE DIRECTIONS

Work continues to understand the pathogenesis of WM, with exciting leads for both genetic and environmental etiologies in at least some, if not at all, cases. Continued study of the similarities and contrasts between WM and the primary autoimmune diseases may lead to a better understanding of the mechanisms of both diseases. Ultimately, this information may lead to improved targeted therapies.

Treatment results remain unsatisfactory, and new approaches are needed. Current therapies have not changed the natural history of the disease. Multiinstitutional trials are essential, given the low incidence of the disease. Radiolabeled monoclonal antibodies, effective in other indolent lymphomas, are under investigation for patients with WM. Work also continues to better define the most effective dose and schedule for the monoclonal antibody rituximab in WM. Ultimately, new strategies for tumor-specific, rational drug development are needed (161).

34 AMYLOIDOSIS

Mark B. Pepys, M.D., Ph.D., and Philip N. Hawkins, Ph.D.

Amyloidosis is a disorder of protein folding, characterized by extracellular deposition of abnormal protein fibrils (1). The underlying molecular abnormalities may be either acquired or hereditary, and about 20 different proteins can form clinically or pathologically significant amyloid fibrils *in vivo* (Table 34.1 and Table 34.2). Amyloid deposits also contain glycosaminoglycans, some of which are tightly associated with the fibrils, and a nonfibrillar plasma glycoprotein, amyloid P component (AP). Small, focal, clinically silent amyloid deposits in the aortic wall, brain, heart, seminal vesicles, and joints are a universal accompaniment of aging. However, clinically important amyloid deposits usually accumulate progressively, thereby disrupting the structure and function of affected tissues and leading inexorably to organ failure and death. No treatment yet exists that specifically causes resolution, but intervention that reduces availability of the amyloid fibril precursor proteins may lead to regression of this condition.

TABLE 34.1. Acquired Amyloidosis Syndromes

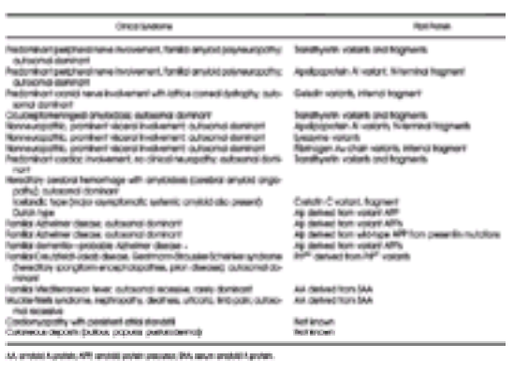

TABLE 34.2. Hereditary Amyloidosis Syndromes

Clinically significant amyloidosis is not rare. Amyloid deposits in the brain and cerebral blood vessels are a central part of the pathology of Alzheimer disease, which is the fourth most common cause of death in the Western world, whereas amyloid is present in the islets of Langerhans of the pancreas in all patients with type 2, maturity-onset, diabetes mellitus. Amyloid deposition in the bones, joints, and periarticular structures eventually affects most patients who receive long-term hemodialysis for end-stage renal failure and is the most frequent cause of serious morbidity among the approximately 800,000 such patients worldwide. Systemic amyloidosis complicating myeloma and other B-cell dyscrasias, or chronic infections and inflammatory diseases, is important because the diagnosis is often difficult and the prognosis is poor, but effective treatments are increasingly available. Hereditary amyloidosis is extremely rare, except in a few geographic foci, but its diversity is remarkable. It is important because of its poor prognosis, the complexity of clinical management, the difficult genetic issues involved, and its considerable value as a

model for understanding the pathogenesis of amyloid deposition.

Although some correlations exist between fibril protein type and clinical manifestations, many forms of acquired and hereditary amyloidosis have little or no concordance between the fibril protein, or the genotype of its precursor, and the clinical phenotype. Evidently, certain genetic and environmental factors, which are distinct from the amyloid fibril protein itself, determine whether, when, and where clinically significant amyloid deposits form. The nature of these important determinants of amyloidogenesis is obscure. Furthermore, the mechanisms by which amyloid deposition causes disease are poorly understood. Whereas a heavy amyloid load is invariably a bad sign, there is often a poor correlation between the local amount of amyloid and the level of organ dysfunction. Active deposition of new amyloid is often associated with enhanced deterioration compared with stable, long-standing deposits. Nascent or newly formed amyloid fibrils, generated *in vitro,* are also cytotoxic to cultured cells, whereas aged or *ex vivo* fibrils are generally inert, although it is not known how this relates to effects *in vivo.*

AMYLOID FIBRILS

Regardless of their diverse protein subunits, amyloid fibrils of different types are remarkably similar: usually straight, rigid, nonbranching, of indeterminate length, and 10 to 15 nm in diameter (2). They are insoluble in physiologic solutions and relatively resistant to proteolysis, and they bind Congo red dye and produce pathognomonic green birefringence when they are viewed in polarized light (3). Electron microscopy reveals that each fibril consists of two or more protofilaments, the precise number varying with the fibril type. The X-ray diffraction patterns of all the different *ex vivo* amyloid fibrils and synthetic fibrils formed *in vitro* demonstrate the presence of a common core structure in the filaments, in which the subunit proteins are arranged in a stack of twisted antiparallel b-pleated sheets lying with their long axes perpendicular to the fibril long axis (4,5). Observations show that many different proteins, including molecules totally unrelated to amyloidosis *in vivo,* can be refolded after denaturation *in vitro* to form typical, stable, congophilic cross-b fibrils (6,7). Although it is not clear why only the 20 or so known amyloidogenic proteins adopt the amyloid fold and persist as fibrils *in vivo,* a major unifying theme that is currently emerging is that in all cases studied the precursors are relatively destabilized (8,9). Even under physiologic or other conditions they may encounter *in vivo,* they populate partly unfolded states involving loss of tertiary or higher-order structure that readily aggregate with retention of b-sheet secondary structure into protofilaments and fibrils. Once the process has started, seeding may also play an important facilitating role, so amyloid deposition may progress exponentially as expansion of the amyloid template “captures” further precursor molecules.

REACTIVE SYSTEMIC (AA) AMYLOIDOSIS

Associated Conditions

Amyloid A protein (AA) amyloidosis occurs in association with chronic inflammatory disorders, chronic local or systemic microbial infections, and occasionally malignant neoplasms. In Western Europe and the United States, the most frequent predisposing conditions are idiopathic rheumatic diseases (Table 34.3). Amyloidosis complicates up to 10% of cases of rheumatoid arthritis and juvenile inflammatory arthritis, although for reasons that are not clear, the incidence is lower in the United States than in Europe. Amyloidosis is exceptionally rare in systemic lupus erythematosus and related connective tissue diseases, as well as in ulcerative colitis, in contrast to Crohn disease. Tuberculosis and leprosy are important causes of AA amyloidosis, particularly where these infections are endemic. Chronic osteomyelitis, bronchiectasis, chronically infected burns, and decubitus ulcers, as well as the chronic pyelonephritis of patients with paraplegia, are other well-recognized associations (Table 34.3). Hodgkin disease and renal carcinoma, which often cause fever, other systemic symptoms, and a major acute-phase response, are the malignant diseases most commonly associated with systemic AA amyloid.

Chronic inflammatory disorders
Rheumatoid arthritis
Juvenile inflammatory arthritis
Ankylosing spondylitis
Psoriasis and psoriatic arthropathy
Reiter syndrome
Adult Still disease
Sohgal syndrome
Crohn disease
Familial Mediterranean fever and other periodic fevers
Chronic microbial infections
Leprosy
Tuberculosis
Bronchiectasis
Chronic pyelonephritis and decubitus ulcers in paraplegia
Osteomyelitis
Whipple disease
Neoplasms
Hodgkin's disease
Renal carcinoma
Castleman disease

TABLE 34.3. Conditions Associated with Reactive Systemic (AA) Amyloidosis

Clinical Features

AA amyloid involves the viscera, but it may be widely distributed without causing clinical symptoms (10). More than 90% of patients present with nonselective proteinuria resulting from glomerular deposition, and nephrotic syndrome may develop before progression to end-stage renal failure. Hematuria, isolated tubular defects, nephrogenic diabetes insipidus, and diffuse renal calcification occur rarely. Kidney size is usually normal but may be enlarged or, in advanced cases, reduced. End-stage chronic renal failure is the cause of death in 40% to 60% of cases, but acute renal failure may be precipitated by hypotension or salt and water depletion after surgical procedures, excessive use of diuretics, or intercurrent infection, and it may be associated with renal vein thrombosis. The second most common presentation is with organ enlargement, such as hepatosplenomegaly or thyroid goiter, with or without overt renal abnormality, but in any case amyloid deposits are almost always widespread at the time of presentation. Involvement of the heart and gastrointestinal tract is frequent but rarely causes functional impairment.

AA amyloidosis may become clinically evident early in the course of associated disease, but the incidence increases with duration of the primary condition. The mean duration of chronic rheumatic diseases such as rheumatoid arthritis, ankylosing spondylitis, or juvenile rheumatoid arthritis before amyloid deposition is diagnosed is 12 to 14 years, although it can present much sooner. For most patients, the prognosis is closely related to the degree of renal involvement and the effectiveness of treatment of the underlying inflammatory condition. In the presence of persistent, uncontrolled inflammation, 50% of patients with AA amyloid die within 5 years of the diagnosis of amyloid deposition; however, if the acute-phase response can be consistently suppressed, the proteinuria can cease, renal function is retained, and the prognosis is much better. The availability of long-term hemodialysis and transplantation prevents early death from uremia *per se,* but amyloid deposition in extrarenal tissues is responsible for a less favorable prognosis than in other causes of end-stage renal failure.

AA protein

The AA protein is a single nonglycosylated polypeptide chain usually of mass 8,000 d and containing 76 residues corresponding to the N-terminal portion of the 104-residue serum AA protein (SAA) (11). Smaller and larger AA fragments, even some whole SAA molecules, have also been reported in AA fibrils. SAA is an apolipoprotein of high-density lipoprotein particles and is the polymorphic product of a set of genes located on the short arm of chromosome 11. SAA is highly conserved in evolution and is a major acute-phase reactant in all species in which it has been studied. Most of the SAA in plasma is produced by hepatocytes in which the synthesis is under transcriptional regulation by cytokines, especially interleukin-1, interleukin-6, and tumor necrosis factor, acting through nuclear factor kB and possibly other transcription factors. After secretion, it rapidly associates with high-density lipoproteins from which it displaces apolipoprotein A-I (apoA-I). The circulating concentration can rise from normal levels of up to 3 mg/L to more than 1,000 mg/L within 24 to 48 hours of an acute stimulus, whereas with ongoing chronic inflammation, the level may remain persistently high. Certain isoforms of SAA, the products of different genes, are predominantly synthesized elsewhere in the body by macrophages, adipocytes, and certain other cells. Although they also associate with high-density lipoproteins, their acute-phase synthesis is stimulated differently, and they presumably have different functions. There is also a closely related family of high-density lipoprotein trace apoproteins that are not acute-phase reactants and that have been designated constitutive SAAs, although they do not form amyloid.

Circulating SAA is the precursor of amyloid fibril AA protein, from which it is derived by proteolytic cleavage (12,13). Such cleavage can be produced by macrophages and by a variety of proteinases, but it is not known whether, in the process of AA fibrillogenesis, cleavage of SAA occurs before or after aggregation of monomers. Persistent overproduction of SAA, causing sustained high circulating levels, is a necessary condition for deposition of AA amyloid, but it is not known why only some individuals in this state develop amyloidosis. In mice, only SAA2, one of the three major isoforms of murine SAA, is the precursor of AA in amyloid fibrils. Human SAA isoforms are more complex, but homozygosity for particular types seems to favor amyloidogenesis, although there may also be ethnic differences (14).

The normal functions of SAA are not known (11), although modulating effects on reverse cholesterol transport and on lipid functions in the microenvironment of inflammatory foci have been proposed. A protein, homologous with SAA, produced by rabbit fibroblasts has been reported to act as an autocrine stimulator of collagenase production *in vitro.* Other reports of potent cell regulatory functions of isolated, denatured, delipidated SAA have yet to be confirmed with physiologic

preparations of SAA-rich high-density lipoproteins. Regardless of its physiologic role, the behavior of SAA as an exquisitely sensitive acute-phase protein with an enormous dynamic range makes it an extremely valuable empiric clinical marker. It can be used to monitor objectively the extent and activity of infective, inflammatory, necrotic, and neoplastic disease. Furthermore, routine monitoring of SAA should be an integral part of the management of all patients with AA amyloidosis or disorders predisposing to it, because control of the primary inflammatory process to reduce SAA production is essential if the amyloidosis is to be halted, enabled to regress, or prevented. Automated immunoassay systems for SAA are available standardized on a World Health Organization International Reference Standard (15).

AMYLOIDOSIS ASSOCIATED WITH IMMUNOCYTE DYSCRASIA (AL AMYLOIDOSIS)

Associated Conditions

Almost any dyscrasia of cells of the B-lymphocyte lineage, including multiple myeloma, malignant lymphomas, and macroglobulinemia, may be complicated by immunoglobulin light-chain (AL) amyloidosis, but most cases are associated with otherwise “benign” monoclonal gammopathy. AL amyloidosis occurs in up to 15% of patients with myeloma, in a lower proportion of those with other malignant B-cell disorders, and probably in fewer than 5% of patients with “benign” monoclonal gammopathy. In some cases, deposition of AL amyloid may be the only evidence of the dyscrasia. A monoclonal paraprotein or free light chains can be detected in serum or urine of only about 90% of patients with AL amyloid, but detection of immunoglobulin gene rearrangement in bone marrow or peripheral blood sometimes confirms a monoclonal gammopathy in the remaining cases. The paraprotein may also appear after presentation and diagnosis of the amyloid, and subnormal levels of some or all serum immunoglobulins or increased numbers of marrow plasma cells may provide less direct clues to the underlying cause. Until recently, it was the practice to diagnose apparently “primary” cases of amyloidosis, with no previous predisposing inflammatory condition or family history of amyloidosis, as AL type by exclusion. However, autosomal dominant hereditary nonneuropathic amyloidosis, particularly that caused by variant fibrinogen a chain, may be poorly penetrant and of late onset, so there may be no family history. The coincident occurrence of a monoclonal gammopathy may then be gravely misleading, and it is essential to exclude by genotyping all known amyloidogenic mutations and to seek positive immunohistochemical or biochemical identification of the amyloid fibril protein in all cases.

Clinical Features

AL amyloidosis occurs equally in men and women, usually after the age of 50 years, but occasionally in young adults. It has a lifetime incidence and is the cause of death of between 0.5 and 1 per 1,000 persons in the United Kingdom. The clinical manifestations are protean, because virtually any tissue other than the brain may be directly involved (16). Uremia, heart failure, or other effects of the amyloid usually cause death within a year of diagnosis, unless the underlying B-cell clone is effectively suppressed.

The heart is affected in 90% of patients with AL amyloidosis, in 30% of whom restrictive cardiomyopathy is the presenting feature and in up to 50% of whom it is fatal. Other cardiac presentations include arrhythmias and angina. Renal AL amyloidosis has the same manifestations as renal AA amyloidosis, but the prognosis is worse. Gut involvement may cause motility disturbances (often secondary to autonomic neuropathy), malabsorption, perforation, hemorrhage, or obstruction. Macroglossia occurs rarely but is almost always pathognomonic. Hyposplenism sometimes occurs in both AA and AL amyloidosis. Painful sensory polyneuropathy with early loss of pain and temperature sensation, followed later by motor deficits, is seen in 10% to 20% of patients, and carpal tunnel syndrome occurs in 20%. Autonomic neuropathy leading to orthostatic hypotension, impotence, and gastrointestinal disturbances may occur alone or together with the peripheral neuropathy, and it has a poor prognosis. Skin involvement takes the form of papules, nodules, and plaques, usually on the face and upper trunk, and involvement of dermal blood vessels results in purpura occurring either spontaneously or after minimal trauma and is common. Articular amyloidosis is rare but may mimic acute polyarticular rheumatoid arthritis, or it may present as asymmetric arthritis affecting the hip or shoulder. Infiltration of the glenohumeral joint and surrounding soft tissues occasionally produces the characteristic “shoulder pad” sign. A rare but serious manifestation of AL amyloidosis is an acquired bleeding diathesis that may be associated with deficiency of factor X and sometimes also factor IX, or with increased fibrinolysis. It does not occur in AA amyloidosis, although in both AL and AA disease, patients may have serious bleeding in the absence of any identifiable factor deficiency.

AL Proteins

AL proteins are derived from the N-terminal region of monoclonal immunoglobulin light chains and consist of the whole or part of the variable (V_L) domain. Intact light chains may rarely be found, and the molecular weight therefore varies between about 8,000 and 30,000 d. The light chain of the monoclonal paraprotein is either identical to, or clearly the precursor of, AL isolated from the amyloid deposits.

AL is more commonly derived from l chains than from k chains, even though k chains predominate among both normal immunoglobulins and the paraprotein products of immunocyte dyscrasias. A new l chain subgroup, l_{VI}, was identified first as an AL protein in two cases of immunocyte dyscrasia–associated amyloidosis before it had been recognized in any other form, and it has subsequently been observed in many more cases of AL amyloidosis. Furthermore, increasing evidence from sequence analyses of Bence Jones proteins of both k and l types from patients with AL amyloidosis, and of AL proteins themselves, indicates that these polypeptides contain unique amino acid replacements or insertions compared with nonamyloid monoclonal light chains. In some cases, these changes involve replacement of hydrophilic framework residues by hydrophobic residues, changes likely to promote aggregation and insolubilization, and in others the monoclonal light chains from patients with amyloidosis have been demonstrated directly to have decreased solubility and a greater propensity for precipitation than control nonamyloid monoclonal light chains (17). The inherent “amyloidogenicity” of particular monoclonal light chains was elegantly confirmed in an *in vivo* model in which isolated Bence Jones proteins were injected into mice (18). Animals receiving light chains from patients with AL amyloidosis developed typical amyloid deposits composed of the human protein, whereas animals receiving light chains from patients with myeloma but without amyloidosis did not.

SENILE AMYLOIDOSIS

Autopsy studies show that some amyloid is present in all persons older than 80 years, but whether this contributes to the aging process or whether it is an epiphenomenon that becomes clinically important only when it is extensive is not known.

Senile Systemic Amyloidosis

Up to 25% of elderly persons have microscopic, clinically silent systemic deposits of transthyretin amyloid involving the heart and blood vessel walls, smooth and striated muscle, fat tissue, renal papillae, and alveolar walls. In contrast to most other forms of systemic amyloidosis, including hereditary transthyretin amyloidosis caused by point mutations in the transthyretin gene, the spleen and renal glomeruli are rarely affected. The brain is not involved. Occasionally, more extensive deposits in the heart, affecting ventricles and atria and situated in the interstitium and vessel walls, cause significant impairment of cardiac function and may be fatal. The transthyretin involved is probably usually of the normal wild type, but cases with transthyretin variants that may be hereditary have been described.

Transthyretin

Transthyretin, formerly known as prealbumin, is a normal nonglycosylated plasma protein, with a relative molecular mass of 54,980 d. It is composed of four identical noncovalently associated subunits, each of 127 amino acids. It is produced by hepatocytes and the choroid plexus and is a significant negative acute-phase protein. Each tetrameric molecule is able to bind a single thyroxine or triiodothyronine molecule, and up to 15% of circulating thyroid hormone is transported in this way. Transthyretin also forms a 1:1 molecular complex with retinol-binding protein, which transports vitamin A.

Transthyretin is encoded by a single copy gene but is appreciably polymorphic, and about 70 different point mutations encoding single-residue substitutions have been identified so far. Normal wild-type transthyretin is an inherently amyloidogenic protein that forms the fibrils in senile systemic amyloidosis, and *in vitro* exposure to reduced pH is sufficient to generate transthyretin amyloid fibrils from the pure protein. Most of the variant forms of transthyretin have been associated with hereditary amyloidosis and show decreased stability *in vitro* compared with the wild type. Transgenic mice expressing human transthyretin Val30Met in the liver develop extensive systemic amyloidosis, but no amyloid deposits have yet been reported in the peripheral nerves, even when the transgene is expressed in the choroid plexus and transthyretin amyloid is deposited in the meninges and choroid plexus. This is another example of the presence of important unknown factors, other than an amyloidogenic protein itself, that determine where and when clinical amyloidosis develops (19).

Individuals heterozygous for transthyretin mutations have a mixture of wild-type and variant transthyretin monomers in their circulating transthyretin, and if they develop amyloidosis, both forms are often present, although the variant may predominate in the amyloid fibrils. Although cleavage fragments of transthyretin are commonly present, intact transthyretin subunits are also found, and fibrillogenesis does not depend on an initial proteolytic step.

Senile Focal Amyloidosis

Microscopic and clinically silent amyloid deposits of different fibril types, localized to particular tissues, are almost always present in elderly persons. The most common form is found in the media of the aortic wall of virtually all persons older than 60 years. The fibrils consist of a 50-residue peptide, named medin, derived by cleavage

from the coagulation factorlike domain of the protein lactadherin (20). Deposits of Ab protein (see later) as amyloid in cerebral blood vessels and intracerebral plaques seen in “normal” elderly brains may or may not represent a harbinger of Alzheimer disease, had the patient survived long enough. Amyloid deposits are present in most osteoarthritic joints at surgery or autopsy, usually in close association with calcium pyrophosphate deposits, affecting the articular cartilage and joint capsule. However, neither the clinical significance of this age-associated articular amyloid nor its biochemical nature is known. The corpora amylacea of the prostate are composed of b_2-microglobulin amyloid fibrils. Amyloid in the seminal vesicles is derived from an as yet unidentified exocrine secretory product of the vesicle cells. Isolated deposits of cardiac atrial amyloid consist of atrial natriuretic peptide. Focal amyloid deposits sometimes present in atheromatous plaques of elderly persons contain fibrils composed of the N-terminal fragment of wild-type apoA-I.

CEREBRAL AMYLOIDOSIS

The brain is a common and important site of amyloid deposition, although possibly because of the blood–brain barrier, there are no deposits in the cerebral parenchyma itself in any form of acquired systemic visceral amyloidosis. However, cerebrovascular transthyretin amyloid may occur in familial amyloid polyneuropathy resulting from the most common transthyretin Val30Met variant, and oculoleptomeningeal amyloidosis is caused by other rare transthyretin variants. The common and major forms of brain amyloid are confined to the brain and cerebral blood vessels, with the single exception of cystatin C amyloid in hereditary cerebral hemorrhage with amyloidosis, Icelandic type, in which major, although clinically silent, systemic deposits are present.

Alzheimer Disease

By far the most frequent and important type of amyloid in the brain is that related to Alzheimer disease, which is the most common cause of dementia. This disease affects more than 3 million persons in the United States and a corresponding proportion of other Western populations. It is generally a disease of the elderly, and its prevalence is therefore increasing. The clinical differential diagnosis of senile dementia and the positive identification of Alzheimer disease are difficult and often of limited precision in life. However, intracerebral and cerebrovascular amyloid deposits are hallmarks of the neuropathologic diagnosis. The amyloid fibrils are composed of Ab protein, a 39- to 43-residue cleavage product of the large amyloid precursor protein (APP) (21). Most cases of Alzheimer disease are sporadic, but some families have an autosomal dominant pattern of inheritance and usually an early onset. About 20 families have causative mutations in the *APP* gene on chromosome 21, and most other kindreds have mutations in the genes for presenilin 1 (chromosome 14) and presenilin 2 (chromosome 1) (22,23). All these mutations are associated with increased production from APP of Ab1-42, the most amyloidogenic form of Ab. Because all persons with Down syndrome (trisomy 21), develop Alzheimer disease if they survive into their 40s, there is evidently a close link among APP, Ab overproduction, Ab amyloidosis, and the pathogenesis of Alzheimer disease, although it remains unclear whether or how Ab *per se,* or the amyloid fibrils that it forms, contributes to the neuronal loss that underlies the dementia. Synthetic Ab fibrils formed *in vitro* are markedly cytotoxic and cause death of cultured cells by apoptosis and necrosis, but to what extent these findings reflect phenomena that may be responsible for neurodegeneration *in vivo* is not clear. Controversy exists about the correlation between the severity of dementia in Alzheimer disease and the extent of amyloid angiopathy and plaques. Nevertheless, the finding that patients with Alzheimer disease caused by APP and presenilin mutations have exactly the same neuropathology as sporadic cases, including tangles, argues strongly that the APP and Ab-protein pathway can be of primary pathogenetic significance.

In addition to the Ab amyloid deposits in the brains of patients with Alzheimer disease and Down syndrome, extensive “amorphous” deposits of Ab are also found throughout the brain. These do not stain with Congo red and are detectable only by immunohistochemical staining. Their significance is unknown. They apparently precede the appearance of histochemically identifiable amyloid but are not necessarily the precursor of it because they are present in areas, such as the cerebellum, in which Ab amyloid is not seen. The nonfibrillar, nonamyloid protein, apolipoprotein E (apoE), is demonstrable in many amyloid deposits, including those of Alzheimer disease. The *ApoE4* gene (chromosome 19), encoding one of the three isoforms of this apolipoprotein, is strongly associated with predisposition to develop Alzheimer disease and with increased amounts of amyloid in the brain, but the underlying mechanisms are unknown.

Another neuropathologic feature of Alzheimer disease and some other neurodegenerative conditions is the neurofibrillary tangle located intracellularly within neuronal cell bodies and processes. These tangles have a characteristic ultrastructural morphology of paired helical filaments, and, although they bind Congo red and then give the pathognomonic green birefringence of amyloid when they are viewed in polarized light, they are completely different structurally from amyloid fibrils. They are composed of an abnormally phosphorylated form of the normal neurofilament protein, t.

Senile Cerebral Amyloidosis and Amyloid Angiopathy

The cerebral blood vessels contain Ab amyloid in up to 60% of aged brains of nondemented persons, and there may also be focal intracerebral Ab amyloid plaques. These deposits are usually clinically silent and may or may not represent harbingers of Alzheimer disease, had the patients survived long enough. Sometimes, the amyloid angiopathy is more extensive, and it is a rare but important cause of cerebral hemorrhage and stroke, to be distinguished from atherosclerotic cerebrovascular disease.

Ab Protein

The fibril protein in the intracerebral and cerebrovascular amyloid of Alzheimer disease, Down syndrome, and hereditary amyloid angiopathy of Dutch type is a 39- to 43-residue sequence derived by proteolysis from the high-molecular-weight precursor protein, the APP, encoded on the long arm of chromosome 21 (22,23). Several isoforms of APP are generated by alternative splicing of transcripts from the 19-exon gene, and yielding three major forms: APP695, APP751, and APP770. These are each single-chain, multidomain glycoproteins with the carboxy-terminal 47 residues within the cytoplasm, a 25-residue membrane-spanning region, and the rest of the molecule lying extracellularly. APP751 and APP770 contain a 56-residue Kunitz-type serine proteinase inhibitor domain encoded by exon 7. After glycosylation and membrane insertion, APPs are cleaved extracellularly by so-called APP secretase activity, close to the transmembrane sequence, releasing, in the case of the isoforms containing the proteinase inhibitor domain, a molecule known as proteinase nexin II, which avidly binds factor XIa, trypsin, and chymotrypsin, as well as epidermal growth factor–binding protein and the g subunit of nerve growth factor. Although mRNA encoding APP695, which lacks the proteinase inhibitor domain, is the predominant species found in the brain, whereas mRNA for APP751 is the most abundant in other tissues, 85% of secreted APP in the brain is proteinase nexin II. APP secreted by a glial cell line is substantially glycosylated with chondroitin sulfate glycosaminoglycan chains. APP also undergoes high-affinity interactions with heparan sulfate. These observations suggest that APP may have important functions in cell adhesion, cell migration, and modulation of growth factor activities. APP proteinase nexin II is present in and released by platelets and probably functions in the clotting cascade.

The amyloidogenic Ab, encoded by parts of exons 16 and 17, corresponds to the part of the APP sequence that extends from within the cell membrane into the extracellular space. Secretase cleavage of APP to release the soluble form therefore cannot generate intact Ab itself or larger fragments containing it. However, there is an alternative processing pathway for APP, in which it is taken up whole by lysosomes and is cleaved to yield fragments that do contain the whole Ab sequence. Furthermore, APP cleaved at the N terminus of Ab and free soluble Ab itself are normally produced by cell lines and by mixed brain cells in culture and are present in the cerebrospinal fluid. However, the source of the Ab in the intracerebral amorphous deposits and of that which aggregates as amyloid fibrils in the brain and cerebral blood vessels is still not known. The 42-residue form of Ab is markedly the most amyloidogenic, and all the mutations in the APP and presenilin genes that are associated with hereditary Alzheimer disease result in increased production of this Ab1-42. Increased availability of the precursor is thus responsible for amyloidogenesis, but the pathogenesis of neuronal damage and dementia is unknown.

Hereditary Cerebral Hemorrhage with Amyloidosis: Hereditary Cerebral Amyloid Angiopathy

DUTCH TYPE

In families originating in a small region on the Dutch coast, the autosomal dominant inheritance of recurrent normotensive cerebral hemorrhages starting in middle age results from deposition of a genetic variant of Ab as cerebrovascular amyloid. These persons also have “amorphous” Ab deposits in the brain and early senile plaques, without congophilic amyloid cores. Multiinfarct dementia occurs in survivors, but some patients become demented in the absence of stroke. Amyloid outside the brain has not been reported.

ICELANDIC TYPE

Cerebrovascular amyloid deposits composed of a fragment of a genetic variant of cystatin C are responsible for recurrent major cerebral hemorrhages starting in early adult life in members of families originating in western Iceland. There is autosomal dominant inheritance, and appreciable but clinically silent amyloid deposits are present in the spleen, lymph nodes, and skin. There is no extravascular amyloid in the brain, and the neurologic deficits, often including dementia, of surviving patients are compatible with their cerebrovascular disease.

CYSTATIN C

Cystatin C (formerly called g-trace) is an inhibitor of cysteine proteinases, including cathepsins B, H, and L. It is encoded by a gene on chromosome 20 and consists of

a single nonglycosylated polypeptide chain of 120 residues. It is present in all major human biologic fluids at concentrations compatible with a significant physiologic role in proteinase inhibition. The normal concentration in cerebrospinal fluid is 6.5 mg/L (range, 2.7 to 13.7, n = 34), but it is much lower (2.7 mg/L; range, 1.0 to 4.7, n = 9) in patients with the Icelandic type of hereditary cerebral amyloid angiopathy, in whom fragments of the Gln 68 genetic variant of cystatin C form the amyloid fibrils. This reduced concentration is useful diagnostically and is evident even in presymptomatic carriers of the cystatin C gene mutation. The point mutation that causes the disease encodes a Gln for Leu substitution in the mature protein, and the amyloid fibril protein consists of the C-terminal 110 residues of the variant. This amino-terminally truncated form is not detectable in the cerebrospinal fluid of affected patients, a finding suggesting that cleavage takes place either in close proximity to fibril deposition or is a postfibrillogenic event. The variant cystatin C is less stable than the wild type and readily forms fibrils *in vitro.* It is not known whether cerebral hemorrhage in cystatin C amyloidosis is caused simply by the damaging effects of vascular amyloid deposition or whether deficiency in inhibitory capacity for cysteinase proteinases also plays a part.

Cerebral Amyloid Associated with Prion Disease

The neuropathology of a group of progressive, invariably fatal spongiform encephalopathies that are transmissible and in some cases are hereditary sometimes includes intracerebral amyloid plaques and amyloid cerebral angiopathy. These diseases, sporadic and familial Creutzfeldt-Jakob disease, the familial Gerstmann-Sträussler-Scheinker syndrome, and kuru, are caused by prions (PrP^{Sc}), conformational isoforms of the normal physiologic cellular prion protein (PrP^{C}) (24). The human diseases are closely related to several animal diseases: scrapie of sheep and goats; transmissible encephalopathy of mink, elk, and male deer; and bovine spongiform encephalopathy. New-variant Creutzfeldt-Jakob disease is apparently the result of transmission of bovine spongiform encephalopathy to humans (25). The significance of amyloid *per se* in these disorders is not clear, because it is not always detectable histologically and is not seen, for example, in fatal familial insomnia or in bovine spongiform encephalopathy, which is apparently a result of transmission of ovine scrapie to cattle. When scrapie or its human counterpart is transmitted to experimental animals by inoculation of affected brain tissue, the development of intracerebral amyloid depends on the strain of infectious agent and the genetic background of the recipient. Even when amyloid is present in the brain, it is not seen elsewhere, for example, in the spleen, although the spleen is a rich source of the infective agent. However, when the infective agent is exhaustively and highly purified from brain or spleen, it forms typical congophilic amyloid fibrils, composed of the proteinase resistant subunit that is the prion, PrP^{Sc}; and when amyloid deposits are present in affected brains, they immunostain with antiprion antibodies. The amyloid fibril protein is thus directly related to the cause of the encephalopathy, but gross amyloid deposition is evidently not necessary for expression of disease. Neuronal damage may perhaps be caused by cytotoxic prefibrillar PrP^{Sc} aggregates or by other mechanisms entirely (26). This situation is different from that of the extracerebral amyloidoses and of cystatin C and nonhereditary cerebral amyloid angiopathies, in which amyloid deposition is invariably present when there is clinical disease.

HEREDITARY SYSTEMIC AMYLOIDOSIS

Familial Amyloid Polyneuropathy

Familial amyloid polyneuropathy is an autosomal dominant syndrome with onset at any time from the second decade onward, characterized by widespread progressive amyloid deposition leading to peripheral and autonomic neuropathy and varying degrees of visceral involvement affecting the heart, kidneys, thyroid, adrenals, and frequently the vitreous of the eye. There is usually amyloid deposition in blood vessel walls and the connective tissue matrix throughout the body. In addition to the major foci in Portugal, Japan, and Sweden, familial amyloid polyneuropathy has been reported in most ethnic groups throughout the world. Considerable variation exists in the age of onset, rate of progression, and involvement of different systems, although within families the pattern is usually consistent. The disease is characterized by remorseless progression, and the disorder is invariably fatal. Death results from the effects and complications of peripheral or autonomic neuropathy or from cardiac or renal failure.

Familial amyloid polyneuropathy is caused by mutations in the gene for the plasma protein transthyretin, formerly known as prealbumin, the most frequent of which causes Met for Val substitution at position 30 in the mature protein, but more than 60 amyloidogenic mutations have been described (19). There is often little correlation between the underlying mutation and the clinical phenotype, which is evidently determined by other genetic and possibly also environmental factors, although in a few cases certain mutations are uniquely associated with particularly aggressive or relatively organ-limited disease. The amyloidogenic transthyretin mutations are not always penetrant, and even asymptomatic Met30 homozygotes older than 60 years have been reported. Rare kindreds with the apoA-I Arg26 variant, which usually causes nonneuropathic amyloidosis, may present with prominent peripheral neuropathy resembling transthyretin familial amyloid polyneuropathy.

Familial Amyloid Polyneuropathy with Predominant Cranial Neuropathy

Originally described in Finland but now reported in other ethnic groups, this autosomal dominant hereditary amyloidosis presents in adult life with cranial neuropathy, lattice corneal dystrophy, and distal peripheral neuropathy (27). Patients may have skin, renal, and cardiac manifestations, and microscopic amyloid deposits are widely distributed in connective tissue and blood vessel walls, although life expectancy approaches normal. The amyloid fibrils are derived from variants of the actin-modulating protein, gelsolin, encoded by point mutations. Individuals homozygous for these mutations have severe renal amyloidosis in addition to the usual neuropathy.

Gelsolin

Gelsolin (mass 90,000 d) is a widely distributed cytoplasmic protein that binds actin monomers, nucleates actin filament growth, and severs actin filaments. Alternative transcriptional initiation and message processing from a single gene on chromosome 9 are responsible for synthesis of a secreted form of gelsolin (mass 93,000 d), which circulates in the plasma at a concentration of about 200 mg/L. Its function in the blood is not known but it may be related to clearance of actin filaments released by dying cells.

In the Finnish type of hereditary amyloidosis, the amyloid fibril protein is a 71-residue fragment of variant gelsolin with Asn substituted for Asp at position 15, corresponding to residue 187 of the mature molecule, and the same mutation has been discovered in affected kindreds from different ethnic backgrounds. One Danish family with the same phenotype has a different mutation at the same nucleotide, predicting a Tyr for Asp substitution at residue 187. Synthetic and recombinant peptides, including the Asn for Asp187 substitution, are less soluble than the wild-type sequence and readily form amyloid fibrils *in vitro* (28).

Nonneuropathic Systemic Amyloidosis

The patterns of organ involvement and overall clinical phenotype vary among families in this rare autosomal dominant syndrome of major systemic amyloidosis without clinical evidence of neuropathy. The kidneys are often most severely affected, leading to hypertension and renal failure, but the heart, spleen, liver, bowel, connective tissue, and exocrine glands may all be involved. After clinical presentation, usually from the second decade onward, one sees inexorable progression to organ failure, which requires transplantation, or to death. The amyloid proteins identified so far are genetic variants of apoA-I, lysozyme, and fibrinogen Aa chain. Although symptoms usually start in early adulthood, presentation may be as late as the sixth decade in a few kindreds, and growing evidence suggests incomplete penetrance in many families with fibrinogen Aa-chain variants.

Apolipoprotein A-I

ApoA-I is the most abundant apolipoprotein of high-density lipoprotein particles and participates in their central function of reverse cholesterol transport from the periphery to the liver. ApoA-I variants are extremely rare and may be phenotypically silent or may affect lipid metabolism. However, nine different variants of apoA-I, including single- and multiple-residue substitutions and deletions, have been associated with amyloidosis (29,30,31 and 32). Although it is inherited as an autosomal dominant, and usually highly penetrant, trait, there are marked variations in age and manner of presentation even in the same family and in different kindreds with the same mutation. The amyloid fibril protein consists, in all cases studied, of the first 90 or so N-terminal residues even when the causative variant residues are more distal. Wild-type apoA-I is also amyloidogenic and forms the deposits associated with atheromatous plaques in the elderly (33), and the various amyloidogenic mutations presumably encode sequence changes that render apoA-I less stable or more liable to cleavage to yield the fibrillogenic N-terminal fragment.

Lysozyme

Lysozyme (EC 3.2.1.17) is the classic bacteriolytic enzyme of external secretions, discovered by Fleming in 1922. It is also present at high concentration in articular cartilage and in the granules of polymorphonuclear leukocytes, and it is the major secreted product of macrophages. Lysozymes are present in most organisms in which they have been sought, although their physiologic role is not always clear. The complete structures of hen egg white and human lysozymes are known to atomic resolution and their catalytic mechanism, epitopes, folding, and other aspects of structure-function relationship have been analyzed exhaustively. This understanding contrasts with the absence of detailed three-dimensional structural information on all other amyloid fibril proteins and their precursors, except transthyretin and b_2-microglobulin. There is only one copy of the lysozyme gene in the human genome, and no mutations in the coding region other than those causing amyloidosis are known, nor is any disease associated with lysozyme other than amyloidosis. The amyloidogenic mutations encode Ile56Thr in one family and Asp67His in others

(34,35). These dramatic changes in residues that are extremely conserved throughout the lysozyme and related a-lactalbumin protein families destabilize the native fold so the variants readily populate partly unfolded states even under physiologic conditions and spontaneously aggregate *in vitro,* and evidently also *in vivo,* into amyloid fibrils (9). A polymorphic variant of lysozyme has been discovered, but its relationship with amyloidosis has yet to be elucidated.

Fibrinogen Aa Chain

Four different mutations in the fibrinogen Aa chain have been reported to cause systemic amyloidosis. All encode sequence changes located in the protease-sensitive C-terminal portion of the chain: Glu526Val and Arg554Leu are single-residue substitutions, whereas 4904delG and 4897delT produce frame shifts and premature termination of the protein (36,37,38 and 39). The amyloid fibrils consist of peptides from the C-terminal portion of the Aa chain encompassing the variant region; and in the case of the 4897delT mutation, the protein is a hybrid of normal wild-type sequence and a novel sequence encoded as a consequence of the mutation-induced frame shift. Haplotype analysis suggests that all the genes encoding the Glu526Val variant may be derived from a common founder. A rapidly increasing number of kindreds is being identified in which penetrance is so limited, or presentation is so late in life, that no family history is obtained (40,41). This form of systemic amyloidosis is thus likely to be much more common than previously recognized.

Cardiac Amyloidosis

Cardiac amyloidosis, without overt involvement of other viscera or neuropathy, progressing inexorably to death, is associated with certain transthyretin gene mutations and is inherited as an autosomal dominant with variable penetrance (Table 34.2). By far the most common variant is Ile122 transthyretin, which occurs in 4% of African-Americans and frequently causes cardiac amyloidosis from the sixth decade onward (42).

Familial Mediterranean Fever

Familial Mediterranean fever is an autosomal recessive disorder caused by mutations in the gene on chromosome 16 that encodes a neutrophil-specific protein of unknown function, called pyrin or marenostrin (43). The disease is characterized by recurrent episodes of fever, abdominal pain, pleurisy, or arthritis, and it predominantly occurs in non-Ashkenazi Jews, Armenians, Anatolian Turks, and Levantine Arabs. In Sephardic Jews of North African origin and in the other ethnic groups except Armenians and to a lesser extent Ashkenazi Jews, untreated familial Mediterranean fever is eventually complicated in a high proportion of cases by typical systemic AA amyloidosis. Furthermore, some patients with familial Mediterranean fever present with AA amyloidosis before they have experienced any symptoms, and this circumstance is consistent with the finding that a substantial acute-phase plasma protein response is frequently present even in asymptomatic persons. The different incidence of amyloid in patients with familial Mediterranean fever from different ethnic groups is not wholly explained by their specific pyrin gene mutations and is another illustration of the unknown genetic determinants of clinical amyloidosis.

HEMODIALYSIS-ASSOCIATED AMYLOIDOSIS

Almost all patients with end-stage renal failure who are maintained on hemodialysis for more than 5 years develop amyloid deposits composed of b_2-microglobulin (44). These deposits are predominantly osteoarticular and are associated with carpal tunnel syndrome, large joint pain and stiffness, soft tissue masses, bone cysts, and pathologic fractures. Renal tubular amyloid concretions may also form. The serious clinical problems associated with b_2-microglobulin amyloidosis constitute the major morbidity in patients undergoing long-term dialysis. Furthermore, in some such patients, more extensive deposition occurs, most commonly in the spleen but also in other organs, and a few cases of death associated with systemic b_2-microglobulin amyloid have been reported. The b_2-microglobulin is derived from the high plasma concentrations that develop in renal insufficiency and are not cleared by dialysis. This type of amyloid also occurs in patients undergoing continuous ambulatory peritoneal dialysis and has even been reported in a few patients with chronic renal failure who had not received dialysis.

b_2-Microglobulin

b_2-Microglobulin is a nonglycosylated, nonpolymorphic single-chain protein of 99 residues with a single intrachain disulfide bridge (relative molecular mass 11,815 d) encoded by a single gene on chromosome 15. It becomes noncovalently associated with the heavy chain of major histocompatibility class I antigens and is required for transport and expression of the complex at the cell surface. Amino acid sequence homology places b_2-microglobulin in the superfamily that includes immunoglobulins, T-cell receptor a and b chains, Thy 1, major histocompatibility class I and II molecules, and secretory component. Its three-dimensional structure is a typical b barrel with two antiparallel pleated sheets comprising three and four strands respectively, and it closely resembles an immunoglobulin domain.

b_2-Microglobulin is produced by lymphoid and various other cells in which it stabilizes the structure and function of class I antigens at the cell surface. When these complexes are shed by cleavage of the heavy chain at the cell surface, free b_2-microglobulin is released. The circulating concentration of b_2-microglobulin is 1 to 2 mg/L, and the protein is rapidly cleared by glomerular filtration and then is catabolized in the proximal renal tubule. Impairment of renal function is associated with retention of b_2-microglobulin and increased circulating levels because no other site exists for its catabolism. Daily production of b_2-microglobulin is about 200 mg, and in patients with end-stage renal failure who are undergoing hemodialysis, plasma b_2-microglobulin levels rise to and remain at levels of about 40 to 70 mg/L. Isolated unaltered b_2-microglobulin can form amyloidlike fibrils itself *in vitro,* and most studies of *ex vivo* b_2-microglobulin fibrils show the whole intact molecule to be the major subunit, although fragments and altered forms of b_2-microglobulin have also been reported.

ENDOCRINE AMYLOIDOSIS

Many tumors of APUD (amine precursor uptake and decarboxylation) cells that produce peptide hormones have amyloid deposits in their stroma. These are probably composed of the hormone peptides, and in the case of medullary carcinoma of the thyroid, the fibril subunits are derived from procalcitonin. In insulinomas, the amyloid fibril protein is a novel peptide, called islet amyloid polypeptide (IAPP), and also amylin, which was first identified in that site and was subsequently shown to be the fibril protein in the amyloid of the islets of Langerhans in type 2, maturity-onset diabetes (45). IAPP is an almost universal feature of the pancreatic islets in type 2 diabetes and becomes more extensive with increasing duration and severity of the disease. Although the amyloid itself is probably not initially responsible for the metabolic defect in this form of diabetes, progressive amyloid deposition leading to islet destruction probably does contribute to the pathogenesis (46).

Islet Amyloid Polypeptide

IAPP amylin is a 37-residue molecule encoded by a gene on chromosome 12 and with 46% sequence homology to the neuropeptide, calcitonin gene–related peptide (CGRP). IAPP is produced in the b cells of the pancreatic islets of Langerhans and is stored in and released from their secretory granules together with insulin. It has been reported to modulate insulin release and to induce peripheral insulin resistance, vasodilatation, and lowering of plasma calcium, but neither its physiologic role nor its contribution to diabetes is known.

Amyloidogenicity of IAPP depends on the amino acid sequence between residues 20 and 29, as shown by *in vitro* fibrillogenesis with synthetic peptides (47). The synthetic decapeptide IAPP20-29 and even the hexapeptide IAPP25-29, Gly-Ala-Ile-Leu-Ser-Ser, form amyloidlike fibrils *in vitro,* whereas other IAPP fragments do not. A correlation also exists between conservation of this sequence and deposition of IAPP amyloid in the islets of diabetic animals of different species. However, the role of the amyloid in diabetogenesis remains to be established. In the degu, a South American rodent, spontaneous diabetes is associated with islet amyloid composed of insulin, and xenogeneic insulin can also form amyloid in humans at sites of repeated therapeutic insulin injections.

RARE LOCALIZED AMYLOIDOSIS SYNDROMES

Amyloid deposits localized to the skin occur in both acquired and hereditary forms. Primary localized cutaneous amyloidosis presents in adult life as macular or papular lesions, the fibrils of which may be derived from keratin. Hereditary cutaneous amyloid lesions are rare, of unknown fibril type, and sometimes are associated with other, nonamyloid, multisystem disorders. Amyloid deposits in the eye cause local problems in the cornea (corneal lattice dystrophy) or conjunctiva, whereas orbital amyloid presents as mass lesions that can disrupt eye movement and the structure of the orbit. In one such case, the fibril protein has been identified as a fragment of IgG heavy chain.

Localized foci of AL amyloid can occur anywhere in the body, in the absence of systemic AL amyloidosis, the most common sites being the skin, upper airways and respiratory tract, and urogenital tract. These foci may be associated with a local plasmacytoma or B-cell lymphoma producing monoclonal immunoglobulin, but often the cells, which must be present to produce the amyloidogenic protein, are scattered inconspicuously in the affected tissue. The clinical problems caused by these space-occupying amyloidomas are usually cured by surgical resection, but surgery is not always possible.

GLYCOSAMINOGLYCANS

Amyloidotic organs contain more glycosaminoglycans than normal tissues, and at least some of this material is a tightly bound, integral part of the amyloid fibrils. These fibril-associated glycosaminoglycans are heparan sulfate and dermatan sulfate in all forms of amyloid that have been investigated. Fibrils isolated by water extraction and separated from other tissue components contain 1% to 2% by weight of glycosaminoglycans, none of which is covalently associated with the fibril protein. In systemic AA and AL amyloidosis, the only forms in which this has been studied so far, one sees marked restriction of the heterogeneity of the glycosaminoglycan chains, a finding suggesting that particular subclasses of heparan and dermatan sulfates are involved (48). Immunohistochemical studies demonstrate the presence of proteoglycan core proteins in all amyloid deposits, and these are closely related to fibrils at the ultrastructural level. However, in isolated fibril preparations, much of the glycosaminoglycan material is free carbohydrate chains, and it is not yet clear whether this represents aberrant glycosaminoglycan metabolism related to amyloidosis or is just an artifact of postmortem core protein degradation.

The significance of glycosaminoglycans in amyloid remains unclear, but their universal presence, intimate relationship with the fibrils, and restricted heterogeneity all suggest that they may be important. Glycosaminoglycans participate in the organization of some normal structural proteins into fibrils, and they may have comparable fibrillogenic effects on certain amyloid fibril precursor proteins. Furthermore, the glycosaminoglycans on amyloid fibrils may be ligands to which serum AP (SAP), another universal constituent of amyloid deposits, binds.

AMYLOID P COMPONENT AND SERUM AMYLOID P COMPONENT

Amyloid deposits in all different forms of the disease, both in humans and in animals, contain the nonfibrillar glycoprotein AP (49). AP is identical to and is derived from the normal circulating plasma protein, SAP, a member of the pentraxin protein family that includes C-reactive protein. Human SAP is secreted only by hepatocytes, is a trace constituent of plasma (women: mean, 24 mg/L; standard deviation, 8, range, 8 to 55, n = 274; men: mean, 32 mg/L; standard deviation, 7; range, 12 to 50, n = 226), and is not an acute-phase reactant. Nevertheless, apart from the fibrils themselves, AP is always by far the most abundant protein in all amyloid deposits.

SAP consists of five identical noncovalently associated subunits, each with a molecular mass of 25,462 d, which are noncovalently associated in a pentameric disclike ring. The tertiary fold of the subunit is dominated by antiparallel b sheets, forming a flattened b barrel with jellyroll topology and a core of hydrophobic side chains (50). This is the so-called “lectin fold,” shared with a variety of other animal, plant, and bacterial carbohydrate-binding proteins (lectins). SAP is a calcium-dependent ligand-binding protein, the best-defined specificity of which is for the 4,6-cyclic pyruvate acetal of b-D-galactose, but it also binds avidly and specifically to DNA, to chromatin, to glycosaminoglycans, particularly heparan and dermatan sulfates, and to all known types of amyloid fibrils. This last is the interaction responsible for the unique, specific, accumulation of SAP in amyloid deposits. Aggregated, but not native, SAP also binds specifically to C4-binding protein and fibronectin from plasma, although SAP is not complexed with any other protein in the circulation. In addition to being a plasma protein, SAP is also a normal constituent of certain extracellular matrix structures. It is covalently associated with collagen and other matrix components in the lamina rara interna of the human glomerular basement membrane and is present on the microfibrillar mantle of elastin fibers throughout the body (51,52).

No deficiency of SAP has been described, and it has been stably conserved in evolution. It has a single copy of its gene on chromosome 1 and no polymorphism of the amino acid sequence, and the single biantennary oligosaccharide chain attached to Asn32 is the most invariant glycan of any known glycoprotein. These indications that SAP is likely to have important physiologic functions have been confirmed by the finding that mice with targeted deletion of the SAP gene spontaneously develop marked antinuclear autoimmunity and immune complex glomerulonephritis (53). Studies of these SAP knock-out mice also show that SAP is involved in host resistance to a wide range of infections.

The SAP molecule is highly resistant to proteolysis, and, although SAP is not itself a proteinase inhibitor, its binding to amyloid fibrils *in vitro* protects them against proteolysis (54). Once bound to amyloid fibrils *in vivo,* SAP persists for prolonged periods and is not catabolized at all, in contrast to its rapid clearance from the plasma (half-life 24 hours) and prompt catabolism in the liver. These observations suggest that SAP may contribute to persistence of amyloid deposits *in vivo;* and, indeed, SAP knock-out mice show retarded and reduced induction of experimental AA amyloidosis, a finding confirming that SAP is significantly involved in the pathogenesis of amyloidosis (55).

Other Proteins in Amyloid Deposits

Certain plasma proteins other than the fibril proteins themselves and SAP have been detected immunohistochemically in some amyloid deposits. These proteins include a_1-antichymotrypsin, some complement components, apoE, and various extracellular matrix or basement membrane proteins. None of these match the universality or the quantitative or selective importance of SAP, and their role, if any, in the pathogenesis of amyloid deposition or its effects is not known, although experiments in transgenic and knock-out mice indicate that apoE may play a crucial role in Ab amyloid deposition.

DIAGNOSIS AND MONITORING OF AMYLOIDOSIS

Until recently, amyloidosis was an exclusively histologic diagnosis, and red-green birefringence of deposits stained with Congo red and viewed in polarized light remains the current standard. Furthermore, immunohistochemical staining of amyloid-containing tissue is the simplest method of identifying the amyloid fibril type. However, biopsies provide extremely small samples and therefore cannot provide information on the extent, localization, progression, or regression of amyloid deposits. A major advance in the clinical evaluation of amyloidosis has been the development of radiolabeled SAP as a specific tracer for amyloid (56,57). Combined scintigraphic imaging and metabolic analyses with labeled SAP have provided a wealth of new information on the natural history of many different forms of amyloid and their response to treatment.

Histochemical Diagnosis of Amyloid

BIOPSY

Amyloid may be an incidental finding on biopsy of the kidneys, liver, heart, bowel, peripheral nerve, lymph node, skin, thyroid, or bone marrow. When systemic amyloidosis is suspected clinically, biopsy of rectum or subcutaneous fat is the least invasive. When biopsy is performed by experienced physicians, amyloid can usually be detected in these sites in more than 90% of cases of systemic AA or AL disease. However, routine histopathologic examination has a substantially lower detection rate (i.e., many false-negative results) as well as a significant incidence of false-positive results. This situation reflects both laboratory technique and observer expertise, as well as variations in biopsy size. Direct biopsy of a clinically affected tissue is more likely to be positive but is more invasive.

CONGO RED AND OTHER HISTOCHEMICAL STAINS

Many cotton dyes, fluorochromes, and metachromatic stains have been used, but Congo red staining, and its resultant red-green birefringence when viewed with high-intensity polarized light, is the pathognomonic histochemical test for amyloidosis (3). The stain is unstable and must be freshly prepared at least every 2 months. Section thickness of 5 to 10 µm and inclusion in every staining run of a positive control tissue containing modest amounts of amyloid are critical.

IMMUNOHISTOCHEMISTRY

Although many amyloid fibril proteins can be identified immunohistochemically, the demonstration of amyloidogenic proteins in tissues does not, on its own, establish the presence of amyloid. Congo red staining and red-green birefringence are always required, and immunostaining may then enable the amyloid to be classified. Antibodies to SAA protein are commercially available and always stain AA deposits; the situation is similar with anti–b_2-microglobulin antisera and hemodialysis-associated amyloid. In AL amyloid, the deposits are stainable with standard antisera to k or l in only about half of all cases, probably because the light-chain fragment in the fibrils is usually the N-terminal variable domain, which is unique for each monoclonal protein. Immunohistochemical staining of transthyretin, Ab, and prion protein amyloid may require pretreatment of sections with formic acid or alkaline guanidine or deglycosylation.

ELECTRON MICROSCOPY

Amyloid fibrils cannot always be convincingly identified ultrastructurally, and electron microscopy alone is not sufficient to confirm the diagnosis of amyloidosis.

PROBLEMS OF HISTOLOGIC DIAGNOSIS

The tissue sample must be adequate (e.g., the inclusion of submucosal vessels in a rectal biopsy specimen), and failure to find amyloid does not exclude the diagnosis.

The unavoidable sampling problem means that biopsy cannot reveal the extent or distribution of amyloid. Experience with Congo red staining is required if clinically important false-negative and false-positive results are to be avoided. Immunohistochemical staining requires positive and negative controls, including demonstration of specificity of staining by absorption of positive antisera with isolated pure antigens.

Nonhistologic Investigations

A two-dimensional echocardiography image showing small, concentrically hypertrophied ventricles, generally impaired contraction, dilated atria, homogeneously echogenic valves, and “sparkling” echodensity of ventricular walls, is virtually diagnostic of cardiac amyloidosis. However, clinically significant restrictive diastolic impairment may be difficult to detect even by comprehensive Doppler and other functional studies. Imaging after injection of isotope-labeled calcium-seeking tracers has poor sensitivity and specificity and is of no clinical use.

In patients with known or suspected hereditary amyloidosis, the gene defect must be characterized. If amyloidotic tissue is available, the fibril protein may be known, and the corresponding gene can then be studied; however, if no tissue containing amyloid is available, screening of the genes for known amyloidogenic proteins must be undertaken.

Biochemical and immunochemical screening tests for the presence in the plasma of amyloidogenic variant protein products of mutant genes also exist (e.g., for transthyretin and apoA-I variants), but molecular genetic analysis of DNA is easier to perform and is the most direct approach. However, regardless of the DNA results, it is desirable, if possible, to identify the respective protein in the amyloid directly.

Serum Amyloid P Component as a Specific Tracer in Amyloidosis

The universal presence in amyloid deposits of AP, derived from circulating SAP, is the basis for the use of radioisotope-labeled SAP as a diagnostic tracer in amyloidosis (56,57). No localization or retention of labeled SAP occurs in healthy persons or in patients with diseases other than amyloidosis. Radioiodinated SAP has a short half-life (24 hours) in the plasma and is rapidly catabolized with complete excretion of the iodinated breakdown products in the urine. However, in patients with systemic or localized extracerebral amyloidosis, the tracer rapidly and specifically localizes to the deposits, in proportion to the quantity of amyloid present, and it persists there without breakdown or modification. For clinical purposes, highly purified SAP is isolated from the plasma of single accredited donors and is oxidatively iodinated under conditions that preserve its function intact. The medium-energy, short half-life, pure g emitter iodine-123 is used for scintigraphic imaging, and the long half-life isotope iodine-125 is used for metabolic studies. The dose of radioactivity administered (less than 4 mSv) is well within accepted safety limits, and more than 2,000 studies have been completed without any adverse effects. In addition to high-resolution scintigraphs, the uptake of tracer into various organs can be precisely quantified, and, together with highly reproducible metabolic data on the plasma clearance and whole-body retention of activity, the progression or regression of amyloid can be monitored serially and quantitatively (58).

Important observations regarding amyloid (which have been made for the first time *in vivo*) include the following: the different distribution of amyloid in different forms of the disease; amyloid in anatomic sites not available for biopsy, such as the adrenals and spleen; major systemic deposits in forms of amyloid previously thought to be organ limited; a poor correlation between the quantity of amyloid present in a given organ and the level of organ dysfunction; a nonhomogeneous distribution of amyloid within individual organs; and evidence for rapid progression and sometimes regression of amyloid deposits with different rates in different organs. Examples of major regression of amyloidosis, when it has been possible to reduce or eliminate the supply of fibril precursor, are encouraging. Labeled SAP studies thus make a valuable contribution to the diagnosis and management of patients with systemic amyloidosis, and these are available routinely for all patients with known or suspected cases of amyloidosis in the British National Health Service National Amyloidosis Centre at the Royal Free Hospital, London.

MANAGEMENT OF AMYLOIDOSIS

Although no treatments yet exist that specifically promote the mobilization of amyloid, substantial advances have been made in the management of systemic amyloidosis, particularly the institution of active measures to support failing organ function while attempting reduce the supply of the amyloid fibril precursor protein. Serial SAP scintigraphy in more than 1,000 patients with various forms of amyloid has confirmed that control of the primary disease process, or removal of the source of the amyloidogenic precursor, usually results in regression of existing deposits and recovery or preservation of organ function (58,59). This finding strongly supports aggressive intervention, and relatively toxic drug regimens or other radical approaches can be justified by the poor prognosis. Such an approach, leading to reduced morbidity rates and improved survival periods, is the basis for the establishment of the British National Health Service National Amyloidosis Centre. However, clinical improvement in amyloidosis is often delayed long after the underlying disorder has remitted, a finding reflecting the gradual regression of the deposits that is now recognized to occur in most patients. Continuing production of the amyloid precursor protein should be monitored as closely as possible long term, to determine the requirement for and intensity of treatment for the underlying primary condition. In AA amyloidosis, such monitoring involves frequent estimation of the SAA level, and in AL amyloidosis, it requires monitoring of monoclonal plasma cell proliferation and immunoglobulin light-chain production.

The treatment of AA amyloidosis ranges from potent antiinflammatory and immunosuppressive drugs in patients with rheumatoid arthritis to lifelong prophylactic colchicine administration in patients with familial Mediterranean fever to surgical intervention in conditions such as refractory osteomyelitis and tumors in Castleman disease. The alkylating agent chlorambucil can induce rapid and complete remission of inflammatory activity in many patients with rheumatoid and juvenile chronic arthritis (10), but its use must be considered carefully because it is not licensed for this indication, it is potentially carcinogenic, and it causes infertility.

Treatment of AL amyloidosis is based on the treatment of myeloma, although the plasma cell dyscrasias in AL are often subtle. Prolonged low-intensity cytotoxic regimes such as oral melphalan and prednisolone are beneficial in about 20% of patients. Dose-intensive infusional chemotherapy regimens such as vincristine, doxorubicin (Adriamycin) and dexamethasone and autologous peripheral blood stem cell transplantation are currently being evaluated with far more promising early results (60). However, extremely rigorous patient selection for organ transplantation is essential because the procedure mortality rate is high in persons with multiple amyloidotic organ involvement, especially patients with autonomic neuropathy, severe cardiac amyloidosis, or a history of gastrointestinal bleeding, and those older than 55 years.

Patients with the disabling arthralgia of b_2-microglobulin amyloidosis may respond partially to nonsteroidal antiinflammatory drugs or glucocorticoids, but even the most severe symptoms usually vanish rapidly after renal transplantation. The basis for this remarkable clinical response is unclear because, although renal transplantation rapidly restores normal b_2-microglobulin metabolism, regression of b_2-microglobulin amyloid may not be evident for many years (61).

Hepatic transplantation is effective in patients with familial amyloid polyneuropathy associated with transthyretin gene mutations because the variant amyloidogenic protein is produced mainly in the liver (62). Successful liver transplantation has now been reported in hundreds of patients with this condition, and although the peripheral neuropathy usually only stabilizes, autonomic function can improve substantially, and the associated visceral amyloid deposits have been shown to regress in most cases (63). Important questions remain about the timing of the procedure, but, so far, early intervention seems advisable.

Supportive therapy remains critical in systemic amyloidosis, with the potential for delaying target organ failure, maintaining quality of life, and prolonging survival while the underlying process can be treated. Rigorous control of hypertension is vital in renal amyloidosis. Surgical resection of amyloidotic tissue is occasionally beneficial, but, in general, a conservative approach to surgery, anesthesia, and other invasive procedures is advisable. Should any such procedure be undertaken, meticulous attention to blood pressure and fluid balance is essential. Amyloidotic tissues may heal poorly and are liable to bleed. Diuretics and vasoactive drugs should be used cautiously in patients with cardiac amyloidosis because these drugs can reduce cardiac output substantially. Dysrhythmias may respond to conventional pharmacologic therapy or to pacing. Replacement of vital organ function, notably dialysis, may be necessary; and cardiac, renal, and liver transplant procedures have a role in selected cases.

Finally, certain different therapies aimed specifically at inhibiting amyloid fibril formation or promoting fibril regression are currently under development and will be evaluated clinically within the next few years. These approaches, directed at generation of precursor proteins, the protein folding process, formed fibrils, glycosaminglycans, and SAP, offer hope that amyloidosis may become a treatable condition in the future.

35 EOSINOPHILIA

Peter F. Weller, M.D.

Various infectious, allergic, neoplastic, and other, often idiopathic, diseases can be associated with increased eosinophil numbers in the peripheral blood or tissues (Table 35.1). Eosinophilia develops when specific stimuli enhance eosinophilopoiesis (Chapter 22). Among the three eosinophil growth factor cytokines, granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukin-3 (IL-3), and IL-5, IL-5 is principally responsible for increases in eosinophilopoiesis (Chapter 22). With helminth parasites, the parasite-elicited eosinophilia is attributable to IL-5 produced by the Th2 subset of $CD4^+$T lymphocytes that can also elaborate a restricted number of other cytokines, including IL-4, which may promote heightened immunoglobulin E (IgE) production. Increases in IgE are often, but not uniformly, found in association with eosinophilia, notably in both allergic diseases and helminth infections. In several idiopathic eosinophilic disorders, concomitant increases in IgE are not present, and the immune mechanisms responsible for the eosinophilia remain to be ascertained.

TABLE 35.1. Eosinophil-Associated Diseases and Disorders

Based on published studies establishing the normal range of blood eosinophils, eosinophil numbers in excess of their usual level of less than 450/µL of blood define blood eosinophilia. Quantitation of blood eosinophils does not require the use of absolute eosinophil counts and can be calculated from differential cell counts of Wright-stained blood smears (1). Blood eosinophil numbers exhibit a mild diurnal variation, being higher in the early morning and falling as endogenous glucocorticoid levels increase (2). In addition, blood eosinophilia may fluctuate. Blood eosinophil numbers can be decreased by stress (3), as well as by intercurrent bacterial and viral infections (see later). With leukopenia in another white cell line, the percentages of eosinophils in the differential leukocyte count may be elevated without constituting a true increase in the absolute magnitude of circulating eosinophils.

Blood eosinophil numbers do not necessarily indicate the extent of eosinophil involvement in affected tissues. Eosinophils normally are principally tissue-dwelling leukocytes predominantly distributed in specific tissues, including the respiratory, gastrointestinal, and lower genitourinary tracts (Chapter 22). In addition, eosinophils are recruited into tissue sites in various diseases processes, and the tissue eosinophilia need not be reflected by the concomitant level of blood eosinophilia. Moreover, routine histopathologic staining with eosin lacks sensitivity to detect eosinophils in tissues, and techniques that use the cationic protein content in eosinophil-specific granules are more sensitive for fully enumerating eosinophils in tissues. Fluorescent staining techniques, based on granule fluorescence after staining with Fisher Giemsa stain (4,5), or fluorescein isothiocyanate (6), help to detect tissue eosinophilia. In tissues, loss of morphologically intact eosinophils, resulting from degranulation or cytolysis (7), leads to underestimation of eosinophils, whose prior presence can be evidenced by immunofluorescent detection of residual eosinophil granule cationic proteins, including major basic protein and eosinophil cationic protein (8).

In patients with eosinophilias of various causes, circulating blood eosinophils can exhibit morphologic and functional alterations consequent to being "activated" *in vivo* (9) (Chapter 22). Morphologic alterations include cytoplasmic vacuolization, alterations in granule numbers and size, and losses within specific granules of eosinophil major basic protein–containing cores or matrix. In the idiopathic hypereosinophilic syndrome (HES), the extent of cytoplasmic vacuolization and of hypogranularity has been correlated with the development of cardiac disease (2). A propensity for endomyocardial damage is a recognized complication of various diseases marked by sustained eosinophilia. This cardiac involvement can include early necrosis and subsequent formation of intraventricular thrombi and endomyocardial fibrosis with secondary mitral or tricuspid regurgitation. The damage to the heart is the same whether the eosinophilia is from HES (10,11 and 12) or other causes. Eosinophilic diseases associated at times with endomyocardial damage include the following: eosinophilic leukemia (13); eosinophilia with carcinomas or Hodgkin or non-Hodgkin lymphomas (14,15); eosinophilia from GM-CSF or IL-2 administration (16) or drug-reactions (17); and eosinophilia from helminth infections such as trichinosis, visceral larva migrans, and filariases (18,19,20,21 and 22). More recently, endomyocardial involvement has been recognized in association with eosinophilic Churg-Strauss vasculitis (23). Although diverse eosinophilic diseases can cause the same forms of cardiac disease, most patients with eosinophilia develop no evidence of endomyocardial damage. Thus, the pathogenesis of eosinophil-mediated cardiac damage involves both heightened numbers of eosinophils and some activating events, as yet ill-defined, that promote eosinophil-mediated endomyocardial damage. Patients with sustained eosinophilia should be monitored by echocardiography for evidence of cardiac disease.

The approach to a patient with eosinophilia is directed by a synthesis of information from the patient's history, the nature and types of associated clinical findings and organ involvement, and pertinent laboratory and imaging studies. Because eosinophilia (usually mild) is frequently a concomitant of common allergic diseases, these diseases should be considered, as should adverse reactions to medications. Second, because eosinophilia is common with helminthic parasite infestation, these infections should be evaluated, based on pertinent travel or other exposure histories and on associated clinical manifestations. Potentially occult strongyloidiasis merits special attention, because this infection may present with eosinophilia (24,25), it can persist for decades after acquisition, and it can cause potentially fatal dissemination if glucocorticoids are administered (26). A serologic test for *Strongyloides* helps to ascertain that occult infection with this parasite neither is the cause of eosinophilia nor is likely to disseminate with subsequent glucocorticoid administration (24). Finally, other eosinophil-associated syndromes are considered based on specific organs involved (e.g., eosinophilic pneumonia, eosinophilic gastroenteritis) or other clinical and pathologic features associated with eosinophilia.

ALLERGIC DISEASES ASSOCIATED WITH EOSINOPHILIA

Eosinophilic diseases in this category include atopic and related diseases and drug-induced eosinophilias, two of the more common causes of eosinophilia.

Atopic and Related Diseases

Peripheral blood eosinophilia may be associated with allergic rhinitis but is less common than nasal eosinophilia as an indicator of nasal allergy (27). Nasal eosinophilia, which correlates with the signs and symptoms of allergic rhinitis (28), helps to distinguish allergic rhinitis from viral infections and vasomotor rhinitis and is an indicator of responsiveness to topical glucocorticoids (27,29). Nasal eosinophilia may be present in patients with other conditions, including patients with asthma who have no symptoms of nasal allergy. Patients with nasal polyposis also have lesional and nasal secretion eosinophilia (30), and some manifest the triad of asthma, aspirin sensitivity, and nasal polyposis. Eosinophilia of involved tissues is frequent in chronic sinusitis (31).

Asthma has long been recognized to be associated with eosinophilia (2). Usually, low-grade blood eosinophilia is common, especially in allergic asthma, and in both allergic and nonallergic asthma, eosinophil numbers are increased in airway tissues (32).

Medication-Related Eosinophilias

The administration of diverse therapeutic agents, including herbal or “natural” therapies (33,34 and 35), can elicit eosinophilia. Although these reactions are often considered to represent hypersensitivity reactions, in most instances of drug-associated eosinophilia, the mechanisms leading to eosinophilia are not yet defined. Eosinophilia may develop without other manifestations of adverse drug reactions, such as rashes or drug fevers. In addition, drug-induced eosinophilia may be associated with distinct clinicopathologic patterns in which tissue eosinophilia accompanies drug-induced diseases that are characteristically limited to specific organs with or without associated blood eosinophilia. In the absence of organ involvement, blood eosinophilia by itself need not mandate cessation of drug therapy, if such therapy is medically indicated. Drug-induced blood eosinophilia, however, should prompt an evaluation to determine whether organs, including the lungs, kidneys, and heart, are involved in the eosinophil-associated drug reaction. If organ involvement develops, cessation of drug administration is necessary.

Some cytokines used as therapeutic agents are potential causes of eosinophilia. GM-CSF, but not granulocyte colony-stimulating factor, stimulates eosinophilopoiesis as well as the development of neutrophils. GM-CSF can cause prominent blood and tissue eosinophilia and, less commonly, eosinophil-associated diseases, including eosinophilic pneumonia (36) and eosinophilic endomyocardial fibrosis (16). IL-3 administration also stimulates eosinophil production (37). Administration of IL-2– or IL-2–stimulated lymphocytes frequently is followed by the development of eosinophilia (38,39), most likely from IL-2–stimulated production of IL-5 (40,41). Eosinophilic myocarditis and endocardial thrombosis has developed as a complication of high-dose IL-2 therapy (42). IL-4 can induce mild eosinophilia (43).

Diverse agents are capable of eliciting the development of pulmonary eosinophilia, including many antimicrobial agents and nonsteroidal antiinflammatory agents (NSAIDs) (44,45). The clinical patterns of presentation vary, and some patients have presented with acute or chronic eosinophilic pneumonia. Blood eosinophilia is usually, but not always, present, and if blood eosinophilia is absent, sputum or bronchoalveolar lavage (BAL) fluid eosinophilia is necessary to help make the diagnosis (45). A distinct eosinophilic pleuropulmonary reaction can be caused by dantrolene (46), and it is associated with pleural and blood eosinophilia.

In drug-induced acute interstitial nephritis, eosinophilia is common in the involved kidneys, urine, and, at times, blood. In addition to eosinophilia, fever, rash, and arthralgia support the diagnosis, but they are commonly absent in cases of drug-induced acute interstitial nephritis (47). Agents that elicit acute interstitial nephritis include methicillin and other penicillin congeners, NSAIDs, cimetidine, sulfonamides, captopril, allopurinol, phenytoin, rifampin, ciprofloxacin, aztreonam, triazolam, and warfarin (Coumadin). Eosinophiluria is not uniformly present in all patients with drug-induced interstitial nephritis. The sensitivity of eosinophiluria for acute interstitial nephritis is 40% to 60% (47,48), and when more than 10% urine eosinophils are present, the positive predictive value is 48% to 57% (48,49).

Acute necrotizing eosinophilic myocarditis is a serious but uncommon type of hypersensitivity myocarditis (50). Reactions to medications, such as ranitidine (51) or penicillin, are responsible in some cases. A syndrome of hepatitis with eosinophilia can be a manifestation of reactions to drugs, including minocycline, choline magnesium trisalicylate, halothane, methoxyflurane, salicylazosulfapyridine, ranitidine, carbamazepine, phenytoin, sulfa antibiotics, and trovafloxacin (52). Other medication-related eosinophilic responses include drug-induced hypersensitivity vasculitis (53), as well as forms of gastroenterocolitis elicited by medications, including clozapine (54) and NSAIDs (55). Patients with the syndrome of asthma, nasal polyps, and aspirin sensitivity often have eosinophilia (56). Adverse reactions to contaminated L-tryptophan in “natural” medications was previously a cause of an eosinophilia-myalgia syndrome (33,34). Not all medication-elicited eosinophilias are serious, however. Asymptomatic drug-induced eosinophilia occurs and need not cause cessation of medication usage (57,58).

INFECTIOUS DISEASES ASSOCIATED WITH EOSINOPHILIA

Eosinophilia accompanies only specific infectious diseases. Acute bacterial, viral, or protozoan parasitic infections characteristically produce eosinopenia. Even in patients with eosinophilia from helminth parasitic or allergic diseases, the development of bacterial or viral infections suppresses blood eosinophilia during these intercurrent infections. This suppression results from heightened endogenous glucocorticoid production as well as from inflammatory mediators released during these infections (59). Eosinopenia, with either serious bacterial infections or marked inflammation, accounts for the absence of otherwise expected eosinophilia in some patients with helminthic infections (26). Elevated or even normal blood eosinophil numbers in a febrile patient strongly suggest a noninfectious cause, perhaps an eosinophilic syndrome–related illness or adrenal insufficiency.

Parasitic Infections

Infections with a diversity of multicellular helminth parasites characteristically elicit eosinophilia (26). The magnitude of the eosinophilic response to helminths is determined both by the host's immune response and by the parasite, including its distribution, migration, and development in the infected host. The level of eosinophilia parallels the extent of tissue invasion by helminthic larvae or adults. For several helminthic infections, migrations of infecting larvae through the tissues are greatest early in infections; hence, the magnitude of the elicited eosinophilia is greatest during these early phases. For established infections, tissue eosinophilia around helminths may not be accompanied by blood eosinophilia when the organism is antigenically sequestered within tissues (e.g., intact echinococcal cysts) or is limited solely to the intestinal lumen (e.g., adult *Ascaris,* tapeworms). Intermittent leakage of fluids from echinococcal cysts can transiently stimulate increases in blood eosinophilia and elicit allergic (urticaria, bronchospasm) or anaphylactic reactions (60,61).

Consideration of helminth causes of eosinophilia is guided by the clinical findings and by a geographic history of potential exposure to infection (26). Several helminths can lead to long-lasting eosinophilia. Although stool examinations help to identify enteric helminths, many helminths capable of eliciting eosinophilia dwell in tissues or blood. Some tissue- or blood-dwelling helminths that are not diagnosable by stool examinations but can cause marked eosinophilia require diagnostic examinations of blood or biopsied tissues or specific serologic tests (26). Infections with these characteristics include filarial infections, trichinosis, and visceral larva migrans. Among the helminths, the principal parasite that needs to be evaluated is *Strongyloides* because, as noted earlier, it may cause fatal disseminated infections in patients unwittingly given glucocorticoid therapy. Enzyme-linked immunosorbent assay serologic testing is useful in detecting strongyloidiasis even when fecal examinations are unrevealing (62).

In contrast to infections with helminth parasites, infections with single-celled protozoan parasites do not characteristically elicit blood eosinophilia, except for two enteric protozoan organisms: *Dientamoeba fragilis* and *Isospora belli* (26).

Specific Fungal Infections

Two fungal diseases are associated with eosinophilia: aspergillosis, in the form of allergic bronchopulmonary aspergillosis (63) (Chapter 70), and coccidioidomycosis (26). Blood eosinophilia, peaking during the second or third week of illness, occurs with primary coccidioidal infection (64). Coccidioidal infection should be in the differential diagnosis of eosinophilic pneumonia (65). Eosinophilia, at times prominent, also may develop in patients with disseminated coccidioidomycosis (66,67). Coccidioidal infections also are a common cause of eosinophilic meningitis (68).

Human Immunodeficiency Virus and Other Retroviral Infections

Eosinophilia may accompany human immunodeficiency virus (HIV) infections for several reasons. First, leukopenia may lead to an increased eosinophil percentage without true eosinophilia. Second, adverse reactions to medications may elicit eosinophilia, and therapy with GM-CSF can stimulate eosinophilia. Third, patients with acquired immunodeficiency syndrome are at risk of developing adrenal insufficiency from cytomegalovirus and other infections, and eosinophilia may reflect the adrenal insufficiency (69). In addition, often modest eosinophilia is observed in some HIV-infected patients (70,71). Eosinophilia also accompanies eosinophilic folliculitis in HIV infection. Finally, marked hypereosinophilia has developed in patients with HIV infection, including some with the hyperimmunoglobulin E syndrome and some with exfoliative dermatitis (72,73,74 and 75). Eosinophilia frequently develops in patients with human T-cell lymphocytotrophic virus type I (HTLV-I) infections (76).

MYELOPROLIFERATIVE AND NEOPLASTIC DISEASE

Eosinophilia may occur with certain neoplastic diseases, as well as with a heterogeneous disorder, idiopathic HES.

Idiopathic Hypereosinophilic Syndrome

Idiopathic HES is not a single entity but rather a constellation of leukoproliferative disorders characterized by sustained overproduction of eosinophils (77,78). The three diagnostic criteria for this syndrome are the following: (a) eosinophilia in excess of 1,500 eosinophils/μL of blood persisting for longer than 6 months; (b) lack of an identifiable parasitic, allergic, or other cause of eosinophilia and an absence of other, even idiopathic, eosinophilic syndromes clinically distinct from HES; and (c) signs and symptoms of organ involvement (77). Not all patients with prolonged eosinophilia develop organ involvement, and many have benign courses. Some patients with HES exhibit features common to myeloproliferative disorders, including elevated vitamin B_{12} levels, abnormal leukocyte alkaline phosphatase scores, splenomegaly, cytogenetic abnormalities, myelofibrosis, anemia, erythrocyte abnormalities including teardrop forms, myeloid dysplasia, and basophilia. Patients with these features are less likely to respond to prednisone and are more likely to require alternative therapies. However, patients with HES rarely have expansions of cell lines other than eosinophils to the extent seen in myeloproliferative disorders and do not usually develop myelofibrosis severe enough to be associated with pancytopenia or acute leukemia. The clinical manifestations, severity, and therapeutic responsiveness vary for different patients with HES. Because the foregoing diagnostic criteria are sufficiently broad to include a diversity of eosinophilic disorders, HES represents a collection of varied disorders. In some patients with HES, the disorder has been correlated either with clonal expansions of $CD4^+CD3^-CD8^-$ Th2-like lymphocytes (79,80 and 81) or with other aberrant T cells elaborating IL-5 (82). A patient with eosinophilia associated with polyclonal expansion of activated $CD3^+$ T cells expressing natural killer (NK) cell markers (CD16 and CD56), associated with IL-2 and IL-15 overproduction, has been reported (83). In other patients, however, it appears that overproduction of IL-5 is not solely responsible for the eosinophilia (77). Clonal abnormalities in the eosinophil lineage have been reported in few patients (84,85 and 86). For many patients with HES, the causes of the eosinophilia are not currently understood.

In addition to eosinophilia and other hematologic abnormalities, the organ system most commonly involved is the heart (77). Cardiac damage progresses through three stages: the first involves acute necrosis in the early weeks, the second involves the development of endocardial thrombi over many months, and the third is the fibrotic stage after 2 or more years of disease. The first stage is frequently clinically occult. There is damage to the endocardium and infiltration of the myocardium with eosinophils and lymphocytes with histopathologic evidence of myocardial necrosis, eosinophil degranulation, and eosinophil microabscesses. A similar acute eosinophilic myocarditis can develop with hypersensitivity reactions and may be more fulminant (50). In patients with acute-stage myocardial necrosis, splinter hemorrhages may be prominent; but clinical cardiac findings are often absent, although rare deaths can result from acute progressive cardiac disease (12). Echocardiography and angiography detect no abnormalities in this stage, and endomyocardial biopsy is needed to make the diagnosis (12). Glucocorticoid therapy during the acute stage may help to control and prevent the evolution of myocardial fibrosis (12).

The second stage of heart disease, the formation of thrombi along the damaged endocardium, affects either or both ventricles and rarely the atria (10,77). Outflow tracts near the aortic and pulmonic valves are usually spared. Finally, in the fibrotic stage, progressive scarring may lead to entrapment of the chordae tendineae with the development of mitral or tricuspid valve regurgitation and endomyocardial fibrosis producing restrictive cardiomyopathy (77). Patients with HES often present at the later thrombotic and fibrotic stages. Common manifestations include dyspnea, chest pain, signs of left or right ventricular congestive heart failure, murmurs of mitral regurgitation, cardiomegaly, and T-wave inversions (10). Echocardiography is valuable in detecting intracardiac thrombi and the manifestations of fibrosis, which include thickening of the posterior mitral valve leaflet and its attachment to a thickened posterior wall, as well as increases in intensities of endomyocardial echoes in areas of endomyocardial fibrosis (77). Cardiac catheterization demonstrates increased right and left ventricular end-diastolic pressures, and angiography can demonstrate valvular incompetence as well as delineate apical obliteration or irregularities (12). Cardiac biopsies confirm the diagnosis, although in patients with intense fibrosis in late disease, biopsy instruments may fail to obtain samples.

The risks of developing cardiac disease in two series of patients with HES were not related to the extent of eosinophilia or to the duration of HES (87,88). Patients who developed evident cardiac disease were more likely to be male, to be HLA-Bw44 positive, and to have splenomegaly, thrombocytopenia, elevated levels of vitamin B_{12}, hypogranular or vacuolated eosinophils, and abnormal early myeloid precursors in their blood (88). Those patients with HES who were free of cardiac disease tended to be female and to have angioedema, hypergammaglobulinemia, elevated serum levels of IgE, or circulating immune complexes (88).

In HES, neurologic involvement can take three forms: embolic disease originating from the heart; diffuse encephalopathy; and peripheral neuropathy, especially mononeuritis multiplex (89). Other organs systems that can be involved in HES include the skin, liver, spleen, gastrointestinal tract, and lungs (77).

No specific diagnostic tests exists for HES. Early reports emphasized the mortality related to this disorder, but many of these deaths resulted from congestive heart failure and complications of endomyocardial damage (90). For many patients, if the sequelae of organ damage, especially to the heart, can be managed, HES can have a prolonged course over decades. For those patients with eosinophilia without organ damage, no therapy need be administered. For those requiring therapy, prednisone is the initial agent, administered at 60 mg per day in adults. Patients more likely to respond to prednisone alone are those with angioedema, urticaria, or elevated serum IgE levels and those who experience prolonged eosinopenic responses to single doses of prednisone (91,92). Patients less likely to respond to prednisone include those with splenomegaly and with cardiac or neurologic dysfunction at the time of presentation (91). For those not responsive to prednisone, daily hydroxyurea was previously shown to be effective (93), but the currently preferred therapy for HES is interferon-a (94). Medical management of cardiac complications, including arrhythmias and congestive heart failure, and surgical replacement of damaged valves are important and effective measures in the longer-term management of HES (77).

Eosinophilia with Tumors or Leukemias

Eosinophilic leukemia is distinctly uncommon. Acute eosinophilic leukemia can be distinguished from HES when one notes a marked increase in the number of immature eosinophils in the blood or bone marrow (with more than 10% blast forms in the marrow), infiltration of tissues with immature cells of predominantly eosinophilic type, and a clinical course similar to that of other acute leukemias, including pronounced anemia, thrombocytopenia, and susceptibility to infections (2,95). In addition, patients with eosinophilic leukemias often exhibit a clonal cytogenetic abnormality. Eosinophilia is a characteristic of the M4Eo subtype of acute myeloid leukemia, having the common M4 characteristic of chromosomal 16 abnormalities. In addition, several rare forms of eosinophilic leukemia, each with specific cytogenetic and molecular genetic abnormalities, have been recognized (95). Eosinophilia may accompany chronic myelogenous leukemia but is uncommon with acute lymphoblastic leukemia. Eosinophilia may accompany some lymphomas, including Hodgkin disease, especially the nodular sclerosing form (96), T-cell lymphoblastic lymphoma, and adult T-cell leukemia/lymphoma (95). A few patients with carcinomas, especially of mucin-producing epithelial cell origins, have associated blood and tissue eosinophilia. Eosinophilia may accompany angioimmunoblastic lymphadenopathy, mycosis fungoides, Sézary syndrome, and lymphomatoid papulosis (82,97). Eosinophilia occurs in about 20% of patients with systemic mastocytosis and may be the presenting finding in the absence of cutaneous manifestations (98).

ORGAN SYSTEM INVOLVEMENT AND EOSINOPHILIA

Eosinophilic syndromes limited to specific organs, such as eosinophilic pneumonia (99) or eosinophilic gastroenteritis (100), characteristically do not extend beyond their own target organ. Therefore, these syndromes lack the multiplicity of organ involvement often found with HES and do not have the predilection to develop secondary, eosinophil-mediated cardiac damage, for reasons that are not known. These distinct eosinophilic syndromes therefore can usually be separated from HES, although individual patients may on occasion present with overlapping features that complicate classification.

Skin and Subcutaneous Diseases

Various cutaneous diseases can be associated with increased numbers of blood eosinophils, including atopic dermatitis, blistering disorders such as bullous pemphigoid, drug reactions, and two diseases associated with pregnancy, herpes gestationis and the syndrome of pruritic urticarial papules and plaques of pregnancy. Eosinophilic pustular folliculitis is seen mostly in patients with HIV infections and in those treated for hematologic malignant disease or after bone marrow transplantation (101,102). For patients with cutaneous involvement and eosinophilia, angiolymphoid hyperplasia with eosinophilia and Kimura disease (103), eosinophilic cellulitis (Wells syndrome) (104), eosinophilic fasciitis (105), and eosinophilic pustular folliculitis can be differentiated on the basis of the histopathologic features of biopsied lesions. A distinct syndrome of unknown origin, episodic angioedema with eosinophilia, is characterized by recurring episodes of angioedema, urticaria, fever, and marked blood eosinophilia (106). The clinical course of this disease, with its prominent periodic occurrences of angioedema and eosinophilia, and its lack of association with cardiac damage distinguish it from HES.

Gastrointestinal Diseases

Eosinophilic gastroenteritis represents a heterogeneous collection of disorders in which one may note eosinophilic infiltration of the mucosa, the muscularis, or the serosa, the last of which can lead to eosinophilic ascites (100). Although some patients have demonstrable intolerance to milk proteins, the disease usually remains idiopathic but usually responds to glucocorticoid treatment. Common symptoms include abdominal pain, diarrhea, vomiting, and nausea. Although ultrasound or computed tomography can detect areas of intestinal wall thickening, gastric or intestinal biopsy is needed to make the diagnosis.

Eosinophils are present in the lesions of collagenous colitis and ulcerative colitis, but blood eosinophilia is usually absent. Gastrointestinal eosinophilia elicited by intestinal helminths and eosinophilic enterocolitis resulting from hypersensitivity reactions to medications must be excluded in patients with these diseases who have tissue eosinophilia.

Pulmonary Eosinophilias

Blood eosinophilia can infrequently accompany pleural fluid eosinophilia, which is a nonspecific response seen with various disorders including trauma and even repeated thoracenteses (107). Several pulmonary parenchymal disorders may be associated with eosinophilia. Helminth parasites are responsible for four forms of eosinophilic lung disease (26). The first is Loeffler syndrome, which is marked by blood eosinophilia, eosinophilic patchy pulmonary infiltrates that appear and resolve over weeks, and, at times, bronchospasm. This syndrome is typically caused by those helminth parasites (*Ascaris lumbricoides* and, less commonly, hookworm and *Strongyloides*) that migrate through the lungs early in their developmental life cycles (26). Stool examinations are not helpful because the pulmonary response is elicited by infecting larval forms months before productive egg laying from later adult stages would begin in the intestines. The diagnosis is made on epidemiologic grounds or, less commonly, by detecting larvae in sputum or BAL fluids (26,108). The second form of helminth-induced lung disease is the syndrome of tropical pulmonary eosinophilia, which develops in a few patients infected with lymphatic-dwelling filarial species (26,109). Clinically, this syndrome is characterized by marked blood eosinophilia, paroxysmal nonproductive cough, wheezing, and occasional weight loss, lymphadenopathy, and low-grade fevers. On chest radiographs, increased bronchovesicular markings, diffuse interstitial lesions 1 to 3 mm in diameter, or mottled opacities, usually more prominent in lower lung fields, are common. Patients have markedly increased numbers of blood and alveolar eosinophils and elevations in both total serum IgE and antifilarial antibodies. A third form of helminth-induced lung disease is caused by helminths that invade the pulmonary parenchyma, notably lung flukes that cause paragonimiasis (26). The fourth form of lung disease is caused by larger than usual numbers of helminth organisms that are carried hematogenously into the lungs. Examples include schistosomiasis, trichinosis, and larva migrans (26). Bronchopulmonary aspergillosis constitutes another type of eosinophil-associated pulmonary disease.

Two forms of idiopathic eosinophilic pneumonia are recognized. In chronic eosinophilic pneumonia, patients typically exhibit peripheral pulmonary infiltrates that may extend across lobar fissures (110). Blood eosinophilia is present in most, but not all, patients. This disease of unknown origin is responsive to glucocorticoids but is prone to relapse (111). An acute form of eosinophilic pneumonia, manifest by fever, pulmonary infiltrates, and respiratory insufficiency, is diagnosable by demonstrating eosinophils in BAL fluids or by lung biopsy (112). Acute eosinophilic pneumonia responds to glucocorticoid treatment and does not relapse.

The major vasculitis associated with eosinophilia is Churg-Strauss syndrome (113). A history of asthma, nonfixed pulmonary infiltrates, blood eosinophilia greater than 10%, paranasal sinus abnormalities, mononeuropathy or polyneuropathy, and a blood vessel biopsy specimen demonstrating extravascular eosinophils characterize this syndrome (114). For patients with vasculitis, the presence of four or more of these six criteria yielded a sensitivity of 85% and a specificity of 99.7% for Churg-Strauss vasculitis (114). Late-onset asthma is common and may be antecedent for several years. Asthma, eosinophilia, and, at times, transient pulmonary infiltrates antedate the development of systemic vasculitis in about half the cases. Pulmonary involvement is seen in almost all patients, and pulmonary infiltrates occur in three fourths of patients. Nasal and sinus involvement is common. Glucocorticoid treatment of asthma may mask the evolution of Churg-Strauss syndrome (115). Use of anti–cysteinyl leukotriene agents for asthma has been associated with the onset of the Churg-Strauss syndrome. In many, but not all, patients, these agents have permitted diminished glucocorticoid dosing for asthma, but the precise relationship of these drugs with the development of this syndrome remains to be delineated (116). In addition to frequent pulmonary disease, neurologic, cutaneous, cardiac, and gastrointestinal organ involvement is common (113).

Medications and other drugs are capable of eliciting pulmonary eosinophilia (45). Commonly implicated medications include NSAIDs and antimicrobial medications. Toxic agents, including those from occupational exposures, also can cause pulmonary eosinophilia (45). Each of these reactions has a defined etiologic stimulus and hence differs from idiopathic and other eosinophilic diseases, but the clinical presentation of drug- and toxin-elicited pulmonary eosinophilias can resemble that of other forms of pulmonary eosinophilia, including acute or chronic eosinophilic pneumonia.

Rheumatologic Disorders

Of the various forms of vasculitis, only two are commonly associated with eosinophilia. The principal eosinophil-related vasculitis is Churg-Strauss syndrome, as discussed in the previous section. Cutaneous necrotizing eosinophilic vasculitis with hypocomplementemia and eosinophilia is a distinct vasculitis of small dermal vessels that are extensively infiltrated with eosinophils. This form of vasculitis may occur in patients with connective tissue diseases (117). In addition, eosinophilia may uncommonly accompany rheumatoid arthritis itself but is more commonly the result of adverse reactions to treatment medications (including NSAIDs, gold, and tetracyclines) or concomitant vasculitis. A syndrome, characterized by the association of nodules, eosinophilia, rheumatism, dermatitis, and swelling (NERDS), includes prominent paraarticular nodules, recurrent urticaria with angioedema, and tissue and blood eosinophilia [Zenarola, 1995 #5320].

Immunologic Disorders

Some primary immunodeficiency syndromes are associated with eosinophilia. The hyper-IgE syndrome is characterized by the following: recurrent staphylococcal abscesses of the skin, lungs, and other sites; pruritic dermatitis; hyperimmunoglobulinemia E; and eosinophilia of the blood, sputum, and tissues (118). Eosinophilia is characteristic of Omenn syndrome, combined immunodeficiency with hypereosinophilia (119).

Infiltration of eosinophils accompanies rejection of lung (120), kidney (121), and liver (122,123 and 124) allografts. Tissue and blood eosinophilia occurs early in the rejection process, and eosinophil counts and granule protein levels (in urine or BAL fluids and in involved allograft tissues) have correlated with prognosis, severity, and response to rejection therapy.

Endocrine Diseases

Because glucocorticoids normally exert eosinopenic effects, the loss of endogenous adrenoglucocorticoid production in Addison disease, adrenal hemorrhage, or hypopituitarism can cause blood eosinophilia (125,126).

Other Causes of Eosinophilia

The syndrome of atheromatous cholesterol embolization can be associated with eosinophilia and eosinophiluria (127,128). Uncommonly, kindreds with hereditary eosinophilia have been recognized (129). Irritation of serosal surfaces can be associated with eosinophilia, and related diseases can include Dressler syndrome, eosinophilic pleural effusions (107), peritoneal and, at times, blood eosinophilia developing during long-term peritoneal dialysis (130), and perhaps the eosinophilia that may follow abdominal irradiation (131).

36 MASTOCYTOSIS

Dean D. Metcalfe, M.D.

Mastocytosis is a relatively rare disease characterized pathologically by mast cell hyperplasia in the skin, bone marrow, lymph nodes, liver, gastrointestinal tract, and spleen. Clinical features include pruritus, urtication, nausea, vomiting, abdominal pain, diarrhea, headache, flushing, and vascular instability. Urticaria pigmentosa, the most common skin manifestation of mastocytosis, was described by Nettleship in 1869 (1). Excessive numbers of mast cells were recognized in the lesions of urticaria pigmentosa by Unna in 1887 (2). In 1949, Ellis reported the case of a child with urticaria pigmentosa, with the first postmortem evidence suggesting that mast cell hyperplasia in skin could be associated with systemic disease (3). Since then, the clinicopathologic diversity of mastocytosis has been increasingly recognized. These developments have been accompanied by a rapid expansion in knowledge of the growth, differentiation, and biologic expression of mast cells, including the recognition of the origin of mast cells from $CD34^+$ human pluripotent cells (4), the description of mast cell growth factors including interleukin-3 (IL-3) (5) and kit ligand or stem cell factor (SCF) (6), the recognition that SCF is the one essential growth factor for human mast cells (7), and the description of various pleomorphic and redundant mast cell–derived mediators (8).

The prevalence of mastocytosis is unknown. It has been reported to be the diagnosis in 1 patient per 1,000 to 8,000 new cases seen in a dermatology clinic (9). Mastocytosis can occur at any age, and its distribution between men and women is approximately equal. Approximately 50 cases of familial mastocytosis have been reported (10). Most cases of mastocytosis are sporadic.

CLINICAL SIGNS AND SYMPTOMS

Urticaria pigmentosa is the most common skin manifestation of mastocytosis in both children and adults. The individual lesions of urticaria pigmentosa manifest as small, yellow-tan to reddish-brown macules or slightly raised papules. Lesions are less likely to appear on the palms, soles, face, and scalp. Mild trauma, such as scratching or rubbing of the lesions, may provoke urtication and erythema at the site of the macules; this is known as the Darier sign. Pruritus occurs and may be exacerbated by changes in temperature, skin friction, ingestion of hot beverages or spicy foods, ethanol, and certain drugs.

In diffuse cutaneous mastocytosis, the entire cutaneous integument is involved. The skin is normal to yellow brown and is diffusely thickened. Diffuse cutaneous mastocytosis usually occurs before the age of 3 years. Children with urticaria pigmentosa or diffuse cutaneous mastocytosis may experience bullous eruptions with hemorrhage (11). Blisters erupt spontaneously or occur in association with infection or immunization. Blisters may appear at birth and thus are in the differential diagnosis of neonatal disorders with blisters.

Telangiectasia macularis eruptiva perstans is a rare form of mastocytosis. In this pattern of disease, the skin is covered with tan to brown macules and patchy erythema. Telangiectasias are observed (12). Solitary lesions called mastocytomas are rare. Their onset is generally before the age of 6 months, and in most cases these lesions spontaneously involute.

Gastrointestinal symptoms develop in up to 80% of adult patients with systemic disease (13). The most common gastrointestinal symptom is abdominal pain, followed by diarrhea, nausea, and vomiting. Peptic ulcer disease occurs in up to approximately 40% of adult patients with systemic disease, with some evidence of malabsorption in approximately 30% (13). Malabsorption is usually not severe and is manifested primarily as mild steatorrhea with impaired absorption of D-xylose or vitamin B_{12}.

Approximately 60% of patients with mastocytosis have evidence of liver disease. Severe liver disease, however, is uncommon, except in patients with aggressive forms of mastocytosis (14). The most common chemical abnormality is an elevated alkaline phosphatase level, which directly correlates with hepatomegaly, splenomegaly, liver mast cell infiltrations, and fibrosis. Patients with systemic disease frequently exhibit splenic involvement manifested by splenic enlargement (15), and spleens weighing more than 700 g are seen in patients with severe disease. Portal hypertension and ascites associated with liver fibrosis, nodular regenerative hyperplasia, portal venopathy, and venoocclusive disease are unusual. Peripheral lymphadenopathy occurs in up to 26% of patients with systemic disease, and central lymphadenopathy is seen in 19% of patients at the time of diagnosis (15).

Hematologic abnormalities are frequent in patients with mastocytosis sent to referral centers such as the Mayo Clinic in Rochester, Minnesota, and the National Institutes of Health in Bethesda, Maryland. In one study, 3 of 13 patients with isolated cutaneous disease had anemia, thrombocytosis, eosinophilia, or lymphopenia. Twenty-two of 32 patients with systemic disease had at least one of the following: anemia (50%), thrombocytopenia (19%), thrombocytosis (9%), leukopenia (9%), leukocytosis (31%), eosinophilia (21%), monocytosis (18%), lymphopenia (32%), or lymphocytosis (14%) (16). Hematologic abnormalities were infrequently reported in other studies (17,18), a finding suggesting that, in general, the prevalence of hematologic abnormalities in patients with mastocytosis is less than the data from large referral centers suggest.

Skeletal changes are believed to contribute to musculoskeletal pain in up to 28% of patients. Radiographically detectable lesions are present in up to 70% of patients with systemic disease. The proximal long bones are most often affected, followed by the pelvis, ribs, and skull. Skeletal scintigraphy (bone scan) is more sensitive than a radiographic survey in detecting and locating active lesions (19). In addition, both the degree of abnormalities on the initial bone scan and the progression of scintigraphic abnormalities with serial scanning correlate with more aggressive forms of mastocytosis. In patients with severe or advanced disease, pathologic fractures may occur.

Patients with mastocytosis may report cutaneous flushing. In severe cases, vascular collapse may occur. Flushing is variably provoked by alcohol, aspirin, exercise, or infection.

Headache, decreased attention span, memory impairment, irritability, difficulty in concentration, inability to work, problems in interpersonal relations, poor motivation, confusion, anger, and depression have been reported as mental manifestations of mastocytosis in adults (20). In contrast, in one study that assessed behavioral problems in a group of pediatric patients with mastocytosis, no clear behavioral disorder was found to exist in children with mastocytosis compared with other medically ill children (21).

PATHOBIOLOGY

Human mast cells arise from $CD34^+$ progenitor cells (4), which are kit^+ and $CD13^+$ (22) under the influence of SCF. Mast cell survival in tissues is believed to depend on the local production of SCF by stromal cells (6). SCF then acts in concert with other locally produced factors to determine the final mast cell phenotype.

The identification of mast cells as hematopoietically derived cells whose growth and differentiation depends at least in part on SCF suggests that one cause of mastocytosis may relate to an overproduction of mast cell growth factors. Production of SCF by keratinocytes in the skin of patients with urticaria pigmentosa (23) could be one explanation of the mast cell hyperplasia in such lesions (24). Our group has been unable to demonstrate that the levels of SCF are elevated in sera or skin blister fluids from patients with mastocytosis.

An alternate hypothesis about the origin of mastocytosis is that activating mutations in kit permit the evolution of mastocytosis by driving excess proliferation of mast cell precursors and by facilitating mast cell survival. This idea was suggested by early data on mast cell growth and development that showed that more mast cells could be found in culture in the presence of SCF when mast cell progenitors were obtained from patients with mastocytosis compared with hematologically normal donors (25). Subsequent analysis of c-*kit* obtained from peripheral blood mononuclear cells of patients with mastocytosis revealed that a subset of these patients with a hematologic disorder had a point mutation at amino acid 816 resulting in substitution of Val for Asp (26). This mutation was identical to 1 of 2 mutations reported in the HMC-1 cell line and had been shown to cause ligand-independent phosphorylation of kit (27). The subsequent identification of this mutation in the skin, but not in the bone marrow or blood, of a child with mastocytosis (28) contributed to the idea that lesional skin of patients with mastocytosis, in which cells bearing the mutation would be concentrated, should be the best tissue in which to identify mutated kit. Subsequently, it was found that of 11 adults examined, all had an activating mutation in

codon 816 in lesional skin. Among the children examined, 4 with severe disease had codon 816 activating mutations; 3 had a dominant inactivation mutation substituting lysine for glutamic acid in position 839. Three children with sporadic disease had no mutations. No c-*kit* mutations were found in 3 patients with familial mastocytosis (29). Follow-up studies have also shown that the c-*kit* mutation can be identified in lymphocytes and myelomonocytic cells as well as in mast cells (30). Thus, it appears that in most adults with mastocytosis, an activating mutation at codon 816 is present and may permit mastocytosis to develop. Additional genetic polymorphisms, mutations, and chromosomal changes may then determine the eventual disease course. In children, the situation is more varied, and other causes of disease are possible. The identification of mutations in kit in mastocytosis may eventually aid in assigning prognosis and in developing a more objective classification for mastocytosis (31).

The mast cell hyperplasia in mastocytosis is associated with evidence of abnormal levels of circulating mast cell mediators, including histamine (32) and mast cell tryptase (33). Mediators, including histamine, tryptase, heparin, tumor necrosis factor-a, prostaglandin D_2 (PGD_2), leukotriene C_4, cytokines, and platelet-activating factor, undoubtedly contribute to the pathogenesis of mastocytosis.

The prevalence of atopy in persons with urticaria pigmentosa is similar to that in the general population (34). However, total serum IgE levels are significantly lower. This finding may relate to an increased adsorption of circulating IgE to an increased number of tissue mast cells.

The skin of patients with urticaria pigmentosa (Fig. 36.1) contains increased numbers of mast cells, with highest concentrations under the pigmented lesions (Fig. 36.2). Mast cells first appear to concentrate near vessels and with time appear at greater distances from vessels (24). Small vessel hyperplasia is attributed to mast cell heparin and mast cell cytokines that facilitate vessel proliferation. Blisters in children associated with cutaneous disease contain not only histamine, but also PGD_2 and platelet-activating factor (35). Diffuse cutaneous mastocytosis is associated with a remarkable diffuse mast cell infiltrate throughout the dermis. Patients with significant dermal infiltration with mast cells may have prolonged bleeding times resulting from mast cell–associated heparin (36).

Figure 36.1. Urticaria pigmentosa in an adult patient with indolent disease. (See Color Figure 36.1.)

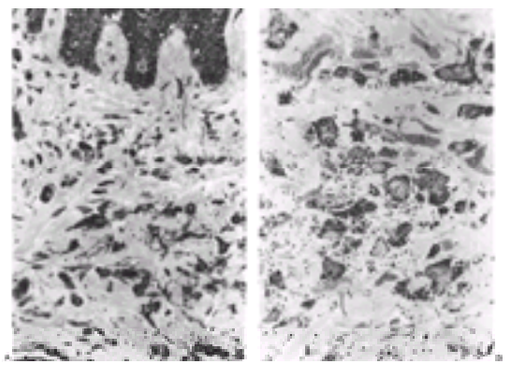

Figure 36.2. A and **B:** Light micrographs of a skin lesion from a patient with urticaria pigmentosa showing mast cell proliferation in the dermis. A specimen of lesional skin was obtained by biopsy, embedded in epoxy resin, sliced 1-µm thick, and stained with Wright-Giemsa stain. (**A** ×520; **B** ×1,310). (Courtesy of Dr. John P. Caulfield.)

Most patients with dyspeptic-type abdominal pain have evidence of gastric hypersecretion (13). The plasma concentration of histamine correlates with the basal acid output but not with the maximal acid output. These findings are consistent with the hypothesis that elevated systemic levels of mast cell–derived histamine lead to increased gastric acid secretion, which, in turn, promotes gastritis and peptic ulcer disease.

Nonpeptic abdominal pain, located in the lower abdomen, is not relieved by antacids and is not associated with gastric hypersecretion. This pain is often cramping and may result from the local production of lipid-derived mediators. Evidence of malabsorption may be found in association with these complaints. Diffuse small intestinal mucosal dysfunction has been proposed as the basis of malabsorption (37). A structural basis for this intestinal mucosal dysfunction has been suggested by the finding of blunted villi and an increase in mucosal mast cells in the mucosa (13,37). No differences in gastric emptying studies or mouth-to-cecum transit time were found between patients with systemic mastocytosis with or without diarrhea or nondyspeptic abdominal pain and control subjects (13). An increase in intestinal transit thus does not appear to contribute to symptoms.

Gastrointestinal peptides alter gastrointestinal transit and motility; they also can degranulate mast cells and can lead to the production of mast cell cytokines (38). Thus, mast cells may release mediators in response to neuropeptides or may release neuropeptides themselves that can affect motility. An elevated level of vasoactive intestinal peptide was observed in one patient with mastocytosis (39). A second study measured gastrointestinal peptide concentrations in six patients with mastocytosis with diarrhea or nondyspeptic abdominal pain and control subjects; no significant differences were found in mean plasma concentrations of neurotensin, substance P, or motilin. Patients had lower mean plasma concentrations of gastrin and substance P than did control subjects (13). These results do not exclude the possibility that increased or altered local release of these peptides is relevant.

In lymph nodes, mast cell infiltrates are most common in the paracortex, followed by the follicles, the medullary cords, and the sinuses. Early infiltrates are exemplified by clusters of mast cells. Eosinophils accompany mast cell infiltrates in lymph node tissues in approximately one half of the patient's lymph nodes (15). Blood vessel proliferation sometimes occurs in lymph nodes in the paracortical areas infiltrated by mast cells. Some patients exhibit extramedullary hematopoiesis.

Tissue fibrosis is most frequently found in the liver (14) and bone marrow (16). Liver fibrosis may be minimal, moderate, or severe. Fibrotic patterns include periductal patterns and portal-to-portal fibrosis. Various degrees of trabecular fibrosis are common in the spleen (15). This fibrosis may relate to the ability of mast cells to produce certain connective tissue components (40), and mast cells synthesize transforming growth factor-b and other agents that may promote fibrosis (8).

The bone marrow is the most useful biopsy site for establishing the diagnosis of systemic mastocytosis (41,42 and 43). Examination of the bone marrow reveals mast cell infiltrates and allows examination of the hematopoietic marrow, which provides important prognostic information. The morphologic appearance of mastocytosis-related bone marrow infiltrates in trephine core biopsy sections is unique. Infiltrates in the bone marrow are usually focal, although they may be diffuse. Focal mastocytosis lesions are most commonly situated paratrabecularly (Fig. 36.3). Perivascular and parafollicular distributions are the next most common. Lesions consist of nodular aggregates of spindle-shaped mast cells, frequently accompanied by lymphocytes and eosinophils. Mast cells have oval to elongated nuclei and eosinophilic cytoplasm. They may or may not appear granular by light microscopy with hematoxylin and eosin stains. The bone marrow lesions are cellular in early stages of the disease. As the disease progresses, the number of mast cells may decrease, and the lesions may become fibrotic. Mastocytosis infiltrates in the bone marrow may be associated with osteosclerotic or osteolytic changes in the bone trabeculae.

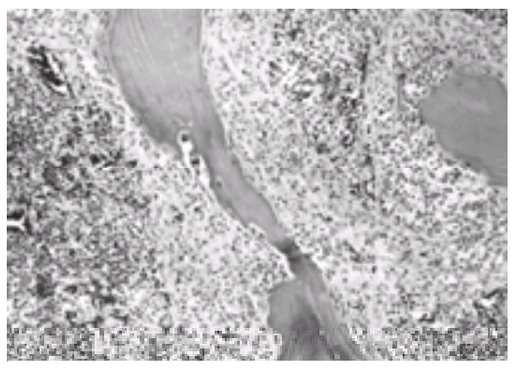

Figure 36.3. Light micrograph of a bone marrow specimen from a patient with systemic indolent mastocytosis. The specimen is stained with hematoxylin and eosin (×400).

Special stains are often used to confirm the presence of mast cells. The metachromatic staining of mast cell granules decreases during routine processing of specimens. Optimal staining is achieved with immunohistochemistry to detect mast cell tryptase.

Prognostic features of bone marrow in mastocytosis have been reported. Hypercellular bone marrow with a decreased percentage of fat cells is a significant predictor of poor prognosis (43). The hypercellular marrow, in most cases, is caused by an increase in hematopoietic elements or extensive mast cell infiltration. Most patients with mastocytosis with a hypercellular hematopoietic marrow have an associated hematologic disorder. Approximately one third of all adult patients referred to the Mayo Clinic or the National Institutes of Health have associated hematologic disorders, defined by traditional criteria (16,43), including dysmyelopoietic syndromes, myeloproliferative disorders, *de novo* acute leukemia, malignant lymphoma, and chronic neutropenia. Chromosomal abnormalities in mastocytosis have been reported but are not consistent (44). Patients with mastocytosis with hematologic disorders have significantly reduced 5-year survival rates (43). Although systemic mast cell lesions in patients with hematologic disorders may be discovered incidentally during examination of bone marrow biopsy specimens, most patients present with manifestations of mastocytosis including urticaria pigmentosa, organomegaly, increased excretion of histamine metabolites, and elevated levels of serum mast cell tryptase; the hematologic disorder is detected after mastocytosis is diagnosed.

The relative number of mast cells in the bone marrow aspirate is not always a useful measure of pathologic mast cell infiltrates. In some cases, no mast cells are found in the bone marrow aspirate despite evidence of mastocytosis in trephine core biopsy sections. Mast cell hyperplasia in bone marrow occurs in conditions other than systemic mast cell disease, including uremia (45), osteoporosis (46), and hematologic conditions such as lymphomas, preleukemias, and leukemias (47,48 and 49). Because the number of mast cells varies in persons with and those without mastocytosis, no criteria exist to distinguish mast cell hyperplasia from mastocytosis solely on the basis of the bone marrow aspirate.

Bone marrow infiltration with mast cells is associated with radiographically detectable lesions. Osteoporosis is common (50). Bone changes may result from the action of mast cell–derived heparin, proteases, cytokines, and lipid-derived mediators on bone deposition and on osteoclast and osteoblast function.

DIAGNOSIS

Mastocytosis is diagnosed on the basis of presentation, physical examination, laboratory studies, and histologic findings. This information is also used to classify disease and to assign prognosis (51) (Table 36.1). Patients with cutaneous or indolent mastocytosis have a good prognosis, whereas patients in the other groups tend to develop more complications and to exhibit a more rapid disease course. Indolent mastocytosis is defined by the presence of syncope, elevated levels of mast cell–derived mediators in blood or urine, cutaneous disease, ulcer disease, malabsorption, bone marrow involvement, skeletal disease, hepatosplenomegaly, and lymphadenopathy. Most patients diagnosed as having mastocytosis are placed in the indolent category. Most patients with indolent disease experience symptom progression but can be managed successfully for decades with medications that provide symptomatic relief. The next most common form of mastocytosis is that associated with a hematologic disorder. In this group, examination of the bone marrow and peripheral blood reveals the hematologic abnormality. The prognosis of these patients is determined by the course of the associated hematologic disorder. Patients in the following category have an aggressive form of mastocytosis but do not have a distinctive hematologic disorder or mast cell leukemia. These patients have poor prognostic features, they have a rapid increase in mast cell number, and they are difficult to manage medically. One subset of patients with aggressive mastocytosis has a distinct syndrome termed *lymphadenopathic mastocytosis with eosinophilia* because of the pronounced eosinophilia, hepatosplenomegaly, and lymphadenopathy. Mast cell leukemia is a rare form and has the most fulminant disease course (52). The peripheral blood smear reveals numerous immature mast cells. Mast cell leukemia is distinguished from the other categories by its unique pathologic and clinical picture.

Cutaneous mastocytosis
1. Urticaria pigmentosa
2. Diffuse cutaneous mastocytosis
3. Mastocytoma of the skin
Systemic mastocytosis without an associated hematologic disorder
1. Indolent
2. Smoldering
Systemic mastocytosis with an associated hematologic disorder
1. Myeloproliferative
2. Myelodysplastic
Systemic aggressive mastocytosis
Mast cell leukemia
Mast cell sarcoma
Extracutaneous mastocytoma

Adapted from WHO classification.

TABLE 36.1. Classification of Mastocytosis

Most patients with indolent mastocytosis have either urticaria pigmentosa or diffuse cutaneous mastocytosis. Urticaria pigmentosa is less common in patients with mastocytosis and an associated hematologic disorder and in those with aggressive mastocytosis, and it is rarely observed in patients with mast cell leukemia. The clinical diagnosis of urticaria pigmentosa should be confirmed with a skin biopsy (12,24). Although there is often a 15- to 20-fold increase in mast cells beneath the urticaria pigmentosa lesion, occasionally only a 2- to 4-fold increase in mast cells occurs. Similar 2- to 4-fold increases in mast cells have been found in patients with recurrent anaphylaxis (24), scleroderma (53), chronic urticaria (54), and prolonged antigenic contact (55). Thus, the diagnosis of urticaria pigmentosa cannot be made solely on the basis of small increases in dermal mast cells. Cutaneous responses to intradermal histamine are unchanged in patients with urticaria pigmentosa (56).

Mastocytosis should be suspected in patients without skin lesions in the presence of one or more of the following features: unexplained ulcer disease or malabsorption, radiographic or technetium-99 bone scan abnormalities, hepatomegaly, splenomegaly, lymphadenopathy, peripheral blood abnormalities, and unexplained flushing or vascular collapse. Elevations in the levels of plasma (32,57) or urinary histamine or histamine metabolites (58), PGD_2 metabolites in the urine (59), and plasma mast cell tryptase (33) are not diagnostic, but they suggest the possibility of mastocytosis. Plasma mast cell tryptase is actually a mixture of a- and b-tryptases. Most commercial assays measure total tryptase. However, clinical data demonstrate that a-tryptase is the form elevated in mastocytosis, whereas b-tryptase becomes elevated during a systemic allergic reaction. As these tests become available, it may be possible to distinguish more clearly between mastocytosis and anaphylaxis resulting from an allergic reaction (33).

In the absence of skin lesions, patients suspected of having mastocytosis should undergo a bone marrow biopsy and aspiration to confirm the diagnosis and to determine the disease category. Patients with urticaria pigmentosa or diffuse cutaneous mastocytosis should also undergo this procedure if they have peripheral blood abnormalities, hepatomegaly, splenomegaly, or lymphadenopathy, to determine whether they have an associated hematologic disorder. Mast cell leukemia is a distinct clinical entity. The bone marrow is hypercellular, with diffuse infiltration with atypical mast cells (52). In patients with mast cell leukemia, more than 10% of the circulating nucleated cells are atypical mast cells, and this percentage may increase to more than 90% of all circulating nucleated cells during the course of the disease. Mast cell leukemia differs from the rare case of aggressive mastocytosis with a terminal leukemic phase, in which circulating mast cells appear late in the course of the disease and the percentage of circulating cells that are mast cells is relatively low. Histologic study of other tissue specimens such as lymph nodes, spleen, liver, and gastrointestinal mucosa may help to define the extent of mast cell involvement. Surrogate plasma markers of bone marrow disease, including soluble

kit and soluble CD25, have been described, and the circumstances in which progressive elevations of these molecules correlate with more severe bone marrow disease (60). These tests are not yet widely available.

A 24-hour urine study of 5-hydroxyindoleacetic acid and urinary metanephrines may be necessary to eliminate the possibility of a carcinoid tumor or pheochromocytoma. Patients with mastocytosis do not excrete increased amounts of 5-hydroxyindoleacetic acid. Idiopathic anaphylaxis and flushing must also be considered. Angioedema, which may occur in patients with anaphylaxis, is rarely present in patients with mastocytosis. Patients with such anaphylaxis, flushing, and angioedema do not have histologic evidence of significant mast cell hyperplasia and should have normal plasma histamine or tryptase levels between episodes (33).

TREATMENT

The control of mast cell mediator–induced signs and symptoms is a major objective in the treatment of patients in all categories of mastocytosis. H_1 receptor antagonists reduce pruritus, flushing, and tachycardia. Pruritus is also reduced by efforts to retain skin moisture. H_2 receptor antagonists and proton pump inhibitors are used to treat gastric hyperse cretion and to prevent gastritis and peptic ulcer disease. Hypotensive episodes are treated with epinephrine (61). If hypotensive episodes are frequent, there may be value in prophylaxis with H_1 and H_2 antihistamines. Patients should be trained to medicate themselves with epinephrine and to seek medical assistance promptly if they experience a hypotensive episode. Hypotension has been observed after insect stings (62), as well as after administration of contrast media. If subcutaneous epinephrine is inadequate in the treatment of the hypotensive episode, intensive therapy as for anaphylaxis must be instituted.

Aspirin and other nonsteroidal antiinflammatory drugs have therapeutic value in the treatment of recurrent hypotension and possibly severe flushing in that they block the synthesis of PGD_2 (59). However, aspirin and the other nonsteroidal antiinflammatory drugs may exacerbate gastritis in patients with mastocytosis. Some patients also have a severe hypotensive response to aspirin ingestion. Because of these difficulties, aspirin should be added to the antihistamine regimen only when symptoms are severe and are otherwise uncontrolled. Aspirin should be administered initially under controlled circumstances, with personnel and equipment available for resuscitation.

Methoxsalen with long-wave ultraviolet radiation relieves pruritus and whealing after 1 to 2 months of treatment (63). Improvement is associated with a transient decrease in dermal mast cells. Pruritus recurs 3 to 6 months after therapy is discontinued. Some patients report a diminution in the number or intensity of cutaneous lesions after repeated exposure to natural sunlight. Topical glucocorticoids may be applied under occlusion for 8 hours a day over 8 to 12 weeks for the treatment of urticaria pigmentosa or diffuse cutaneous mastocytosis. Lesions eventually recur after therapy is discontinued (64), although the treatment may lead to improvement in cutaneous lesions for up to 1 year.

The treatment of intestinal disease is determined by the degree of cramping, diarrhea, and malabsorption. Anticholinergic agents may give partial relief. Oral cromolyn sodium is of value, particularly in the management of abdominal symptoms (17,18,65). In patients with severe malabsorption, systemic glucocorticoids are effective. Ascites, which is more often seen in mastocytosis with an associated hematologic disorder and in aggressive mastocytosis, is also difficult to control. Portal hypertension in one patient was successfully managed with a portacaval shunt (66). Another patient with exudative ascites was treated successfully with systemic glucocorticoid therapy (67).

Patients with mastocytosis and an associated hematologic disorder are managed as dictated by the specific hematologic abnormality (68). Chemotherapy has not been shown to produce remission or to prolong survival in patients with mast cell leukemia, and it has no place in the treatment of indolent mastocytosis. The results of one study suggested that splenectomy may improve the length of survival in patients with forms of mastocytosis associated with poor prognosis (69).

Patients with aggressive mast cell disease have been variably reported to respond to interferon-a (70,71). Anecdotal reports have described a partial remission with interferon-g (72,73).

Other experimental approaches include the use of antihistamines with mast cell–stabilizing properties such as ketotifen and azelastine. Ketotifen relieves the pruritus and whealing associated with mastocytosis. However, in a double-blind, placebo-controlled trial of ketotifen versus hydroxyzine in the treatment of pediatric mastocytosis, ketotifen offered no advantage over hydroxyzine (74). Similarly, in a double-blind trial of azelastine versus chlorpheniramine in the treatment of adults with mastocytosis, azelastine, although effective in relieving skin symptoms, offered no advantage over chlorpheniramine (75).

The management of patients with mastocytosis who require surgical procedures must take into account the potential for mast cell activation and subsequent release and generation of potent mediators such as histamine, PGD_2, leukotriene C_4, and platelet-activating factor, which, in concert, may cause severe hypotension and cardiac arrhythmias. Therefore, anesthetic management should include avoidance of histamine-releasing drugs, immediate accessibility to pharmacologic agents including epinephrine to reverse an acute severe attack, and consideration of premedication with H_1 and H_2 antihistamines. With these precautions, patients with mastocytosis may be carried safely through operative procedures (76,77).

PROGNOSIS

Prognosis depends on the category of mastocytosis to which a patient is eventually assigned. Certain variables are strongly associated with poor survival (16,43): constitutional symptoms, anemia, thrombocytopenia, abnormal liver function test results, lobated mast cell nuclei, a low percentage of fat cells in the bone marrow biopsy specimen, and an associated hematologic disorder. Other variables that may be associated with poor prognosis are the presence of hepatomegaly or splenomegaly and the absence of urticaria pigmentosa and skin and bone symptoms.

Patients with indolent mastocytosis who have only skin involvement have the best prognosis. Isolated urticaria pigmentosa in children resolves in at least 50% of patients by adulthood (78). Urticaria pigmentosa in adults with indolent mastocytosis usually evolves into systemic disease. Occasional patients convert to mastocytosis with an associated hematologic disorder; these patients have a course that depends largely on the prognosis of the specific hematologic disorder. Survival time for patients with aggressive mastocytosis is years with intense symptom management. The mean survival time of patients with mast cell leukemia is usually less than 6 months.

37 RHEUMATOID ARTHRITIS

Pércio S. Gulko, M.D., and Robert J. Winchester M.D.

Rheumatoid arthritis (RA) is a chronic systemic autoimmune inflammatory disease that develops in genetically predisposed persons. It primarily affects the synovial membranes of multiple joints in a characteristic accumulative and symmetric fashion. If untreated, RA can lead to joint destruction and systemic injury, resulting in disability, joint deformity, decreased life expectancy, and high medical care–related costs.

The prevalence of RA for most of the population groups in the world is about 0.5% to 1% (1). This value is found regardless of urban or rural status and the presence or absence of distinct environmental conditions. A few population groups have an elevated prevalence, notably Native American tribes, such as the Pima (5.5%), Chippewa (6.8%), and Yakima (3.4%) (2). In contrast, lower rates are found in some Chinese (0.3%), Southeast Asians (0.2%), and certain African tribes (0.3%) (3). Genetic and not environmental factors appear to account for the differences in prevalence. The genetic differences include the frequency of human leukocyte antigen (HLA)-DRB1 alleles that encode the shared epitope and likely other genes within and outside the major histocompatibility complex (MHC) gene region.

STAGES IN THE DEVELOPMENT OF RHEUMATOID ARTHRITIS

The development of RA progresses through a series of stages from genetic predisposition to frank joint destruction. A general scheme for the development of the disease through six hypothetical stages is illustrated in Fig. 37.1. In each of these stages, from susceptibility genes to interaction with the developmental mechanisms of the joint, it appears that normal biologic processes and genes controlling them are subverted or exploited to result in the inappropriate process that results in RA. To date, no evidence has emerged of a distinctly pathogenic gene allele that is involved in the disease process. It is conceivable that the susceptibility genes are in fact normal allelic polymorphisms that, in the presence of the other susceptibility alleles, will culminate in the development of the disease.

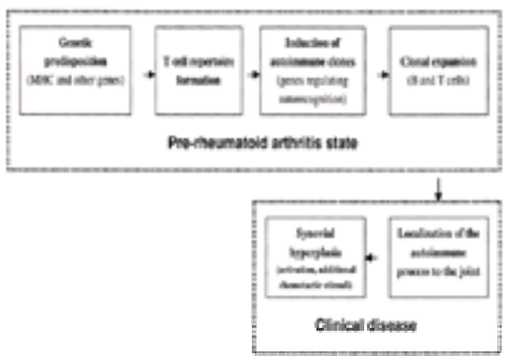

Figure 37.1. Six hypothetical stages in the development of rheumatoid arthritis.

Genetic Predisposition

There is a clear genetic basis for disease susceptibility. There appears to be a complex mode of inheritance under polygenic regulation. A major part of the genetic contribution to disease susceptibility is provided by certain MHC genes, most notably, the class II alleles encoding a common amino-acid sequence motive in the third diversity region of the HLA-DR molecule, initially designated the *shared epitope.* It is probable that these genes act to determine susceptibility by serving as the selective elements for the T-cell receptor (TCR) repertoire. We suggest that RA should be considered a disease in which alleles of a number of germline genes,

including those within and outside the MHC, establish an initial susceptibility state. For the MHC genes and likely some other genes that determine susceptibility, this will be through their interaction with the totality of self-peptides, resulting in the formation of a somatic T-cell repertoire that contains a proportion of autoreactive T-cell clones. The state of the genetically dependent, but not determined somatic immune genome, is the outcome of exposure to the range of self-peptides and processing pathways, which are presented by MHC molecules that are all under genetic control. The intricate series of stochastic events involved in the selection, expansion, and regulation of these repertoires makes the action of the susceptibility genes highly epistatic and extremely difficult to define (4).

Although MHC genes are central to the development of RA, several non-MHC genes (*loci*) also appear necessary. These latter genes have not yet been identified, however (5,6 and 7). Rodent models of autoimmune arthritis also support the concept of a complex mode of inheritance with both a dominant role for MHC alleles and clear involvement of multiple non-MHC genes (8,9,10,11,12,13,14 and 15).

Development of the Autoimmune Response

The autoimmune response underlying RA is envisioned as centered on the cognitive interaction of autoreactive T cells and B cells in response to the presentation of self-peptides by MHC class II molecules that contain the shared epitope. The nature of the peptide involved in this immune recognition event is unknown, however, and it will be argued in a later section that there may not be a single inciting peptide. Moreover, the initial triggering event that results in the abrogation of the state of tolerance in the autoreactive clones is unknown, if it indeed exists. The role of environmental factors in disease susceptibility, and in the specific evolution of the T-cell and B-cell repertoires toward those capable of sustaining development of the response that ultimately leads to RA, are also largely undefined.

One of the features of the autoimmune response that may antedate the development of overt RA is the production of certain autoantibodies. of these, rheumatoid factor (RF), an autoantibody directed to the Fc region of immunoglobulin G (IgG), is the best-studied marker of this autoimmune response. Newer work showing that the autoantibodies of RA may recognize other nonimmunoglobulin molecules will also be discussed. Although RFs can occur in normal immune responses, in RA it is commonly present in large quantities and in multiple isotypes, and it shows extensive somatic mutation as evidence of antigen-driven selection. All these features reflect the fact that the kind of RF found in RA is an intrinsic result of the cognitive T- and B-cell interactions that uniquely reflect the autoimmune response of RA. Increasing evidence is being accumulated to show that in some persons the development of RF precedes the appearance of clinically detectable RA by months to years. In these persons, the development of RF is the first marker for the development of the autoimmune response (16,17). There is also strong positive evidence that implicates RF as an intrinsic component of the immune response in RA derived from prospective epidemiologic studies. Aho and associates followed up on 7,217 persons and identified 21 instances of new RA. In 15 of these individuals, elevated titers of RF were identified in the stored preillness serum sample obtained up to 3 years before evidence of arthritis. In the six RF-negative persons, the preillness sample had been obtained more than 4 years before development of RA (16). Additionally, RFs were demonstrable among 39% of unaffected first-degree relatives in multicase RA families, and their occurrence was strongly associated with HLA-DR4 (18). Whereas the pathogenic role for RFs remains uncertain, the weight of evidence strongly favors the presence of RFs or related autoantibodies as a characteristic of the immune process leading to RA.

Localization of the Autoimmune Response to the Joint

Rheumatoid arthritis can have profound systemic features, such as lung disease, pericarditis, splenomegaly, vasculitis, and granulomatous nodule formation. Its dominant feature is the localization of the autoimmune response to the synovial membrane and initiation of joint disease. This localization could reflect an immune response driven by a synovial antigenic peptide. Alternatively, and perhaps more likely, the systemic nature of the disease and the lack of an identified suitable candidate joint-specific antigenic peptide suggest that the peptide, or peptides, driving the autoimmune response may be more generally distributed. In this view, localization of the autoimmune response to the joint would be largely attributable to the particular biology of the synovium. The joint is organized to accomplish enhanced immune surveillance of the joint cavity and removal of cartilaginous debris resulting from wear and tear. Recent studies on the gene expression phenotype of the fibroblast lineage synoviocytes identified several molecules that are likely involved in the histologic patterning of the joint and normal joint function (19,20). Information about the genes expressed in RA synoviocyte lines provided several insights into the biology of the joint and how features of this biology are subverted by the process of RA. The identification of these gene products provides evidence of how the synoviocyte can chemoattract T cells and B cells to the synovial membrane and interact with them. These interactions could underlie the development and intensification of the autoimmune response and foster its localization to the joint, as will be discussed later.

Initiation of Arthritis and Synovial Hyperplasia

In addition to the potential role of fibroblast lineage synoviocytes in the afferent limb of the autoimmune response underlying RA, these synoviocytes respond to the presence of this immune response in the joint by undergoing marked hyperplasia. This is likely a paracrine-mediated response to products such as interleukin-1 (IL-1) and tumor necrosis factor (TNF), which are elaborated largely by the monocyte/macrophage component of the autoimmune response. This component is highly dependent on transcription factors, such as NF-kB. Information is being obtained about the nature of the synoviocyte cell membrane receptors that provide the molecular basis of cell–cell and cell–matrix interactions involved in both the patterning of the normal joint and the development of hyperplasia.

Development of Sustained Arthritis

Conceivably, the autoimmune process required to initiate the arthritic process also requires local synovial changes that include macrophage activation, synovial fibroblast hyperplasia, and increased expression of genes that will contribute to the persistence of the inflammatory process in the joint. Extensive neovascularization also is required for arthritis persistence. The dominant role of lymphocytes in early stages of the illness appears somewhat diminished after initiation of the disease. There is evidence to suggest that, at some point after onset of the disease, monocytes and macrophages and synovial fibroblasts take a more central role in the persistence of the disease. Perhaps sustained disease develops in patients with abnormalities in downregulatory pathways that otherwise would have controlled the autoimmune inflammatory process.

Joint Destruction

The cartilage and contiguous bone of the joint become altered and ultimately are destroyed by the hyperplastic synovial lining cells. They elaborate a variety of cytokines capable of reprogramming the patterns of gene expression of bone and cartilage through paracrine mechanisms and elaborate degradative enzymes capable of altering the matrix of the connective tissue. Moreover, cell—cell interactions may be involved. Among the insights into the biology of the joint provided by the gene expression studies is the fact that intimal synoviocytes are closely related to mesenchymal stem cells. This finding raises the question of whether the hyperplastic synoviocytes are embryologic progenitors of the cartilage and bone cells that they seemingly seek to destroy in later stages of the disease. The biologic significance of the destructive interaction between synoviocytes, bone, and cartilage assumes new importance when considered in this light. It also raises the possibility of the development of new therapeutic approaches aimed at inducing the hyperplastic synoviocytes to differentiate into the cells they seek to destroy.

RESTRUCTURING THERAPEUTIC STRATEGIES

In recent years, growing knowledge of the immunopathology of RA as well as its genetic basis has contributed to the development of new therapeutic agents, some of which have been demonstrated to be quite effective in the treatment of disease. An accumulating body of evidence supports the concept that early institution of therapy with disease-modifying antirheumatic drugs (DMARDs), like methotrexate or agents that block effector molecules like TNF-a, is beneficial. These agents slow disease progression, decrease joint damage, improve quality of life (21,22 and 23), and enhance survival (24). We appear to be at the beginning of a most promising phase of drug development for this disease.

This chapter is an interpretative presentation of certain aspects of the current understanding of the pathophysiology and genetic basis of RA as well as its clinical characteristics and treatment. Although the general features of the etiology and pathogenesis of RA are understood along the lines of the overall paradigm of stages in the development of the disease, a number of vexing questions about the nature of the disease remain unanswered and are emphasized here. A major theme of the chapter is subversion of normal physiologic elements and mechanisms into disease processes.

GENETIC PREDISPOSITION

Formal Genetics

From the perspective of the rheumatologist caring for a patient with RA, the illness usually appears to be a sporadic event that often makes its appearance only well into adulthood. Yet, as with many diseases in which autoimmune reactions are found, there is a clear genetic basis associated with particular MHC alleles, non-MHC alleles, sex status, as well as the participation of still undefined stochastic processes. Family and twin studies on the occurrence of RA permit an estimation of the contributions of heredity and environment and characterization of some general features of the genetic predisposition. There is definite familial aggregation, with the

risk of finding an affected relative of a patient with RA estimated at 2.3 (25).

The I_{MZ} (prevalence of disease among monozygotic twins divided by the prevalence of the disease in the general population) can be viewed as an estimate of the maximum genetic risk for the disease. In RA, the I_{MZ} has been estimated to be between 12 and 62. Comparison of the elevated concordance rates for RA in monozygotic versus to dizygotic twins further supports the genetic basis of the disorder; however, the concordance rate in monozygotic twins is not absolute, being estimated between 15% and 30% in varying populations, at different times, and using different ascertainment methods (26). The frequency with which RA is found in the second twin when it is identified in the first is 15.4% for monozygotic and 3.6% for dizygotic twins according to findings in the study of Silman et al. (26). The concordance rate was slightly higher, that is, 16.9%, when twin pairs who were RF positive were studied. When these data are reported in terms of cases per 1,000 years of observation, the prevalence rates are 12 for monozygotic twins, 2.2 for dizygotic twins, and 0.5 for the general population. One factor influencing concordance is that twins develop RA at different times. Silman et al. showed that the concordance rate increases with time from the day when the first twin develops RA, when it is essentially zero, to a rate of approximately 40% when 30 years of follow-up are available (27). This finding suggests the importance of stochastic factors in the causation of RA, a point that is discussed subsequently. This does not necessarily imply that environmental factors play a predominant role because, as is discussed in more detail subsequently, MHC genes act in a developmentally complex manner to select the TCR repertoire with which they will interact. This stochastic somatically generated T-cell repertoire is the key to the immune system's ability to function in health as well as in autoimmune disease.

MHC Class II Genes

IDENTIFICATION of SUSCEPTIBILITY WITH PARTICULAR MHC ALLELES THAT ENCODE THE SHARED EPITOPE

The recognition of class II MHC molecules over two decades ago and the appreciation of their involvement in the regulation of the immune response were the basis for a large number of genetic epidemiologic studies on the relationship of the susceptibility of RA to particular MHC specificities. The history of the development of this knowledge provides an important insight into the way HLA operates to determine susceptibility. Initially, these relationships were defined by using serologic techniques (28). RA was strongly associated with the HLA-DR4 specificity in initial studies in Northern American and Northern European Caucasoid populations and certain other ethnic groups; however, this association was not replicated in Southern European and Eastern Mediterranean Caucasoids (29,30,31,32,33 and 34). The highest relative risks for DR4 and RA were found in Mexicans and the Chippewa Nation of American Indians, being 14.6 and 13.4, respectively (2,35), although some of their potential genetic antecedents had much lower relative risks, such as Southern Spaniards 1.8, Japanese 2.9, and Siberians 4.0 (36,37 and 38). As a group, the information emerging from these generally excellent studies was dismayingly different from population to population. The application of a monoclonal antibody (mAb) 109d6 to patients with RA identified an epitope shared by a proportion of RA patients (39,40). Although this antibody did not recognize HLA-DR4, its use came at an important moment during the period of divergent conclusions regarding DR4 because it provided renewed motivation to pursue the notion that the MHC alleles involved in RA susceptibility shared a structural feature. Ultimately, it provided additional insight into the nature of the amino acid motif responsible for the shared epitope.

With the anticipation that the structural differences responsible for the different subtypes of DR4 delineated by MLC typing (41,42) would illuminate the problem of RA susceptibility, an extensive effort was made to sequence the relevant DQ and DR subregion genes in the DR4 haplotype (43). RA susceptibility was associated only with certain HLA-DR4 alleles, including HLA-DRB1*0401, *0404, and *0405, but not *0402 and *0403 (44). The predominant alleles encoding the HLA-DR4 specificity vary in different populations. Thus, if a particular ethnic group has a high frequency of HLA-DRB1*0401, as in Central and Northern Europeans, *0404, as in Scandinavians, or *0405, as in Asians, only in those populations will RA be associated with HLA-DR4. Conversely, if the population has a high frequency of HLA-DRB1*0402 or *0403, as in Southern European or Eastern Mediterranean peoples, then RA will not be associated with the HLA-DR4 specificity. This was followed by an analysis of the structure of DR1 alleles in individuals with RA by Merryman et al. (45).

Detailed analysis of DR4 haplotypes was begun at the level of molecularly defined epitopes recognizable by monoclonal antibodies (39,46,47). In parallel, these haplotypes were dissected in terms of their gene structure (43,45,47). This effort provided the information leading to the recognition that all the alleles associated with RA susceptibility encoded a sequence of leu-gln- arg/lys- ala at positions 67, 70, 71, and 74 of the DRB1 chain. This relationship initially was reported by Gregersen et al. (44) as the shared epitope hypothesis. It was one of the first instances of an attempt to relate the molecular basis of disease susceptibility to a particular defined conformation or structure in an MHC molecule. The designation of this sequence motif as an “epitope” reflected the earlier data on serologic associations and attempted to communicate that the motif was a hypothetical structure that determined disease susceptibility through its function in the MHC molecule. Notably, any allele that encoded a negatively charged amino acid in this motif, including HLA-DRB1*0402 and *0403, was not associated with susceptibility to RA. Supporting the identification of this region with susceptibility, other alleles, such as HLA DRB1*0101, that were associated with RA susceptibility also exhibited this same shared motif of amino acids (28).

The subsequent delineation of the crystallographic structure of the MHC class II molecule revealed that the shared epitope motif of amino acids occupies a prominent position at the apex of the upwardly arching rim of the HLA-DR molecule formed by the a-helix (Fig. 37.2). Thus, the shared epitope forms a major portion of the pocket that binds the fourth amino acid side chain (peptide-4, or P4) of the peptide bound by the MHC molecule. Moreover, the prominent position of the shared epitope motif on the face of the molecule facing the abTCR also implied that this structure would interact with the abTCR. The implication of this structural feature is that the shared epitope operates during the embryologic development of the T-cell repertoire as an important selective structure. Here it both regulates binding of the particular self-peptides presented by the MHC molecule and directly interacts with abTCR contact residues. It appears that a abTCR clonal repertoire selected by MHC molecules with neutral or positive charges in the shared epitope region is capable of developing the autoreactive state that results in RA. Conversely, the T-cell repertoire selected by MHC molecules with negative charges in this region is not capable of mediating RA.

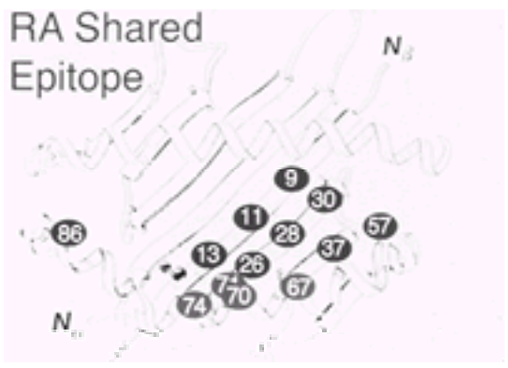

Figure 37.2. Human leukocyte antigen DR locus (HLA-DR) and the “shared epitope” location in the a helix, amino-acid positions 67 through 74.

Subsequently, particularly strong support for the identification of RA susceptibility with the shared epitope was provided by epidemiologic studies in various Native Americans delineating an association with DRB1*1402, which encodes the HLA-DR6 (Dw16) serologic specificity but also encodes the shared epitope sequence motif (48). The genetic susceptibility of RA in Native Americans is of particular interest because the predominant HLA-DR4 allele is HLA-DRB1*0403. This allele is decreased in frequency in RA, whereas the DRB1*1402 is present in 91% of Native Americans with RA (49). Further work proved that the actual epitope recognized by mAb 109d6 was a slightly different structure from the shared epitope described already, which led to both the identification of DR10 as an allele related to RA susceptibility and expansion of the concept of the shared epitope (47,50,51). Figure 37.3 shows that the critical part of the epitope recognized by mAb 109d6 is determined by the presence of arginine at two polymorphic residues at positions 70 (arg) and 71 (arg), probably in conjunction with the side chains of the surrounding nonpolymorphic residues. This consensus structure differs from the center of the postulated sequence of the shared DR4-DR1 epitope leu-gln-arg/lys-ala by the substitution of an arg (R) for gln (Q) at position 70. In the case of DR10, which is clearly associated with RA, the analogous sequence is leu-arg- arg- ala. It seems likely that both the DR4-DR1 leu-gln-arg/lys-ala sequence and the leu-arg-args-ala sequence are involved in determining susceptibility. The consensus sequence between the DR4-DR1 sequences motif and the DR10 sequence motif is leu-arg/gln-arg/lys- ala, (Fig. 37.3), emphasize the importance of positively charged amino acids in this region of the MHC molecule for disease susceptibility. The crystallographic image of HLA-DRB1*0401 presenting two different type II collagen peptides is depicted in Fig. 37.4.

More recently, it was demonstrated that the overexpression of either one of two shared-epitope alleles (HLA-DRB1*0101 and *0401) in transgenic mice makes the animals highly susceptible to collagen-induced arthritis (CIA) (52,53 and 54). These findings provided additional evidence to support the importance of these alleles in disease regulation.

CONTRIBUTION OF MHC GENES TO SUSCEPTIBILITY

The I_s approach can be used to estimate the relative contribution of HLA alleles to susceptibility. Using a published series of HLA-typed RA-affected sibling pairs, a figure of 1.8 is derived (55). This value can be expressed as a proportion of the total I_s for the condition. An approximate figure of 37% is derived (56). This is, of course, the lowest estimate of the contribution of HLA alleles. This estimate does not take into account unshared pairs of alleles that are, however, equivalent in a functional immunologic sense, that is, identical by function, such as the presence of the shared epitope. The calculation nevertheless suggests that although HLA alleles, as we currently understand them, are a large single genetic factor for RA susceptibility, a considerable portion of the genetic component in RA may be non-HLA derived (56). Alternatively, a portion of the susceptibility could depend on currently unrecognized functional similarities of different HLA molecules.

The presence of the shared epitope on the class II alleles associated with susceptibility to RA is found in most individuals with RA. The frequency of shared epitope positivity in RA varies from population to population because the frequency of those alleles varies in different ethnic populations, from about 25% to 90% (28,49,57,58). Because genetic and disease prevalence data are not uniformly available in enough ethnically defined populations, RA develops in roughly from 1 in 20 to 1 in 100 of those inheriting alleles that encode the shared epitope. Reciprocally, RA develops in from 1 in 500 to 1 in 1,000 persons who lack a shared epitope allele.

There is evidence in certain populations that the severity of RA may be influenced by the allele involved in determining susceptibility. In a prospective 6-year study of the course of RA in HLA-typed individuals, the frequency of DR4 was 59.2% in those who had progressive disease and 34.8% in those with mild disease (59). DR4 positivity was associated with nearly all measures of severity, including joint scores, functional assessment, radiologic classification, and use of second-line drugs. Similar results were found in Japanese patients (60). In another study, HLA-DR1 was increased only in those with mild RA (61,62). Further support for an association between the presence of the shared-epitope alleles and increased disease severity in both RF-positive and -negative patients comes from studies done predominantly in tertiary care centers in both established (59,63,64) and recent-onset disease (65,66,67 and 68). Other reports are not consistent with these findings (69), particularly in community-based studies (70,71), emphasizing that this question requires additional study.

POSSIBLE MECHANISMS FOR THE ACTION OF THE SHARED EPITOPE

Multiple Equivalent Peptides

The identification of the shared epitope motif emphasizes the general functional equivalence of several otherwise structurally disparate alleles, at least from the perspective of encoding the molecular basis of susceptibility to RA. So what is the implication of this observation in terms of the trimolecular complex of MHC, peptide, and TCR involved in a presumptive immune recognition event? The implications for this association are not easy to translate into a conventional peptide-binding model. The fact that the DRB1 alleles encoding the shared epitope motif differ in all peptide-binding pockets other than that binding the P4 side chain argues against the recognition of a single peptide in RA. It is more likely that multiple equivalent peptides that share the P4 side chain, but perhaps differ elsewhere, are recognized in RA patients with different DRB1 alleles and are the putative driving peptides.

Stochastic Somatic Genetic Mechanism

The location of the shared epitope on the face of the molecule interacting with the TCR also directs attention to the potential role of the shared epitope in selecting the CD4 abTCR repertoire, as mentioned. This suggests that a subset of the CD4 T-cell ab TCR repertoire is critically dependent on the presence of the shared epitope structure. This subset of the abTCR repertoire likely mediates the critical immune recognition events in RA. Because the somatic generation of the repertoire is stochastic, this introduces a stochastic somatic genetic mechanism between the germline genes and the expression of the RA susceptibility phenotype.

This stochastic somatic genetic mechanism likely accounts for the much less than complete concordance exhibited by monozygotic twins who are identical at the germ line but differ in terms of the somatic genetics of TCR repertoire formation and its peripheral maintenance.

In the calculation of the proportional effect of the environment on susceptibility, the degree of nonconcordance between monozygotic twins is used to imply a significant role for environmental factors. In the case of RA and other autoimmune diseases, however, it is likely that much of the non–germ line “environmental” contribution actually comes from the stochastic somatic genetics of TCR repertoire formation. Exposure to a variety of environmental bacterial or viral antigens could cause further expansion of the TCR clone through cross-reactive mechanisms. It should be emphasized that the MHC susceptibility genes are not pathologic variants, nor does the process of TCR repertoire selection appear to be intrinsically pathologic, as shown by the healthy non–disease-concordant twins.

ISSUE OF SHARED EPITOPE “HOMOZYGOSITY” AND RA SEVERITY

Given the relatively high frequency of alleles in the general population encoding the shared epitope, a considerable proportion of persons with RA would be expected to be “homozygous” for two shared epitope alleles based on chance occurrence. There is evidence that persons who have inherited two alleles that encode shared epitopes have a higher risk of developing RA, approximately twice that of those with a single shared epitope allele (72,73). These data suggest that the contribution of HLA may fit better with a recessive model or, less likely, an additive dominant model (74). Bearing on the importance of sharing two HLA alleles is a study of concordance among members of a sibship for RA, which is 15.5% if the two siblings share two HLA haplotypes, 7.1% for one, and 5.2% for no sharing (75). The HLA status of a twinship has a major role in RA concordance. In DR4-negative monozygotic twins, the concordance rate was 6%. For twins who are DRB1*0401/0404

(Dw4/Dw14), the concordance rate was elevated to nearly 50%. A clear dose effect was evident when twins were stratified according to whether they had zero, one, or two haplotypes encoding the shared epitope, the concordance being, respectively, 5%, 13%, and 28% (26). The heightened susceptibility is entirely consistent with the preceding discussion of the role of susceptibility alleles on repertoire and self-peptide antigen presentation.

Whether a double dose of susceptibility alleles or a particular susceptibility allele contributes a higher risk for more severe disease remains unanswered. The biochemical studies of Nepom et al. (30) on early onset RA provided the first suggestion that a double dose of susceptibility alleles or a particular susceptibility allele might contribute a higher risk for severe disease. They described persons who had DR4 encoded by both MHC haplotypes usually involving Dw14 (*0404 or *0408) or Dw4 (*0401); this notion was expanded by several groups (76,77). Weyand et al. (64) studied 102 patients with seropositive, erosive RA by genotyping for both HLA-DRB1 alleles. They were categorized according to the expression of one or two disease-linked HLA-DRB1 alleles; 46% had a double dose of the shared epitope. Twenty-eight patients expressed HLA-DRB1*04 variants on both alleles, and 19 combined an HLA DRB*04 variant with HLA-DRB1*0101 or DRB1*1402. Nodular disease was present in 100% of patients typed as HLA-DRB1*04/04 and in 59% of patients typed as HLA-DRB1*04 and who had inherited only a single dose of the disease-linked sequence. Other extraarticular manifestations were present in 61% and 11% of these two patient groups, respectively. Joint surgery was required in 61% and 25% of the two groups, respectively. Although in this population the Dw4/Dw14 heterozygosity was not as prominent as in the Nepom study, the same fundamental conclusion was reached, that is, that two doses of the susceptibility alleles were associated with increased disease severity. Subsequently, Weyand et al. also demonstrated that the presence of shared epitope alleles correlated with increased disease severity in RF-negative patients as well (78).

In other studies, however, the effect of two doses of susceptibility alleles is often relatively modest or not detectable. For example, in a prospective, population-based study of 532 British patients with inflammatory polyarthritis, the most obvious effect of the presence of alleles encoding the shared epitope was on the development of erosions for those who carried at least one DRB1 shared epitope allele. Only a slightly greater effect was seen in those “homozygous” for two shared epitope-bearing alleles (79). Furthermore, studies based in nontertiary care centers (70,71) and studies of African-American (80) and Hispanic-American (81) patients with RA found no association between the presence of shared epitope alleles and increased disease severity. There is also the issue of recent-onset disease versus long-duration disease where there is also conflicting data, with several studies describing increased disease severity in shared epitope-positive patients (67,68), whereas others find no such increased risk (69). In view of the importance of the question and the disparate results of studies in different ethnic groups, this question of gene dose effect and disease severity remains an area of interest.

NON-HLA GENES WITHIN THE MHC

In addition to the HLA-DRB1 contribution, other non-HLA MHC genes may be involved in the disease susceptibility. Mulcahy et al. reported that the TNFc1 alleles encoded in the MHC in the class III region contribute to RA susceptibility independently of the shared epitope (82). Although the mechanism of the contribution of this polymorphism is not delineated, in view of the importance of TNF in the pathogenesis of RA, it is a potentially important observation. One additional study of multiplex RA families provides support for the involvement of this allele in susceptibility (7).

Because of its involvement in peptide processing in antigen-presenting cells, HLA-DM, an interesting RA candidate gene, has been studied. There have been three studies from France. Two found an increased frequency of HLA-DMA*0103 in RA (83,84), and the third one identified an increased frequency of HLA-DMB*0101-0101 homozygote genotype among RA patients: 70.8% compared with 50% of the controls (85). Two other studies, one from Canada (86) and one from Thailand (87), however, found no associations between RA and HLA-DMA or DMB alleles. This association remains controversial.

The fact that HLA-DQ8 (DQA1*0301 and DQB1*0302) transgenic mice develop severe CIA (88) led Zanelli et al. to propose that this gene would be critical in RA (89). This group found that peptides derived from RA-associated HLA-DRB1 alleles fail to induce a DQ8-restricted T-cell response and hypothesized that HLA-DQ8 presentation of shared-epitope-derived peptides has a critical role in shaping the pathogenic T-cell repertoire. Although this hypothesis is interesting, it has not been supported by recent studies (68,90,91).

Quadri et al. found an association between the HSP70-1B promoter allele and RA (92). These authors did not make adjustments for the presence of the shared epitope alleles, however, and their findings could have been accounted for by linkage disequilibrium between the HSP70-1B and the shared epitope alleles.

Non-MHC Genes

STRATEGIES FOR IDENTIFYING NON-MHC SUSCEPTIBILITY GENES THAT REGULATE DIFFERENT STAGES OF DISEASE DEVELOPMENT

The identification of HLA-DRB alleles associated with susceptibility followed from the knowledge that these genes regulate aspects of immune responsiveness. Additional genes regulating cellular functions in each one of the hypothetical stages of RA development also could be candidate susceptibility/severity genes and potential targets for therapy. Identification of these additional genes among the estimated 30,000 genes constituting the human genome is challenging, however, several approaches facilitate this endeavor.

Linkage analysis is an approach to gene identification that can be used to map regulatory genes without prior knowledge of their location in the genome. This powerful technique identifies the cosegregation between a phenotype and genotype. It is critical to have a well-defined phenotype before the mapping effort. RA is a heterogeneous disease with manifestations that may vary from one patient to the other, creating potential confusing factors. Because large numbers of multicase families or affected sibling pairs are required for linkage studies, the fact that most RA patients do not have affected first-degree relatives necessitates that the studies be performed at a multiinstitutional center. Furthermore, because the usual age of onset of RA is between age 40 and 50, most RA patients do not have both parents alive for transmission disequilibrium testing, another type of linkage/association testing. Despite the difficulties involved in this kind of analysis, the studies published so far have been encouraging (see following discussion).

A second approach that may facilitate the genetic dissection of RA is an extension of the classic clinical investigation approach of delineating the pathophysiology of the disease. This involves searching for the genetic control of particular immunologic or biologic manifestations of RA that are termed *subphenotypes*. For instance, whether certain genes are responsible for particular elements in the distinctive fibroblast lineage intimal synoviocyte phenotype or in RF production. For example, a certain gene may be important to the capacity of a fibroblast lineage intimal synoviocyte to degrade cartilage and its subphenotype and that property contributes to RA susceptibility. Because other different genes also may contribute to RA susceptibility, the contribution of this particular gene to the complete phenotype of RA is more difficult to identify. By deconstructing the complex phenotype of RA into a series of distinct subphenotypes, the likelihood of identifying the genetic basis of RA should be enhanced.

A third approach is to use animal models of autoimmune arthritis in inbred rodent strains to identify a candidate gene or locus that regulates susceptibility or severity. The massive efforts in analyzing the genomes of a number of species provided detailed information regarding homologous (syntenic) chromosomal regions among each of the various species. This facilitates moving from studying a region in a rodent genome to the homologous region in the human genome. The utility of the animal models derives from the large numbers of offspring that can be generated in a short time from controlled crosses among inbred strains that differ in the susceptibility to disease (8,9,10,11,12,13,14 and 15). This minimizes genetic heterogeneity and controls environmental factors that may interfere with the genetic analyses of RA in humans. Additionally, the use of animal models has been considered critical to prove a phenotypic effect caused by a particular genomic interval in polygenic diseases. The possibility of genetic manipulations through the breeding of congenic animals carrying a single or multiple susceptibility loci in different genetic backgrounds, and the adjustments for the presence of different MHC genes create a unique experiment, decreasing the number of confounding factors, which could not be achieved in human studies. This strategy has been used in the study of several forms of autoimmune diseases, including autoimmune arthritis, and among other advantages permits a clearer study of gene-to-gene interactions (*epistasis*). Interestingly, most of the susceptibility or disease severity regulatory loci mapped by different groups in autoimmune arthritis in mice or rats are located to regions involved in the regulation of other forms of autoimmune diseases. This suggests that at least some of these loci may contain genes common to more than one autoimmune disease. Rodent models of autoimmune arthritis also provide a better opportunity to study different time points during disease development, from very early prearthritic stages to chronic and erosive disease. For example, two inbred rat strains that share the same MHC haplotype, DA and ACI, have a similar autoimmune response to autologous rat collagen immunization, as measured by the IgG anti-rat collagen antibodies, but only one (DA rat) develops CIA. Analysis of the non-MHC genes responsible for the localization of the autoimmune response to the joints identified one regulatory locus that reached logarithm of odds (LOD) scores significant for linkage and three others that reached suggestive levels (8). An analysis of the genes located within those genomic intervals may provide candidate genes for testing in RA. Similar to the approach in humans, the identification of subphenotypes in experimentally induced disease also should facilitate this approach to gene identification in animal models.

A fourth approach for additional gene discovery efforts has been the use of differential gene subtraction or expression strategies to identify candidate genes (20,93,94,95 and 96). The rationale motivating this approach is that the identification of a gene highly differentially expressed in a cell type involved in RA implies the possibility that the overexpression has either a germline or somatic genetic basis and may identify certain candidate susceptibility genes. This strategy would be of particular importance in dissecting the regulation of different stages of disease course, particularly the later stages, where T cells may be less conspicuously involved, with a more central role for macrophage and fibroblast lineage intimal synoviocytes (97,98 and 99). A similar strategy could be used to determine which genes, downregulation or upregulation, are critical for clinical improvement and response to drug therapy.

Each of these four approaches results in the identification of specific candidate genes. The relevance of these genes to RA susceptibility may be tested simply by the

statistical methodology of association tests, similar to studies that demonstrated the role of HLA-DRB1 shared epitope alleles in RA susceptibility.

NON-HLA SUSCEPTIBILITY AND SEVERITY GENES

In the case of non-MHC genomic regions regulating disease susceptibility, linkage studies involving families with multiple affected first-degree relatives identified a number of candidate regions. This is a particularly promising moment in RA genetics because of the immense effort being put into the human genome project and identification of susceptibility genes in large cohorts of polygenic diseases, including RA. Most of the loci identified by one group could not be replicated by the other, however, which emphasizes the need for extensive cross validation of the results in independent study populations. Indeed, to date, only limited cross validation of the results from study to study has been done.

The first study was done with a relatively small number of families and identified linkage to chromosome 7 region 7q35, where the TCRb chain gene is located (100). Linkage to this region has not been confirmed in subsequent studies. Whereas other genes, such as IL-2, IL-4, IL-10, corticotropin releasing hormone (CRH), and natural resistance-associated macrophage protein-1 (NRAMP-1) have been studied in association or linkage analyses, the results were either negative or achieved borderline statistical significance (101,102 and 103). A recent study of cytokine genes found no association of the IL-1-receptor antagonist (IL-1RA) and IL-10 genes but did find an increased frequency of one IL-4 gene (5q31-33) polymorphism (RP1) in RA patients compared with controls, but the result did not reach significant *p* values (104). The same study found that the IL-1b exon 5 allele E2 correlated with increased risk for erosive disease in the shared-epitope–positive patients [odds ratio (OR) of 8.2] (104).

The European Consortium on RA Families studied 114 affected sibling pairs from 97 families and reported a genome-wide scan that identified significant linkage with only the HLA region and nominal linkage for 19 markers in 14 other regions (6). Four of the loci implicated in insulin-dependent diabetes mellitus (IDDM) overlap with these regions. Two of these loci (18q22-23 and 3q13) were further analyzed in a second set of 194 RA sib pairs from 164 nuclear families. The *p* values for the 3q13 locus improved and reached levels suggestive of linkage, although not definitive, and appeared to interact with the HLA locus. Candidate genes for the chromosome 3 locus include CD80 and CD86, molecules involved in the costimulation of T cells. Also, this study estimated the HLA and the chromosome 3 locus contribution to RA to be 33% and 16%, respectively.

In a study of 41 Japanese families with at least one affected sib pair, Shiozawa et al. identified significant evidence for linkage with loci located in chromosomes 1p36, 8q21, and Xq24-q27 (5). Chromosomes 1 and X loci overlap with two of the loci identified by the European Consortium.

A third genetic analysis of multiplex RA families by Bali et al. (7) focused on certain candidate gene regions and the MHC. These investigators found evidence of independent effects of the shared epitope and TNFc in disease susceptibility, supporting the previous findings of Mulcahy et al. (82). These researchers also found *p* values suggestive of linkage in different regions, with the most significant ones being 2p13-p11.1 and 15q15. Using a relative pair analysis, but not the sib pair analysis, Bali et al. also found *p* values suggestive of linkage at 1p12-q21 and 10q23-q24. of these loci, only 2p13 overlaps a locus described by the European Consortium. Currently, the North American Consortium for RA is collecting 1,000 affected sib pairs, which is expected to identify loci that contribute with a small relative risk and to validate some of the loci previously described. This consortium will also address a significant portion of the issue of sample power to detect linkage.

SEX AND SEX CHROMOSOMES

Several intriguing relations have been found between gender, gonadal hormones, and RA. These are discussed subsequently in the section entitled “Other Features of RA, Pregnancy-associated Remission.” RA, like many other autoimmune diseases, is more common in women than in men; the generally accepted ratio is 3:1. It is extremely rare before puberty, and its incidence peaks in women around the perimenopause years. Some women with RA experience a striking remission during pregnancy, and epidemiologic studies showed that pregnancy has a protective effect on susceptibility. This finding suggests that sex hormones, or factors associated with the inheritance of two X chromosomes, could favor the expression of RA in female subjects. Although both the European consortium (6) and the Japanese study (5) identified a susceptibility locus in chromosome X, Xq24-q27, there has been limited insight into the genes responsible for this effect in humans. Studies of experimental arthritis in animals support the importance of gender and hormonal influences. Recent work in an F2 intercross between DA (collagen-induced arthritis [CIA] susceptible) and ACI (CIA-resistant) rats demonstrated that the presence of the Y chromosome was significantly protective against disease development and reduced disease severity (8). Joe et al. studied CIA in congenic rats (105), and their results suggested that certain non-MHC regulatory loci regulate disease severity in a sex-dependent manner. It remains unknown whether the susceptibility gene's effect is dependent on gonadal hormones or on epistatic interactions with genes located either in the X or the Y chromosomes.

NON-MHC LOCI REGULATING RODENT MODELS OF AUTOIMMUNE ARTHRITIS

Several models of autoimmune arthritis have been used to gain insight into the pathogenesis of RA. These consist of CIA, complete Freund's adjuvant-induced arthritis (AIA), pristane-induced arthritis (PIA), incomplete Freund's adjuvant oil-induced arthritis (OIA), and proteoglycan-induced arthritis (PROIA). Using either intercrossing or backcrossing strategies between susceptible and resistant inbred animals, different investigators identified a number of regulatory genes, a significant percentage of which map to regions homologous to those regulating RA or other autoimmune diseases in humans or rodents (106). These findings further exemplify the relevance of the rodent studies, which are likely to facilitate the gene discovery effort in RA.

INITIATION OF THE AUTOIMMUNE RESPONSE

The fact that RA usually begins decades after birth raises the question of what precipitates the development of the disease. This question is common to studies on all autoimmune diseases and concerns the lack of information about how “tolerance to self” is broken to result in autoimmunity and subsequently in an autoimmune disease. That is, we do not understand the ongoing processes involved in the regulation of autorecognition and how these operate in the sculpting of lymphocyte repertoires. The regulation of the self-tolerance and the self-immune recognition is one of the likely key steps toward explaining why identical twins, who share the same germ-line genome, are not fully concordant for the expression of the disease [see Ollier and Winchester for a more extensive discussion of the initiation of autoimmunity (4)].

In RA, the coefficient of familial clustering, l_s, estimated from the ratio of the disease prevalence among siblings and to its prevalence in the general population (107), ranges from 5 to 10 (56). By comparison, conditions such as IDDM and primary biliary cirrhosis (108) have l_s values of 15 and 100, respectively. The lower l_s in RA likely reflects an enhanced dependency on events involved in the generation of the somatic immune repertoire capable of self-reactivity or perhaps lower disease gene penetrance as another somatic regulatory factor.

Given the presence of a MHC molecule with the shared epitope, in order for disease to occur, a potentially autoreactive clone first must arise in the positive selection phase of repertoire formation. This T-cell clone would likely be selected on the peptide that ultimately could drive the rheumatoid process. Then the second requirement is that the clone must evade negative selection. These processes may be largely stochastic or dependent in part on the action of additional undiscovered genes. The potentially autoreactive clone is now in the quiescent state of clonal ignorance, which is one form of “tolerance,” and it remains unexpanded and inactivated. Activation and expansion of this clone could be the consequence of any of a large number of events. These might include exposure to a superantigen, stimulation by a mimetic peptide from an infectious agent, and pure bystander cytokine-mediated activation of the autoreactive clone by physiologic immune responses.

Regulatory events may inhibit this clonal expansion, presenting another possible opportunity for the effect of novel genes on the disease process and a further contribution to the low level of penetrance. Antigenic cross-reactivity between the shared epitope and prokaryotic protein sequences (109) have been proposed to act as a “drive” at these latter levels of repertoire expansion. The leu-gln-arg/lys-ala shared epitope sequence, along with the intervening amino acids, is present in both gp110, an Epstein–Barr virus EBV glycoprotein (110), and dnaJ, an *Escherichia coli* heat shock protein (111). This could lead to the activation and expansion of low affinity and potentially self-reactive T cells, capable of recognizing heat shock proteins expressed in the inflamed joint (109) that might drive and precipitate a sustained arthritis. Although these molecular mimicry hypotheses are interesting, their role in disease pathogenesis remains to be determined.

Specific Infectious Agents

The appearance of RA in a previously healthy person led many clinical investigators to search for an infectious agent, with the hypothesis that the synovial immune response was evidence of chronic infection of the joints. Attempts to isolate organisms such as mycoplasmas and numerous other bacteria, including diphtheroids, streptococci, and L-phase bacteria from joint fluids, however, have been unsuccessful or attributed to laboratory contamination. Similar negative conclusions have been reached about the role of parvoviruses, oncornaviruses, coronavirus, and myxoviruses in RA (112,113,114,115,116 and 117).

Other viruses also received special attention, particularly EBV. Sera of patients with RA often have antibodies to a nuclear antigen expressed in EBV-infected B lymphocytes demonstrable by a precipitation reaction (118). The nuclear antigen was designated RANA (RA-associated nuclear antigen), and its main epitope recognized by the RANA antibodies is the glycine/alanine repeat sequence on the EBV p62 nuclear antigen-1 (EBNA-1). The possibility has been considered that this molecular mimicry between an epitope encoded by EBV and an autoantigen could contribute to the breakdown of tolerance and autoimmunity in RA (119). The

subsequent finding that there was enhanced spontaneous outgrowth of EBV-infected B-lymphoblastoid cell lines from RA peripheral blood lymphocytes due to a T-cell deficiency in suppressing their emergence (120,121) reinforced interest in EBV. However, this latter observation was explained by a secondary nonspecific deficiency in T-cell function common to most chronic autoimmune diseases (122), making specific infection by this agent unlikely to be the etiology of the disease.

Nevertheless, the fact that EBV infection has occurred could alter the T-cell repertoire in a selective manner in that person because of the example of molecular mimicry between EBV gp110 and the “shared epitope” on the MHC molecules. Both contain the amino acid motif leu-gln-arg-ala-ala (123). It is possible that persons who inherit this MHC structure have developed a T-cell repertoire enriched for clonal receptors that recognize “self” during the phase of positive selection of the repertoire. Exposure of persons who have the T-cell repertoire biased by the presence of the shared MHC epitope to this EBV sequence might be anticipated to have a different consequence in terms of enhancing specific clonal responses than would occur in persons who lack the shared epitope.

Both EBV RNA and DNA have been identified in the synovium of RA patients (124,125), in both leukocytes and nonleukocyte lining cells. Koide et al. established a spontaneous EBV-infected synovial fibroblast cell line from an RA patient (126). T cells reactive to EBV lytic antigens also were identified in the RA synovium (127). It remains unknown whether these findings are in fact important in the regulation of synovitis and whether similar findings are present in other tissues, representing a nonspecific homing of EBV-infected leukocytes to the synovial membrane.

Retroviral infection as an etiologic factor is another controversial topic. No evidence of the presence of retroviruses has been obtained (128,129). In southern Japan, however, where human T-cell leukemia virus-1 (HTLV-1) is endemic, infection by this agent may induce an erosive polyarthritis, rheumatoid factor negative, that resembles RA. The *tax* gene is the likely candidate to initiate alterations in gene expression in the infected cells through a transactivation mechanism (130,131). This is suggested by the spontaneous erosive arthritis seen in *tax*-transgenic mice (132). Moreover, Trabandt et al. suggested the presence of increased levels of retrovirally related sequences in RA synovial tissues (133). Although further work is certainly warranted, at this time there is no conclusive evidence that implicates a microorganism as a causative agent in RA.

Sex Hormones as Modulators of the Immune Response

Male patients with RA are reported to have lower levels of testosterone than controls (134,135), although cause and effect have not been analyzed. The peak of disease onset around the perimenopause period in women suggests a correlation between decreasing levels of gonadal hormones and disease onset and that both estrogen and testosterone could have a suppressive role on the immune responses that cause RA. Both estrogens and androgens are, in fact, capable of modifying the immune response, including the production of T-helper cell 2 (Th2) cytokines by autoreactive T cells (136). Synovial macrophages and synovium-infiltrating CD29+ memory CD8+ T cells express estrogen receptors (137), suggesting that estrogens could directly modulate some functions of these cells. Based on this evidence, gonadal hormone therapy has been tested in RA; however, the results were less than optimum.

FEATURES OF THE AUTOIMMUNE RESPONSE

There are three central areas of knowledge about the autoimmune response in RA: First, the basis of disease susceptibility is defined by class II MHC alleles encoding the shared epitope. Second, the features of RF production, along with other autoantibodies by the B-cell component, reflect extensive evidence of cognate T-cell help, including somatic mutation of RF to higher affinity, high titer, and polyclonality, along with the finding of extensive isotype switching. Third, activated T cells elaborate cytokines such as IL-1 capable of altering the pattern of gene expression in synovial fibroblasts and macrophages. Taken together, these events imply the paradigm of an immune recognition event that involves the presentation of peptide by MHC class II molecules to CD4 T-cells. These T-cells then participate in the provision of antigen-specific cognate help to B cells as well as activating monocytes and other cells by paracrine mechanisms of delayed-type hypersensitivity.

Consistent with this paradigm, the tissues beneath the synovial lining cell layer become the site of a remarkable and often well-organized infiltration of both T and B cells that in every respect appear to be engaged in a purposeful immune response. Germinal centers develop, and RAG genes are expressed by the infiltrating lymphocytes (138), suggesting that B cells undergo local affinity maturation and that T-cells may be selected for optimum cognate interaction. The pattern and degree of lymphocytic infiltration are variable among individuals, however, as well as during the course of disease. Indeed, sometimes the lymphocytic infiltration regresses late in the course of the illness while the intimal synovial lining hyperplasia persists. Lymphocytes are often also a conspicuous cell in the synovial fluid, where they are accompanied by neutrophils. Unfortunately, although the description of the immune processes found in the synovial tissues is becoming increasingly comprehensive, consistent, and elegant, there is still no clear notion of what peptides are driving the T-cell or indeed the B-cell component of the response.

As discussed in the introductory section of this chapter, there is considerable evidence, based on the appearance of RF in healthy persons before the development of joint disease, to suggest that the autoimmune response of RA may be initiated without first affecting the joints. It will be argued that localization of the autoimmune process to the joints and its subsequent intensification appear likely to be fostered by the unique biology of the synovial lining. Thus, in addition to being the target of the efferent effects of the autoimmune response, the synovial lining appears also to participate in the afferent circuits, leading to its localization and intensification. These aspects of the interaction between the immune response and the synovial lining are discussed in the following section on the synovium, which describes the features of the T-cell and B-cell response.

T-lymphocytes

Phenotype and Activation State

The T-lymphocytes in the synovial tissue and fluid consist of relatively equal proportions of CD4 and CD8 cells. The T cells of both the blood, and particularly the joint fluid, express a variety of activation markers; however, there is a curious dichotomy in the expression of the T-cell activation markers HLA-DR and IL-2 receptor (CD25). The major proportion of the T-cells expressing HLA-DR molecules as activation markers are found in the CD8 T-cell lineage, whereas CD4 T-cells predominantly express IL-2 receptors (CD25) as their activation marker (139,140). As anticipated, both the activated CD4 and CD8 T cells in the joint exhibit a predominant memory cell phenotype of $CD45RO^{bright}$ and CD29 (141). Moreover, both CD4 and CD8 T-cell repertoire in the synovium contain oligoclonal expansions, reflecting an antigen-driven process (142,143,144 and 145). Conversely, in the blood, the highest level of IL-2 receptor (CD25) expression is on the CD45RO-negative naive compartment of CD4 T cells (146). Cells of this phenotype are considered not to have had previous exposure to antigenic stimulation. It may be that expression of IL-2 receptor is the initial step in the induction of the CD4 T cell into the CD45RO-positive, CD29-positive memory cell phenotype.

Most T cells infiltrating rheumatoid synovium express the chemokine receptors CXCR3 and CCR5 (147). These receptors are preferentially expressed in Th1 cells (148), a fact consistent with the functions of the T cells described in the autoimmune paradigm. IP-10, a chemokine ligand for CXCR3, is produced by RA synovial fibroblast cultures (149) whereas Mig, another CXCR3 binding chemokine, has not yet been studied in the rheumatoid synovium. The CCR5 chemokine ligands regulated on activation normal T-cell expressed and secreted (RANTES) (150,151), macrophage inflammatory protein-1a (MIP-1a) (151,152), and MIP-1b (151) are expressed in large amounts by the RA synovium. As discussed subsequently, synoviocytes produce stomal cell–derived factor-1 (SDF-1), a chemokine that binds to the CXCR4 chemokine receptor expressed by naive T cells as well as members of the monocyte lineage. Antibodies to RANTES ameliorated adjuvant-induced arthritis in rats (153), suggesting that the production of RANTES may be generally important in the biology of synovitis. The concept that chemokines have an important role in the localization of antigen-specific T cells and in the inflammatory process to the synovial membrane is suggested by several facts. These include production of chemokines by synovial fibroblasts, that the infiltrating lymphocytes express the corresponding receptors for the cytokines, and the improvement of arthritis in experimental animal models with the use of antichemokine therapy.

ROLE OF T CELLS

Given the degree of circumstantial evidence supporting a pathogenic role for T cells in RA, the expectation of investigators was that the T-cell compartment in the synovium would resemble an *in vitro* stimulated T-cell culture in terms of signaling and cytokine production. The characteristics of the T cells infiltrating synovium include hyporesponsiveness, reflected by a reduced response to mitogenic stimulation and decreased Ca^{2+} influxes (154,155); impaired TCRz-chain–mediated signaling (156); a lower T-cell proliferation rate; and reduced expression of T-cell–derived cytokines, such as IL-2 and interferon-g (IFN-g) (157). These findings initially raised the question of how critical T cells really are in RA and led to the postulate that T cells might have a more critical role in early stages of RA, but during the chronic stages, monocytes and synovial fibroblasts would be the cells coordinating the inflammatory process. Smeets et al., however, identified no significant difference between synovium-infiltrating T cells from early and late stages of RA, and both groups had low percentages of T cells expressing activation markers or IFN-g (158). Moreover, studies in CIA showed increased numbers of T cells and oligoclonal expansions during the early stages of the disease, followed by a polyclonal T-cell infiltrate (159) with increasing numbers of monocytes and monocyte/macrophage-derived cytokine production (160).

A more likely explanation for this seeming degree of hyporesponsiveness in RA synovia is that this is the physiological state of lymphocytes in a chronic ongoing immune response *in vivo*. CTLA-4 is expressed in the T-cell-activation cascade and serves to downregulate T-cell responsiveness. This occurs because CTLA-4 competes with CD28 molecules on T cells for interaction with the costimulatory B7 molecules on the antigen-presenting cell, depriving the T cell of the second signal provided by the costimulatory circuit. Moreover, interaction of CTLA-4 with B7 initiates a signaling pathway that further inactivates T cells by binding to the TCRzchain, thus preventing phosphorylation of this signal transduction molecule (161). CTLA-4 is indeed expressed in high levels by synovium-infiltrating T-lymphocytes (162,163).

It is likely that the physiologic expression of CTLA-4 by activated T cells infiltrating the synovium accounts for a significant part of the decreased T-cell functions seen in RA.

The attenuation of the TCR signaling and T-cell functions, including cytokine production, could also be explained in part by the chronic exposure of the synovial T cells to high levels of TNF, a phenomena that has been shown in a TCR transgenic animal model to regulate T-cell functions (164,165). Asymptomatic synovitis may precede the onset of clinical RA; conceivably, when disease manifests itself, high levels of TNF are already present in the synovium, interfering with T-cell functions. It will be of interest to study T-cell functions of patients treated with anti-TNF agents, with the prediction that their responsiveness may increase.

On the other hand, several factors could explain why T cells are important in disease pathogenesis, despite the small production of IL-2 and IFN-g by the synovium-infiltrating lymphocytes. (a) T cells in the tissues are largely memory phenotype T cells, which elaborate little IL-2. These cells would require little IL-2 to maintain their function because they have high-affinity IL-2 receptors. (b) The presence of many cells with IL-2 receptors may consume detectable IL-2, which perhaps accounts for the divergence between mRNA for IL-2 and the amount of the cytokine detected at the level of protein (166,167). (c) The proportion of immunologically specific T cells in an immune reaction may be on the order of well under 10% of all T cells, thus requiring only small amounts of IL-2 and IFN-g.

Additional evidence for the importance of T cells and their costimulatory interaction with antigen-presenting cells comes from animal models of autoimmune arthritis. Studies of CD28-deficient DBA/1 mice revealed that these mice are highly resistant to CIA and have markedly reduced levels of IgG and IgM anticollagen antibodies (168). Similar effects were seen with the use of anti-CD40 ligand antibodies, which also prevented the development of CIA (169).

In recent years, several new pathways have emerged that regulate T-cell function in the rheumatoid synovium. *In vitro* studies showed that macrophage-derived IL-12, a Th1-driving cytokine, was capable of inducing synovial T cells to produce IFN-g (170). This observation raises the issue of whether monocyte-derived cytokines *in vivo* can override the decreased T-cell responses and impaired signaling. IL-15 was identified in the RA synovium and shown to be capable of activating T cells in the absence of IL-2 and to induce the production of TNF-a (171), a cytokine of major importance in RA, produced by fibroblasts and macrophages. Subsequent work from the same group demonstrated that blocking IL-15 interaction with its receptor prevented the development of autoimmune arthritis in mice (172), further supporting the importance of this molecule in disease pathogenesis.

The cytokine IL-18, also known as IFN-g inducing factor, was identified in the RA synovial membrane and found to be capable or inducing both IFN-g and TNF-a production by synovial infiltrating lymphocytes. Furthermore, administration of IL-18 to mice with CIA increased susceptibility to disease and severity, supporting the *in vitro* findings that this cytokine may have an important role in disease pathogenesis (173).

Some of the CD8+ T cells present in the RA synovial tissue appear to have an antiinflammatory activity that is at least partially mediated by the release of IL-16, downregulating the production of Th1 cytokines by CD4+ T cells (174). CD8+ regulatory T cells also appear to operate through secretion of Th2 cytokines such as IL-4 (175).

Taken together, these findings suggest that the T cell has a major role in the sustained injury phase of RA. Moreover, they indicate that the seemingly lower level of T-cell activation is exactly what would be anticipated in a sustained immune response driven by T-cells.

T-CELL REPERTOIRE

The vast majority of T cells infiltrating the synovium express ab TCRs. Several laboratories have carefully investigated the representation of the TCRs in the tissue in an effort to characterize the biologic nature of the lymphocytic infiltration. One of the questions asked was whether the infiltration was primarily monoclonal or oligoclonal. This was addressed using a variety of methods, and in each study the answer was that the large majority of infiltrating T cells are of polyclonal origin (176,177), suggesting that a nonantigen-specific recruitment process accounts for most tissue T cells. The second question was whether any samples exhibited evidence of the possibility of clonal predominance. Here the answer was affirmative in that in a small proportion of cases, up to 12%, dominant patterns of TCR rearrangements were found (176). Moreover, in another study, two of three samples obtained early in the course of the disease had evidence for dominant Vb rearrangements, but none was found in six patients with more established disease (178). A different approach to this question of identification of antigen-specific T cells was developed using the addition of IL-2 to expand selectively only the T cells that express the IL-2 receptor. Clones derived by this method illustrated a greater degree of oligoclonal rearrangement (179).

Weyand et al. identified $CD4+CD28^-$ expansions in the peripheral blood of RA patients (180). These investigators determined that those cells are CD40 ligand negative, perforin positive, and capable of cytotoxic activity (181). They associated the presence of these cells with extraarticular manifestations (182). Further functional characterization of these cells is certainly awaited, and they remain to be identified in the rheumatoid synovium.

Oligoclonal expansions also have been identified among the synovium-infiltrating CD8 cells (143,183). These CD8 expansions may persist in the synovium for long periods (184), and they have not been functionally characterized.

Wagner et al. identified a tenfold contraction of the TCR repertoire in RA patients compared with healthy controls or other chronic inflammatory diseases (142). This contraction was present in both the CD4+ naive and memory cell compartment and correlated with shorter telomere lengths, suggesting an enhanced cell turnover. Although these data suggest abnormalities in CD4 cells homeostasis, it remains to be better understood how these abnormalities could influence the development of RA.

The suggestion that T cells might have been specifically responding to mycobacterial heat shock proteins led to an examination of the gdTCR repertoire composition because these receptors are used to recognize certain mycobacterial products (185). Only a small proportion of synovial samples exhibit increases in the representation of bearing gdT cells, however (186,187). The cells staining positively for gd chain were located principally in small perivascular aggregates (186). gd T cells may have a regulatory or cytotoxic function. Whereas their role in the rheumatoid synovitis remains mostly unknown, the finding that these cells do not appear to be critical for the development of autoimmune arthritis in mice suggests that they are not a critical component (188).

B Cells and Autoantibody Production, Including Rheumatoid Factors

Although the T cell receives a prominent place in the pathogenesis of RA, it also plays several other critical roles. Indeed, the B cell is likely essential for the development and sustenance of the autoimmune response itself. Although the initial event leading to loss of tolerance might be mediated by a dendritic cell, cognate interactions via the B cells may provide more efficient costimulatory signaling to T cells in the afferent portion of the development of a sustained autoimmune response. In part, this interaction could be due to the concentration of stimulating peptides presented by their MHC molecules that results from their capture of specific antigen by surface immunoglobulin. The importance of B cells can be seen in rodent models of autoimmune arthritis, where the absence of B cells protects animals from disease (189). Second, the B cells produce autoantibodies, notably including RFs, that form immune complexes capable of interacting with monocytes and other cells expressing Fc and complement receptors and with fluid-phase effector systems such as complement. The engagement of these systems results in the production of the proinflammatory cytokines, such as TNF and IL-1 by macrophages, or inflammatory mediators derived from the complement cascade.

The phenotype of the B cells in RA synovial fluid and peripheral blood is distinctive. Although not appreciably increased in number, a large proportion actively secretes immunoglobulin (190,191,192,193 and 194). Synovial fluid and synovial membrane lymphocytes exhibit 10- to 15-fold more plaque-forming cells than blood lymphocytes. A large proportion of B-lymphocytes in RA expresses the CD5 molecule. The elevation of CD5-positive B-cells is greatest in those with high RF levels, and comparable elevations are not found in systemic lupus erythematosus (SLE) (195). B cells in the synovium also exhibit activation molecules (196). For example, among the markers expressed by B cells is CD23, a low-affinity receptor for IgE (FceRII) predominantly expressed by mature B cells. B cells from RA patients have increased expression of this molecule (197,198), emphasizing the activation state of the B cells. Levels of soluble CD23 correlate with disease activity (198). Furthermore, antibodies to CD23 ameliorate murine CIA (199). Additionally, the introduction of the CD23 gene knockout into the CIA-susceptible DBA/1 strain delayed the onset and reduced disease severity while not significantly modifying the magnitude of the B- and T-cell autoimmune response (200). These findings demonstrate that CD23 could have an important role in the regulation of RA through mechanisms that likely involve the regulation of B-cell function or the soluble form of CD23.

Another set of experiments that support a role for B cells came from studies using the K/BxN TCR transgenic mice that develop a spontaneous erosive arthritis (201). Like in CIA, this model depends on cognate T- and B-cell responses (202); however, the antigen here is the glucose-6-phosphate isomerase, a glycolytic pathway enzyme (203). It remains unknown whether these findings also apply to the human disease, but it certainly raises an interesting issue about disease development through mechanisms fundamentally different from an immune response to a joint-specific peptide and the important role of B cells in the response.

As with T cells, the migration of B cells into the synovium is likely mediated by cytokines and chemokines produced by the fibroblast lineage synoviocytes and macrophages, including SDF-1 and IL-6. SDF-1 is also an important B-cell developmental and maturation factor, as revealed by the observation that mice lacking SDF-1 show defects on B-cell lymphopoiesis (204). It is likely that the cytokine and cell receptor interaction in the synovium milieu is highly supportive of B-cell

differentiation, as discussed subsequently. These factors may be of major importance in the development of the pathogenic autoimmune response of RA.

In some synovia, B cells organize into conspicuous classic germinal centers, whereas in others the cytoarchitectural organization is less striking. The expression of RAG genes by synovial lymphocytes (138) suggests that B cells undergo local affinity maturation and that cognate interactions with T-cells are occurring. The presence of RF isotype switch and somatic mutation variants, discussed later, within RA synovial B cells supports the interpretation that the B-cell aggregates within synovial lining are clonally related and exhibit all the features of a germinal center that has received T-cell cognate help. Supporting evidence for involvement of Th functions in RF production includes that blood lymphocytes stimulated by pokeweed mitogen require T-cell help for the production of RFs (205,206 and 207). Other evidence for the participation of the T cells includes the presence of class switching to IgG and IgA isotypes, supported by the finding of the same idiotypes on IgM and IgG RFs (208). Williams et al. showed in a detailed analysis that RF H-chain sequences undergo both somatic mutation and isotype switching (209). Size analysis revealed oligoclonal RF+ populations and identically sized VH-D-JH transcripts of different immunoglobulin isotypes. Sequencing of individual chains demonstrated a clonal relationship between IgM and IgA RF, suggesting that this isotype switch occurred in the synovium. Furthermore, most somatic mutations were found to have occurred after the isotype switch, which suggests that the RA synovial microenvironment sustains somatic mutation and isotype switching in RF-specific B lymphocytes akin to secondary lymphoid organs.

Rheumatoid Factors

GENERAL FEATURES

Several autoantibodies are produced in RA, of which the RFs are the best studied. RFs, a distinctive feature of RA, are autoantibodies of IgM, IgG, or IgA class that react with antigenic epitopes present on the constant region of native IgG molecules. RFs are members of a larger class of antiimmunoglobulins that also include antiidiotypic antibodies directed to regions around the combining site and homoreactant or pepsin agglutinator antibodies directed to cryptic sites revealed by degradation. Although many of the detection systems used to measure RFs involve aggregated or otherwise altered IgG, there is no evidence that RFs have a preferential specificity for determinants on altered IgG molecules. The apparent preference for these indicator systems is due to the multiplicative effect on avidity of the interaction of RF with multiple IgG molecules on one particle or surface. RFs are by far the major autoantibody produced in RA patients but, as discussed later, are not the only autoantibody. In some samples, more than half the serum and joint fluid IgG is found in the form of RF complexes. The sites of RF production include many germinal centers in rheumatoid synovial tissues (210). Up to 50% of the plasma cells in the synovial tissues contain RFs, most of the RF-specific cells are revealed using a plaque-forming cell assay or by staining for IgG-RF rather than IgM-RF (192,211). Many more cells produced IgG-RF than IgM-RF in synovial tissues compared with that produced by the blood.

The presence of serum RF detectable by conventional testing methods is a characteristic feature of RA; however, it does not appear to be an essential element for the disease. Some have used this and the fact that RF may be found in normal persons as a specious argument against the importance of RF in RA. Additional information acquired in several aspects of the study of RA has provided a clearer picture of the important place of autoantibodies such as RF in RA. (a) The RFs in RA differ from those found in normal individuals in that they reflect the presence of a strong antigen-driven immune response, as reflected by the their pattern of somatic mutations away from germ line, high titer, and isotype. (b) RF positivity may precede the development of RA by several years (16,17). (c) RFs appear to be the major subclass of a still larger group of partially cross-reactive autoantibodies, as discussed subsequently. (d) Although indeed some patients with RA test negative for RF, in some instances, this reflects the difficulty of detecting certain forms of RF by conventional tests.

TYPES

Rheumatoid factors may be subdivided into three subgroups: monoclonal RFs equivalent to those arising from a transformed B cell that do not exhibit significant mutations from their germ-line origin. These are mainly of IgM isotype, they utilize a limited number of V-region gene elements, they remain in or near a germ-line sequence, and they form mixed cryoprecipitates with IgG molecules. The disease associations of this group are a variety of B-cell neoplasias, including chronic lymphocytic leukemia, Waldenström macroglobulinemia, other lymphomas that are often extremely low grade, and benign monoclonal proliferations. Some diseases with autoimmune features including Sjögren syndrome are characterized by RFs that fit into this classification. Most, but not all, the RFs in Sjögren's syndrome are in germ-line configuration and are of IgM isotype, indicating little or no role for somatic hypermutation and passage through a germinal center reaction in their generation (212). RFs of this group are often termed *cold reactive RFs* to describe their property of forming cryoprecipitates (213). They are not found in RA.

The second group of RFs is a minor component of the normal immune response to certain antigens or infectious agents. These RFs are somewhat similar to the monoclonal RFs in their characteristics, but they are more polyclonal and rarely form cryoprecipitates. Some of these are polyspecific, whereas others appear to be monospecific for IgG (214). These RFs, along with other antiimmunoglobulins, occur naturally in patients with chronic infections and are particularly well known in subacute bacterial endocarditis (SBE). Williams and Kunkel (215) showed that sustained RF production depends on the continuing presence of the infection and that RF disappears with effective treatment with antibiotics. RFs can be induced by immunization of animals with bacteria (216,217). They are also found in persons with various other chronic infections, such as tuberculosis, leprosy, syphilis, and kala azar. RFs also have been observed to appear transiently in normal military recruits subjected to heavy immunization schedules (218). The variable regions of these RFs undergo considerable hypermutation, but, in contrast to antibodies against exogenous antigens, there is a strong selection against mutations that result in replacement of amino acids in the hypervariable or complementarity-determining regions. Furthermore, there was no increase in the affinity of these RFs with the accumulation of mutations (214,219). This suggests that high-affinity RF variants are tolerized during the hypermutation process, and there is a peripheral mechanism operating on certain autoreactive B cells in normal individuals that, although not deleting or anergizing all autoreactive cells, prevents the generation of high-affinity autoantibodies (219).

The third group of RFs found in RA are polyclonal and are present in all isotypes; these use a variety of V-region gene elements and are considerably removed from germ-line structure. They are characterized by extensive mutation that involves amino acid replacements leading to higher affinity, indicating antigen-driven selection (220,221 and 223). These RFs have a broader pH optimum, reacting well at pH 8 or 9, and do not form mixed cryoprecipitates. They are characterized as “warm reactive.” There is considerable evidence that T-cell help is involved in the production of this variety of RF from B cells that have passed through germinal centers. In particular, the structural relatedness of IgM RF in the synovium of RA patients argues strongly in favor of antigen-driven selection (222,223 and 224).

GENE USAGE OF RF AND IMPLICATIONS FOR AN ANTIGEN-DRIVEN RESPONSE

The findings from molecular analyses of RF-producing clones from RA joint tissues argue persuasively that they use a different repertoire of V genes. Robbins et al. (225) published the first sequence of the heavy and light chains from a RA synovial B-cell clone that had been obtained without EBV transformation and showed that it used the Humhv1f10 Vh1 gene (226). Sequencing a set of clones also derived from rheumatoid synovial material (227), Pascual et al. significantly extended this line of inquiry by identifying two new RF-related V genes, designated GL-SJ2 Vh3 and the A23 Vk2 gene (228,229). New V-region genes encoding IgH chains with RF specificity were also reported by Ermel et al. (222), demonstrating that the repertoire of V-region genes used in the synthesis of immunoglobulin molecules with RF specificity was large. Similar results were obtained by other investigators (230,231). Olee and colleagues also identified the germ-line counterparts of genes used to synthesize IgG RFs. They found up to 16 somatic mutations in a gene encoding a RF heavy chain, which otherwise might encode an element in the physiologic natural antibody repertoire (231). Two groups studied the kappa light-chain recombinants from RA synovium by an extensive sequence analysis (232,233). Numerous somatic replacement mutations were found in the antigen-binding site, many of which contained non-germline-encoded nucleotides (N regions) at the site of V kappa–J kappa joining. The combination of N-region addition and variation in the sites of V kappa–J kappa splicing generated unusually long complementarity-determining region 3 (CDR3) regions and charged amino acids near the V kappa–J kappa splice site. The pattern of somatic mutations supports the interpretation that these synovial plasma cells are the product of antigen-driven selection. The extent of N-region addition raised the additional possibility that these antibodies derive from an unusual set of B cells that have escaped normal regulation. Taken together, these data strongly support the interpretation that an antigen-driven mechanism underlies the RF response in RA. McGee et al. reported that B-lymphocytic clonal expansions in blood were identified by double staining for the B-cell marker CD19 plus either k or l. The fraction of clonally expanded B cells in RA was more than 50% higher than in controls and correlated with RF titer (234).

FORMATION OF COMPLEXES BY RHEUMATOID FACTORS

Franklin et al. and Kunkel et al. first clearly recognized the singular property of RF to complex with autologous IgG in serum (235,236). This was also the earliest demonstration of circulating immune complexes in a disease. The method these investigators used, analytical ultracentrifugation, remains the best method for examining this type of molecular association under conditions that approximate those occurring in the body. IgM RF circulates complexed to five IgG molecules.

At least eight different antigenic sites that are recognized by polyclonal RFs from RA patients have been identified on the Fc portion of the IgG molecule by using reactivity with overlapping peptides obtained from IgG. Some of these are in the hinge region (Cg2), and others are in the C-terminal portion (Cg3) (237,238). Most of these autoantigenic sites are present on each of the four subclasses of human IgG molecules: IgG1, IgG2, IgG3, and IgG4. Certain of the antigenic sites are also present on Fc region of IgG from other species, notably the rabbit and sheep. One variety of IgM RF that recognizes determinants on IgG1, IgG2, and IgG4, but not IgG3 molecules, a pattern designated as *Ga specificity*, binds particularly well to serum IgG. These RFs with Ga specificity cannot be detected in the usual assays unless all serum IgG is removed (239). This variety of RF is termed *hidden RF*. Group A streptococcal protein A apparently also binds to this site (240). That IgG is not necessarily the inciting or the only member of the immunoglobulin family with which RFs react was shown in a study that identified reactivity with b_2 microglobulin (241).

The ultracentrifugation technique also first revealed IgG RF (226). The complexes of IgG and IgG RF found in serum were seen to sediment as a spectrum of complexes ranging between 7S (monomeric IgG) and 19S or greater (³5 IgG or IgG RF molecules). Complexes involving IgG RFs have a distinct molecular conformation that enables them to interact with various molecular receptors of immune effector systems of the body. This can be demonstrated simply by allowing serum containing such complexes to react with preparations of purified IgM RF or C1q in solution or in agarose double-diffusion experiments. The purified IgM RF identifies the presence of immunoreactant IgG complexes in the patient's serum by the formation of a distinct precipitin band that is not given with monomeric IgG. The exact form that the IgG/anti-IgG complexes assume in joint fluid or serum is still not completely defined, but several models are postulated. In one model, the IgG RFs cluster around the several epitopes on the constant region of an IgG molecule. This form would be especially favored if the steric location of the IgG antigenic determinant recognized by the RF was situated symmetrically so that both arms of the RF could combine with determinants on a single IgG molecule. A second arrangement is that of a growing tree with each IgG RF binding either a molecule of IgG or another IgG RF. Pope et al. proposed one of the most interesting patterns of association. They obtained evidence that some IgG RFs form a self-associating complex in which the steric factors of the location and orientation of the antigenic determinant favor a parallel–antiparallel interaction between two IgG RFs in which the antibody serves as the antigen. This complex also would be stabilized by the presence of two binding sites locking two molecules together, which greatly augments the avidity of the complex (242); however, it likely would not bind C1q.

VASCULITIS AND CIRCULATING COMPLEXES

Circulating complexes formed through the action of IgG RFs or IgM RFs are thought to be central to the vasculitic phenomena in the disease (243,244 and 245). The contribution of T cells has not been evaluated by contemporary techniques, however. Pernis et al. and Conn et al. demonstrated deposition of immunoglobulin, RF and complement molecules in the vessel walls of patients with necrotizing vasculitis (243,245). Mongan et al. (244) reported that necrotizing vasculitis is found primarily in patients with extremely high RF titers as well as significantly lowered hemolytic complement titers. Zubler et al. found that serum of patients with these features reacted with a sensitive C1q binding test for immune complexes (246). IgG-RF has been highly associated with the pathologic process in RA, both in synovial fluids and in necrotizing vasculitis (192,247).

RHEUMATOID FACTOR COMPLEXES AS PROINFLAMMATORY IMMUNOREACTANTS

A pathogenic role for IgG complexes containing IgG RF is supported by markedly diminished levels of complement proteins and total hemolytic complement activity in the synovial fluid as shown by several investigators (248,249 and 250). The joint fluid IgG complexes have been implicated as the basis for intraarticular complement activation (251). The levels of IgG RFs are usually much greater in the joint fluid than in the serum. This is evident first at the level of B-cell precursors that are the antecedents of RF-producing cells. A variety of physical and immunologic measurements also support the presence of elevated levels of IgG RF in the joint fluid. IgG in the form of complexes also accounts for a remarkably large amount of the IgG in joint fluid, in the range of several milligrams per milliliter (251,252 and 253). Joint fluid complexes are considerably larger and react both with C1q and RFs, whereas the smaller complexes in serum reacted only with IgM RFs (251,253). As little as two or three IgG molecules were sufficient to confer demonstrable reactivity with IgM RFs, but at least five or six IgG molecules had to be present in complexes that reacted with C1q (252,254). Elevated turnover of both IgG and the C4 complement component in individuals with RA support the participation of complexes containing RFs in initiating inflammation. This enhanced turnover correlates with elevated titers of RFs and is especially high in those with extraarticular disease (255,256). Taken together, considerable evidence suggests that a proportion of the immune complexes involving IgM and IgG RF forming in RA fix and activate complement and are processed by phagocytic and other systems with considerable inflammatory consequences.

Deposition of immunoglobulins and complement in the matrix of the synovium and their phagocytosis by neutrophils (257,256,257,258 and 259) has been shown. Immunoglobulin deposits were absent from cartilaginous areas covered with pannus but could readily be detected on the free surface (260). These observations were used to suggest that immunoglobulin deposits on cartilage represent antigen persistence in immune complexes initiating pannus formation (261).

Other Autoantibodies and the Potential Relation to Rheumatoid Factors

Other autoantibodies have been described in RA, and certain of these may provide clues to understanding the nature of RF. Among the best known are IgG antibodies to native collagen II that have been described in the serum of 15% to 27% (262,263) and in the synovial fluid of 52% (264) of RA patients. Cook et al. described a reduction in the rate of anticollagen antibodies after 1 year of follow-up, and this reduction correlated with the development of radiographic erosive changes (263). Evidence from rodent models of autoimmune arthritis, where disease is induced with type II collagen and adjuvant injections, showed that IgG anti-collagen antibodies are required for the development of the disease and also can induce transient disease in passive transfer experiments (265,266 and 267). Epitope mapping analyses have identified the immunodominant and critical domains of the collagen molecule regulating rodent anticollagen antibody production. It remains unknown whether these anticollagen antibodies have a pathogenic role in human disease.

Autoantibodies to cytoskeletal elements—such as the cytokeratins, vimentin, and a perinuclear body containing filaggrin in buccal mucosal cells are found in RA (268,269). Their identification adds a new dimension to the study of the pathogenesis of RA because they may be particularly important for integrating some of the RF-negative cases into pathogenic schemes involving the B-cell arm of autoimmune recognition. Antiperinuclear factor (APF) has been reported to be highly specific for RA compared with other arthropathies and to be positive in 28 of 33 (85%) RA cases with extremely low or negative RF, reducing the number of “seronegative” RA from 33 of 119 to 5 of 119 (270). A recent metaanalysis that included 939 patients with RA, 1,539 with other rheumatic diseases, and 375 from healthy controls or patients with unclassified rheumatic diseases calculated a sensitivity of 75% and a specificity of 93% for APF positivity (271). Kessel et al. pointed out that antikeratinocyte antibody (AKA) positivity could be useful in distinguishing RA from hepatitis C–associated polyarthritis, where the rate of positivity in association with positive RF was only 8% (272). Another recent study analyzed the role of APF, AKA, and anti-RA33 in early onset RA. Among RF-negative patients, 51.7% were positive for AKA, APF, or anti-RA33 antibodies. Positivity of AKA, APF, and anti-RA33 usually persisted throughout follow-up, whereas in this series RF was lost by 58% of patients with early, RF-positive disease (273). AKA has been reported as an independent risk factor for the development of radiographic damage in RA (274). An enzyme-linked immunosorbent assay (ELISA) test for the measurement of antifilaggrin antibodies(AFA) using filaggrin purified from human skin as an antigen was applied to 306 patients with recent-onset inflammatory joint diseases (275). The APF and AFA results on those with peripheral polyarthritis or oligoarthritis were in good agreement, whereas AKA and AFA only partially overlapped. The AFA test detected 10 of 22 of the RF-negative erosive cases, particularly those with a large number of erosive joints, supplementing RF in the prediction of erosiveness. Similar results were obtained by Vincent et al., who performed a detailed characterization of the serologic distinction between epitopes recognized by AKA and AFA sera (276). Perinuclear staining pattern of antineutrophil cytoplasmic antibodies (p-ANCA) also was described in one third of Felty syndrome patients (277). Sa, another novel peptide, 50 to 55 kd autoantigen, present in placenta and spleen by Western blotting, elicits autoantibodies, predominantly of the IgG isotype. They are found in 27% of RF-negative and 50% of RF-positive RA patients but at low or negative levels in RF-positive individuals with diseases other than RA. The specificity for RA was 98.9%, positive predictive value 96.7%, and negative predictive value 69.8% (278,279,280 and 281). Anti-Sa was not associated with either RF or with anti-A2/RA33. Anti-RA33 was present in 21 RA sera, only eight of which also contained anti-Sa; 51% of RA patients were positive for at least one of these two autoantibodies, and 18 of these patients were RF negative.

Antibodies to the main epitope recognized by the RANA antibodies, the glycine/alanine repeat sequence on the EBV p62 nuclear antigen-1 (EBNA-1), are elevated to about fourfold greater titers in RA sera than in controls. They cross-react with epitopes on keratin, actin, and collagen (119), raising the possibility that this molecular mimicry might contribute to the breakdown of tolerance and autoimmunity in RA.

Antibodies to calpastatin (282), p64 (283), and cyclic citrullinated peptide (284) have been described. The last two in particular appear to be highly specific for RA in limited studies.

It has been known for many years that RFs react with epitopes on rabbit IgG, usually with analogous structures also found on human IgG. Fang et al. conducted a study of a subpopulation of RFs from RA patients who reacted exclusively with rabbit but not human IgG. They observed that certain of these anti-rabbit IgG RF also had specificity for other mammalian antigens, including cytoskeletal proteins and intracellular proteins found in HeLa cells as well as for antigen present in an extract prepared from the cell wall of group A streptococci (285). This finding expanded the understanding of the meaning of RF in RA by emphasizing the potential relationship of RF to other autoantibodies and also by emphasizing that autologous reactivity with IgG is not an essential feature. These non-Ig antigens, along with others described in this section (e.g., the spectrum of AKA, APF, anti-RA33 autoantibodies), raise the possibility that the antigenic drive in RA consists of one or several molecules that are distinct from IgFc regions but that share conformational epitopes capable of initiating spreading reactions via a B-cell mechanism.

ARTHRITIS, SYNOVIAL HYPERPLASIA, AND JOINT DESTRUCTION

The hyperplastic response of the intimal synovial membrane to the autoimmune response of T cells and B cells that accumulate in the subintima establishes the locus for much of what will become the joint inflammation of RA. This intimal hyperplastic response also mediates the destruction of joint tissues that is the dominant clinical characteristic of the disease. The remarkable degree of hyperplasia exhibited by the intimal synovial lining cells is presumably driven, at least in part, by paracrine factors such as IL-1 and TNF elaborated by the inflammatory autoimmune response. This section first reviews the characteristics of the normal synovial membrane. Our viewpoint is that much of the pathology of RA derives from the expansion of normal biologic processes of the joint by the consequences of the autoimmune response. The section then discusses the cellular abnormalities seen in the synovial membrane in RA. The distinctive phenotype of fibroblast lineage synoviocytes cultured from RA leads to a presentation of gene-discovery studies directed at understanding this phenotype and gaining insight into the nature of synovitis and the biology of the normal joint. One of the major consequences of the gene-discovery effort was the unexpected finding that fibroblast lineage intimal synoviocytes, and

presumably those engaged in destruction of cartilage and bone, were nearly indistinguishable from mesenchymal stem cells. Thus, among the hyperplastic synoviocytes of the pannus are cells that are the embryologic precursors of the cells they seek to destroy. Additional insights into the molecular basis of cell–cell and cell–matrix interactions underlying synovitis provided by the gene discovery effort are discussed also. The genetic susceptibility and other potential factors involved in the regulation of the fibroblast lineage synoviocyte biology are also within the scope of this chapter. Experimental animal models of arthritis have contributed greatly to our increased understanding of the genetic regulation and pathogenesis of RA, and findings originated from such studies are incorporated herein.

Relevant Features of the Normal Joint

The joint is a functionally unique structure primarily formed from mesenchymal cells. The normal synovial membrane is lined by a layer of interspersed specialized cells that is one to three cells thick (Table 37.1, Fig. 37.5). About two thirds of the specialized cells lining the joint cavity are fibroblast lineage intimal synoviocytes and belong to the fibroblast lineage (19,286,287). Through their unique and increasingly defined pattern of gene expression, the fibroblast lineage intimal synoviocytes appear to be differentiated to perform a series of functions critical to the biologic function of the normal joint. This phenotype also appears to confer the potential for a special role in fostering the development and synovial localization of the autoimmune response underlying RA and to participate in joint destruction. The remainder of the lining is composed of monocyte lineage intimal synoviocytes that are derived from the CD14-positive branch of the monocyte lineage (288). The two types of intimal synoviocytes originally were named *type B* and *type A*, respectively according to their appearance in electron microscopy (289). The progenitors of the monocyte lineage intimal synoviocyte enter the intima after leaving blood vessels and differentiate into their mature form in response to guidance clues and interactions apparently provided by the fibroblast lineage intimal synoviocytes. The molecules that are responsible for this critical phase of joint histogenesis are beginning to be identified. The function and especially the interactions of these two cell types are of special importance in understanding both the biology of the normal joint and the inflammation of RA.

TABLE 37.1. Fibroblast Lineage Intimal Synoviocyte Functions

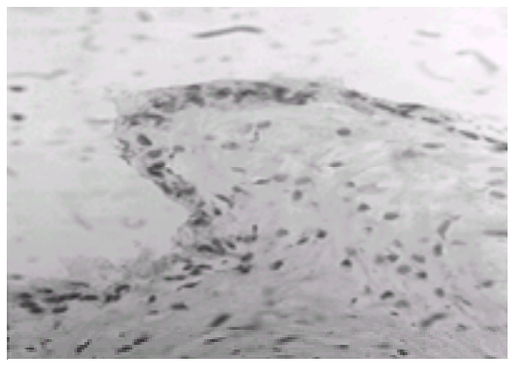

Figure 37.5. Noninflammatory osteoarthritis synovial membrane showing two or three layers of lining cells stained for stromal cell–derived factor-1 (SDF-1). (See Color Figure 37.5.)

The two varieties of intimal synoviocytes together have five major functions, including (a) the production of extracellular matrix fibrous and ground substance components that integrate the intima with the subintima; (b) expression of cell surface receptors specialized for interactions with the subjacent extracellular matrix fibrous components (expression of receptors and counterreceptors that mediate the close cell–cell interactions responsible for the patterning of the intima); (c) synthesis of components of the synovial fluid, notably hyaluronate and factors for the nutrition of the chondrocytes and the avascular cartilage, and elaboration of the molecules that provide lubrication for cartilage motion; (d) matrix remodeling through the production of metalloproteinases and other proteinases; (e) immune surveillance of the joint cavity and removal of cartilage debris resulting from weight bearing and other joint stresses. (19).

Several features distinguish the normal fibroblast lineage intimal synoviocyte from typical fibroblasts, including the following (Table 37.1):

1. Polarization unusual for a typical connective tissue fibroblast in which the receptors for interaction with collagen and other fibrous elements of the subintimal matrix are disposed only on the abluminal surface of the cell while the luminal side interacts with the synovial fluid.
2. Extensive cell–cell interactions. The fibroblast lineage intimal synoviocyte exhibits, in addition to the homotypic cell–cell interaction with each other, a receptor-mediated heterotypic interaction with monocyte lineage intimal synoviocytes. In electron microscopic studies, tight junctions or desmosomes, characteristic of epithelial cells, are not seen, suggesting that homotypic and heterotypic cellular interactions during the continued histogenesis of the synovial lining are perhaps entirely receptor mediated. Evidence for the presence of various receptor/counterreceptor interactions that could mediate these interactions is reviewed subsequently. Additionally, matrix components like collagen VI have been implicated in maintaining cells attached to each other and to the matrix (290).
3. The fibroblast lineage intimal synoviocytes appear responsible for the localization and guidance clues that result in the entrance of monocytes in the intima and their subsequent differentiation into monocyte lineage intimal synoviocytes. These and other features of the fibroblast lineage intimal synoviocyte appear to confer the potential for a role in both the afferent and effector pathways of the pathogenesis of RA, as discussed (19). Several comprehensive reviews of the synoviocyte and synovitis provide additional information (19,287,291).

Beneath the intimal lining layer lies a thin zone of vascular connective tissue, the *subintima.*There is no basement membrane separating the intima and the subintima. In contrast to the fibroblast lineage intimal synoviocyte, the subintimal synoviocytes appear to be more typical connective tissue fibroblasts. Monocyte lineage cells are not conspicuous. The subintima may contain variable numbers of adipocytes.

During fetal development, cavitation occurs within the primitive mesenchyme along planes destined to become the articular surfaces of synovial joints. These planes are delimited by cells that are the anlage of the intima. Evidence suggesting that joint cavitation is dependent on the behavior of primitive fibroblasts that are the precursors of synoviocytes or adjacent developing chondrocytes has been presented (292). Macrophages enter the site of the future joint at the periphery of the joint interzones but are not located near to where cavity formation occurs.

Clues about the Synoviocyte from Studies on the Distinctive Phenotype of Cultured Rheumatoid Arthritis Fibroblast Lineage Synoviocytes

It has long been recognized that synoviocytes obtained from synovial tissue of patients with RA do not revert to an entirely typical fibroblast lineage morphology and behavior (289,293,294). They rather maintain a complex distinctive phenotype that includes fibroblast lineage cells with varying degrees of “stellate” morphology, enhanced growth, increased glucose consumption, altered adherence behavior, constitutive overproduction of metalloproteinases, and the elaboration of proinflammatory cytokines (295,296,297 and 298) as well as loss of contact inhibition (293). This phenotype is infrequently found in similarly cultured synoviocytes obtained from normal synovia or osteoarthritis synovia that lack lining cell hyperplasia and any inflammatory cell infiltration. In addition, cell lines exhibiting elements of this distinctive phenotype are not uniquely specific for RA, as they are also demonstrable in cultures initiated from a number of different entities characterized by chronic inflammation and synovial hyperplasia, including psoriatic arthritis (298,299). Cells freshly isolated from a rheumatoid synovium exhibiting the striking stellate or dendritic morphology strongly express HLA-DR, presumably reflecting the effect of paracrine factors (297,300). Their fibroblast nature has been established by their lack of the property of enhanced endocytosis or phagocytosis; their lack of expression of CD14, Fc receptors, or the leukocyte common antigen CD45 (301); and their

expression of a number of genes from vimentin to type I collagen, characteristic of fibroblasts (19). When preparations of these cells are placed in culture, the preponderance of these cells lose expression of HLA-DR, but the complex stellate morphology may remain in varying proportions along with the distinctive phenotype.

SYNOVIAL GENE-DISCOVERY EFFORTS

The pattern of gene expression in lines of cultured RA synoviocytes has been characterized in a series of studies (20,297,298 and 299,302,303). To identify the genes responsible for the distinctive phenotype of the cultured synoviocytes obtained from a RA patient, a gene discovery approach has been taken that is based on identifying genes similarly and differently expressed compared with a line derived from a selected osteoarthritis sample. One recent approach (20) was based on the construction of representational difference libraries (304,305). It involved a cloning procedure with polymerase chain reaction (PCR) amplification of cDNA to generate simplified representations of the expressed genes from RA and osteoarthritis (OA) synovia, followed by repeated modified subtractive steps using the OA sample and subsequent sequencing to identify the genes. Several genes were identified, many of which were constitutively expressed at high levels in RA fibroblast lineage synoviocyte lines as demonstrated by Northern analysis (Table 37.2). Included among these are genes encoding matrix components: collagens, biglycan, laminin, fibronectin, crystallin, and proteoglycans; proteinases and inhibitors, including matrix metalloproteinases (MMPs) and cathepsins; genes involved in cell–cell, cell–matrix interactions; receptors, such as MAC-2BP, vascular cellular adhesion molecules-1 (VCAM-1); cytokines, chemokines such as SDF-1; growth factors; genes reflecting the operation of activation pathways, oncogenes, transcription factors; and others with still unclear functions in the synovium (19,20). The identification of SDF-1 was confirmed by Zvaifler et al. (306). We interpret these findings to imply that the genes found constitutively overexpressed in the RA fibroblast lineage synoviocyte culture are expressed at high levels in fibroblast lineage intimal synoviocytes and are primary markers of the phenotype of this lineage. Moreover, identification of additional genes has been reported, including various embryonic growth factors, from the wingless (wnt) and frizzled (fz) families, implicated in cell-fate determination in both bone marrow progenitors and limb-bud mesenchyme (307). Each of these groups similarly interpreted their results to suggest that the unusual phenotypic properties of RA fibroblasts in culture are attributable to their replacement with primitive fibroblast lineage synoviocytes with characteristics of immature bone marrow and mesenchymal cells. These genes can mediate chemotaxis of T- and B-lymphocytes and monocytes into the synovial membrane and participate in further cell differentiation. Sen et al. (307) provided additional evidence in support of the above concept by transfecting *wnt5a* into normal fibroblasts, which induced increased amounts of IL-8, IL-6, and IL-15 protein secretion, similarly to the levels produced by cultured fibroblast lineage synoviocytes from RA.

Genes preferentially expressed in RA synovial cultures: intimal origin	Genes expressed in both RA and OA synovial fibroblast cultures: intimal and subintimal origin
Biglycan	Adrenomedullin
IFN-induced 56 kd	α subunit of Gs GTP binding protein
IFN-induced 71 kd 2'5'-oligoadenylate synthetase	α-B-crystallin
IGF-BP5	B94 protein
Lumican	β subunit of prolyl-4-hydroxylase
Mac2-binding protein	Candidate sulphatase
ML2122	Cathepsin B
SDF-1α	Collagen α 1 type III
Semaphorin 3C/E	Collagenase IV
SLIT-3	Complement C1r
VCAM-1	Complement C1s
	Complement factor B
	DNA-binding protein TAXREB107
	Elongation factor 2
	Epithelin
	Extracellular protein (SI-5)
	HLA-E heavy chain
	IFN γ IEF SSP 5111
	Manganese superoxide dismutase
	Milk-fat globule protein
	Muscle fatty-acid binding protein
	NM8 protein
	Osteoblast specific factor 2

HLA-E, human leukocyte antigen-E; IFN, interferon; IGF-BP5, insulinlike growth factor binding protein-5; OA, osteoarthritis; RA, rheumatoid arthritis; SDF-1α, stromal cell-derived factor 1α; VCAM-1, vascular cell adhesion molecule-1.

TABLE 37.2. Genes Identified Through a Subtraction Method Differently Expressed in RA and OA Fibroblast Lineage Synoviocyte Cultures and Correlation with Their Possible Lineage Origin

Clues about Fibroblast Lineage Synoviocyte Biology from the Constitutive Production of SDF-1 by Some Synoviocytes

The identification of the high level of constitutive expression of SDF-1 by RA compared with low levels in OA synoviocytes was of special interest. First, SDF-1 is one of the most efficacious chemokines in inducing T-cell and monocyte migration (308). Second, SDF-1 is an important B cell developmental and maturation factor, as revealed by the observation that mice lacking SDF-1 show defects on B-cell lymphopoiesis (309).

MESENCHYMAL STEM CELLS AND FEATURES OF THE FIBROBLAST LINEAGE SYNOVIOCYTE

The unique pattern of expression of SDF-1 by RA synoviocyte lines is similar to that seen in mesenchymal stem cells. This suggests that some fibroblast lineage synoviocytes represent a form of less differentiated cells, closer to, if not indistinguishable from, the mesenchymal stem cell than to a well-differentiated fibroblast. An overall scheme of differentiation in the fibroblast lineage (310) proposes a pluripotent stem cell termed the *mesenchymal stem cell* or the *marrow stromal cell*, and a series of committed progenitors for each of the differentiated fibroblast lineages that constitute this connective tissue cell family. These include the connective tissue fibroblasts in various tissues and more specialized cells, such as osteoblasts and osteocytes, chondroblasts and chondrocytes, smooth-muscle cells, adipocytes, neuroglial astrocytes (311), and the fibroblast lineage intimal synoviocytes of the joint. Marrow stromal cells are readily isolated from bone marrow and maintain a stable phenotype in culture (312,313). Marrow stromal cells express SDF-1 and phenotypic markers like vimentin, tenascin, the integrin subunits, a_5b_1, a_vb_3, and a_vb_5 epithelin, SH2, SH3, intercellular adhesion molecule-1 (ICAM-1), VCAM-1, Thy-1, CD40, and CD44H (314,315,316 and 317).

The expression of SDF-1 and other genes in RA synoviocytes, to be discussed subsequently, indicates that the mesenchymal stem cell of the bone marrow closely resembles the fibroblast lineage intimal synoviocyte (19,20,306), although the two populations might not be identical in that myelopoiesis is not an overt finding in the joint. Nevertheless, the possibility that a particular population of synoviocytes might share with marrow stromal cells the ability to differentiate into osteoblasts and adipocytes, as is the case for the marrow stem cells (318), remains an important unanswered question in synovial biology.

GENES LIKELY CONSTITUTIVELY EXPRESSED IN FIBROBLAST LINEAGE INTIMAL SYNOVIOCYTES

The specialized functions of the fibroblast lineage intimal synoviocytes are mediated by either quantitative differences in the expression of genes also found on other members of the fibroblast lineage or the qualitative expression of genes unique to the synoviocyte sublineage. The genes identified by the subtraction library method as differentially expressed in RA synoviocyte cultures are candidates for comprising the fibroblast lineage intimal synoviocyte phenotype (20). These include differentially expressed chemokines, such as SDF-1, connective tissue matrix components like biglycan and lumican, adhesion molecules like VCAM-1 (Fig. 37.6), and other molecules of a less clear function in the synovial tissue, such as SLIT-3, and semaphorin 3C, MAC2-binding protein, insulinlike growth factor binding protein-5 (IGFBP-5), IFN-inducible 56-kd protein, and IFN-induced 71-kd 2'5' oligoadenylate synthetase (Table 37.3). Additionally, one gene that was not homologous to any known gene was overexpressed in RA synovial fibroblast lineage cultures (ML2115).

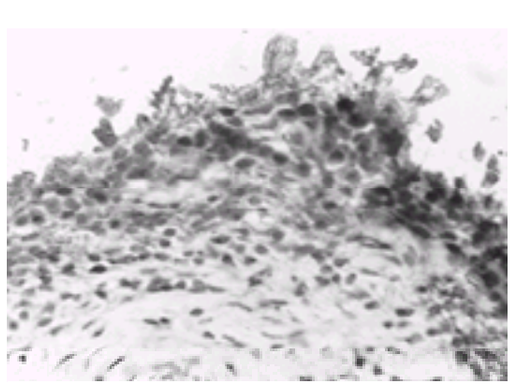

Figure 37.6. Rheumatoid arthritis. The synovial lining hyperplasia stained for vascular cell adhesion molecule-1 (VCAM-1).

TABLE 37.3. Genes Expressed by Fibroblast Lineage Synoviocytes[a]

Edwards and colleagues identified VCAM-1 as being expressed by normal fibroblast lineage intimal synoviocytes (292,319), and this observation supports the interpretation that the remaining genes found by the subtraction method are characteristic of fibroblast lineage intimal synoviocytes. In addition, several other genes were identified as being selectively or more highly expressed by fibroblast lineage intimal synoviocytes, either from staining patterns in normal or diseased synovial membranes or from cultured cells. These include other chemokines, such as IL-8, RANTES, MCP-1 (20,150,320,321), cytokines like TNF-a, IL-1, IL-6, granulocyte-macrophage colony-stimulating factor (GM-CSF) (98,99,322,323), IL-11 (324,325), metalloproteinases and other proteinases (94,326,327), adhesion molecules like ICAM-1 (328,329,330,331 and 332), integrins (333) and CD44 (331,334,335), and costimulatory molecules like CD40 (336) (Table 37.3).

GENES EXPRESSED BOTH IN FIBROBLAST LINEAGE INTIMAL AND SUBINTIMAL SYNOVIOCYTES

Numerous genes were similarly expressed in the RA and OA synovial fibroblast cultures and likely are genes expressed by both cultured fibroblast lineage intimal and subintimal synoviocytes. Among these genes are some involved in cellular and matrix turnover, such as collagenase IV, genes involved in the inflammatory response like manganese superoxide dismutase, complement factor B, IFN-g, IEF SSP 5111, HLA-E heavy chain, and other genes with unknown function in the synovium, for example, NMB protein, aB crystallin, B94 protein, and muscle fatty-acid–binding protein. Other genes were shown to be either similarly expressed in synovial fibroblasts from patients with a variety of diseases or specifically expressed in both intimal and subintimal layer by *in situ* hybridization or staining with monoclonal antibodies (Table 37.2 and Table 37.3).

RELEVANCE OF THE DISTINCTIVE PHENOTYPE OF RA SYNOVIOCYTE CULTURES TO SYNOVIAL BIOLOGY

Based on the gene discovery findings, there are several possible explanations for the distinctive phenotype and function of these RA synoviocytes in long-term cultures (Table 37.4). Each has a different implication in terms of whether the genes found to be overexpressed in these cultures are identifiable in the normal synovium. First is the lineage hypothesis, where there is an increased number of normal fibroblast lineage intimal synoviocytes with mesenchymal stem cell characteristics, expressing normal amounts of transcripts per cell; however, because this distinct cell population is overrepresented, the absolute pattern of gene expression is increased (19). The distinctive phenotype observed in these cultures would be the normal phenotype of the fibroblast lineage intimal synoviocyte found in the normal joints in all individuals (20). The differences in culture phenotype between inflammatory and noninflammatory synovitis would simply reflect the increased proportion of fibroblast lineage intimal synoviocytes compared with subintimal synoviocytes in the starting culture material obtained from a joint with intimal hyperplasia. In support of this hypothesis is the pattern of gene expression seen in synovial fibroblast clones generated from RA and OA: High levels of SDF-1 and bone morphogenic protein receptors (BMPR) that characterize mesenchymal stem cells were seen more often in clones generated from RA than from OA synovial fibroblast cell cultures. Yet several clones originated from OA had a high level of SDF-1 and BMPR gene expression, which was interpreted as clones representing the normal number of intimal mesenchymal stem cell–like synoviocytes (R. Winchester, unpublished observations). This explanation possibility remains the most likely one. The second hypothesis is the overexpression phenotype in which the starting phenotype of the individual's prearthritis intimal synoviocytes is due to genetically determined increased expression of a gene that predisposes to immunologically mediated arthritis. In the third hypothesis, the phenotype could be a consequence of a disease-specific sustained modulation in gene expression in the intimal and subintimal fibroblast lineage cells of the joint, where the long exposure of synovial fibroblasts to increased amounts of proinflammatory cytokines would lead to a persistent state of cell activation with increased cytokine and oncogene expression (298,299,302,337). Although this hypothesis cannot be excluded, it is unlikely that cells would maintain a cytokine–cytokine receptor dependent phenotype in the absence of that cytokine. The fourth hypothesis suggests that cells could be primarily “transformed,” as suggested by Trabandt and colleagues (338) where the disease of RA results from an immune response against the agent responsible for the transformation, a possibility for which there is little support.

Normal intimal cell phenotype
Differences represent different percentages of intimal versus subintimal cells in the synovial tissue
Normal intimal cell phenotype is dependent on genetic polymorphisms in arthritis susceptibility genes
Disease-specific sustained modulation in gene expression
Local paracrine regulation
Phenotypic “imprinting”
Transformed cells
Secondary to unidentified viral infection

TABLE 37.4. Four Possible Explanations for the Distinct Phenotype of Rheumatoid Arthritis Cultured Synovial Fibroblasts

GENOMIC DISSECTION OF THE FIBROBLAST LINEAGE INTIMAL SYNOVIOCYTES PHENOTYPE

Several susceptibility loci have been identified both in rodents and humans, as discussed already. Although it is not known which genes account for those susceptibility loci, several map to genomic regions that contain some of the genes discussed in this chapter that are differentially expressed in synovial cells from RA patients (Table 37.5). Therefore, some of these genes are candidate susceptibility genes and may be involved in the regulation of the synovial fibroblast function. We hypothesize that the inheritance of certain alleles may facilitate transcription, inducing increased expression of certain genes in tissues such as the synovium. Additionally, some of those genes may be involved in the regulation of disease severity as well (8,9,13,339,340).

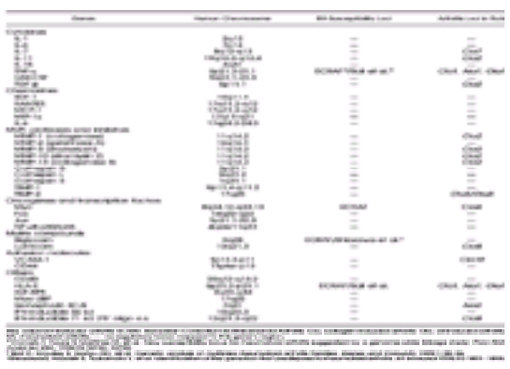

TABLE 37.5. Genes Differentially Expressed in Cultured Rheumatoid Fibroblastoid Intimal Cells, Their Chromosomal Location, Their Relationship with Susceptibility Loci Identified in Linkage Studies in Rheumatoid Arthritis and With Homologous Loci Regulating Experimental Arthritis in Rats

Role of Molecules Identified in Fibroblast Lineage Synoviocytes Involved in the Proinflammatory Response and Intensification of Synovitis

CHEMOKINES, CYTOKINES, AND GROWTH FACTORS

Chemokines

In addition to SDF-1 (20), numerous other chemokines have been identified as likely to be overexpressed by the fibroblast lineage intimal synoviocytes, including IL-8 (341), GRO-a (342), MCP-1 (320,341), and MIP-1a (152). Expression of chemokines and their receptors has been demonstrated to have a critical role in the regulation of the attachment of leukocytes and endothelial cells and in their passage into the tissues (308,343). Among chemokines, SDF-1 is one of the most efficacious in T-cell and monocyte migration (308). Both CD4+ and CD8+ cells, as well as CD45RA+ naive and, less effectively, CD45RO+ memory T-lymphocyte subsets in peripheral blood are subject to SDF-1 chemoattractive effects (344). Similarly, monocyte-lineage dendritic cells acquire CXCR4 on induction with GM-CSF and IL-4 (345). Several antichemokine strategies targeting RANTES (153) and MCP-1 (346) have been used in animal models of arthritis with good results and may prove promising strategies for clinical studies.

Cytokines and Growth Factors

There is an increased expression of several cytokines, including TNFa, IL-1, IL-6, IL-11, IL-15, GM-CSF, transforming growth factor (TGF), platelet-derived growth factor (PDGF), and basic fibroblast growth factor (bFGF) by fibroblast lineage synoviocytes (94,98,99,323,324 and 325,347,348,349,350,351 and 352). These cytokines importantly influence the activation state of the endothelium by affecting the expression of particular genes. The migration of a given inflammatory cell into the synovium is not a random event but one determined by the prior immunologic history of the particular cell as well as that of the endothelium. The increased production of certain cytokines like IL-1 and TNF-a activates the endothelium and initiates overexpression of certain adhesion molecules enhancing directed cellular egress. Accordingly, the activation status of the endothelium in concert with chemokine production could greatly facilitate the localization of inflammatory and autoimmune cells to the synovial membrane, further perpetuating the disease process and tissue injury. The hyperplastic RA synovium, with its increased number of fibroblast lineage synoviocytes, appears to have a critical role in the chemotaxis of monocytes, T-, and B-lymphocytes into the synovial membrane, as evidenced by their increased production of proinflammatory molecules involved in the activation of endothelial cells like TNF, IL-1, and IL-6 as well as chemokines like IL-8 (341), RANTES (150,151), GRO-a (342), MCP-1 (320,341), MIP-1a (353), MIP-1b (354), IP-10 (149), and SDF-1 (20) (Table 37.3).

MOLECULES INVOLVED IN CELL–CELL INTERACTIONS AND OTHERS OF UNCLEAR FUNCTION IDENTIFIED IN FIBROBLAST INTIMAL

Several molecules expressed by fibroblast lineage intimal synoviocytes appear to be candidates for mediating cell–cell interactions involved in the histogenesis of the normal synovium, including monocyte lineage–fibroblast lineage and fibroblast lineage–fibroblast lineage synoviocyte interactions. Some of these genes have a well-defined role in cell–cell interactions, and others have the potential to act as cell interaction receptor–ligand systems but also have other actions.

Among the well-recognized adhesion molecules and receptors differentially expressed in the rheumatoid fibroblast lineage intimal synoviocytes are VCAM-1 and MAC-2BP, also termed *90k tumor associated protein*. VCAM-1 was described previously as markedly increased on RA synoviocytes (292,355), and it binds circulating monocytes and lymphocytes expressing the a_4b_1 [very late antigen-4 (VLA-4)] integrin. Additionally, VCAM-1 may have a role in the formation of germinal centers in the rheumatoid inflammatory synovium. Based on these data, it appears that normal fibroblast lineage intimal synoviocyte cells can support the development of germinal centers, B-cell migration, and affinity maturation. Furthermore, several additional molecules produced by the synoviocyte can interact to facilitate other aspects of B-cell development, such as IL-6. MAC-2BP binds to the macrophage-associated lectin Mac-2 (galectin-3) (356,357) and is increased in the serum of cancer and human immunodeficiency virus (HIV)–positive patients. MAC-2BP also binds to the monocyte CD14 structure in the presence of LPS and LPS-binding protein (358). Binding of MAC-2BP to these receptors induces monocyte lineage cells to secrete IL-1 (359).

The overexpression of the semaphorin 3C, a human homolog of mouse semaphorin E by synovial fibroblasts (20,360), is intriguing because the semaphorins are a family of transmembrane signaling and secreted guidance glycoprotein molecules that are implicated in directing axonal extension and operate broadly in neuronal patterning (361). Neuropilin, the receptor for semaphorin, is expressed on vascular endothelial cells, and neuropilin expression is upregulated by TNF-a and is implicated in angiogenesis as a coreceptor of vascular endothelial growth factor (VEGF).

Molecules Involved in Cell–Matrix Interaction Expressed by Fibroblast Lineage Intimal Synoviocytes

Several matrix component genes exhibited a pattern of expression suggesting that they are constitutively produced by fibroblast lineage intimal synoviocytes. Lumican was identified as likely to be constitutively expressed by fibroblast lineage intimal synoviocytes (20). Although lumican's role in the synovium is not understood, its role in corneal transparency (362) and in the inhibition of macrophages adhesion to intact corneal keratan sulfate proteoglycans are of interest. Biglycan, another gene likely to be constitutively expressed by fibroblast lineage intimal synoviocytes, is a dermatan sulfate-proteoglycan. It is both induced by TGF-b and binds TGF-b (363), suggesting that it may downregulate TGF-b activity by sequestering this growth factor in the extracellular matrix.

Hyaluronan, which is an abundant constituent of the extracellular matrix and is especially increased in the synovial fluid, may modulate local chemokine production through the interaction between its low-molecular-weight forms (fragments) with CD44 (see later) (364).

Fibroblast lineage intimal synoviocytes strongly express IGFBP-5 (20), an important regulator of fibroblast growth that increases IGF-1 binding to the fibroblast membrane by attaching to the extracellular matrix proteins, including types III and IV collagen, laminin, and fibronectin (365). The increased expression of IGFBP-5 seen in scleroderma skin fibroblast (366) and alveolar rhabdomyosarcoma cell lines (367) suggests that this gene is involved in the regulation of mesenchymal cellular functions, including proliferation and perhaps the hyperplasia seen in RA synovium.

INITIATION OF HYPERPLASIA AND DEVELOPMENT OF SUSTAINED ARTHRITIS

In addition to the likely role of the fibroblast lineage intimal synoviocyte in facilitating the afferent limb of the development of the autoimmune response underlying synovitis, the intima also plays a major part in the loss of function and joint destruction that characterize fully developed RA. A feature of the rheumatoid synovium is the marked hyperplasia of the lining layer and the apparent invasion and destruction of cartilage and other joint structures by the mesenchymally derived fibro-blasts and the bone marrow derived monocyte lineage cells (Fig. 37.6). The changes in the lining during hyperplasia include a massive increase in the number of fibroblast lineage intimal synoviocytes and an altered cell–cell relationship with the monocyte lineage synoviocytes.

In RA, it is unknown whether initiation of the autoimmune response and its localization to the joint occur in the setting of entirely normal intima or whether minor degrees of nonspecific hyperplasia could play a role in localizing an immune response into the joint through the repertoire of immunologically relevant molecules expressed by these cells. Hyperplasia could be initiated by a nonspecific minor traumatic event or even driven by a local immune response to a common pathogen, and the constitutive production of chemokines might provide a nonantigen-specific mechanism for localizing potential pathogenic immune responses to the joint. In other words, the production of such chemoattractant molecules would be part of the normal function of the fibroblast lineage intimal synoviocytes and would have increased transcription when either activated or subjected to an inflammatory “imprinting” or when the number of cells increases. The unusual behavior of fibroblast lineage intimal synoviocytes in culture may reflect this behavior.

Hyperplasia appears to be an intrinsic response of intimal synoviocytes to injury and healing. The synovial membrane undergoes this striking change in its form and in its pattern of gene expression, transforming from a nutritive tissue into one that is the central agent of joint destruction. The destruction occurs through expression of enhanced levels of degradative enzymes and through secretion of cytokines that can act to alter the pattern of gene expression in the chondrocyte or osteocyte. This alteration in the synovium involves a massive influx of monocyte-lineage cells and extensive neovascularization as well as marked hyperplasia of the intimal synoviocytes, which is likely mediated, in part, by the genes described already. Three sets of biologic events are evident: (a) the intrinsic biology of the fibroblast lineage intimal synoviocyte, where increased cell number simply is reflected as increased local concentration of mediators and cell surface molecules; (b) the pathways of mutual interaction of fibroblast lineage and monocyte lineage intimal synoviocytes; and (c) paracrine influences of the products of the autoimmune response on the intimal synoviocytes. It is possible that the loss of normal cell-matrix signals due to hyperplasia and its replacement by more extensive cell-cell receptor interactions result in reverse signaling that leads to a perpetuation of the hyperplasia.

Several cytokines produced in the synovium are candidates for mediating the paracrine effect that results in hyperplasia. IL-1 induces the expression of more IL-1a and IL-1b, in a positive feedback loop (368). IL-1 also induces transcriptional activation of protein kinase C and, by a separate pathway, induces the synthesis of prostaglandin E2 (PGE_2) (369). Fibroblast lineage intimal synoviocyte is one of the sources of increased amounts of this cytokine (370) in that macrophages also produce them. These two pathways initiated by IL-1 also converge to regulate the transcriptional activation of stromelysin. IL-1 induces fibroblast lineage synovial cell

lines to increase IL-6 gene expression by an incompletely defined pathway that is suppressed by corticosteroids (351). Similarly, IL-8 expression is induced by the addition of IL-1 or TNFa (371), although to much lower levels than those elaborated by synovial monocyte lineage cells from RA samples. IL-1 induces the expression of GM-CSF mRNA with a maximum at 4 hours (349). IL-1 also induces the production of fibronectin and types I and III collagen (372).

Fibroblast lineage intimal and subintimal synoviocytes and synovial monocytes and macrophages produce TNF-a, and among several functions, TNF-a is capable of inducing fibroblast lineage intimal synoviocytes cellular proliferation, MMPs (349), and cathepsin production (373), enzymes involved in tissue degradation (see below). As with IL-1, the addition of TNF-a to fibroblast lineage cell cultures induces the expression of GM-CSF (349). Several studies documented the importance of TNF in the development of arthritis, including a TNF-transgenic mouse that develops chronic arthritis (374), and the significant improvement of disease with agents targeting TNF (375,376 and 377); see the section on therapy.

Interleukin-6, a cytokine with effects on B-cell differentiation, is constitutively expressed in synovial fibroblasts obtained from RA (322,323). This cytokine appears critical to the development of arthritis in mice since gene-targeted mutation prevents disease (378). IL-6, particularly in the presence of soluble IL-6 receptor, induces synovial fibroblast proliferation and IL-1 production (379). IL-6 upregulates osteoclast activity and may mediate the development of bone loss and erosions in RA. On the other hand, IL-6 is a potent inducer of tissue inhibitor of metalloproteinase-1 (TIMP-1) (380,381), an inhibitor of MMPs, raising the complexity of its functions as potentially protissue or antitissue damaging, perhaps dependent on the other synovial environment conditions.

Hyperplasia could be explained by abnormalities in the regulation of the normal cell turnover, with increased cellular proliferation or decreased cell death. Mitotic figures have been reported to be uncommon in sections of the RA synovium, and therefore abnormalities in apoptosis regulatory pathways were hypothesized. Early studies described an increased number of apoptotic cells in the rheumatoid synovium (382,383). Additional studies described somatic mutations of p53 tumor suppressor gene in RA fibroblast lineage synoviocytes (384), and the inactivation of p53 in synovial fibroblasts was capable of changing the proliferation rate of the cells (385). Still, it remains unclear what percentage of fibroblast lineage synoviocytes have such mutations and how relevant are those mutations, if rare, in the regulation of synovium hyperplasia. Fas is expressed by these cells, and anti-Fas antibodies are capable of inducing apoptosis of the fibroblast lineage synoviocytes, indicating that this pathway is preserved in RA (383). TGF-b, which is highly expressed in the RA synovium, decreases Fas expression and could contribute to a decreased rate of cell death (386). Anti-Fas antibodies have been used successfully to treat murine autoimmune arthritis in the HTLV-I Tax-transgenic mouse, a spontaneous model of arthritis that shares several similarities with RA. It is conceivable that either somatic mutations in critical cell-cycle regulatory molecules or an antiapoptotic effect from cytokines or other factors present in the RA synovium could contribute to the synovial hyperplasia.

Fibroblasts from hyperplastic RA synovial tissue have increased expression of transcription factors like NFkB (387) and AP-1 (388), which regulate the transcription of several cytokines, including TNF and IL-1 as well as cell proliferation and programmed cell death. Recent studies by Miagkov et al. using the streptococcal cell wall–induced arthritis (SCWIA) and PIA, two well-established models used to gain insight into the pathogenesis of RA in Lewis and DA rats, respectively, described the expression of NF-kB as coinciding with the onset of arthritis. They also noted overexpression of NF-kB-protected synovial fibroblasts from TNF and FasL-induced cell death (389). Additionally, the same study concluded that NF-kB inhibition increased the rate of synovial fibroblast apoptosis and protected animals from developing arthritis, establishing an additional link between NF-kB expression and hyperplasia. It has been demonstrated that AP-1 regulates IL-1 transcription in the RA synovium (388,390) and also that AP-1 inhibition prevents joint destruction in CIA in mice (391). Transfection of synovial fibroblasts with jun D inhibited the proliferation and production of proinflammatory cytokines and MMP by RA synovial cells, mainly as a result of the inhibition of their transcription via downregulation of the AP-1 transcription factor (392).

Monocytoid Infiltration

The biology of the normal synovial lining includes a specific cytoarchitectural relationship between monocyte lineage cells and fibroblasts. In RA, there is an abundance of monocytoid lineage cells occupying sites rather diffusely distributed through the subsynovial tissues or locally enriched along the outer layer of the synovial lining. These cells exhibit varying and often marked degrees of differentiation and activation. It is likely that some or all of these monocytes are activated by lymphokines and that, when activated, they release degradative enzymes, monokines, and other factors.

Monocytes and macrophages are a major source of IL-1, IL-6, and TNF, cytokines involved in the synthesis of MMPs, the principal enzymes involved in cartilage degradation. Also, these cytokines are involved in angiogenesis, endothelial cell activation, and upregulation of adhesion molecules, which facilitate the migration of leukocytes out of the vessels and into the synovium. In fact, therapeutic strategies aiming to antagonize IL-1 with IL-1 receptor antagonist has been effective in clinical trials, and anti-TNF-a strategies have obtained approval from the Food and Drug Administration (FDA) because of its high efficacy (see section on therapy). Furthermore, mice with a disrupted IL-6 gene are either resistant to (378) or develop milder and delayed-onset disease (393) in CIA, making this molecule another potentially good target for drug development. Additionally, a recent study using a combined strategy of subtraction and semiquantitative reverse transcriptase (RT)-PCR identified several known cytokines genes, including IL-1, TNF, and IL-6, chemokines, other genes, and yet unknown genes that were differentially expressed in the activated peripheral blood monocytes from RA patients (394). The better characterization of these known and yet unknown genes is likely to contribute to a clearer understanding of the role of monocytes in the pathogenesis of RA.

Several Fc receptors promote phagocytosis and the release of proinflammatory mediators from monocytes and macrophages. The Fcg receptor IIB, a gene capable of suppressing responses from macrophages, B cells, and mast cells has been shown to be critical in resistance to autoimmune arthritis, CIA, in mice (395). The introduction of the Fcg-RIIB gene knockout into the CIA-resistant strain C57BL/6 ($H\text{-}2^b$) rendered these mice highly susceptible to this erosive arthritis and with increased levels of anticollagen antibodies, similarly to those seen in a highly susceptible strain, the DBA/1. It was not clear from the study whether this increased liability to disease is accounted specifically by one single-cell lineage or whether it involves all different cells that express this gene. Again, this demonstrates the importance of regulatory genes in preventing the development of an autoimmune response or its localization to the target organ or tissue.

Neutrophil

The synovial fluid contains an abundance of neutrophils in varying stages of activation. There is abundant evidence of fixation and activation of complement and immune complexes as well as various proinflammatory cytokines capable of inducing and modulating this response. Neutrophils are largely absent from the synovial tissues, but their capability to produce a number of proinflammatory molecules, such as prostaglandins, nitric oxide, and oxygen radicals among others, suggests that they are indeed involved in the joint destructive processes. The extent of this exudative reaction varies considerably among the joints, between individuals, and in the course of the disease.

Blood neutrophils are found in a state of heightened activation. There is an increased proportion of morphologically polarized cells that correlates with enhanced expression of the CD11b/CD18 (CR3) integrin (396). Similarly, using different methodology, activated neutrophils were demonstrated in synovial fluid effusions (397,398). It remains to be considered an alternative mechanism if cytokines derived from other cells responding to the proinflammatory state in RA also activate neutrophils. Support for this pathway was provided by finding elevated IL-8 levels in synovial fluid (399). Adhesion of neutrophils to inflamed endothelium and their subsequent diapedesis and trafficking to the joint space are also characteristic events in the rheumatoid joint. This is a stepwise process (400) initiated by retardation of free-flowing neutrophils by E and L selectins, which induces the cells to roll slowly along the endothelium. Because the circulating neutrophils in the blood of patients with RA are activated, this process is facilitated compared with that in normal subjects.

Evidence to suggest an important role for neutrophils in arthritis also comes from mice that lack GM-CSF and studies of Felty's syndrome patients. GM-CSF knockout mice are resistant to CIA, despite evidence for autoimmune responses to collagen (401), demonstrating that, in addition to the autoimmune response, processes involved in the localization of this response to the synovium are also critical. Patients with Felty's syndrome, a form of RA that has neutropenia and mild or no arthritis (see later), reportedly have flareups of arthritis that develop as the neutropenia resolves.

The chemokine IL-8, derived from monocytes responding to the proinflammatory state in RA, is another pathway for activating neutrophils (402,403). Support for this latter pathway is provided by the finding of elevated levels of IL-8 in synovial fluid (399), which correlates directly with the number of infiltrating neutrophils (404). Additionally, yet unidentified factors produced by synovial fibroblasts have been demonstrated to maintain the viability and to augment the function of cultured neutrophils (405).

Mast Cells

Mast cells are a conspicuous component in the rheumatoid synovium (406) and are also found in the synovial fluid. The extent of the mast cell infiltration parallels the degree of lymphocytic infiltration (407). The overall mean synovial mast cell density can be as high as 40.3 cells/mm^2, with regional densities of 60.6 and 34.2 mast cells/mm^2 in the superficial and deeper synovial layers, respectively (408). Gotis-Graham et al. found that the mast cell triptase (MCT)–only positive subset predominates, outnumbering MCT and chymase positive (MCTC) by 3:1 (408). These same researchers also found a significant correlation between the histologic inflammation index and the MCT density. Stem cell factor (SCF) produced by fibroblast lineage synoviocytes induces MC chemotaxis. Furthermore, TNF-a, which is abundant in the rheumatoid synovium, augments SCF expression in fibroblast lineage synoviocytes (409).

The rheumatoid synovial fluid produces mast cell growth factors (157). RA, but not OA, synovial mast cells express significant amounts of C5aR (CD88) (410) and

release histamine in response to anti-IgE (410, 411) and to rHuC5a (410). Mast cell degranulation induced artificially in rheumatoid synovial explant cultures consistently resulted in an increased production of PGE_2 and had variable effects on the quantification of released MMPs, suggesting that mast cells may contribute to the regulation of specific MMPs (412). Studies with cultured fibroblast lineage synoviocytes treated with histamine further corroborated the preceding findings by inducing increased amounts of MMP-1, a response that was mediated by H1 receptors (413) and suggesting that mast cells may participate in the regulation of the proinflammatory processes that ultimately lead to cartilage and joint destruction.

Angiogenesis

Angiogenesis is a prominent feature of the rheumatoid synovium and has been the subject of numerous reviews (414). Several factors produced by the synovium and synovium-infiltrating cells induce angiogenesis, including TNFa, IL-1, IL-6, IL-8, IL-15, GRO-a, PECAM, VEGF, and integrins like a_vb_4 and a_vb_3. Several other angiogenic molecules are produced by the rheumatoid synovium. PDGF is structurally related to VEGF and is also an angiogenic factor produced by the rheumatoid synovium. bFGF and aFGF have been identified in the rheumatoid synovium and are potent angiogenic factors. bFGF is more specifically produced by fibroblast lineage synoviocytes (354). In addition, bFGF receptor is also expressed in high amounts in T-cell-rich areas of the rheumatoid synovium (415). IGF-1 is present in the RA synovial fluid and induces endothelial proliferation and chemotaxis (416).

Antiangiogenic strategies have been developed, and one that antagonized a_vb_3 was highly effective in the treatment of a rabbit experimental model of arthritis (417). It will be interesting to see the efficacy and safety of this and other new antiangiogenic agents that are going into clinical trials, at this moment primarily in cancer, in arthritis research.

TISSUE INJURY MEDIATED BY FIBROBLAST LINEAGE INTIMAL SYNOVIOCYTES

The transition of the synovial membrane in RA from a nutritive tissue into one that is the central agent of joint destruction is one of the most troublesome events in the disease. The biologic significance of this transition is heightened by recent observations that suggest the intimal synoviocytes responsible for the destruction of bone and cartilage are closely related to the mesenchymal stem cells, the progenitors of the same osteocytes and chondrocytes. The tissue destruction is mediated in part through expression of enhanced levels of degradative enzymes, capable of altering matrix structure and, likely, through secretion of cytokines that act to alter the pattern of gene expression in the chondrocyte or osteocyte, leading to tissue disruption.

Cartilage injury likely proceeds by two distinct mechanisms.The first is an indirect mechanism in which cytokines released by the synovial lining cells and infiltrating mononuclear cells activate chondrocytes to a pattern of gene expression that results in remodeling and degradation of the cartilage matrix; for example, IL-1 stimulates chondrocytes to release degradative enzymes (418,419). The second is a direct mechanism in which metalloproteinases and other enzymes released by the synovial lining cells and perhaps the infiltrating macrophages directly act to digest the matrix (129, 420). The junction between the hyperplastic synovium and the cartilage appears to be the principal early site of tissue damage and erosive changes. Assessment of the rate and character of cartilage injury has been determined by measuring the fine structure of the products of proteoglycan fragmentation. The glycosaminoglycan-rich region of the core protein predominates during the early phase of cartilage injury before there is significant damage evident on conventional radiographs (421). Later, when frank radiographic changes are evident, the joint fluid contains an abundance of hyaluron-binding domains and lesser amounts of the glycosaminoglycan-rich region of the core protein.

Immune Processes and their Consequences

The different elements present in the synovium interact with each other at different levels. It was first postulated by Krane and Dayer that the lymphocytic response initiates the cascade of immune interactions and cytokines by acting directly on the target fibroblast cells and indirectly on them by activating monocytelike cells to release additional cytokines. As discussed previously, the T-cell compartment does not secrete overwhelming amounts of lymphokines; however, how much cytokine is enough cytokine to sustain the pattern of activation and injury is an unanswered question. Considerable attention has been directed to the major role played by cells in the monocyte compartment in mediating aspects of the cytokine-driven process leading to tissue destruction (422). An important role for the monocyte in producing angiogenic factors has been postulated that emphasizes the multiple feedback loops on which the immune response of RA is built (97). Still more recently, the pattern of gene expression in the fibroblast lineage synoviocyte was recognized to be persistently modulated, either reflecting exposure to inductive components in the inflammatory milieu or due to intrinsic characteristics of this cell lineage. As discussed already, the hyperplastic synovium in RA would lead to an overall increased expression of certain genes involved in chemotaxis, cell activation (cytokines), and synthesis of degradative enzymes (Table 37.3) (19,298,423).

Role of Cell–Matrix Interaction

CD44, one of the critical adhesion molecules for leukocyte extravasation, is also a hyaluronan binding protein. Hyaluronan is an abundant constituent of the extracellular matrix and is especially increased in the synovial fluid. Both high- and low- (fragments) molecular-weight forms bind to CD44. In alveolar macrophages, lower-molecular-weight hyaluronan fragments induce the production of chemokines such as IL-8 and MIP-1a through its receptor CD44; the high-molecular-weight fragments inhibit chemokine production (364). CD44 is predominantly expressed by fibroblast lineage intimal synoviocytes (334,335). Although this pathway has not been extensively studied in fibroblast lineage synoviocytes, one could envision similar effects in the synovium. It is also conceivable that a similar concept may apply to other matrix components. For instance, if intact and large matrix components predominate in the synovium, representing absence of injury, a chemokine/cytokine inhibitory signal would predominate. On the other hand, when traumatic or inflammatory injury occurs, signaling through small hyaluronan fragments/CD44 and maybe through biglycan, lumican, or other component fragments and other receptors would activate a proinflammatory response to remove cellular debris or fight infection. Furthermore, blocking antibodies targeting CD44 prevent the development of arthritis in a murine experimental model (424), further supporting a major role for this molecule in disease pathogenesis.

Proteinases, Proteinase Inhibitors, and Cartilage Injury

MATRIX METALLOPROTEINASES

This class of enzymes consists of collagenase, stromelysin, and gelatinase, which, in concert, can attack all elements of connective tissue, thus participating in physiologic remodeling or pathologic destruction. All are synthesized as proenzymes and are activated by proteolytic cleavage. These enzymes, their transcription regulation, cellular sources, and role in tissue destruction were discussed in part in the preceding section. These molecules are particularly interesting in regard to the mechanism of synovitis because, first, they are induced from low basal levels by a variety of cytokines present in the rheumatoid synovium (IL-1, TNF, and oncostatin M), and they are also constitutively expressed by the lining cells. Second, the cells that produce them are centrally involved in rheumatoid synovitis, namely monocytes, neutrophils, fibroblasts, chondrocytes, and endothelial cells. There is an active effort in pharmaceutical companies to develop MMP antagonists.

Collagenases

Collagenases cleave fibrillar (undenatured) collagens types I, II, and III at one specific site in their triple helical domain. Along with other metalloproteinases, they digest type VII and X collagens. Collagenases are elaborated by mesenchymal cells and by neutrophils and monocytes. Neutrophils store collagenase in granules. The mesenchymal cell variety of collagenase has been strongly implicated in synovitis by the finding that its mRNA is expressed at high levels in the synovial lining (425). The identification of abundant collagenase at the protein level in the vicinity of erosions, but not in equivalent abundance in other regions of the synovium, suggests that it may play a special role at these sites (426).

Stromelysins

The primary action of stromelysin is to cleave proteoglycan core and link proteins, fibronectin, elastin, and procollagens I, II, and III, thereby mediating the remodeling of most of the matrix components other than collagen. Stromelysin also participates in collagenase activation (427). Stromelysin mRNA is strongly expressed in RA fibroblast lineage intimal synoviocytes cells (423,425). Immunohistochemical staining reveals that stromelysin protein is present in fibroblasts and endothelial cells (369) as well as in monocyte lineage lining cells using *in situ* probing (327). Using *in situ* hybridization, collagenase mRNA was colocalized with that for stromelysin, suggesting that the production of these two metalloproteinases is coordinated (327,425). The fact that disruption of the stromelysin 1 (MMP-3) gene did not protect mice from developing cartilage destruction in murine CIA suggests that redundant or compensatory functions exist among MMPs or between MMPs and other genes (428).

Gelatinase

Gelatinase cleaves denatured collagens types I, II, and III and digests native types IV, V, VII, X, and XI. Levels of gelatinase mRNA vary considerably from sample to sample of synovial lining but are commonly elevated in both OA and RA.

Cathepsins

Cathepsins are cysteine proteinases that are produced by the rheumatoid synovium and induced by TNF-a (373). Cathepsin L is one of the major Ras-induced proteins in Ras-transformed cells and is expressed in half the rheumatoid synovia, being localized to the fibroblast lineage intimal synoviocytes (429). Cathepsin B was identified both in fibroblast lineage synoviocytes from OA and RA, likely representing gene expression by both the intimal and subintimal fibroblast lineage synoviocytes (20).

Tissue Metalloproteinase Inhibitors

The activated metalloproteinases bind stoichiometrically to a_2-macroglobulin in the plasma, but their major regulation after activation is through the two tissue inhibitors of metalloproteinases, TIMP-1 and TIMP-2 (430,431). These two homologous molecules are secreted in a highly regulated manner by cells elaborating metalloproteinases. The TIMPs also stoichiometrically bind to the metalloproteinases (430). It appears that the ratio of synthesis of TIMP to specific metalloproteinase is a critical index of the potential of a tissue to mediate matrix remodeling. In cultured fibroblast lineage synoviocytes from OA patients, there is a much higher average ratio of TIMP to stromelysin than is found in RA (423). Although IL-6 is thought to be a proinflammatory cytokine critical for the development of autoimmune arthritis in rodents (378), it does not appear to induce MMP expression directly (432). On the contrary, IL-6 can be a potent inducer of TIMP-1 (380,381). Although oncostatin M can induce MMP expression, particularly in the presence of IL-1 (433), it can also induce TIMP-1 expression much as LIF does (381,434), further demonstrating the complexities of the molecular interactions in different tissue environment conditions.

OTHER FEATURES OF RHEUMATOID ARTHRITIS

Pregnancy-associated Remission

DISEASE BEHAVIOR DURING PREGNANCY AND POSTPARTUM

Another phenomenon relating to the female RA patient is the occurrence of significant and occasionally striking improvement or remissions in disease activity during pregnancy (435,436 and 437). Whereas pregnancy-associated improvement usually appears in the first trimester, the most striking decrease in disease activity occurs in the third trimester. Recently, in a study by Barrett et al. (438), the largest prospective study of pregnancy in RA done so far, no consistent pattern could be identified. These researchers found that 16% of 95 RA patients achieved remission during pregnancy, two thirds reported significant improvement in swelling and pain, but 16% to 20% reported either no changes or disease worsening. RF-negative women were more likely to achieve remission than RF-positive women (28% versus 10%). Swollen and tender joint counts during pregnancy were in general low (counts of only 2).

A related observation is that there is a reduction in the incidence of RA during pregnancy, which is compensated by a numerically greater incidence of disease appearing in the 3 months postpartum (439). Interestingly, prepartum RF positivity appears to be a risk factor for the onset of RA in the postpartum period, as suggested by Iijima et al. (440). These investigators followed 410 healthy pregnant subjects prospectively and found that two patients, 22% of the RF positive and none of the RF negative patients, developed RA in the postpartum period.

Besides the increased risk for disease onset in the postpartum period, RA patients who experienced improvement in disease activity during pregnancy commonly notice a flareup in the postpartum period. The same study described by Barrett et al. (438) also followed up on pregnant RA patients through the postpartum period. The health assessment questionnaire (HAQ) scores, validated questionnaires that are used to measure health status, did not differ between the last trimester and the first and sixth month postpartum; however, joint counts were significantly higher in the postpartum period. At 6 months postpartum 66% and 77% of the women reported worsening of their joint swelling and pain, respectively; most of that deterioration occurred by the first month (438).

IMMUNOLOGIC AND HORMONAL MECHANISMS IN DISEASE IMPROVEMENT DURING PREGNANCY

Numerous mechanisms are likely involved in the disease improvement seen in some RA patients, but it remains unclear why some patients improve and others do not. Possible mechanisms include (a) changes in the production of different cytokines with a shift toward the predominance of Th2 cytokines; (b) an immunosuppressive effect in cellular immune responses mediated by estrogens; (c) a pregnancy-induced down-regulation of the synovial production of certain proinflammatory cytokines, growth factors, and proteinases; and (d) HLA differences between mother and child that would contribute to a downregulation of the immune responses through yet uncharacterized mechanisms. Although there is evidence to support a role for all four of these mechanistic processes, none has been thoroughly studied or understood.

The Th2 cytokines, particularly IL-4, increase as pregnancy progresses (441). Additionally, there is constitutive production of Th2 cytokines (IL-4, IL-5, and IL-10) in the maternal–fetal interface (442), and the human placenta at term expresses high levels of IL-10 (443). A shift in the cytokine balance to Th2 occurs during pregnancy and is probably essential for the pregnancy to proceed, as suggested by murine studies in which the administration of Th1 cytokines induced fetal resorption [for review, see Elenkov et al. (444)]. IL-2 production by peripheral whole blood from pregnant RA patients is decreased, more so in the third trimester, and soluble TNF receptors p55 and p75, which bind and interfere with TNF function, were increased, again most significantly in the third trimester, whereas TNF-a and IL-1 b remained unchanged (445). Thus, the suppression of Th1 cytokines, which is essential for fetal survival, may be a central factor in the immunomodulatory function of pregnancy in the disease activity of patients with RA, shifting the immune response from Th1 to Th2.

Estrogen production increases during pregnancy, and its immunoinhibitory functions (see preceding discussion on gonadal hormones) may be involved in this cytokine shift. Conceivably, these functions operate through cytokine-independent pathways as well. In mice with CIA, estrogen given postpartum prevents the normally seen postpartum flareup of RA (446). Individual variability on the magnitude of the increase of the estrogen levels during pregnancy or the patient's immune system's capacity to produce Th2 cytokines are possible variables that could predict disease improvement or remission during pregnancy.

A third possibility was raised in a study by Hart and Reno (447), who studied the pattern of expression of 17 genes in the synovium of pregnant rabbits and controls. They found alterations in several of these genes, suggesting that pregnancy can affect the biology of the normal synovium and likely of the rheumatoid synovium as well. Although these researchers studied a few genes, a broader analysis of other synovial gene products would contribute to clarifying the spectrum of changes induced by pregnancy. Whether estrogens or nonsynovial cytokine changes induced by pregnancy account for the synovial gene expression changes remains to be determined. The basis of this difference in the effect of pregnancy was studied by Nelson and colleagues, who noted that pregnant individuals who do not experience a remission were more likely to share HLA alleles with the husband and the fetus, especially those at the HLA-DQ locus (448,449).

The fourth and particularly intriguing mechanism was proposed by Nelson et al. (448,449 and 450). Because an immune response to paternally inherited fetal HLA occurs during normal pregnancy and RA has a known HLA class II association, the hypothesis that maternal–fetal disparity in HLA alloantigens might be associated with the pregnancy-induced remission of RA was tested. Maternal–fetal disparity in alleles of HLA- DRB1, DQA, and DQB occurred in 26 of 34 pregnancies characterized by remission or improvement (76%) compared with 3 of 12 pregnancies characterized by active arthritis (25%) (OR, 9.7; $p = 0.003$). The difference between the two groups was most marked for alleles of HLA-DQA (450). van der Horst-Bruinsma et al. also found that DQA1 and DQB1 incompatibility between mother and child contributes to a favorable effect on the course of RA and may postpone the risk of RA onset during pregnancy (451). Identification of the regulatory mechanism may be challenging. For instance, in another study, simple maternal exposure during pregnancy to either fetally inherited paternal HLA-DR1 and DR4 genes or to paternal DR genes similar to their own did not appear to contribute to postpartum maternal susceptibility of RA (452). These findings suggest the possibility that immunologic mechanisms involved in maintaining the immunologically privileged status of the fetal “allograft” influence processes essential to the presence of the inflammation of RA. Clearly, delineating the mechanisms involved in the pregnancy-induced remission would provide a new lead to the therapy of this disease.

PROLACTIN AND LACTATION

The onset of RA or a flareup during the postpartum could also point to a pathogenic role of hormones produced during the lactation period. The relative risk accounted for by breastfeeding in RA susceptibility and disease severity remains controversial (453). Barrett et al. (438), in a prospective study, compared disease activity during pregnancy and at 6 months postpartum among 49 nonbreastfeeders, 38 first-time breastfeeders, and 50 repeat breastfeeders. After adjustment for several possible confounding factors, including treatment, they found that first-time breastfeeders had increased disease activity at 6 months postpartum. Although there were limitations with the self-reported strategy used, this study provided prospective evidence in support of the previous clinical impression.

It is not clear why RA patients would experience disease exacerbation during the postpartum period. Hormonal changes, including the production of prolactin, certainly are among the most obvious possibilities. In fact, even male patients with RA have higher serum prolactin levels than normal controls (454) or other chronic nonautoimmune inflammatory diseases (455). High prolactin levels significantly correlated with the duration of RA and with functional stage according to the Steinbrocker classification, but they were not correlated with the low levels of androgens observed in male patients with RA (454). In mice, administration of prolactin

during the period of induction of CIA makes the arthritis worse, but treatment at later stages has no effect (456). Furthermore, administration of the prolactin inhibitor bromocriptine to arthritic mice in the postpartum period induced a 50% reduction in disease severity compared with the clinical exacerbation of disease seen in untreated animals (457). Conceivably, prolactin could operate as an end-stage proinflammatory mechanism for accumulating events that achieve the climax in the postpartum period.

Among other immunoregulatory effects, prolactin increases nitric oxide and TNF synthesis by neutrophils (458), enhances natural killer cell function, and can increase IL-2 and IFN-g production by lymphocytes (459). Prolactin receptors are expressed in primary lymphoid organs, such as in bone marrow and thymus. In peripheral organs, all B cells and macrophages and 70% of both CD4+ and CD8+ T cells are prolactin receptor positive, further supporting the concept that prolactin may regulate the development and function of the immune responses. On the other hand, proinflammatory cytokines like TNF-a and IFN-g can decrease the pituitary production of prolactin (460), again pointing to the complexity of networks involved in the neuroimmune regulation.

Previous Use of Oral Contraceptives

A related question is whether oral contraceptive use diminishes the incidence of RA. This possibility has received considerable attention since an initial study suggested it (461), and the question of its generality and significance has been the subject of reports with differing conclusions. Brennan et al., in a review of the literature, concluded that only current use of oral contraceptive is protective for the development of RA (462). A carefully done metanalysis of 15 studies on oral contraceptives and RA found no conclusive evidence of a protective effect of oral contraceptives on the risk of developing RA (463).

Neuroendocrine Abnormalities

HYPOTHALAMIC–PITUITARY–ADRENAL AXIS

Although RA patients have normal cortisol and adrenocorticotropic (ACTH) levels, if one considers the stress associated with this chronic disease, this would be interpreted as inappropriately normal. This suggests a blunted hypothalamic–pituitary–adrenal (HPA) axis responsiveness. The regulation of ACTH levels is affected by IL-6 levels and other cytokines. Additionally, cortisol clearly affects the immune response, and its impaired production is likely involved in the regulation of disease activity (464).

CATECHOLAMINES

Catecholamines are involved in the normal stress response likely present in chronic diseases. *In vitro* studies have shown that Th1, but not Th2, T-cell clones express b_2-adrenergic receptors (465). On stimulation with b_2-adrenergic drugs, Th1 clones showed an increase in intracellular cyclic adenosine monophosphate (cAMP) and inhibition of the production of IFN-g, whereas IL-4 synthesis by Th2 clones was unchanged (465). Additionally, b_2 agonists inhibit IL-12 production by human monocytes and dendritic cells (466). These data suggested that increased catecholamine synthesis or the use of b-adrenergic agonists could be beneficial in the treatment of RA, a disease thought to involve Th1 cytokines in its pathogenesis. Malfait et al., in fact showed that daily administration of salbutamol was effective in the treatment of established CIA in mice, decreased joint damage, and reduced IL-12 and TNF-a release by peritoneal macrophages in a dose-dependent manner (467). Additionally, salbutamol treatment also decreased TNF release by synovial cells from arthritic mice, and decreased the CII-specific IFN-g production and proliferation of draining lymph node cells. *In vivo*, salbutamol specifically blocked mast cell degranulation in joint tissues. It will be interesting to see whether this strategy will prove beneficial as an adjuvant to the treatment of RA.

CLINICAL FEATURES AND DIAGNOSIS

Disease Presentation and Articular Manifestations

The onset of RA may vary from acute to one of an insidious character in which low-grade fever, stiffness, fatigue, joint pain, and swelling progress over weeks to months. The course of RA also varies from patient to patient. The classic additive pattern consists of an accumulation of newly involved joints, with inflammation persisting in those that were first involved. A small percentage of patients exhibit a monocyclic course in which, after a period of arthritis, the disease goes into complete remission. Most commonly, however, the disease has a chronic pattern, alternating periods of improvement with periods of exacerbations ultimately causing joint erosions, malalignments, and deformities (Fig. 37.7). In 10% to 20% of cases, RA may present as palindromic rheumatism with recurrent and self-limited (days) episodes of nonerosive monoarthritis/oligoarthritis (468).

Figure 37.7. Hand radiographs of a patient with rheumatoid arthritis revealing extensive erosive changes in the wrist, carpal joints, proximal interphalangeal joints, and metacarpophalangeal joints.

Arthritis in RA occurs in a characteristic pattern with pain and swelling of the small joints of the hands and feet, particularly the proximal interphalangeal (PIP), metacarpophalangeal (MCP), and metatarsophalangeal (MTP) joints. In addition, the arthritic process commonly involves wrists, elbows, shoulders, knees, ankles, temporomandibular joints, cervical spine, and, to a lesser degree, the hip joints. The pattern of arthritis typically involves the joints on both sides of the body in a symmetric distribution.

Whereas most joints are affected, certain joints like the distal inter-phalangeal (DIP), sacroiliac, thoracic, and lumbar spine joints are rarely involved in RA. Similarly, enthesitis, the inflammation of the bone insertion site of the tendons typically seen in the spondyloarthropathies, is not present in RA.

Extraarticular Manifestations

Rheumatoid arthritis is a systemic disease that may involve organs other than the joints. The extraarticular manifestations range from anemia of chronic diseases, subcutaneous nodules, and ocular involvement to necrotizing vasculitis and Felty's syndrome. Extraarticular disease correlates with a higher risk for erosive changes, disability, and decreased life expectancy with death from a variety of causes (469,470). Titers of RFs are usually elevated, and circulating immune complexes involving IgG RF may be identified in association with decreased complement levels (244,469). The presence of antinuclear antibodies and eosinophilia also correlate with increased risk for extraarticular disease. In the following paragraphs, we review some aspects of the extraarticular manifestations in RA. The reader is referred to rheumatology textbooks for a more complete review of extraarticular manisfestations and laboratory abnormalities of RA.

SUBCUTANEOUS NODULES

Rheumatoid nodules develop in 20% of patients with RA and are a unique feature of the disease. Typically, the rheumatoid nodule is found at pressure areas in the subcutaneous tissue overlying bone, such as the olecranon and digits, but they also occur in the synovium, tendons, myocardium, pericardium, lung, central nervous system, and ocular sclerae. At the earliest stage, the nodule is characterized by a perivascular round cell infiltration in the terminal vascular bed with proliferation of fibroblasts and monocytoid cells. At its advanced and characteristic stage, the nodule is dominated by a central necrobiotic mass, which is essentially devoid of blood vessels. Surrounding this are palisades of activated cells that express monocyte lineage markers and MHC class II molecules (471,472). At the periphery is a sparse inflammatory infiltrate composed of T cells with a CD4/CD8 ratio like that of the peripheral blood.

FELTY'S SYNDROME

Felty's syndrome typically occurs much later in the course of RA, sometimes after the joint disease activity has become somewhat quiescent. Neutropenia often associated with thrombocytopenia along with splenomegaly in a patient with RA constitute the syndrome. As mentioned, vasculitis also may be seen in association with Felty's syndrome. Nonvasculitic chronic leg ulcers also have been described. The neutropenia has been related to high levels of circulating immune complexes as well as to specific antineutrophil antibodies (473). Coating of neutrophils or platelets by complexes or antibodies may facilitate their clearance by the reticuloendothelial system. The response to splenectomy is variable, and the procedure is not routinely recommended. In addition to methotrexate and other cytotoxic agents, the recent use of granulocyte colony-stimulating factor (G-CSF) and GM-CSF has been helpful in treating neutropenia (474,475). Interestingly, there have been descriptions of reactivation of previously quiescent arthritis in RA patients in association with the improvement of the neutrophil counts (476). This suggests that, whereas some of the extraarticular manifestations of Felty's syndrome are neutrophil independent and occur despite neutropenia, neutrophils, or the granulocyte-stimulating factors may have a significant role in the activity of the joint disease in RA, as discussed in the pathogenesis section of this chapter.

Diagnostic Criteria

The American College of Rheumatology (ACR), formerly the American Rheumatism Association, published the revised criteria for the diagnosis of RA in 1988 (477). These criteria were established in an attempt to create a uniform nomenclature and disease definition, thus facilitating comparison of studies done in different research institutions. In reality, these criteria are widely disseminated among physicians and are used for diagnosis. The criteria are listed in Table 37.6. A person who fulfills four of these seven criteria is said to have RA, with criteria 1 through 4 present for at least 6 weeks to rule out viral arthritides. The criteria set has a sensitivity of 91.2% and a specificity of 89.3% for RA (477).

TABLE 37.6. 1987 Revised Criteria for the Classification of Rheumatoid Arthritis[a]

The combined use of hand and feet radiographs increases the likelihood of identifying erosive changes at earlier stages, as demonstrated by Paimela et al. (478). These researchers described MTP joint erosive changes in 23% of patients in the first year of illness, but hand involvement was found in only 11%, of whom half also had foot involvement (478).

Studies of recent-onset synovitis cohorts show that most RA patients meet the ACR criteria at an early stage after the disease onset and that it is uncommon that an undifferentiated oligoarthritis, particularly in patients who are RF negative, will progress to meet the criteria for RA (479,480 and 481).

NEW THERAPEUTIC STRATEGIES

The treatment of RA involves several aspects in a multidisciplinary approach that is critical for the achievement of good disease control. Although the ultimate goal of therapy is disease remission, this goal is not commonly achieved. The management goals are to control disease activity, alleviate pain, maintain function for activities of daily living and work, maximize the quality of life, and slow the rate of joint damage. The ACR published guidelines for the management of RA (482). It is beyond the scope of this chapter to review extensively the drugs used in the treatment of RA. For that, the reader is referred to textbooks of rheumatology. This section provides a concise summary of new drugs and recent advances and strategies in the pharmacologic therapy of RA.

Leflunomide

This is a new FDA-approved drug that interferes with dihydroorotate dehydrogenase, an enzyme critical for *de novo* synthesis of pyrimidines. It interferes with T-cell proliferation. Clinical trials demonstrated that it is superior to placebo and similar to sulfasalazine in disease control (483). Also, leflunomide was as effective in disease control and in delaying radiographic disease progression as methotrexate (484). Although long-term safety data are not available, this new drug appears to be quite promising.

Anti-TNF Agents

Strategies aiming to antagonize TNF, both with antibodies to TNF or with the use of a TNF receptor fusion protein (etenarcept), have been shown to be highly efficacious in disease control (375,377,485) with overall good safety profiles, and about 70% of patients achieve significant clinical improvements. These agents achieve clinical response in a few weeks, earlier than other DMARDs. Etanercept is administered as two subcutaneous injections per week, and anti-TNF antibodies intravenously.

Combination Therapy

Combination therapy has been proposed and used for cases that do not respond to a single agent, emphasizing that early intervention and the achievement of disease control improves quality of living, correlates with the maintenance of better function and reduces mortality. Recent studies are also trying to identify early markers for poor response to single-drug therapy, like, for example, the presence of certain shared-epitope-containing alleles (486), and advances in pharmacogenomics should also facilitate this task in the near future.

Several studies have emerged during recent years addressing strategies to treat patients that do not respond to one or multiple DMARDs. The first combination drug trial by McCarty and Carrera (487) showed that the combination of cyclophosphamide, azathioprine, and hydroxychloroquine was highly efficacious but had a high rate of side effects. Among the most important combination trials published after that is the triple-drug regimen described by O'Dell et al., which included methotrexate, sulfasalazine, and hydroxychloroquine (488). The triple-drug combination was more effective than either methotrexate alone or a combination of sulfasalazine and hydroxychloroquine. In another study that enrolled patients with severe RA and partial response to methotrexate, the combination of cyclosporine and methotrexate achieved significant clinical improvement (489). In a third study, Dougados et al. studied recent-onset RA and could not find a significant difference in clinical disease control or radiographic changes in a study that compared sulfasalazine and methotrexate alone or in combination (490). Boers et al. used an alternative strategy in recent-onset RA: These investigators used methotrexate in combination with sulfasalazine and incorporated high-dose prednisone (60 mg daily) therapy for the first few weeks, with a rapid taper to 7.5 mg daily, and compared this regimen to sulfasalazine alone (491). After 28 weeks of follow-up, the intensive/combination therapy group had achieved a statistically significant clinical improvement, with significantly less radiographic damage.

Anti-TNF agents were used in combination regimens. Both the combination of anti-TNF antibodies (492) or etenarcept with MTX (493) achieved significantly better disease control than methotrexate alone. The combination of leflunomide and methotrexate also may become a good alternative once better studied (494).

Although the use of combination therapy in recent-onset disease is still a controversial issue, it is a widely used strategy for severe and refractory disease. The evidence in support of a better disease outcome, quality of living and function, and improved survival associated with clinical response to DMARDs highlights the importance of a dynamic approach to the treatment of RA, trying to maximize clinical improvement and balancing risks of potential drug toxicities.

New Directions for Therapy

Currently, great activity is ongoing in the field of therapy of RA using novel agents that have the potential for specific immunomodulation. These agents include the use of a variety of cytokines like IFN-b, IL-10, and IL-4 or cytokine receptor antagonists such as the IL-1 receptor antagonist. A controlled trial of IL-1 receptor antagonist showed significant improvement in disease activity (495) and reduced joint damage (496).

Other agents include monoclonal antibodies directed against surface structures on T-cells, such as CD4, or toxin-conjugated cytokines, such as those to IL-2, which have the potential of inactivating or extirpating cells in a particular lineage or state of activation (497,498). Anti-T-cell strategies based on anti-CD4 antibodies (499) and IL2-diphtheria toxin fusion protein (500) have provided disappointing results in patients with a difficult-to-treat disease, raising the issue that, although T cells may be critical to the onset of RA, T-cell-independent pathways may be more important during the chronic stages of disease in a subset of patients. At the level of attempting to achieve greater therapeutic finesse, agents are being developed that are directed to the MHC class II molecule or TCRs that are putatively involved in the disease, although here again the rationale for their use is not unambiguous.

Attention is also being given to the possibility of inhibiting the egress of leukocytes into the synovium by blocking antibodies to adhesion molecules (501,502) or antichemokine agents and to antiangiogenic agents (417). Although plasmapheresis was previously ineffective in RA, apheresis with the Prosorba column was recently shown to be an efficacious treatment of RA in patients with active disease who have failed other treatments (503). Interestingly, the patients showed only clinical improvement weeks after completion of the therapy, and there were no significant changes in the levels of immunoglobulins of RFs, leaving no clear idea as to how these columns exert their effect. We are seeing a number of new strategies being used in experimental animal models of arthritis that are likely to go into clinical trial in the near future, including antichemokine agents, as discussed already.

Gene therapy is being actively studied in autoimmune arthritis. Studies using gene therapy with IL-4 and IL-10 into the joints of animals with autoimmune arthritis have been performed, and the reports appear promising (504,505). Another actively used strategy is DNA vaccination, where a blocking immune response against a particular protein is generated. This latter strategy has been used to induce an immune response against certain chemokines expressed in high amounts in both arthritic joints from rats and RA patients. Repeated administration of the constructs encoding MCP-1, MIP-1, or RANTES inhibited the development of adjuvant-induced arthritis, and when each vaccine was administered after the onset of disease, it inhibited progression (506). In another study, vaccination with naked DNA encoding for mycobacterial heat shock protein 65 also protected rats from developing adjuvant-induced arthritis (507), and it certainly will be interesting to see these strategies going into human clinical studies.

CONCLUSION

There is still a lot to be learned and understood about the pathophysiology and the genetic regulation of RA; however, patients already are benefiting from new strategies using combination drug regimens and new therapeutic agents recently approved by the FDA for the treatment of RA. Early use of DMARDs has been shown to modify the disease outcome, quality of life, and survival. The rapid biotechnological and genetic developments most certainly will transfer into better tools for early diagnosis, prognostication, as well as to even better, more specific, and less toxic therapies.

38 JUVENILE RHEUMATOID ARTHRITIS

Alexei A. Grom, M.D., and David N. Glass, M.D.

Juvenile rheumatoid arthritis (JRA) is a chronic idiopathic inflammatory disorder primarily involving joints. The diversity of its clinical symptoms, both at onset and during the course of the disease, and the lack of specific laboratory tests can make the diagnosis problematic. Compounding these difficulties, the diagnostic criteria used in different countries are not the same. Some differences in terminology also exist. The term *juvenile rheumatoid arthritis* is broadly used in the United States and in Canada. In Europe, the term *juvenile chronic arthritis* was in general use until recently. It is being superseded by the umbrella term *juvenile idiopathic arthritis.*

INITIAL DESCRIPTION AND CLASSIFICATION

The first clinical report of juvenile-onset arthritis was supplied in 1864 by Cornil, who described a 29-year-old woman with chronic inflammatory arthritis from the age of 12 years (1). Still's classic presentation of 22 cases appeared in 1897, accompanied by the suggestions that JRA may have different origin from adult rheumatoid arthritis (RA) and may include more than one disease (2). In 1937, Colver presented results of a long-term follow-up study of 63 patients, whose outcomes were relatively good compared with those of patients with adult RA (3).

Attempts to classify disease subtypes have been made since the 1970s (4,5,6,7 and 8). In the Americas, the most frequently used criteria are those of the American College of Rheumatology; these criteria were first published in 1972, and they were then revised in 1977 and again in 1986 (Table 38.1). In the United States, classification has been based on the type of onset, which is determined by clinical manifestations during the first 6 months of the disease. The three major types of onset are pauciarticular (four or fewer joints involved at onset), polyarticular (five or more joints), and systemic (9).

1. Age at onset <16 yr
2. Arthritis in one or more joints, defined as swelling or effusion, or presence of two or more of the following signs: limitation of motion, tenderness or pain on motion, and increased heat
3. Symptoms persistent for 6 wk or longer
4. Type of onset during the first 6 mo classified as
   A. Systemic disease: arthritis with intermittent fever
   B. Polyarthritis: five joints or more
   C. Oligoarthritis (pauciarticular form): four joints or fewer
5. Exclusion of other forms of juvenile arthritis

TABLE 38.1. American College of Rheumatology Criteria for Diagnosis of Juvenile Rheumatoid Arthritis

In 1997 in Durban, South Africa, the criteria for classification of childhood arthritis were reviewed at the meeting of the Pediatric Standing Committee of the International League of Associations for Rheumatology. The classification was expanded to include seven types of the disease: systemic arthritis, oligoarthritis persistent, oligoarthritis extended, polyarticular arthritis rheumatoid factor (RF)–positive, polyarticular arthritis RF-negative, enthesitis arthritis, and psoriatic arthritis (Table 38.2). This new classification is now widely being used in most European countries, with the umbrella term *juvenile idiopathic arthritis* to indicate disease of childhood onset primarily characterized by arthritis persisting for at least 6 weeks and currently having no known cause (8).

Systemic
Polyarthritis (RF positive)
Polyarthritis (RF negative)
Oligoarthritis persistent
Oligoarthritis extended
Enthesitis-related arthritis
Psoriatic arthritis
Other arthritis: fits no other category or fits more than one category

RF, rheumatoid factor.

TABLE 38.2. Durban Classification of Childhood Arthritis

CLINICAL DESCRIPTION BASED ON ONSET TYPE

The *pauciarticular* type is divided into two subtypes (9). *Early-onset pauciarticular JRA* (EOPA-JRA or type 1) occurs mostly in girls less than 6 years of age. Antinuclear antibody (ANA) positivity is a characteristic finding in this group of children with JRA. The large weight-bearing joints are usually the primary sites of the inflammatory activity, and an asymmetric pattern of joint involvement is common. Severe destructive changes are the exception rather than the rule in this type of the disease, although some cartilage erosions may appear. As the disease progresses, it converts to polyarticular disease in as many as 20% of patients (10,11). EOPA-JRA is accompanied in 10% to 20% of patients by chronic anterior uveitis (iridocyclitis), which can lead to loss of vision (12,13). The uveitis is a chronic, nongranulomatous inflammation affecting the iris and ancillary body. The posterior uveal tract is rarely involved. The eye disease may present later than arthritis, and in at least half of the children, it is asymptomatic at early stages. In many instances, it can be detected only by slit-lamp examination. Therefore, it is important that affected children undergo regular slit-lamp examination every 3 months when they are young, with the interval between examinations extending to not more than 1 year as their age increases. The probability that a patient will develop eye disease diminishes markedly after 5 years from the onset of the arthritis. The overall morbidity in EOPA-JRA may be determined more by the outcome of the eye disease than by the outcome of the arthritis.

Late-onset pauciarticular JRA (type 2) occurs more often in boys. Involvement of the spine along with the large joints of the lower extremities is typical. Patients often carry the human leukocyte antigen (HLA)-B27 gene, which is a marker for the development of enthesopathy and even ankylosing spondylitis in some (14). In this form of JRA, the eye disease, also uveitis, is more acute and tends to be self-limiting, in contrast to the ocular effects of EOPA-JRA.

The *polyarticular* type is divided into two subtypes on the basis of the presence or absence of RF. In the group positive for RF, which is relatively small, late onset of the disease is more common, and the course of the disease resembles that of adult RA. RF-negative disease is frequently less severe and may begin at any time during childhood. Some systemic manifestations, such as fever spikes and lymphadenopathy, may be present in both subtypes, but the joint disease usually overshadows the more general symptoms. Although the large joints such as the knees, wrists, and ankles are commonly involved, symmetric inflammation of the smaller, more distal joints is more characteristic. In a significant proportion of patients in this group, the metacarpophalangeal and the proximal interphalangeal joints are involved (15). The spine, especially the cervical region, may be affected. Hip joints are frequently involved at later stages of the disease. The arthritis is typically destructive. Early stages of the disease are characterized by soft tissue swelling and juxtaarticular osteoporosis. Later changes include destruction of the cartilage and bone and eventually bony ankylosis. Subcutaneous nodules (not typical of JRA in general) are common in patients with polyarticular disease. Similar to those in adult with RA, rheumatoid nodules usually appear in areas of pressure such as on elbows and heels and along vertebrae.

The *systemic* form of JRA also appears to be heterogeneous. Some of the patients in this group have relatively mild arthritis with prominent extraarticular features, such as spiking fevers, hepatosplenomegaly, and vasculitis (16). The typical fleeting pink macular rash, pleurisy, and pericarditis (as a part of generalized serositis) are common. Generalized enlargement of lymph nodes, especially in the axilla, is also typical. The joint involvement, like the rash, may be more marked at the time of the temperature elevation and sometimes may be entirely absent when fever is gone. Other patients with the systemic form develop severe, progressive arthritis with an early appearance of erosive changes in the cartilage. This more severe illness is likely to be associated with the HLA-DR4 gene in some populations. These patients can have the worst outcome for joint disease of any group of patients with JRA. Patients with systemic onset may have marked polymorphonuclear leukocytosis and thrombocytosis. RF and ANA are generally negative in this group of patients.

ACUTE COMPLICATIONS

Vasculitis

Rheumatoid vasculitis is uncommon in JRA and occurs most often in the older children with RF-positive polyarthritis (9,16,17). This devastating, widespread, small to medium-sized vessel involvement must be distinguished from benign digital vasculitis, which is more frequent, and it may occasionally be associated with vascular calcification that is seen on radiographs along the course of the digital arteries (18).

Macrophage Activation Syndrome

The macrophage activation syndrome is a rare but serious complication of systemic JRA associated with considerable morbidity and death (19,20). It is a clinical syndrome caused by the excessive activation and proliferation of well-differentiated macrophages. Massive release of proinflammatory cytokines during macrophage activation appears to be the major pathogenic mechanism. The macrophage activation syndrome can be clinically differentiated from a typical exacerbation of systemic JRA by several features that become apparent early in the course of this syndrome. Patients with an exacerbation of systemic JRA usually have a spiking daily (quotidian) or twice-daily (double quotidian) fever, evanescent rash, generalized lymphadenopathy, and hepatosplenomegaly. Marked polymorphonuclear leukocytosis, thrombocytosis, and increased erythrocyte sedimentation rate with hyperfibrinogenemia are common features that reflect the activity of inflammation. Mild elevation of liver enzyme activity is also common. In contrast, persistent, unremitting fever (which is different from the quotidian fever of systemic JRA), mental status changes, and moderately elevated liver enzyme activity, accompanied by a sharp fall in erythrocyte sedimentation rate in association with hypofibrinogenemia, relative leukopenia, thrombocytopenia, prolonged prothrombin time, and easy bleeding, should raise the suspicion of macrophage activation syndrome. The diagnosis is confirmed by demonstration of hemophagocytic histiocytes in bone marrow and lymph nodes.

LONG-TERM COMPLICATIONS

Growth Retardation

The chronic inflammatory process in children with JRA causes problems relating to growth. These may be localized, such as when the disease is associated with epiphyseal overgrowth and premature epiphyseal closure (9). A clinically apparent consequence is the finding of unequal leg length; this finding is particularly typical in EOPA-JRA. Another characteristic localized growth problem is mandibular hypoplasia (21). Chronic inflammation also has an effect on overall growth. These children are frequently smaller than expected, and this effect is compounded by the use of corticosteroid therapy (22,23).

Amyloidosis

Amyloidosis has been described in as many as 50% of patients with systemic-onset JRA in European populations (24,25,26 and 27). It is a much less common finding in the North American populations (28). One European study demonstrated a genetic association between the development of amyloidosis and certain isoforms of amyloid P component (29). However, the finding that patients with JRA who are of European origin and living in the United States develop amyloiodosis only on rare occasions suggests an environmental rather than a genetic cause of this complication. Attempts to associate amyloidosis with major histocompatibility complex (MHC) genes have not been successful (30).

EPIDEMIOLOGY

Overall Incidence and Prevalence

The lack of standard diagnostic criteria has complicated epidemiologic studies as well. Probably, the most accurate study applied the revised American College of Rheumatology classification criteria to the unique database of the Rochester Epidemiology Program Project: in 1983, this study reported an incidence for JRA of 13.9 cases per 100,000 in a year (31). However, the follow-up study, using the same database, noted some decrease in the JRA incidence in the 1990s (32). Results of other population studies are presented in Table 38.3.

Country	Incidence	Reference
Finland	9.2/100,000	174
Finland	19.6/100,000	175
Sweden	10.9/100,000	176
Canada	5.3/100,000	46
United Kingdom	10.0/100,000	177

TABLE 38.3. Incidence of Juvenile Rheumatoid Arthritis in Different Countries

In the Rochester study, the prevalence rate for JRA was 94.3 patients per 100,000 children on January 1, 1980, and 86.1 on January 1, 1990 (32). Based on the extrapolation of these numbers to the entire United States population younger than 16 years of age, there must be 70,000 to 100,000 cases of JRA (active and inactive) in the United States. However, the Rochester study included a predominantly white population. Because the incidence of JRA appears to be lower in the African-American and Asian populations (as discussed in the next paragraph), the real prevalence must be much lower (33). In fact, Gewanter and Baum estimated that, in 1986, only 15,000 to 36,000 children had JRA in the United States (34).

Ethnic Differences

Some evidence indicates that JRA is less frequent in black South African (35) and Chinese populations. Increased frequency in a Native American population has also been reported (36). There are also some differences in disease onset types among ethnic groups (37). It appears that African-American children are more likely to have disease with polyarticular onset compared with white children, in whom the pauciarticular onset type is most common (38). In contrast, in the Japanese population, systemic disease is most common, with relatively fewer cases of pauciarticular JRA (39). Genetic factors (see later) are likely to contribute to these differences.

Age of Onset

Sullivan et al. reported a peak age at onset of 1 to 3 years, with girls dominant in this age group (40). A second, less prominent peak age at 8 to 10 years included more boys with pauciarticular JRA than were present in other groups. In a study by Schaller, the mean age of onset of systemic disease was 5.7 years, of polyarticular disease was 6.5 years, and of a pauciarticular disease was 4.3 years in girls and 10.2 years in boys (41).

Gender Differences

Although equal sex ratios among Indian and black South African patients have been reported (35), most published female-to-male ratios range from 2:1 to 3:1. These numbers depend on the age of onset of the children and the type of the disease (42). For example, EOPA-JRA affecting children less than 8 years old may have a female preponderance as high as 8:1, especially if iridocyclitis is present (12,43,44). In contrast, late-onset HLA-B27–related disease occurs more commonly in boys (12,45). Systemic-onset JRA shows little or no discrimination between the sexes.

Secular and Seasonal Variations

Substantial variation in disease occurrence over extended (secular trends) and shorter (seasonal) periods has been found for JRA in some populations (32,46), but not in others. For instance, a report from the United Kingdom demonstrated the presence of an influenza virus epidemic before an “outbreak” of JRA (47). The strongest seasonal variations have been observed with systemic-onset JRA (48,49), although this appears to be true only in some geographic regions.

PATHOGENESIS

At least some familial predisposition to the disease, characteristic histopathologic features of inflamed synovium, HLA associations, T-cell clonality, and the presence of autoantibodies point to an autoimmune pathogenesis of JRA with involvement of genetic and environmental factors.

Genetic Factors

The level of risk to family members of a JRA proband appears to be increased, although the increase is modest (50,51). Patterns of inheritance consistent with mendelian or monogenic inheritance have not been observed in this disease. Extensive kindreds with multiple affected family members in several generations, as seen in other rheumatic and nonrheumatic autoimmune diseases, are not evident either. In a series drawn from more than 3,000 European patients with juvenile chronic arthritis, Clemens et al. were able to identify only 12 affected sib pairs (52). The JRA Affected Sib Pairs Research Registry in Cincinnati, Ohio, estimates the total number of affected sib pairs at 300 in the United States population of more than 250,000,000 (53). Anecdotal evidence suggests that families with JRA probands have an additional, and perhaps stronger, risk of having other, nonrheumatic autoimmune diseases (54,55).

PREDISPOSING MAJOR HISTOCOMPATIBILITY COMPLEX GENES

Multiple genetic associations involving predominantly the MHC locus suggest a complex genetic trait and also reinforce the idea that JRA is as heterogeneous genetically as it is clinically (51,56). Patients with EOPA-JRA constitute the subtype with the most distinctive HLA associations. Furthermore, in 71 registered affected sib pairs who were the subject of an analysis by Moroldo et al., a high sib-sib concordance of pauciarticular onset disease was noted, a finding suggesting a stronger genetic component in this form of the disease (57). Associations with class II HLA-DR8 (58,59), HLA-DR11 (60,61 and 62), HLA-DR13 (63), and HLA-DPw2 (64,65) specificities have been reported. An HLA-A2 class I association has been found consistently as well (66). Two HLA class II specificities, HLA-DR4 and HLA-DR7, are significantly reduced in frequency, and therefore they appear to be protective (62). DNA sequence-dependent methods have defined more precisely the HLA alleles associated with pauciarticular JRA. It appears that disease susceptibility is associated with particular alleles of each serologically or cellularly defined specificity, for instance, HLA-DRB1*0801 of DR8 and HLA-DPB1*0201 of DPw2 (56).

HUMAN LEUKOCYTE ANTIGEN AND EARLY-ONSET PAUCIARTICULAR JUVENILE RHEUMATOID ARTHRITIS OUTCOME

Determination of HLA specificities using DNA-based methodologies has also better defined the genetic markers of disease outcome in EOPE-JRA. Haplotypes carrying HLA-DRB*0801, HLA-DRB* 1301, and HLA-DP*0201 alleles appear to predispose to pauciarticular JRA in general. In contrast, HLA-DRB1104* haplotypes predispose to eye disease (67); HLA-DQA*0101 haplotypes predispose to a polyarticular, erosive disease outcome, but they are protective against the development of eye disease (68). The HLA-DRB*0101 split of HLA-DR1 is another allele present on HLA HLA-DQA*0101 haplotypes that has been shown to be associated with a polyarticular course. Whether the HLA-DQA*0101 allele or, as suggested by Ploski and colleagues (69), the HLA-DRB1*0101 allele is a better marker for the haplotype is uncertain, but data are compatible with either possibility.

Polygenic Inheritance

The finding that HLA genes from four loci (HLA-A, HLA-DR, HLA-DQ, and HLA-DP) are involved in inherited predisposition to pauciarticular JRA raises the possibility that these genes make up a potential susceptibility haplotype. However, the absence of linkage disequilibrium among the specific HLA genes involved suggests otherwise and provides evidence indicating independent genetic effects at three loci, that is, that EOPA-JRA is truly a polygenic disease. This is illustrated in Table 38.4, which demonstrates the odds ratio obtained by the cumulative addition of risk factors. Such interactions have been demonstrated in other populations (70).

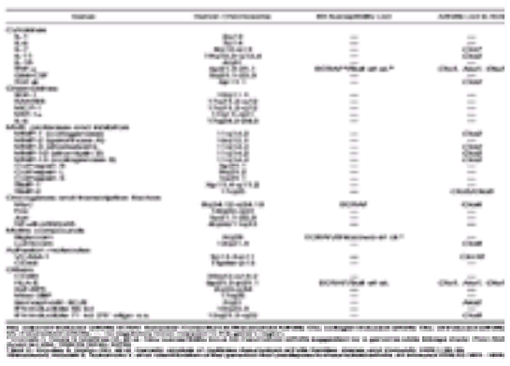

TABLE 38.4. Polygenic Risk in Early-Onset Pauciarticular Juvenile Rheumatoid Arthritis[a]

In a significant proportion of patients with EOPA-JRA, especially those with uveitis, evidence indicates that the development of the disease is associated with the presence of two susceptibility alleles of either HLA-DR or HLA-DQ loci. For example, patients who are heterozygous for HLA-DR5/HLA-DR8 have a particularly increased risk for developing eye disease (71). An HLA-DP gene and a class I gene, HLA-A2, contribute as well, appearing as independent risk factors. Class II gene homozygosity is not increased in patients with pauciarticular JRA, a finding suggesting that a dosage effect of any individual gene does not increase risk in patients (71). MHC associations with other clinical forms of JRA are weaker. As previously mentioned, late-onset pauciarticular JRA has been associated with HLA-B27 (14,45). In polyarticular onset, RF-negative JRA, susceptibility is associated with HLA-DPw3 (72). RF-positive polyarticular JRA has the same HLA-DR4 associations as does adult RA, that is, with HLA-DRB1*0401 and HLA-DRB1*0101 (73). HLA-DR4 associations with the systemic form of the disease have been found in northern, but not southern, European populations (56).

JUVENILE RHEUMATOID ARTHRITIS AND THE HLA-DR1/DR4 SHARED EPITOPE HYPOTHESIS

RA is associated with the presence of the DNA sequence common to HLA-DR1 and some HLA-DR4 specificities (74,75). However, the shared epitope hypothesis applied to RA is not useful for pauciarticular JRA in which HLA-DR4 is protective, and HLA-DR1 haplotypes predispose to a polyarticular outcome. Patients with pauciarticular JRA thus show a dissociation in the effects of the haplotypes involved in the hypothesis: one predisposes and others are protective. Patients with the seronegative polyarticular JRA do not carry the appropriate epitopes. Older patients with JRA with polyarticular disease who are immunoglobulin M (IgM)–RF positive and who have the childhood equivalent of adult RA are the only JRA group in whom this shared epitope hypothesis may hold, but this group accounts for fewer than 10% of all children with JRA.

AGE-SPECIFIC EFFECTS OF MAJOR HISTOCOMPATIBILITY COMPLEX ALLELES

Newer evidence indicates that the genes operative in JRA appear to have a “window-of-effect” during which time they may contribute risk of disease, but they may be neutral or even protective at other times (76). This finding appears to be particularly true in the pauciarticular groups, in which HLA-related risks clearly differ with age. For instance, 50% of the children carrying at least one of the susceptibility MHC alleles have disease onset before their third birthday, a finding suggesting that the period of susceptibility to EOPA-JRA is limited to the first years of life. In contrast, HLA-B27 and HLA-DR4 appear to be associated with the protection against EOPA-JRA early in life, but with an increased risk of other forms of JRA later in childhood (Fig 38.1).

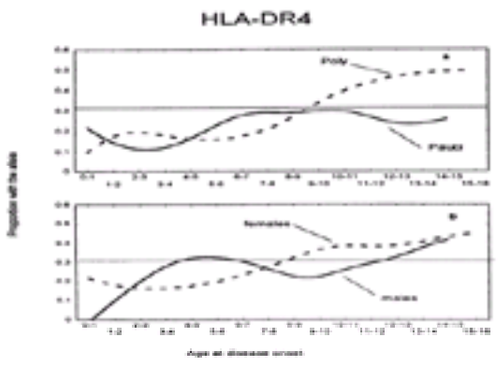

Figure 38.1. Proportion of the study population by disease-onset type **(A)** and by sex **(B),** in each age-at-onset category with the HLA-DR4 allele. The *horizontal line* shows the frequency of the allele in the control group. Pauci , pauciarticular; poly, polyarticular. (From Murray KJ, Moroldo MB, Donnelly P, et al. Age-specific effects of juvenile rheumatoid arthritis–associated HLA alleles. *Arthritis Rheum* 1999;42:1843–1853, with permission.)

PREDISPOSING NON–MAJOR HISTOCOMPATIBILITY COMPLEX GENES

The spectrum of non-MHC genes associated with JRA is expanding rapidly. However, their contribution appears to be less significant than that of MHC genes, and their effects may not be specific to JRA. Table 38.5 lists the non-MHC genes or chromosome regions that have thus far been reported to be associated with JRA. In general, the odds ratios are low, and distinguishing between founder effects (the incomplete mixing of genetically disparate populations) and associations that relate to pathogenesis has been difficult.

From Gross DN, Giannini EH. Juvenile rheumatoid arthritis as a complex genetic trait. Arthritis Rheum 1999;42:2261–2268, with permission.

TABLE 38.5. Nonmajor Histocompatibility Complex Genes Associated with Juvenile Rheumatoid Arthritis

In summary, the occurrence of the disease and of its phenotype is likely to be determined by complex genetic traits with genetic interplay between MHC and non-MHC predisposing alleles (77). Newer methods are available to study the entire genome and thus potentially to locate all the specific chromosomal regions involved in each type of JRA. Implicit in this concept is the likelihood that the genes involved are weakly penetrant, although in most instances they are necessary for expression of the disease and its phenotype (53).

Environmental Factors

Although at least some genetic component is evident in all clinical forms of JRA, the environmental component appears to be stronger for some of them (78). The

infectious origin of JRA has been suspected for a long time (79). However, classic epidemiologic studies have not generally shown clustering of JRA that would imply a definite infectious origin, although some seasonality in systemic-onset disease has been reported (48,49). Documented long-term trends for the incidence of JRA to change over time (32,46) may also signify an environmental or infectious rather than a genetic effect.

Several potential pathogens have been implicated but have not yet been shown to be definitely causal. Rubella virus has been implicated for some time (80,81), and a few persons who receive rubella immunizations develop arthritis similar to that of pauciarticular JRA. Sequence similarities have been shown between HLA-DRB1*0801, DRB1*11, and DPB1*0201, all associated with pauciarticular JRA, and an Epstein-Barr virus protein (82), a finding supporting the hypothesis about the role for molecular mimicry in this form of JRA. Chlamydia has been identified in the joints of some children with arthritis, although the significance of this in the context of JRA is uncertain (83). The clinical presentation of chlamydial arthritis can resemble that of JRA, including the development of iridocyclitis. In a novel study from South Wales, Australia, a relationship was shown between influenza A infection in pregnancy and the subsequent development of polyarticular JRA in later childhood (47). HLA-B27–associated forms of JRA can be triggered by bacterial infections (84), as is the case with HLA-B27–associated disease in adults. Consistent with this finding, an immunodominant epitope, Gro EL of *Escherichia coli* heat shock proteins (hsps), is one target of immune responsiveness in HLA-B27–positive JRA (85). In two studies of long-term trends in the incidence of JRA in Canada and in Rochester, Minnesota, several peaks were noted (32,33,34,35,36,37,38,39,40,41,42,43,44,45 and 46). In Canada, these peaks were concurrent with the increases in confirmed *Mycoplasma pneumoniae* infections, a finding suggesting a possible role for this pathogen as well (46).

PATHOBIOLOGY

The major clinical manifestation of JRA is persistent joint swelling that results from accumulation of synovial fluid and synovial lining thickening.

Synovial Fluid

The volume of synovial fluid in affected joints is increased in JRA, with viscosity decreased mainly because of reduced concentrations of hyaluronic acid. Synovial fluid contains various inflammatory cells, including neutrophils, plasma cells, dendritic cells, and a high proportion of T cells expressing markers of activation (86). These cells are most likely to extravasate from inflamed synovial lining. Mediators of inflammation such as cytokines and cleavage products of the complement system are also abundant (87).

Synovial Tissue

One of the hallmarks of the pathology of both RA and JRA is the tumorlike expansion of inflamed synovial tissue, or pannus, which causes much of the joint damage in this disease (88,89). With the progression of the disease, pannus spreads over the synovial space and adheres to intraarticular cartilage. It is in the areas of pannus-cartilage junction that the cartilage eventually degrades. Such expansion results from the proliferation of synoviocytes and from invasion of the synovial tissue by inflammatory cells recruited from the peripheral circulation. Mitotic figures are rarely seen in synovial histopathologic examination, a finding suggesting that ongoing recruitment of inflammatory cells from peripheral circulation is a major pathway of pannus expansion (90). Pannus growth is also supported by extensive formation of new blood vessels, which provide not only a source of nutrients for growing pannus, but also an increased access for inflammatory cells to infiltrate the synovium and thus further to promote its growth.

Little is known about the major angiogenic factors driving new blood vessel formation in JRA synovium. One study showed strong correlation between increased serum levels of vascular endothelial growth factor and disease activity in polyarticular JRA (91).

Composition of Synovial Tissue Cellular Infiltrate

Initial light and electron microscopic studies of the synovium in JRA revealed prominent infiltration with lymphocytes, plasma cells, macrophages, and proliferation of fibroblast- and macrophagelike sy-noviocytes. Infiltration with inflammatory cells does not appear to be homogeneous: lightly infiltrated areas alternate with areas of heavy cell aggregates (88).

Aggregates are usually seen around or near blood vessels and are composed of clusters of $CD4^+$ cells surrounded by a mantle of mixed CD4 and $CD8^+$ cells and B lymphocytes. $CD68^+$ cells are numerous and are typically found in the cell aggregates. Such a histopathologic pattern in the inflammatory response in JRA resembles that of classic delayed-type hypersensitivity reactions (92). In general, tissues from patients with the polyarticular form of JRA appear to have larger mononuclear cell foci as compared with patients with pauciarticular JRA. However, the tissues cannot be reliably distinguished on this basis (93).

Another prominent feature is the increase in numbers of dendritic cells within the synovial membrane and fluid. Dendritic cells from the synovial compartment are larger than most of those from peripheral blood and have a more extensive Golgi complex (88). They are often found in close juxtaposition with T lymphocytes (94). A distinctive feature of synovial dendritic cells is their high level of HLA-DQ and HLA-DR expression. Such dendritic cells are particularly potent antigen-presenting cells (95). Inasmuch as their only known function is to present antigens, it is reasonable to believe that antigen presentation is taking place in inflamed synovium. This notion is supported by the demonstration that dendritic cells from joints of some patients with JRA stimulate autologous lymphocytes in an autologous mixed lymphocyte reaction (96).

Most of the T cells infiltrating synovium are of a memory phenotype. T-cell activation levels vary among different areas in synovium. Most interleukin-2R–positive ($IL\text{-}2R^+$) cells were found in the “mantle” surrounding the aggregates or in interaggregate areas (93). DNA-synthesizing T blasts represent no more than 5% of all synovial compartment mononuclear cells (97), a finding suggesting that most of these cells are recruited from peripheral circulation. Among radiolabeled blast cells, $CD4^+$ lymphocytes are the dominant cell population (97).

Mechanisms of Recruitment of Inflammatory Cells into Synovium

Mononuclear cell aggregates are found predominantly around blood vessels, particularly postcapillary venules, which have distinct morphologic features (88). They are lined up by tall, metabolically active endothelial cells that express high levels of adhesion molecules, features similar to those observed in venules of lymphoid organs. Some of the postcapillary venules in lymphoid organs are specialized to facilitate the transendothelial migration of circulating lymphocytes (90,98). It appears that high endothelial venules may play a similar role in JRA synovium as well. Thus, Oen et al. demonstrated that $CD4^+$, $HLA\text{-}DR^+$ lymphocytes from peripheral blood of children with JRA adhere to human umbilical vein endothelial cells activated by tumor necrosis factor-a (TNF-a) (99). Given the abundance of TNF-a in JRA synovial tissues associated with high levels of the p55 TNF receptor on the endothelial cells (100), this cytokine is likely to play a pivotal role in the enhancement of inflammatory cell trafficking into inflamed synovium. IL-15 is another cytokine that has been shown to enhance the transendothelial migration of lymphocytes to RA synovium (101). Using RNase protection assay, Scola et al. showed that at the mRNA level, IL-15 appears to be one of the most highly expressed cytokines in JRA synovium as well (102). It also has been shown that very late activation antigen (VLA-1, a surface protein from the integrin family of adhesion molecules that mediates leukocyte adhesion to matrix proteins) is overexpressed on lymphocytes from patients with JRA (103). The recruitment of proinflammatory cells into synovium does not appear to be random. Several studies suggested a possible role for certain chemokines in the selection of the predominantly Th1 lymphocytes (see further). Such recruitment may be both antigen specific as well as antigen nonspecific (104).

T-Cell Contribution to the Disease

T-cell receptor (TCR) ab T lymphocytes are the predominant cell population in the JRA synovium and exhibit phenotypic and functional characteristic of cells that have undergone prior activation *in vivo.* These characteristic include expression of IL-2 receptors (CD25) (105), early activation antigen CD69, CD45RO (memory phenotype), VLA-1 (103), and HLA class II antigens (86,106).

A hypothesis that such activation could be induced by an autoantigen located in the inflamed joints prompted several groups of investigators to look for clonally expanded synovial T-cell populations, an approach that had been successfully used in experimental allergic encephalomyelitis (107). In this model, a known autoantigen (i.e., myelin basic protein) was shown to stimulate expansion of T cells with receptor specificity for this particular antigen. Furthermore, clonally expanded T cells used a limited number of Vb segments in their TCRs. Investigators anticipated that if detected in the synovium of patients with JRA, such cell populations could provide a clue to the identification of the antigens driving the immune response in JRA. The results of these studies, however, were contradictory. Initially, it was shown that clonal expansion of ab T cells in both $CD4^+$ and $CD8^+$ populations could be detected in the synovium of most patients with JRA (108,109,110 and 111). In addition, identical clones with the same receptor specificity were shown to be present in multiple joints of the same person and to persist over a long period (109,111). Some of these clones could be detected in peripheral blood as well, although preferential accumulation of these clonally expanded populations in inflamed synovial tissues was evident (109,110). These findings were thought to be consistent with the concept of persistent antigenic stimulation of T cells in the synovial compartment of patients with JRA. However, the discovery of similar clonally expanded $CD8^+$ populations in peripheral blood of healthy adults (usually older than 35 years of age) (112) made

some investigators question this concept.

Further studies were focused on the analysis of the TCR CDR3 region, the site of specific interaction of the TCR with unique peptide-HLA complexes. Investigators anticipated that expansion of structurally identical clones would indicate an ongoing antigen-driven immune response in the joint. Because the CDR3 region is encoded by the V-(D)-J segments, several studies were carried out to determine whether oligoclonal T-cell populations preferentially used particular Va- or Vb-chain TCR segments. Initially, Sioud et al. detected significantly fewer Vb families in fresh T cells from the synovial fluid than from the peripheral blood (113). These differences were more obvious when IL-2R$^+$ T cells were isolated (108). Restricted usage of Va segments by synovial fluid T cells was noted in this study as well. In a more comprehensive study of synovial fluid samples obtained from 36 patients with different forms of JRA, Thompson et al. showed that most patients with JRA had multiple synovial T-cell clones using different TCR Vb segments (110). However, some differences in patterns of TCR Vb use among clinical subtypes of JRA were noted, a finding suggesting that different antigens may be involved in different clinical forms of JRA. Subsequent extensive DNA sequencing efforts revealed that despite a wide diversity of CDR3 motifs, certain similarities among multiple synovial T-cell clones derived from an individual patient could be found (114). These data provided an indirect support for the concept that the persistent synovial inflammation in JRA may indeed be antigen driven. However, the wide variety of both Va and Vb segments, and the CDR3 motifs used by clonally expanded T-cell populations, precluded their use as potential targets for specific immunotherapy.

gd T CELLS

A clonal analysis of JRA synovial T cells responding to IL-2 revealed the presence of a distinct T-cell population with CD3$^+$ CD4$^-$ CD8$^-$ phenotype (105). Further investigation demonstrated that these cells had gd (instead of ab) TCRs. Subsequent immunohistochemical studies showed that gd T cells comprised about 5% to 10% of T cells infiltrating the JRA synovial membrane (115,116). In most cases, gd T cells are clustered in lymphoid follicularlike structures (116). In approximately 30% of patients with JRA, proportions of gd T cells were found to be increased in synovial fluid relative to peripheral blood (117). Many synovial gd T cells express CD25, CD69, and HLA-DR (115). Clonal expansion of synovial gd T cells has been demonstrated in several studies.

Although the specificity and function of human gd T cells are unknown, at least some of these cells appear to respond to mycobacterial antigens and stress proteins (in particular, hsp 65) (118,119). Synovial fluid T cells from patients with JRA have been shown to respond selectively to mycobacterial antigens and hsps (85). At low levels, hsp is constitutively expressed in practically all organisms, and increased synthesis can be induced by a variety of stress conditions including inflammation. A high degree of homology exists between bacterial and mammalian hsps. During infection, the synthesis of hsp is elevated on both microorganism and host cells. If cross-reactivity occurs between these hsps, it can be inferred that the immune response to hsp would be potentially autoreactive. Using monoclonal antibodies that recognize human hsp 65, high levels of hsp expression were demonstrated within synovial lining cells in JRA synovial tissue (120). Close juxtaposition of gd T lymphocytes and cells expressing hsp has been shown in histochemical studies of multiple sclerosis (121), but whether such events play a pathogenic role in JRA remains to be determined. In fact, one study demonstrated some correlation between the high immune responses to hsp and a relatively benign course of arthritis (122). In another study, a synovial fluid T-cell clone responsive to hsp secreted a Th2 cytokine IL-4 that may have antiinflammatory effects in JRA (123).

T-CELL–DERIVED CYTOKINES

In RA, despite heavy T-cell infiltration, T-cell–derived cytokines are usually detectable only with highly sensitive techniques such as polymerase chain reaction. In contrast, in JRA, T cells appear to be more active (93). Th1 cytokines such as interferon-g or TNF-b are found to be present in most of the synovial tissue and fluid samples (87,124). In one study, TNF-b expression correlated with the occurrence of lymphocytic aggregates (100). Th2 cytokines such as IL-4 are also found occasionally, mainly in tissue and fluid samples obtained from patients with more restricted disease (124). In another study, the *in vitro* production of cytokines by T-cell clones derived from synovial fluids of pauciarticular JRA were Th1/Th0 (125). These findings are consistent with the concept that Th1 cytokine response that has been implicated in orchestrating cell-mediated immune responses may promote disease in JRA (104). IL-10 is another Th2 cytokine that has been consistently found in JRA tissues, although its pathogenic significance is not entirely clear (124).

Investigators have suggested that T cells infiltrating the inflamed synovium in children with JRA are of a skewed cytokine phenotype, perhaps as a result of selective recruitment of cells expressing chemokine receptors characteristic of Th1 cells. This hypothesis has been supported by two studies that demonstrated enrichment of synovial fluid lymphocytes for T cells expressing CCR5 and CXCR3, markers for Th1 phenotype (126,127). Another study showed enrichment of JRA synovial tissues for chemokines capable of stimulating CCR5 and CXCR3 receptors, that is, IP-10 and RANTES (regulated on activation normal T cell expressed and secreted) (102). Another chemokine capable of upregulating interferon-g production, I-309, was found to be abundant in this study as well.

Natural Killer Cells

Natural killer (NK) cells in JRA have been assessed in several studies, with contradictory results. Odum et al. found no significant differences in the distribution of cells bearing CD16$^+$, a surface marker for cytotoxic T lymphocytes (103). However, some functional studies indicated decreased NK numbers (128), and an inverse correlation between disease activity and NK cell content was noted.

Macrophage-Fibroblast Contribution to the Disease

Increased numbers of macrophages and dendritic cells and proliferation of fibroblastlike and macrophagelike synoviocytes are typical fea-tures of JRA synovium (88). The abundance of cytokines secreted by these cells (e.g., IL-1, IL-6, IL-12, and TNF-a) provides further evidence for the major role of these cells in the perpetuation of the synovial inflammation.

Martini et al., in 1986, noted high spontaneous production of IL-1 by mononuclear cells derived from peripheral blood of JRA patients (129). In another study, levels of IL-6 expression in the sera of patients with systemic JRA were shown to correlate with the extent of joint involvement (130). Serum IL-12 levels have been shown to be elevated in patients with JRA (131). In 1991, Eberhard et al. detected TNF-a, TNF-b, and IL-6 in synovial fluids of a large proportion of JRA patients (87).

Prompted by the demonstration of the pivotal role of TNF-a in the inflammatory cascade in RA (132), analysis of TNF expression and the distribution of the TNF receptors in JRA synovial tissues provided further evidence for the role of both TNF-a and TNF-b in the amplification of the synovial inflammation in JRA as well (100). In most of the synovial tissue samples, cells staining for TNF-a were found within dense cellular aggregates and in the “mantle” of cells surrounding the aggregates. The pattern of distribution of TNF-a staining was similar to the pattern observed with CD68 staining. The level of expression of TNF-a correlated closely with the degree of inflammatory infiltration of synovia.

High levels of TNF expression were associated with wide distribution of TNF receptors in most tissues. For instance, staining with the antibodies specific for the p55 and p75 TNF receptors revealed that cells with diverse morphology expressed TNF receptors on their surface. Higher numbers of positive cells were observed in the areas of cellular aggregates adjacent to synovial venules. The most intense staining, however, was observed on the endothelial cells lining the synovial blood vessels (100). Previously, Oen et al. had shown that activated lymphocytes from peripheral blood of children with JRA adhered to vascular endothelial cells stimulated with TNF-a *in vitro* (99). *In vivo,* this would lead to the extravasation of such cells and their accumulation at the site of inflammation. These observations suggest that one of the mechanisms by which TNF-a amplifies inflammation in JRA is its ability to promote trafficking of the inflammatory cells from peripheral circulation into synovium.

Silverman et al., in 1987, demonstrated that supernatants of mononuclear cells obtained from patients with systemic or polyarticular JRA caused elevated proteoglycan release when they were cultured with articular cartilage (133). Key et al. showed that supernatants of monocytes from JRA patients were able to cause bone resorption (134). Although neither of the studies looked at the TNF-a activity in the examined samples, it is likely that the described effects, at least in part, were caused by this cytokine.

The proinflammatory role of TNF-a in the rheumatoid disease does not appear to be limited to synovium. TNF-a is a major proinflammatory cytokine with both local and systemic effects (135). At low concentrations, it acts locally, mostly as a paracrine and autocrine regulator of leukocytes and vascular endothelial cells. These actions contribute to the accumulation of the inflammatory cells at local site of inflammation. When production of TNF-a is increased significantly, it is released into peripheral circulation and has numerous systemic effects (135). For instance, TNF-a acts on hypothalamic regulatory systems to induce fever. It also stimulates hepatocytes to produce certain proteins that are known to constitute the acute-phase response. When TNF-a is produced at high levels over a long period, it also suppresses bone marrow and may cause metabolic alterations leading to cachexia. Although similar clinical symptoms are often observed in JRA, particularly in the systemic form, it is still not clear to which extent they can be attributed to TNF-a. An increasingly beneficial clinical experience with anti TNF-a treatment strategies, however, does provide evidence for the critical role of TNF-a in the developments of the systemic features of JRA as well.

B-Cell Contribution to the Disease

Although T cells are usually more numerous in inflamed synovial tissue, B-cell activity appears to be enhanced in both peripheral blood and synovial compartment. Lindblad et al. described synovial tissue specimens from patients with JRA with significantly increased numbers of immunoglobulin-synthesizing cells (94). These cells tended to be focally aggregated. Functional studies produced similar results. With the use of reverse hemolytic plaque assay, Tsokos et al. demonstrated increased

numbers of B cells spontaneously producing immunoglobulins in the peripheral blood of patients with JRA (136,137). As a consequence of increased B-cell activity, hyperglobulinemia, circulating immune complexes, ANAs, and RFs are common findings in many patients with JRA.

Serum Immunoglobulins

The serum levels of immunoglobulins are elevated in many patients with JRA (138). In the studies conducted by Cassidy et al., 37% of patients with JRA exhibited hyperglobulinemia in at least one immunoglobulin class, and this correlated with the activity of the disease (139). There were also some differences in immunoglobulin levels among different clinical subgroups. The degree of immunoglobulin elevation was greater in patients with polyarticular and systemic disease than in those with pauciarticular JRA. Elevated IgA levels were associated with the appearance of cartilage erosions. Conversely, hypoglobulinemia has also been associated with JRA (140,141), and a few investigators have described a selective decrease in serum IgA concentrations in some patients (139,142).

Rheumatoid Factor

RFs, the autoantibodies directed against the Fc region of human IgG, are found in the serum and synovial fluid of most patients with RA. RF can only rarely be detected in patients with JRA by the classic Rose-Waller reaction or latex fixation method, although the probability of finding it increases with the age and the duration of the disease. Allen and Kunkel demonstrated a so-called hidden RF defined as IgM 19S antiglobulin (143). This antiglobulin is “hidden” because of its occupied binding sites. Gel filtration at acid pH dissociates IgM from IgG and allows IgM RF to fix complement in hemolytic assay. Moore et al. found that hidden RFs correlated with clinically active disease in 67% of patients with JRA (144,145).

Antinuclear Antibodies

The reported incidence of ANAs in patients with JRA varies from 4% to 88%, depending on the clinical subtype and the laboratory technique used (13). Thus, ANAs are uncommon in systemic-onset disease, whereas more than half of children with pauciarticular JRA have ANAs in serum. Children who are ANA positive carry an especially high risk of chronic anterior uveitis (13,146). Rahim et al. demonstrated local synthesis of ANA in the eyes of patients with chronic iridocyclitis. ANAs are occasionally found in patients with polyarticular disease, mostly in those who are RF positive (147).

The full specificity of these antibodies remain to be determined. Some studies indicated that ANAs in most patients are directed to a ribonucleoprotein that requires both RNA and protein components for antigenic integrity (148). Szer et al. concluded that ANA specificity profiles were highly individual and did not appear to correlate with disease subtype or activity (149). Several studies found that antibodies to many antigens typical for other rheumatic diseases, such as the extractable nuclear protein, centromere proteins, scleroderma Scl-70, Ro, La, and double-stranded DNA, are generally absent in JRA. More recently, the antibodies to the 45-kd DEK nuclear antigen, a putative oncoprotein, have been associated with the pauciarticular type of JRA, particularly in patients with a history of iridocyclitis (150). However, the presence of these antibodies does not appear to be limited to JRA (151).

Other Autoantibodies

Anticollagen (152), antiretinal (153,154 and 155), and anti–T-cell antibodies (156,157) have been described, but their relevance to the pathogenesis of JRA remains to be determined. Investigators suggested in one study that anti–T-cell antibodies intensify immunoregulatory disturbances in autoimmune disease (158).

Circulating Immune Complexes and Complement Activation

Abnormal antibody production and probably defects in clearance function of the reticuloendothelial system may result in an increased concentration of circulating immune complexes in serum. Attempts at estimating this increase have yielded inconsistent results. With the help of C1q binding assay, Rossen et al. demonstrated that 22% of patients with JRA have elevated levels of circulating immune complexes, and these investigators found that the concentration of circulating immune complexes correlated with the severity of the disease (159). The polyethylene glycol precipitation method used by Balogh et al. detected circulating immune complexes in the serum of only 1 of 13 patients (160). Using 4 different techniques, Moore et al. were able to demonstrate elevated levels of circulating immune complexes in 79% of patients with JRA by at least a single method (161). Findings in synovial fluid have also been inconsistent. Using the C1q binding assay, Miller et al. found elevated levels of circulating immune complexes in some patients, but the results varied substantially among patients (162). Martin and Pachman, using the Raji method, found normal levels of circulating immune complexes in synovial fluids of patients with pauciarticular JRA (163).

Despite these conflicting results, many investigators think that deposition of circulating immune complexes in synovial compartments may result in complement system activation, which, in turn, causes tissue damage. Indeed, some evidence to support this hypothesis has been obtained. Using a qualitative assay for C3c and C3d, Miller et al. demonstrated these products in the serum of 7 of 10 patients with active systemic disease, in 16 of 29 patients with active polyarthritis, in 7 of 20 with active pauciarthritis, and in only 2 of 20 with inactive disease (164). However, the same study failed to find C3c and C3d in synovial fluid. In contrast, in 1986, Miller et al. demonstrated elevated levels of C3d in some patients with JRA (162). In the same year, Miller et al. characterized systemic and, to a lesser degree, polyarticular subgroups by elevations of both C4d/C4 and C3d/C3 ratios, whereas only the C3d level was increased in pauciarticular disease (165).

Mollnes and Paus contrasted the complement activation cascade (C1 to C5), which participates in inflammatory reactions mostly by releasing anaphylotoxins with the terminal cascade, which results in the formation of the cytolytic macromolecular complex (166). The entire cascade was shown to be involved in the activation process both in peripheral blood and in the synovial compartment. Furthermore, weak deposits of C3b and C3dg, or terminal complement complex were found in the synovial tissue of a few patients with JRA. Neither these studies nor studies of RF revealed any associations between clinical activity and the degree of complement activation. On the contrary, the level of C-reactive protein correlated strongly with the degree of complement activation. The main conclusion drawn from this study was that mechanisms that have other than specific immunologic causes (such as C-reactive protein) may be responsible for complement activation in JRA.

Several studies have shown that the red blood cell C3b receptor may be involved in the impaired clearance of circulating immune complexes (167), but no significant deviations in the expression of this receptor have been found in patients with JRA (168). A general impression is that circulating immune complexes may contribute to the perpetuation of chronic inflammation in JRA, but they do not play a major role in its pathogenesis.

TREATMENT

Traditionally treatment starts with nonsteroidal antiinflammatory drugs. If these drugs prove ineffective, treatment progresses to more aggressive “advanced” pharmacotherapy that includes slow-acting disease-modifying medications (169). Oral or subcutaneously administered methotrexate is clearly gaining favor as a second-line drug for the treatment of JRA. The systemic administration of prednisone and its analogs is limited to short-term use in severe instances of systemic-onset JRA. Cyclosporine has been shown to be effective in treatment of macrophage activation syndrome complicating this form of the disease as well (19). The hepatotoxic effect of salicylate therapy is not uncommon in patients with systemic onset of the disease (170). Intraarticular injections of steroids are commonly used in pauciarticular disease. However, these treatments have had limited effectiveness in modifying the disease processes, perhaps with the exception of methotrexate.

Although several biologic agents have been tried in JRA, only treatment strategies directed against TNF-a have been shown to be effective (171). Two types of TNF inhibitors have been developed: one is a humanized monoclonal antibody (infliximab) that binds TNF-a and selectively blocks its activity. Another TNF inhibitor, etanercept, is a genetically engineered fusion protein consisting of two identical chains of the recombinant extracellular human TNF receptor p75 monomer fused with the Fc domain of human IgG1. It effectively binds both TNF-a and TNF-b and inhibits their activity (172). The ability of etanercept to block both TNF-a and TNF-b may be particularly relevant to JRA, because, in contrast to RA synovium, in which TNF-b is rarely detectable, both cytokines have been shown to be expressed in JRA synovial tissues. A clinical trial of etanercept in patients with polyarticular disease demonstrated a substantial, rapid and sustained clinical response in 76% of patients (171). These results can likely extrapolated to other clinical forms of JRA as well.

PROGNOSIS

In 1991, 31% to 55% of patients with JRA had been reported to have active arthritis 10 years after disease onset (10). Joint space narrowing and cartilage destruction developed in approximately 25% of patients with pauciarticular onset, 50% of patients with polyarticular onset, and 50% of patients with systemic onset. As a result, 9% to 48% of patients with JRA develop marked disability 5 to 15 years after onset of the disease (173), and 30% to 50% of patients with JRA begin their adult lives with active arthritis (10).

The limited effectiveness of existing therapies encouraged many pediatric rheumatologists to consider the earlier use of aggressive treatment in some patients. The introduction of methotrexate as a main second-line medication in the late 1990s and its use early in the course of the disease have seemed to improve the overall prognosis significantly. It remains to be determined to what extent the course of the disease can by altered by TNF blockers. Some evidence indicates, however, that in

adult RA etanercept may significantly slow the progression of cartilage destruction and thus may improve the overall outcome of the disease.

39 SYSTEMIC LUPUS ERYTHEMATOSUS

George Vratsanos, M.D., Insoo Kang, M.D., and Joseph Craft, M.D.

Systemic lupus erythematosus (SLE) is an idiopathic systemic autoimmune disease that is unique among autoimmune illnesses in its breadth of clinical manifestations, in the variability of disease progression, and in the nature of its underlying immunologic abnormalities. SLE potentially involves every organ system. Although it predominantly affects women of child-bearing age, younger and elderly persons also may be affected. The extent of clinical heterogeneity is reflected in the fact that the diagnosis of lupus is used both for the patient with relatively benign skin and joint conditions and for the patient with fulminant, life-threatening disease affecting the central nervous system (CNS), lungs, gastrointestinal tract, and kidneys. This diversity of clinical manifestations demands cognizance on the part of physicians in recognizing this disease in its common and less common presentations and in anticipating potential complications. Judicious therapy requires careful consideration of the extent, severity, and pace of disease.

It has been nearly 50 years since the observation was made that antibodies against normal cellular constituents could be found in the sera of patients with lupus (1,2 and 3). The hallmark of lupus remains the presence of serum antibodies directed against nuclear antigens (antinuclear antibodies, or ANAs). Despite significant advances in describing the specificity and pathogenicity of certain of these autoantibodies, the questions of why they arise and what their role is in disease pathogenesis remain largely unanswered. Development of effective and specific treatment for most of the manifestations of lupus has been impeded by limited understanding of the mechanisms that underlie disease. Specifically, the development of more effective therapies will require an understanding of why tolerance to self-antigens is lost, which genes are responsible for the marked familial predisposition to disease and how these genes interact to cause disease, and the mechanisms whereby these factors lead to chronic tissue injury. This chapter reviews the epidemiology and clinical manifestations of lupus and concludes with a discussion of the current understanding of the underlying immunologic abnormalities that predispose to lupus.

It is interesting to note that convincing evidence for the first description of lupus cannot be found until the 19th century, raising the question of whether lupus is a new disease. Given the variability in disease manifestations, however, it is difficult to determine when the first case of SLE was recognized and reported. Cazenave and Schedel are generally credited with the first description of disease in 1833 (4), when they described cutaneous involvement of the face characteristic of lupus and noted a marked preponderance of women with this condition. Hebra in 1846 described the classic malar rash of acute cutaneous lupus and, along with Kaposi, first described the systemic nature of the disease in the late 19th century (5). The modern study of lupus began in 1948, when Hargraves et al. observed that the sera of lupus patients was capable of inducing the phagocytosis of nucleated cells *ex vivo* (6). This phenomenon (the lupus erythematosus, or LE cell) remained poorly understood until 1957, when Friou, Holman and Kunkel described the binding of factors in lupus sera to the nucleus (1,2). Two years later, the serum binding factor was identified as an antibody to nucleoprotein (3). These serologic abnormalities are unique to lupus and have served as diagnostic criteria formulated by the Rheumatism Association in 1971 (now the American College of Rheumatology, or ACR). They remain invaluable clinical tools in the evaluation of patients with connective tissue disease (7). Importantly, these observations spurred interest in investigating the role of the immune system in the causation of lupus.

EPIDEMIOLOGY

The demographics of SLE are striking: There is a markedly skewed distribution of disease with respect to sex, age, and race (8). SLE is much more frequently found in women, with a female-to-male ratio of 9:1 in adults (9,10). The female-to-male ratio is much smaller in children and in elderly persons, dropping to 2:1. Although SLE can occur at any age, the peak incidence is generally seen between the second and fourth decades of life (9).

The reported prevalence of SLE in the general population of the United States is 40 to 50 cases per 100,000 (11), with an incidence between 1.8 to 7.6 cases per 100,000 people per year (9). Lupus is more common in Asians, African Americans, African Caribbeans, and Hispanic Americans than in whites (11,12 and 13). In addition, disease is more severe among Hispanics and African Americans. Interestingly, lupus is reported to be uncommon in Africa (14), although reporting bias makes definitive conclusions uncertain. The reasons for these ethnic differences remain unknown, prompting investigation into identifying genetic and environmental factors that predispose to systemic autoimmunity.

Genetics

Lupus is a disease with strong genetic predisposition. This is most clearly demonstrated by the high concordance rate (25%–50%) for lupus in monozygotic twins (15,16). The risk of developing lupus in dizygotic twins and in first-degree relatives of lupus patients is also substantial, with a relative risk of 20 (16). Although the genes predisposing to lupus are unknown, various genetic associations with disease have been reported. These include the genes coding for the major histocompatibility complex (MHC), the complement system, proteins involved in programmed cell death (*apoptosis*), and cytokines (17,18).

Of these, the MHC locus has been particularly well studied. There is an increased incidence of different haplotypes encompassing MHC class I, II, and III genes in SLE patients of different ethnic backgrounds; this difference may be due in part to linkage disequilibrium (17,18 and 19). Most of these haplotypes carry human leukocyte antigen (HLA)-DR2 or DR3 (17,18 and 19). Disease associations extend to particular subtypes of the MHC class II DR2 allele: DRB1*1501 is commonly seen in white and Asian persons with lupus, whereas DRB1*1503 is seen in African-American lupus patients. HLA-DR3 (usually associated with a C4A null gene; see later discussion) is seen in lupus patients of European descent. In general, these HLA alleles have a strong association with certain autoantibodies. For example, an association between anti-Ro antibody and DR2/DQw1 has been reported (19), raising the possibility that only certain MHC class II alleles are capable of presenting self-antigen to autoreactive T cells. This appears to be a critical step because activation of autoreactive T cells and subsequent T-cell help to autoantigen-specific B cells are crucial to the production of autoantibodies (to be discussed in the section on immunopathogenesis).

Deficiencies of genes encoding the early components of complement, including C1q, C4, and C2, are strongly associated with SLE (18). Most strikingly, about 90% of patients with C1q or complete C4 deficiency have SLE (20). Similarly, defects in any of the four C4 genes (two genes each for C4A and C4B) are associated with lupus, especially the C4A null deficiency (21). The C4 null allele is the most commonly found complement deficiency seen in lupus, followed by C2 deficiencies. C1s or C1r deficiencies are rare, but these persons again present with SLE. The results of these human studies are consistent with the observation that mice genetically engineered to lack one of the early complement components develop a lupuslike syndrome (22). One hypothesis is that normal physiologic processes such as apoptosis produce a steady stream of self-antigens that must be removed, with the aid of the complement system, to maintain immunologic tolerance. Failure of these or other immune complex removal mechanisms results in excessive stimulation of the adaptive immune system, which triggers systemic autoimmunity.

Associations between allelic polymorphisms of FcgRII, FcgRIII genes, and SLE have been reported in several ethnic groups (23,24 and 25). The FcgRII receptor binds immunoglobulin G (IgG) bound to antigen and is expressed on the surface of phagocytic cells. It differs in its affinity for IgG, depending on the isotype: IgG1 has the highest affinity, followed by IgG3 and IgG2. Ligation of the receptor with IgG bound to antigen results in the uptake of the immune complex and activation of the phagocytic cell. There are two common alleles of FcgRII, with either high (histidine at position 131, H131) or low (arginine 131, R131) affinity for IgG2 and IgG3. An increased frequency of homozygous R131 and a decreased frequency of homozygous H131 have been reported in African-American lupus patients, particularly those with nephritis (23,25). These alterations may result in a decreased ability to remove immune complexes from the serum, thereby promoting their deposition in tissues such as the kidney. This association between Fc receptor polymorphisms and lupus was not found in white, Afro-Caribbean, and Chinese patients with SLE (26). A strong association between alleles of the Fc receptor of natural killer (NK) cells and monocytes/macrophages (FcgRIIIa) having lower affinity for IgG1 and SLE has been reported as well (27).

Low levels of serum opsonins or their receptors also may lead to a decreased ability to remove immune complexes from the circulation. Allelic polymorphisms that result in low levels of serum mannose-binding protein, which can recognize carbohydrate on the surface of bacteria and activate complement, are associated with SLE in patients from different ethnic backgrounds, particularly African Americans (28,29 and 30).

Apoptosis may be important in the initiation and propagation of systemic autoimmunity as a mechanism to generate self-antigens and, as a consequence, immune complexes (to be discussed in the section on immunopathogenesis). The discovery in mice of a mutation in a single gene (*Fas* or CD95 mutation), which results in defective apoptosis of cells, including lymphocytes (31), spurred investigation into whether apoptosis is aberrant in human disease and in murine models of lupus. Individuals with homozygous *Fas* deficiency have been identified (32). They develop lymphadenopathy, splenomegaly, and autoantibodies but do not develop the end-organ disease characteristic of lupus (32). Most lupus patients do not have defective expression of CD95 or its ligand, CD95L: Only one (heterozygous) mutation in *Fas* ligand was found in 75 SLE patients (33). Similarly, a comparison of mRNA expression of Fas, *FasL,* and *bcl-2*, a molecule promoting cell survival, did not find significant differences between lupus patients and controls (34). Homozygous *Fas* deficiency in mice (the *lpr/lpr*mutation) accelerates autoimmune disease but is not necessary or sufficient for the development of systemic autoimmune disease (35). Normal healthy, nonautoimmune mice bred to carry the *lpr/lpr*mutations do not develop significant autoimmune disease (35).

Case-control studies looking for polymorphisms of cytokine and cytokine receptor genes and SLE have yet to identify any major disease associations. An increased frequency of a polymorphism of the interleukin-1 receptor antagonist (IL-1Ra) was reported in one study of white and Japanese SLE patients with discoid lesions and photosensitivity (36,37). Similarly, no major associations between the genes coding for the T-cell receptor (TCR) and disease have been uncovered. One study showed no relation between polymorphisms of TCR Va and Vb chains and SLE (38), suggesting that the germ-line T-cell repertoire is not significantly different in individuals with lupus compared with healthy individuals.

Major advances have been made in understanding the genetics of murine lupus and will be discussed fully in the section on immunopathogenesis. These studies have shown conclusively that loci on murine chromosomes 1, 4, and 7 acting in concert are sufficient to induce the development of systemic autoimmunity and immune complex–mediated glomerulonephritis closely resembling human lupus (39,40). These studies prompted searches for disease-associated loci in syntenic regions of the human genome. Indeed, a telomeric region on 1 (1q41–42) has been associated with lupus in a study of 54 dizygotic sibling pairs concordant for lupus (41). Other groups have not been able to reproduce this genetic association (42), however, and the interested reader should review the editorial that accompanied one of the negative reports (43). Rapid advances in the understanding of the mechanisms by which loci and, ultimately, genes in murine models induce autoimmunity will direct human studies toward the corresponding pathways.

Environmental Factors

A great amount of effort has been spent in the last 30 years trying to elucidate the causes of lupus. No causative factors have been identified, but several environmental triggers of lupus have been established. Ultraviolet (UV) light exposure, especially UVB, can cause flares of systemic lupus, involving both the skin (acute cutaneous lupus) and internal organs. Different types of medications, ranging from antihypertensives to anticonvulsants to antibiotics, have been definitively associated with the development of ANAs and lupuslike disease. It should be noted that the syndrome of drug-induced lupus differs from (idiopathic) SLE in many important respects, including the types of autoantibodies produced and the range of clinical manifestations, which is discussed in the section on drug-induced lupus. Therefore, one must be cautious in extrapolating any mechanisms implicated in causing drug-induced lupus to the study of idiopathic SLE.

One possible molecular mechanism to explain why some lupus patients are photosensitive and how UVB exposure leads to the development of cutaneous lesions was suggested by *in vitro* studies of apoptotic cells. Certain nuclear and cytoplasmic autoantigens specific to lupus (e.g., Ro antigen) are translocated to the cell surface after UVB exposure of keratinocytes from normal subjects (44). What happens next is unclear: Presumably, autoantigens on the cell surface are now “exposed” to the immune system and then can drive an adaptive immune response or be bound by circulating autoantibodies with triggering of an inflammatory cascade. Supporting this notion are data demonstrating that (a) autoantibodies (anti-Ro, anti-La, and anti-RNP) bind to UVB-exposed keratinocytes (45) and presumably injure the cells; and (b) photosensitivity in white SLE patients is associated with an anti-Ro response (46). Not all autoantigens (chromatin, for example) are expressed on the surface of apoptotic cells, however, and therefore there must be other mechanisms that drive the humoral response against these antigens in lupus. In addition, one must explain how this normal physiologic process (apoptosis) leads to disease in patients with lupus but not in healthy individuals. UV light and drugs inducing lupuslike syndromes also can alter cell function by decreasing DNA methylation (thereby increasing gene expression) and enhancing the expression of integrins, such as leukocyte factor antigen-1 (LFA-1) on lymphocytes (47), thereby potentially altering T-cell antigen-presenting cell (APC) interaction.

There is weaker correlation to disease for certain viral infections, diet (e.g., high-fat and high-caloric diets), certain cosmetics (hair dyes and lipstick), and organic solvents (trichloroethene) (10). In addition, psychological factors, such as stress, depression, and fatigue, may exacerbate the manifestations of lupus in some patients. How these putative factors “trigger” disease remains poorly understood. Given the clinical heterogeneity of lupus, it is not surprising that no “smoking gun” has been identified. Patients who have an insidious onset of disease are likely to have different triggers than patients with a hyperacute presentation. In addition, there are likely many different environmental factors that can initiate disease in a genetically susceptible person.

The marked female preponderance of SLE during the reproductive ages has historically driven research into the role of sex hormones in SLE. Estrogen stimulates B cells, T cells, and macrophages *in vitro* to enhance cytokine release and increase the expression of MHC and endothelial adhesion molecules (48). In New Zealand black and white (NZBxNZW) mice, lupuslike disease occurs earlier and is more severe in female mice; chemical or surgical castration improves the disease (49). Decreased levels of androgens, including dehydroepiandrosterone (DHEA), are seen in female lupus patients (50), in addition to abnormal estrogen metabolism. Estrogen use in postmenopausal women is associated with a small increase in risk for developing lupus (51). One must bear in mind, however, that the uneven sex distribution may be due to the absence of gene(s) expressed on the Y chromosome. In some murine models of lupus (BXSB), disease is linked to a locus (*Yaa*) on the Y chromosome (52) whose gene product contributes to B-cell hyperactivity (53).

Finally, viral infections, particularly Epstein-Barr virus (EBV) infection, are possible etiologic agents in lupus. The evidence is circumstantial: Some serologic studies demonstrated increased antibody titers against EBV antigens in SLE patients (54). Polyclonal B-cell activation occurs in lupus, and the observed increases in titer may be attributable to this phenomenon. EBV does infect B cells through the B-cell complement receptor (CD21) and therefore may play a role in increasing B-cell activation in the disease. The data suggesting molecular mimicry between viral and self-antigens are limited to the observation that the Epstein-Barr nuclear antigen II (EBNA II) of EBV and the Sm autoantigen in SLE share partial sequence homology (55). Taken together, however, there is no solid evidence to date supporting a direct causal relationship between an infectious agent and SLE.

CLINICAL MANIFESTATIONS

Systemic lupus erythetmatosus can affect the skin, joints, kidneys, lungs, nervous system, serosal cavities (pleural, pericardial, and peritoneal), hematopoietic system or other organs of the body (Table 39.1) (56,57). Despite great diversity in the clinical manifestations of lupus, certain common clinical features, when taken together, form a pattern of disease unique to lupus. This group of clinical features, in conjunction with characteristic immunologic abnormalities, forms the core of the current diagnostic criteria of the American College of Rheumatology (Table 39.2). Although these criteria were developed for the appropriate classification of patients for clinical studies, they are useful in clinical practice in the evaluation of all patients with systemic rheumatic diseases.

Clinical Signs	%
Fever	84
Arthritis/arthralgias	92
Myalgias	48
Skin involvement	72
Photosensitivity	33
Malar rash	57
Raynaud's phenomenon	18
Psychosis	12
Seizure disorder	14
Pericarditis	31
Pleurisy	45
Pleural effusion	30
Abnormal urinalysis	46
Nephrotic syndrome	23

TABLE 39.1. Cumulative Frequency (%) of Clinical Manifestations in Systemic Lupus Erythematosus

[illegible]	[illegible]

TABLE 39.2. The Revised Criteria for the Diagnosis of Systemic Lupus Erythematosus[a]

Constitutional Symptoms

Nonspecific systemic symptoms, such as malaise, fatigue, fevers, anorexia, and weight loss, are common in SLE patients. The most common presentation of lupus is a mixture of these constitutional complaints with skin, musculoskeletal, and mild hematologic disease. The pattern of organ involvement during the first few years of illness is usually maintained subsequently (58,59). Fatigue occurs in about 80% of SLE patients. Fever is seen in more than 50% of patients, particularly in those with active disease (60). High fevers (>103°F) may accompany acute severe disease, but concurrent infection always should be suspected in a lupus patient with fever. The presence of shaking chills, leukocytosis (especially in the absence of corticosteroid therapy), elevated C-reactive protein (CRP), and normal complement levels are helpful in distinguishing bacterial infection from a lupus flare.

Systemic symptoms usually are accompanied by other organ involvement; therefore, treatment is directed by the extent and severity of the affected organs in an individual patient. The sense of fatigue and malaise often improves with rest and nonsteroidal antiinflammatory drugs (NSAIDs).

Cutaneous Manifestations

The skin and mucous membranes are major targets of the autoimmune response in lupus, affecting over 80% of patients (57) at some point during the course of illness. The dermatologic manifestations of lupus are extremely diverse, ranging from acute, transient facial rashes in adults to bullous disease, to chronic, scarring, and disfiguring rashes of the head and neck. Despite this clinical diversity, most of these rashes share three features in common, and these features offer insight into the immunopathogenesis of disease: (a) they are brought on or are exacerbated by exposure to sunlight (UVB much more than UVA), (b) IgG and complement are found in a characteristic location in the skin, and (c) small blood vessels in the dermis (arterioles, capillaries, and postcapillary venules) are targeted by the inflammatory response. A discussion of these common attributes as they relate to cutaneous lupus is the focus of this section.

Acute cutaneous lupus erythematosus is an erythematous rash of the face that occurs in more than half of patients with SLE. It is a transient, nonscarring erythematous maculopapular rash that can affect the entire face or can be limited to the cheeks (*malar rash*) (Fig. 39.1). Acute cutaneous lupus usually develops after UVB exposure (*photosensitivity*). The malar rash usually lasts for several days and does not scar on resolution of the erythema.

Figure 39.1. Malar rash. An erythematous facial eruption on the malar and chin areas. (Reprinted from the Clinical Slide Collection on the Rheumatic Diseases, American College of Rheumatology, with permission.) (See Color Figure 39.1.)

On histologic examination, there is minimal degeneration of the basal cell layer of the epidermis. Immunofluorescence, however, is striking: IgG and complement are deposited at the dermal–epidermal junction in both affected (lesional) skin and typically in normal-appearing (*nonlesional*) skin as well. These changes are considered to be almost pathognomonic for lupus. These observations suggest that the basal cell layer of the epidermis is being injured through antibody-mediated activation of the complement system or by antibody itself.

The target(s) of these autoantibodies is unknown. Circumstantial evidence implicates the nuclear ribonucleoprotein Ro in the immunopathogenesis of cutaneous lupus. UVB exposure is known to cause the translocation of Ro to the cell surface in keratinocytes, as discussed previously (44). Anti-Ro autoantibodies bind *in vitro* to the surface of UV exposed keratinocytes (45) and presumably contribute to cell injury through a type II or III immunologic mechanism. Finally, photosensitivity in lupus patients is associated with the presence of anti-Ro antibodies. Whether anti-Ro antibody is directly contributing to tissue injury or is binding incidentally to damaged keratinocytes remains unknown, however.

Subacute cutaneous lupus erythematosus (SCLE) is a hyperkeratotic annular or psoriasiform erythematous rash with a predilection for the sun-exposed areas of skin. It is present in about 10% of lupus patients. Conversely, individuals may have this form of cutaneous lupus with minimal to no disease in other organ systems and have an excellent prognosis. The rash is more persistent than acute cutaneous lupus but rarely scars.

The epidermal changes are more prominent in SCLE than in acute cutaneous lupus: There is marked degeneration of the basal layer of the epidermis with a mononuclear cell infiltration of mostly CD4+ T cells about the dermal–epidermal junction and in the dermis around small blood vessels and appendages. Immunofluorescence again reveals IgG and complement deposition at the dermal–epidermal border in a granular pattern suggesting a type III mechanism of immunologic injury. There is an even stronger association with the anti-Ro response than in acute cutaneous lupus; in addition, most patients with SCLE also have the

MHC class II allele HLA-DR3 (61,62). The reasons for this genetic association between autoantibody production and MHC gene remain unknown. One can speculate that some peptide from the Ro antigen is being presented to CD4+ helper T cells by an APC bearing the DR3 molecule, but to date there is no strong evidence to support this hypothesis.

Chronic cutaneous lupus lesions are either circular (*discoid*) or irregular coalescent erythematous papules or plaques with adherent scale (Fig. 39.2). Often the borders of the lesion are erythematous, representing an advancing front of inflammation. The inflammatory cells are again mostly CD4+ T cells in the dermis. The centers of the lesions are often hypopigmented and atrophic. Like acute and subacute lesions, they usually appear on sun-exposed areas with a predilection for the ears, scalp, and face. Unlike acute and subacute cutaneous lupus, however, chronic cutaneous lupus leaves scars that can be quite disfiguring. Occasionally, these lesions may affect the extremities and trunk as well as the sun-exposed areas above the neck (*generalized discoid lupus*). Discoid lesions, like the malar rash of acute cutaneous lupus, are specific for lupus and are therefore included in the ACR diagnostic criteria.

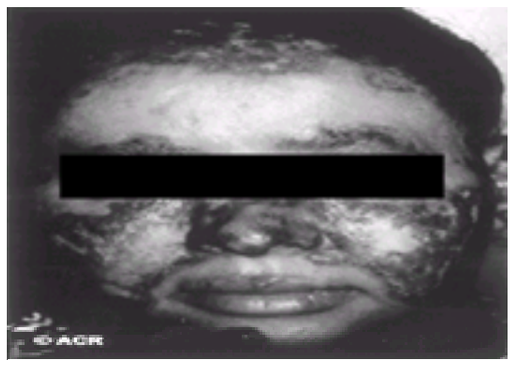

Figure 39.2. Discoid lupus. An erythematous and hyperpigmented rash on the face with central scarring and epidermal atrophy. Follicular plugging is also seen. (Reprinted from the Clinical Slide Collection on the Rheumatic Diseases, American College of Rheumatology, with permission.) (See Color Figure 39.2.)

Chronic cutaneous lupus erythematosus (discoid lupus) lesions develop in up to 25% of SLE patients but may also occur in the absence of any systemic manifestations. These individuals with isolated discoid lupus typically lack any of the characteristic autoantibodies of SLE, including anti-Ro. About 5% to 10% of individuals presenting with discoid lupus without concurrent systemic involvement eventually develop other manifestations of SLE, such as immune-mediated thromobcytopenia.

The preceding discussion of acute, subacute, and chronic cutaneous lupus focused on the role of ubiquitous nuclear autoantigens, such as Ro in immunopathogenesis. If these forms of cutaneous lupus are due to complement activation by antibody (type III mechanism), then one must explain why an immune response against a ubiquitous nuclear antigen is focused at the dermal–epidermal junction in these conditions. Another type of cutaneous lupus (*bullous lupus*) is characterized by an immune response against an antigen normally expressed only in the skin and in the kidney: type VII collagen in the basement membranes of the epidermis and glomeruli, respectively. Direct immunofluorescence of bullous lupus reveals IgG, IgM, and IgA in the basement membrane of the skin, similar to dermatitis herpetiformis. Bullous lupus also is associated with renal disease in SLE, as one would predict based on the distribution of the autoantigen. This form of bullous disease is only seen in lupus.

Alopecia is a common finding in SLE and can be diffuse or patchy and scarring or nonscarring. Diffuse hair loss may accompany acute cutaneous lupus and is usually reversible. Short, fragile, broken hairs also can be seen in the front of the hairline (“lupus hairs”). Hair loss is permanent when it is due to the extensive scarring of discoid lesions.

Mucous membrane involvement with oral, genital, and nasal ulcerations is common in lupus and is seen in 25% to 40% of SLE patients. Ulcers may be seen on the buccal mucosa or the hard palate and are usually painless.

Other mucocutaneous findings in lupus include microvascular lesions such as periungual erythema, livedo reticularis, and Raynaud phenomenon. Small-vessel cutaneous vasculitis also may be seen with lupus. Urticaria and panniculitis (*lupus profundus*) have been described in lupus patients.

Musculoskeletal Manifestations

Joints, muscle, and their supporting structures, such as tendons and ligaments, are commonly involved in lupus, affecting more than 90% of patients (63), and joint pain (*arthralgia*) is often the symptom that brings patients to medical attention. Arthralgia and symmetric arthritis of the hands [wrists, proximal interphalangeal (PIP), and metacarpophalangeal (MCP) joints] and knees are the major joint manifestations, similar to rheumatoid arthritis (RA). In contrast to RA, however, joint involvement in lupus is more migratory and less sustained. Large articular effusions are uncommon, but periarticular swelling is more prominent. Inflammation of periarticular structures can lead to deformities resembling those seen in RA but characteristically leave the articular cartilage intact, that is, without joint erosions. In addition, arthritis in lupus rarely reaches the intensity seen in RA. Tendinitis and tendon rupture also are seen in patients with SLE. Subcutaneous nodules are found in up to 10% of SLE patients, usually in those with positive rheumatoid factor (64).

The immunologic mechanisms underlying arthritis in lupus remain unknown. Synovial biopsy reveals evidence of microvascular injury in the synovium with enlarged endothelial cells with perivascular infiltrates of mononuclear cells (65). These changes are not specific to lupus.

For patients with arthralgia and mild arthritis, analgesics or NSAIDs may provide adequate relief. Hydroxychloroquine is also effective. In patients with more severe arthritis not responding to hydroxychloroquine and NSAIDs, weekly methotrexate should be considered with careful monitoring of liver and renal function (66). Corticosteroid use should be avoided if possible for arthritis in lupus because of well-documented long-term cumulative toxicities (67).

Osteonecrosis (avascular necrosis) should be suspected in SLE patients with localized joint pain, especially in those who are or were on corticosteroids. It is most common in the femoral head, although other sites, such as the shoulders (humeral head), tibial plateau, and scaphoid can be involved (67). Conventional radiographs may be negative in early lesions. In these situations, a magnetic resonance imaging (MRI) scan should be done to detect early changes typical of osteonecrosis.

Muscle pain (*myalgia*) and muscle weakness, especially in the deltoid area and quadriceps, are common in lupus patients. Inflammatory myositis resembling polymyositis or dermatomyositis is rare in lupus, however, occurring in 5% to 10% of SLE patients. These patients often exhibit features of other systemic rheumatic diseases as well. Individuals with a high titer (often >1:10,000) of autoantibody against the small nuclear ribonucleoprotein U1 snRNP can develop an overlap syndrome of lupus, polymyositis, and systemic sclerosis that is known as *mixed connective tissue disease*. Medication-induced myopathy caused by corticosteroids (rarely by hydroxychloroquine) also should be considered in the differential diagnosis of proximal weakness in lupus.

Cardiac Manifestations

Any structure within the heart can be damaged by lupus, including the valves, pericardium, myocardium, conduction system, and coronary arteries. Valvular disease is common in lupus, with 50% to 60% of patients having abnormalities on transesophageal echocardiography (68). The mitral valve is most commonly affected, with thickening, vegetations, regurgitation, or stenosis. Initially, mononuclear cells infiltrate the valve leaflets, leading to thickening. Later, immune complexes, mononuclear cells, and fibrin and platelet thrombi accumulate, producing vegetations. The nature of the infiltrating leukocytes and immune complexes remains unknown. Resolution of the valvulitis usually leads to fibrosis and, in some cases, calcification, leading to varying degrees of valvular regurgitation. Similar observations have been made in inflamed pericardium and myocardium, suggesting a common mechanism of pathogenesis in cardiac disease. Although valvular abnormalities in lupus are usually clinically silent initially, they carry a significant potential (20%) for long-term morbidity and mortality, including stroke, embolic disease, heart failure, infectious endocarditis, and valve failure requiring replacement (68). Interestingly, the course and severity of the valvular disease usually do not mirror the activity of disease in other organs, suggesting that different pathogenic mechanisms are operative in cardiac disease compared with skin, joint, and renal disease.

The major cardiovascular morbidity in lupus is ischemic heart disease resulting from accelerated atherosclerotic coronary disease. Known risk factors include those common to atherosclerotic coronary disease (smoking, hypertension, hyperlipidemia, diabetes mellitus, plasma homocysteine levels) and those unique to lupus, namely, the dose and duration of corticosteroid use and the presence of antiphospholipid antibodies. Pericarditis is the most common cardiac complication attributable to lupus itself. It is usually asymptomatic, but pericardial effusions can be demonstrated in 50% to 60% of patients by echocardiography. Symptomatic pericarditis

occurs in about 25% of patients.

Pulmonary Manifestations

Any component of the pulmonary system, including the lung parenchyma, pleura, pulmonary vessels, and diaphragm, can be affected by SLE [reviewed in (69)]. Pleuritis with or without pleural effusion is the most common pulmonary manifestation of lupus, occurring in 60% to 70% of patients sometime during the course of their illness. Acute and chronic pneumonitis can be seen in lupus but are uncommon, occurring in fewer than 10% of patients. Acute pneumonitis often occurs with concurrent pulmonary hemorrhage resulting in hemoptysis and carries an extremely poor prognosis. Chronic pneumonitis leading to fibrosis is quite rare in lupus, in contrast to the interstitial lung disease of systemic sclerosis, Sjögren syndrome, and polymyositis. Pulmonary hypertension also can occur but is rare in the absence of parenchymal lung disease. Other pulmonary manifestations include pulmonary embolism, bronchiolitis obliterans with organizing pneumonia, and the shrinking lung syndrome. The shrinking (*vanishing*) lung syndrome is characterized by dyspnea, pleuritis, and a progressive decrease in lung volume in the absence of interstitial lung disease (70). It appears to be due to a myopathy or myositis selectively affecting the diaphragmatic muscles.

The immunopathogenesis of the pulmonary manifestations of lupus remains obscure. Similar to cardiac disease, immune complex deposition in the pulmonary microvasculature has been implicated. In acute pneumonitis, alveolar lining cell injury with immunoglobulin and complement deposition is seen with varying degrees of alveolar edema and hemorrhage. In patients who have acute pneumonitis with hemoptysis, the predominant finding on light microscopy has been inflammation and damage to alveolar capillaries with subsequent hemorrhage into the alveolar space. Vasculitis has been documented only rarely. Abnormal endothelial cell–leukocyte interaction may be responsible for the phenomenon of acute reversible hypoxemia in lupus, in which no parenchymal lung disease is demonstrable on computed tomography (CT) scanning. Leukocyte agglutination with subsequent occlusion of the microvasculature has been suggested as a mechanism of pulmonary and other organ dysfunction in lupus (71). This is presumably due to abnormal expression of the endothelial adhesion molecules E-selectin, vascular cell adhesion molecule-1 (VCAM-1), and intercellular adhesion molecule-1 (ICAM-1) in lupus (72).

After infection has been excluded, high-dose corticosteroids with or without other immunosuppressive agents (such as cyclophosphamide) are given for severe pulmonary disease, such as acute hemorrhagic pneumonitis. In rapidly deteriorating patients who do not respond to this approach, intravenous pulse corticosteroids followed by plasma exchange with concomitant immunosuppressive therapy has been used (73,74). The treatment of interstitial lung disease in lupus depends on the degree of chronic (fibrotic) changes detected in the parenchyma. In patients who have interstitial lung disease, high-resolution chest CT (HRCT) can help to guide therapy. A ground-glass appearance on HRCT suggests active inflammation and warrants immunosuppressive therapy. In contrast, a reticular or honeycomb pattern on HRCT likely reflects fibrosis and therefore is unlikely to improve with immunosuppressive therapy. Patients with diaphragmatic myopathy (the shrinking lung syndrome) may benefit from high-dose corticosteroids as well (75,76).

Renal Manifestations

Renal disease is the major cause of morbidity in lupus [reviewed in (77)]; 50% of SLE patients develop clinically significant nephritis characterized by decreased glomerular filtration rate or abnormal urinalysis. The frequency of subclinical renal involvement, however, is greater than 90% because almost all patients with SLE have abnormal renal biopsies if immunofluorescence studies and electron microscopy are performed (56). Although the glomerulus suffers the brunt of the inflammatory process, the renal tubules and interstitium are not spared.

Lupus glomerulonephritis is characterized by the deposition of immune complexes of autoantibody within the glomerulus and is classified based on the site and severity of that deposition. The nature of these immune complexes and the subsequent activation of the complement system are discussed in the section on immunopathogenesis. The World Health Organization (WHO) Classification (Table 39.3) is the most commonly used framework. The clinical utility of this classification lies in its correlation with disease severity and prognosis for preservation of renal function. One must bear in mind that designations applied using this classification scheme are not fixed: Transition from one stage to another is common when sequential biopsies are compared in patients being treated for lupus nephritis, in particular the transition from focal to diffuse proliferative glomerular disease.

Class	Pathologic Finding
I	Normal
IIA	Mesangial deposits
IIB	Mesangial cellular proliferation
III	Focal proliferative glomerulonephritis
IV	Diffuse proliferative glomerulonephritis
V	Membranous glomerulonephritis

TABLE 39.3. World Health Organization Classification of Lupus Nephritis

Renal biopsies with no abnormalities on light microscopy, immunofluorescence studies (for deposition of immunoglobulin and complement), and electron microscopy are designated as WHO class I. The urinalysis and glomerular filtration rates are normal. In class II, or *mesangial nephritis*, IgG and complement deposition can be seen in the mesangium. This triggers recruitment and activation of phagocytic cells (neutrophils and macrophages) in the mesangium. The chemoattractants C3a and C5a are generated. In addition, proinflammatory cytokines are produced by activated T cells and macrophages, including tumor necrosis factor a (TNF-a), interferon-g (IFN-g), IL-6, and transforming growth factor-b (TGF-b). The mesangium is hypercellular on light microscopy. Continued deposition of immune complexes presumably overwhelms the capability of the mesangium to degrade the complexes, leading to “spillage” of immune reactants into adjacent structures, notably the subendothelial space.

Focal proliferative glomerulonephritis (class III nephritis) is characterized by the spread of the inflammatory process into the subendothelial space of the glomerular capillaries. This may be due to deposition of circulating immune complexes in the glomerular basement membrane (GBM) or through the binding of circulating autoantibody to “trapped” antigen in the GBM. These antibodies are usually IgG1 or IgG3, which are effective activators of the complement cascade. Light microscopy shows a proliferative glomerulonephritis that affects fewer than 50% of the glomeruli (“focal” disease) on renal biopsy, although one must consider the possibility of sampling error. Within affected glomeruli, some regions of the glomeruli are spared; that is, there is “segmental” involvement (Fig. 39.3). The changes within the glomerulus can be proliferative, necrotizing, sclerosing, or a combination of these. The clinical consequence is a small decrease in the glomerular filtration rate, proteinuria, and an active urinalysis with microscopic hematuria, proteinuria, and red blood cell or white blood cell casts. If the inflammatory process remains unchecked, some patients will progress to more extensive glomerular disease.

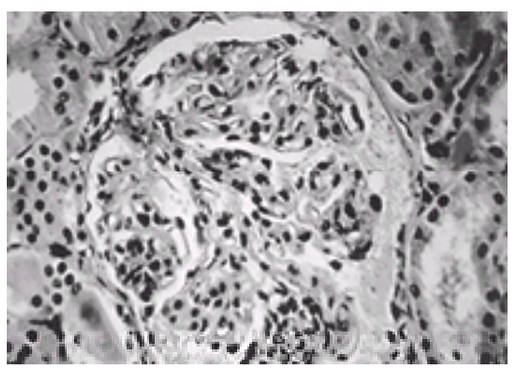

Figure 39.3. Focal proliferative glomerulonephritis. Marked hypercellularity with obliteration of capillary lumens are seen in two glomerular tufts on hematoxylin and eosin staining. The remainder of the glomerulus is normal or minimally affected. (Reprinted from the Clinical Slide Collection on the Rheumatic Diseases, American College of Rheumatology, with permission.)

Class IV nephritis (*diffuse proliferative glomerulonephritis*) is the most ominous form of lupus nephritis because it carries the highest risk of progressing to renal failure. Most (>50%) of the glomeruli are affected with diffuse hypercellularity of mesangial and endothelial cells and capillary loop thickening (Fig. 39.4). Necrosis is often seen within the glomerulus. Immunofluorescence microscopy demonstrates extensive deposition of immunoglobulin and complement in the mesangium and capillary loops (Fig. 39.5). Electron microscopy shows extensive subendothelial and mesangial deposits. Patients with class IV nephritis typically present with severe renal insufficiency as well as significant proteinuria and microscopic hematuria.

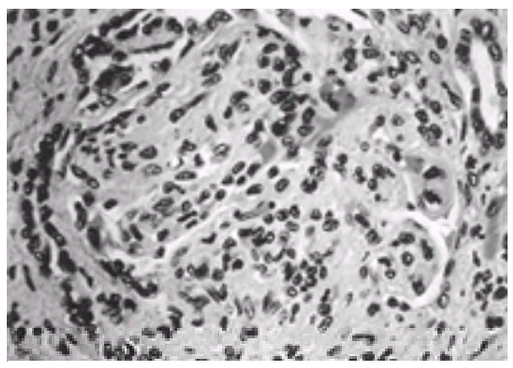

Figure 39.4. Diffuse proliferative glomerulonephritis. Marked hypercellularity with compression of capillary lumens affecting the entire glomerulus with obliteration of the normal glomerular architecture (hematoxylin and eosin staining, high power). (Reprinted from the Clinical Slide Collection on the Rheumatic Diseases, American College of Rheumatology, with permission.)

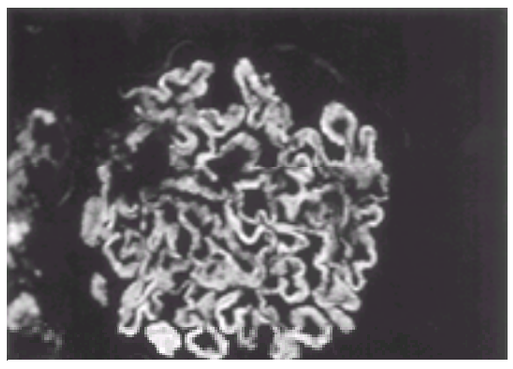

Figure 39.5. Immunofluorescence staining of lupus nephritis. The basement membrane of the glomerulus is partly outlined by irregular deposits of immunoglobulin G (IgG) detected with fluorescein-conjugated rabbit antihuman IgG. (Reprinted from the Clinical Slide Collection on the Rheumatic Diseases, American College of Rheumatology, with permission.)

Class V (*membranous glomerulonephritis*) is characterized by the deposition of immune complexes in the urinary space below the epithelial cells (subepithelial space). These autoantibodies may be binding to antigens on epithelial cells or to cationic antigens that have traversed the GBM. Antibodies binding in the subepithelial space are usually IgG2 or IgG4 (78), which do not bind complement well and therefore would not trigger the same degree of inflammatory reaction as IgG1 or IgG3. Light microscopy shows a diffuse thickening of the peripheral capillary walls in the absence of cellular infiltrate (Fig. 39.6). Electron microscopy reveals subepithelial and intramembranous deposits. In general, affected patients have extensive proteinuria but only minimal elevations of the serum creatinine. Some patients, however, progress to chronic renal insufficiency.

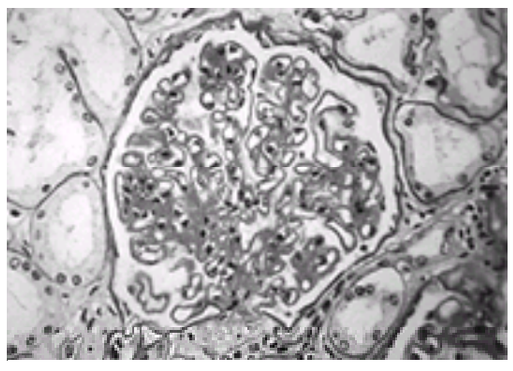

Figure 39.6. Membranous glomerulonephritis. Widespread, uniform thickening of capillary basement membranes of the glomerulus is seen on periodic acid-Schiff staining. (Reprinted from the Clinical Slide Collection on the Rheumatic Diseases, American College of Rheumatology, with permission.) (See Color Figure 39.6.)

The treatment of lupus nephritis should be individualized based on the histopathologic type, activity and chronicity of nephritis, and rate of change in renal function. Patients with mesangial or mild focal proliferative nephritis can be treated with high-dose corticosteroids alone without cytotoxic drugs. Those with severe focal proliferative or diffuse proliferative lupus nephritis should be treated aggressively with a combination of immunosuppressive and cytotoxic drugs, such as cyclophosphamide and high-dose corticosteroids (79). This regimen is more efficacious than corticosteroids alone for severe proliferative nephritis but is associated with significant toxicity. The side effects of cyclophosphamide include increased risk of bacterial and viral infection, especially *Varicella* reactivation, hemorrhagic cystitis, and ovarian failure. There is also a clear increase in the risk of hematologic malignancy and bladder carcinoma. Although there is no well-accepted treatment for pure membranous lupus nephritis, patients with nephrotic range proteinuria or worsening renal function should be considered for high-dose corticosteroids with or without cytotoxic therapy such as intravenous cyclophosphamide (80).

Other therapeutic strategies have been used for severe lupus nephritis, CNS disease, or multisystem disease. Growing clinical evidence reports the successful use of the immunosuppressive/cytotoxic drug mycophenolate mofetil, either at presentation or in patients who have failed intravenous pulse cyclophosphamide therapy (81). In addition, plasma exchange with subsequent intravenous cyclophosphamide followed by prednisone and cyclophosphamide has achieved remission in more than half of the patients with severe lupus (most with lupus nephritis) at almost 4 years of follow-up (73,82). This regimen is associated with a substantially higher risk of potentially fatal bacterial and viral infection, however, than treatment with cyclophosphamide alone (83).

Several animal studies demonstrated the potential of immunobiological agents targeted at specific molecules in the treatment of SLE (84,85,86 and 87). These therapies are discussed fully in the section on immunopathogenesis. These agents interfere with the interaction of T cells with APCs such as B cells, thereby blocking B-cell activation and subsequent T-cell help for pathogenic autoantibody production. The infusion of anti-CD40 ligand antibody in lupus-prone mice not only prevented the development of nephritis but also improved survival in mice with established nephritis (85,86). Treatment of lupus-prone mice with CTLA4-Ig, a fusion protein of the T cell downregulatory molecule CTLA-4 to the Fc portion of a mouse IgG2a monoclonal antibody, decreases autoantibody production and increases survival (84,87). To date, however, these therapies have not been successful in small clinical trials in lupus patients.

Neuropsychiatric Manifestations

Lupus can affect any part of the nervous system, from the CNS, to the spinal cord, to the peripheral nervous system (PNS). Possible CNS manifestations include cognitive dysfunction, depression, psychosis, coma, seizure disorders, migraine, and other headache syndromes, aseptic meningitis, chorea, stroke (due to hemorrhage or thrombosis associated with the antiphospholipid syndrome), and cranial neuropathies (88). The most common neuropsychiatric manifestations of lupus are depression and psychosis. Attributing these changes to lupus itself is difficult and is a diagnosis of exclusion. It is paramount to evaluate patients for potentially reversible causes, such as infection, hypertension, metabolic abnormalities, and toxic effects of medications, particularly corticosteroids. No laboratory tests are available to distinguish reliably between neurologic disease secondary to lupus versus these other etiologies.

The pathogenesis of CNS lupus remains cryptic. Two mechanisms have been implicated: nonvasculitic small-vessel injury and direct cellular damage from autoantibodies. CNS vasculitis is rarely found on histopathologic examination; instead, vasculopathy with leukoagglutination without significant inflammatory infiltrate of vessel walls is usually seen (89). The mechanisms underlying vascular damage, including antiphospholipid antibodies, are unknown. The evidence implicating autoantibodies stems from the observation that IgG antibodies against neuronal antigens are seen in most individuals with diffuse CNS disease and lupus (90,91). These antibodies cross-react with lymphocyte antigens and are cytotoxic to lymphocytes *in vitro* (90). One candidate antigen on neurons is a 50-kd protein present in the membrane of synaptic terminals (92). Antineuronal antibodies are either absent or present in low titer in persons who have non-CNS lupus or other systemic rheumatic diseases. Persistent elevations of IgG anticardiolipin antibodies also have been associated with cognitive dysfunction in SLE (93). Other autoantibodies have been associated with different CNS manifestations of lupus: recent studies showed an association between psychiatric manifestations of SLE, especially depression, and elevated serum levels of antiribosomal P protein antibody (94). At present, however, this observation is of little clinical utility because of the lack of a commercially available test to determine the presence of this autoantibody.

Seizure disorders occur commonly in lupus, affecting 10% to 20% of patients. Seizures may be the only manifestation of lupus at presentation, with individuals years later developing the more common manifestations of disease. Conversely, many of the anticonvulsants used to treat seizure disorders can cause a positive ANA. These persons can therefore be mistakenly diagnosed as having SLE. Stroke in lupus can be due to many different factors, including hypertension secondary to renal insufficiency, thrombosis due to the presence of antiphospholipid antibodies, hemorrhage from severe thrombocytopenia, and embolic disease from infectious or noninfectious mitral valve endocarditis.

Peripheral nervous system disease in lupus may be motor, sensory, or mixed, and produce a relatively symmetric polyneuropathy or mononeuritis multiplex. Rarely, an acute ascending motor paralysis similar to Guillain-Barré syndrome and transverse myelitis occurs.

Unfortunately, no data from randomized controlled studies are available to guide the treatment of neuropsychiatric lupus. Once other causes have been excluded, therapy of neuropsychiatric lupus should be individualized based on the severity of illness and, if possible, on understanding the nature of the underlying process such as inflammation or thrombosis. High-dose intravenous corticosteroids (methylprednisolone) are usually given for severe disease such as cerebritis or acute transverse myelitis, typically followed by pulses of intravenous cyclophosphamide. Given the sparse inflammatory infiltrate seen on the brain or meningeal biopsies in most cases, this is of questionable value. Anticoagulation should be considered for patients who show evidence of cerebrovascular thrombosis.

Hematologic Manifestations

Leukopenia and thrombocytopenia are common hematologic findings in lupus [reviewed in (95)]. Because SLE patients often are taking immunosuppressive drugs, drug-induced hematologic problems always should be ruled out first. Lupus is unique among the systemic rheumatic diseases in that leukopenia rather than lymphocytosis is seen in active disease. For this reason, it is included in the ACR diagnostic criteria for lupus. Leukopenia ranges from 2,500/mm^3 to 4,000/mm^3 and rarely causes any clinical problem. It is usually due to lymphopenia, with a lymphocyte count of less than 1,500/mm^3.

Thrombocytopenia occurs in about 25% to 50% of SLE patients, and antiplatelet antibodies often are demonstrated in these patients. The antigen(s) is unknown. Usually, the thrombocytopenia is not severe enough to warrant specific therapy. Not all lupus patients with antiplatelet antibodies, however, have thrombocytopenia. A patient may have an apparently isolated case of idiopathic thrombocytopenia (ITP) and subsequently develop SLE. Rarely, thrombotic thrombocytopenic purpura (TTP) has been associated with lupus.

Various forms of anemia, including immune-mediated and nonimmune-mediated anemia, occur. The most common form of anemia in lupus is the anemia of chronic disease with low serum iron and total iron-binding capacity and a normal serum ferritin. Autoimmune hemolytic anemia with a positive Coombs test result occurs in 7% to 15% of SLE patients. Some lupus patients, however, have a positive Coombs test result without evidence of hemolytic anemia. Pure red cell aplasia resulting from antibodies against erythroblasts and pancytopenia has been reported rarely in SLE as well (96).

Coagulation abnormalities are also seen in lupus. Autoantibodies directed against protein–phospholipid complexes critical for the initiation of the clotting cascade by the intrinsic pathway (lupus anticoagulant antibodies) can prolong the partial thromboplastin time (PTT). Despite the prolongation of the PTT *in vitro*, patients with these antibodies are at risk for arterial or venous thrombosis (the antiphospholipid syndrome, or APS). Patients with thrombosis secondary to APS should be treated with chronic anticoagulation (97). Low-dose aspirin alone usually is prescribed prophylactically for patients with antiphospholipid antibodies or anticardiolipin antibodies without a history of a thrombosis, although data supporting this approach are lacking.

Splenomegaly and lymphadenopathy occur in lupus. The enlarged nodes are usually soft, nontender, and variable in size. Biopsy demonstrates reactive hyperplasia.

Patients with the anemia of chronic disease do not require specific therapy for the anemia. Coombs-positive autoimmune hemolytic anemia is treated with high-dose corticosteroids. Immunosuppressive drugs such as azathioprine and cyclophosphamide should be considered for refractory cases. Thrombocytopenia is usually not severe in lupus and does not require therapy. When the platelet count goes below 20,000/mm^3 or when there is active bleeding, high-dose corticosteroids are used. For patients who do not respond to high-dose corticosteroids or who require unacceptably high maintenance doses of prednisone, azathioprine, cyclophosphamide, the androgen danazol and splenectomy have been used (98). In emergency situations, intravenous immune globulin can raise platelet counts above dangerously low levels within 1 day. The effect, however, lasts only several weeks (99). Leukopenia is usually not severe enough in lupus to warrant specific immunosuppressive therapy.

Gastrointestinal Manifestations

Hepatomegaly and abnormal liver function tests are frequently detected in SLE patients. Medications such as NSAIDs, azathioprine, and methotrexate are most commonly responsible for abnormal liver function tests. In addition, autoimmune hepatitis should be considered in the differential diagnosis. About 25% to 50% of SLE patients have gastrointestinal symptoms, including dysphagia, abdominal pain, anorexia, nausea, and vomiting, that are most commonly due to side effects of medication. Rarely, these symptoms are due to mesenteric vasculitis, bowel perforation, sterile or spontaneous bacterial peritonitis, or pancreatitis.

Drug-induced Lupus

Certain medications, most commonly procainamide, can cause symptoms and immunologic abnormalities that are somewhat similar to (idiopathic) SLE (Table 39.4). Constitutional, musculoskeletal, and pleuropericardial symptoms dominate the clinical picture; cutaneous, renal, and CNS diseases are distinctly unusual [reviewed in (100)]. The syndrome of drug-induced lupus resolves with discontinuation of the offending agent. The immunologic hallmark of drug-induced lupus is the formation of autoantibodies against histones in all patients who have this syndrome. The panoply of autoantibodies that characterizes idiopathic lupus is not seen. The humoral response in drug-induced lupus usually is focused against the H2A–H2B component of histones complexed to DNA (101) and precedes the development of symptoms in both murine models of the disease and in humans (102). Most patients who develop antihistone antibodies while taking procainamide never develop the syndrome, however. One risk factor for the development of drug-induced lupus is decreased hepatic metabolism of these compounds, that is, the “slow acetylator phenotype,” which is due to decreased acetyltransferase activity in the p450 cytochrome system (103).

Drugs with strong evidence shown by prospective studies
Procainamide, hydralazine, chlorpromazine, isoniazid, methyldopa, minocycline
Drugs with circumstantial evidence
β-Adrenergic blocking agents, mephenytoin, phenytoin, quinidine, rifampin, sulfonamides

TABLE 39.4. Drugs Implicated in the Induction of Lupus-Like Disease

How drugs such as procainamide can trigger autoimmunity remains unclear. *In vitro*, they can be metabolized into cytotoxic compounds by myeloperoxidase in activated neutrophils (104). They may also directly alter lymphocyte function by decreasing DNA methylation, leading to increased expression of adhesion molecules such as LFA-1 (45). In addition, these compounds may augment the positive selection of autoreactive T cells in the thymus; injection of the thymus of nonautoimmune C57BL/6 mice with the hydroxylamine metabolite of procainamide leads to enhanced thymocyte proliferation against chromatin derived peptides. A T-cell–dependent antibody response against the H2A–H2B subunit of chromatin (105,106) follows, although an effect on peripheral tolerance cannot be excluded by these experiments.

Pregnancy and Lupus

There is an increased risk of spontaneous abortion, fetal loss, and prematurity in lupus [reviewed in (107)]. Whether pregnancy can induce a flare of disease remains controversial: Initial studies suggested an increased risk of a lupus flare during pregnancy, but later controlled studies reported that the risk of flare in pregnant women with lupus is the same as that in nonpregnant women, especially when disease activity is under control prior to pregnancy (108). Preeclampsia and eclampsia are other important considerations in the differential diagnosis of the pregnant lupus patient with hypertension and worsening renal function.

A mother with lupus may have a newborn with neonatal lupus characterized by a transient skin rash resembling that seen in acute cutaneous lupus, hepatitis, cytopenias, and heart block. Neonatal lupus is exclusively seen in a lupus mother with anti-Ro or La antibody; the risk for the syndrome is about 1% to 5% in children of mothers with these autoantibodies [reviewed in (109)]. The mechanism of neonatal lupus is believed to be secondary to maternal IgG anti-Ro or anti-La antibody that crosses the placenta and binds neonatal antigens in various organs, including the heart.

Laboratory Tests: Antinuclear Antibodies

The immunologic hallmark of lupus is the presence of ANAs in the serum; 95% to 99% of patients with SLE have ANAs when indirect immunofluorescence is used and human (Hep-2) cells are used as the source of antigen [reviewed in (110)]. For this reason, ANA testing has been incorporated into the evaluation for lupus. In some patients, the titer of certain autoantibodies is also a useful correlate of disease activity. The titer and pattern of staining of ANAs are important; four patterns of staining are recognized: (a) diffuse nuclear, (b) peripheral nuclear; (c) rim, speckled, and (d) nucleolar (Fig. 39.7, Fig. 39.8 and Fig. 39.9). Proper interpretation of the ANA test result by the physician is paramount: Many healthy individuals (5%–8% of the general population) have a positive ANA but never develop any symptoms or signs of a systemic rheumatic disease. In addition, persons who have other systemic rheumatic diseases, such as Sjögren syndrome, systemic sclerosis, and polymyositis/dermatomyositis and other organ-specific autoimmune disease (e.g., chronic autoimmune hepatitis) usually develop ANAs as well. Enzyme-linked immunosorbent assay (ELISA) testing using recombinant protein antigens or purified DNA is done following fluorescent ANA testing to determine the specificity of the ANA.

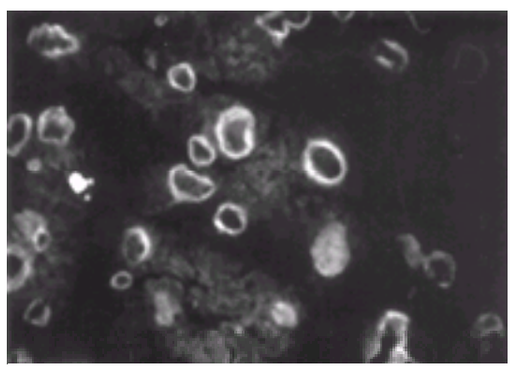

Figure 39.7. Antinuclear antibody: Rim (peripheral) pattern. (Reprinted from the Clinical Slide Collection on the Rheumatic Diseases, American College of Rheumatology, with permission.) (See Color Figure 39.7.)

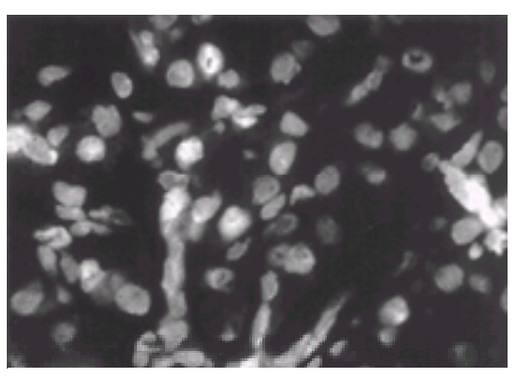

Figure 39.8. Antinuclear antibody: Homogeneous (diffuse) pattern. (Reprinted from the Clinical Slide Collection on the Rheumatic Diseases, American College of Rheumatology, with permission.) (See Color Figure 39.8.)

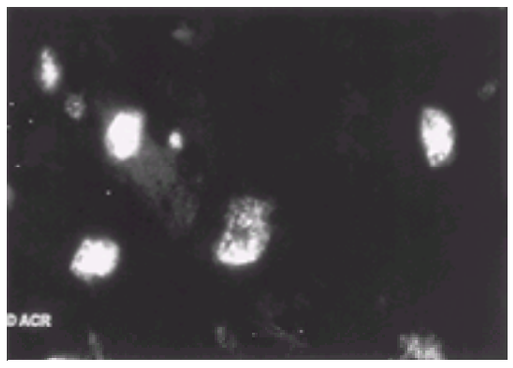

Figure 39.9. Antinuclear antibody: Speckled pattern. (Reprinted from the Clinical Slide Collection on the Rheumatic Diseases, American College of Rheumatology, with permission.)

In SLE, ANAs can be divided into antibodies against chromatin-associated antigens [double-stranded (ds) DNA and histones] and antibodies against ribonucleoproteins (Ro, La, Sm, and U1 snRNP) (Table 39.5). Anti-dsDNA antibodies and anti-Sm antibodies are unique among the autoantibodies because they are seen only in lupus, with anti-dsDNA antibodies typically giving a diffuse or rim pattern and anti-Sm antibodies giving a speckled ANA test result. Antibodies to intact chromatin occur in about 90% of lupus patients, whereas anti-dsDNA antibodies are present in roughly 70%. In some lupus patients, the titer correlates with disease activity, especially renal disease. Anti-Sm antibody occurs in about 20% to 30% of SLE patients and is more common in African Americans with lupus (111).

Target of Antibody	Clinical Associations	Prevalence (%)
dsDNA	Highly specific for SLE Correlates with disease activity, especially with renal disease	70
Histone	SLE Drug-induced lupus	50–70 >90
Sm	Highly specific for SLE	20–30
U1-snRNP	SLE MCTD	30–40
Ro (SS-A)	SLE Neonatal lupus Subacute cutaneous lupus Photosensitivity Sjogren's syndrome	30–60
La (SS-B)	SLE Neonatal lupus Sjogren syndrome	10–15
Ribosomal P antigen	Psychiatric disease, especially depression	10–20

MCTD, mixed connective tissue disease; SLE, systemic lupus erythematosus; snRNP, small nuclear ribonucleoprotein.

TABLE 39.5. Autoantibodies and Their Clinical Association and Prevalence in Sle

Anti-U1RNP is detected in 30% to 40% of SLE patients, and it is also found in high titers in patients with mixed connective-tissue disease. Although commonly associated with Sjögren syndrome, anti-Ro and anti-La antibodies are found in about 30% to 40% and 10% to 15% of SLE patients, respectively. The presence of anti-Ro or anti-La antibodies in a pregnant woman is associated with a 1% to 5% chance of neonatal lupus developing in the infant. Antihistone antibodies are seen in patients with SLE and drug-induced lupus. Other less commonly found ANAs in SLE are anti-Ku antibody, antiproliferating cell nuclear antigen (anti-PCNA), anti-RNA polymerase antibody, and antiribosomal P protein antibody. ANA-negative SLE patients often have anti-Ro antibody by ELISA (112).

Laboratory Studies: Complement

One of the important pathogenic mechanisms of tissue injury in lupus is activation of the classical complement pathway by immune complexes formed between self-antigen and autoantibody. This consumes early components of the complement system. Therefore, patients with active lupus, particularly nephritis, usually have low C3, C4, and total hemolytic complement. Determination of low serum complement levels is useful in helping to distinguish lupus activity from mimics, such as infection. In addition, patients who have a hereditary deficiency of early complement proteins C4 and C2 develop lupus at a young age. Therefore, it is useful to screen for hereditary complement deficiency in children and young adults newly diagnosed with lupus.

Prognosis

Given the variability in the presentation and severity of illness, it is difficult to discern long-term outcomes in patients with lupus. The prognosis and course of disease are variable: Patients may follow a relapsing or relapsing and remitting course, with intermittent flares of lupus superimposed on a “baseline” of chronic disease activity. Alternatively, they may follow a course of chronic, active, progressive disease with cumulative organ damage. Some patients have long-term (>6 months) periods of disease quiescence with no discernible activity on standard measures of disease activity, such as the SLE disease activity index (SLEDAI). Unfortunately, at present, we have no predictors of which clinical course patients will follow and which complications will occur. Fortunately, the overall prognosis (survival) in SLE has improved over the last 3 decades since the introduction of corticosteroid and cyclophosphamide therapy and is now 80% to 90% at 10 years compared with 50% 30 years ago (113). The price for this advance has been steep: Increasing morbidity rates from cardiovascular disease, including stroke and myocardial infarction, have accompanied the use of high-dose corticosteroids for serious manifestations of lupus (114,115). The prevention of atherosclerosis in lupus patients will become paramount in the future.

In addition, for unknown reasons, prognosis is worse for African Americans with lupus, particularly those with renal disease (116). Significant effort should be made in the future to understand the genetic and environmental factors responsible for the poor outcome in some patients.

IMMUNOPATHOLOGY

Autoantibodies in Lupus

The production of high-titer IgG antibodies against ubiquitous intracellular components, including chromatin and ribonucleoproteins, is the hallmark of lupus in humans and in murine models of the disease (8,50). The deposition of immune complexes of these autoantibodies with their respective autoantigens in target organs, such as the kidney, leads to activation of complement and Fc receptor binding (117) with subsequent tissue injury. Presumably, similar mechanisms account for tissue inflammation in other organs, such as the skin and joints.

Proof of the pathogenicity of certain autoantibodies comes from studies of human polyclonal anti-dsDNA and murine monoclonal anti-dsDNA IgG antibodies, which induce glomerular pathology when passively transferred into nonautoimmune mice. In these animals, the glomerular filtration rate is reduced, pathologic proteinuria develops, and mesangioproliferative glomerulonephritis destroys the normal architecture of the glomerulus (118,119). These changes are quite similar to those seen in human lupus. Mice that transgenically express immunoglobulin genes coding for anti-dsDNA antibodies also develop immune complex–mediated proliferative glomerulonephritis (120,121).

Anti-dsDNA antibodies are preferentially deposited in the kidney and can be eluted from the kidneys of animals with spontaneous lupus glomerulonephritis in high concentration relative to their level in serum (122). In humans, increases in serum titer often precede, or are coincident with, worsening of renal disease (123,124). In addition, genetic disruption of the ability of B cells to produce antibody results in markedly diminished glomerular pathology in lupus-prone mice (125). Although following the titer of anti-dsDNA antibodies is clinically useful in many patients with nephritis, the presence of anti-dsDNA antibodies does not always positively correlate with development of renal disease (123,124), nor are they necessary for the development of glomerulonephritis in some patients. Autoantibodies other than those directed against chromatin also can incite immune complex renal disease, and end-organ injury may result from nonantibody-dependent mechanisms (125,126).

The precise site of interactions between autoantibody and autoantigen is unclear. Three hypotheses have been proposed to explain the process by which immune complexes containing antichromatin antibodies are formed [reviewed in (127)]. The first hypothesis proposes that the interaction between these autoantibodies and antigen occurs exclusively in the serum, with subsequent deposition in tissues. This explanation now appears unlikely as the sole reason for the pathogenicity of autoantibodies. Multiple attempts to detect immune complexes containing DNA in the serum of lupus patients have failed (128,129). Further, the passive transfer of preformed complexes containing anti-DNA antibodies in mice has not resulted in glomerular inflammation (130). A second hypothesis postulates that antichromatin antibodies may cross-react with protein and carbohydrate antigens, such as laminin, in the glomerulus to form immune complexes (131,132,133 and 134). Support for this hypothesis comes from the observation that a subset of antichromatin antibodies, generated by immunization with a foreign peptide, are cross-reactive with other autoantigens in lupus, such as the Sm ribonucleoprotein (135). An alternative possibility is that circulating antigen is trapped *in situ* within the kidney and subsequently binds anti-dsDNA antibodies. Evidence for this hypothesis comes from the observation that circulating nucleosomes, normally generated during the process of apoptosis (136,137 and 138), can bind to proteins within the GBM, particularly type IV collagen (139,140,141 and 142). Regardless of the precise mechanism(s) involved, immune complexes are located within the kidney. Phagocytic cells within the kidney bearing Fc and complement receptors then can recognize these complexes either by binding to the Fc portion of IgG or through recognition of opsonins generated by the classic complement pathway. The subsequent inflammatory response leads to destruction of the glomeruli. The importance of this mechanism of tissue injury in lupus is demonstrated in animals with an impaired ability to recognize immune complexes through the Fc portion of IgG. Lupus-prone NZB/NZW mice deficient in the g chain of the Fc receptor have significantly reduced glomerular pathology compared with wild-type controls (117).

It is therefore of great importance to identify the properties that determine the pathogenicity of these autoantibodies. No striking differences in V heavy or light immunoglobulin gene segment use has been found between lupus-prone and nonautoimmune mice or in studies of human lupus patients (143). This suggests that many different V genes are capable of generating an anti-DNA response and that the B-cell germ-line repertoire is not different in patients with systemic autoimmune disease. Therefore, properties of anti-dsDNA antibodies conferred after germ-line gene segment rearrangement strongly influence pathogenicity. These properties include the net charge of the antigen-binding region, the isotype, and the avidity of the antibody for DNA. Cationic antibodies are more likely to be pathogenic (144), presumably because of increased avidity for negatively charged antigens, such as DNA, and preferentially bind in the kidney (145). These cationic antibodies have a high frequency of arginine substitution in the V CDR3 region, and the position of these arginine substitutions is critical to glomerular binding (146). Isotypes that bind complement well (IgG2a) are more pathogenic in murine models than other isotypes (IgG1). Finally, antibodies directed against dsDNA in lupus-prone mice develop greater affinity for dsDNA over time. The net effect of these changes in antibody structure is to increase the affinity of the antibody for autoantigen over time.

ab T CELLS REQUIRED FOR AUTOANTIBODY GENESIS AND DISEASE IN LUPUS

The production of antibodies against chromatin and ribonucleoproteins is antigen driven in human and murine lupus. This conclusion is based on genetic analysis of high-affinity, pathogenic murine IgG antiDNA autoantibodies (147,148,149 and 150). Such work also was performed with human anti-DNA with similar results (151) showing clonal selection, somatic mutation, and selected distribution of replacement of silent mutations in the complementarity-determining regions (CDRs) of the antibody. Sequencing of antibodies directed against dsDNA suggested that these antibodies affinity matured in response to DNA, or perhaps an antigen that mimicked it in charge and conformation [reviewed in (152)]. Apparent antigen selection and somatic hypermutation of autoantibodies suggest that autoreactive B cells in lupus require autoantigen-specific cognate and contact-dependent ab T-cell help [reviewed in (153)], given the requirement of ab T cells for immunoglobulin somatic hypermutation and isotype switching in secondary lymphoid organs. Indeed, evidence supports the notion that autoantibody production in murine lupus is T cell dependent, originally coming from the demonstration that neonatal thymectomy of lupus-prone mice led to abrogation of IgG anti-dsDNA synthesis and glomerulonephritis and to improved mortality (154). Similar results were obtained after treatment of these animals with antibodies that depleted Thy-1-positive cells (155) or $CD4^+$ cells (156). Genetic studies have provided further evidence for the T-cell dependence of disease in murine lupus. Lupus-prone MRL/Fas^{lpr} mice with genetic disruption of $I\text{-}A^b$ lack $CD4^+$ T cells and have decreased penetrance of autoantibodies and glomerulonephritis (157). Similarly, autoantibodies were diminished in MRL/Fas^{lpr} and NZB mice with genetic disruption of CD4 ($CD4^+$ T-cell knockouts) (158) and in lupus-prone mice congenitally deficient in ab T cells. Either $TCRa^{-/-}$ or TCRb ($^{-/-}$ (159,160) Fas-deficient MRL/Fas^{lpr} and Fas-intact MRL/+ $^{Fas-lpr}$ mice have marked reduction in autoantibody production and end-organ disease with enhanced survival compared with abT-cell-intact controls (161).

Data from murine models of lupus support the hypothesis that $CD4^+$ T cells provide help to autoreactive B cells in the production of pathogenic autoantibodies. T cells have been isolated from (NZB x NZW)F_1 and from SNF1 [(SWR x NZB)F] lupus-prone mice that help anti-DNA production *in vitro* and accelerated disease when transferred to prenephritic mice *in vivo* (162,163,164 and 165). Such T cells are activated by peptides of DNA-binding histones from nucleosomes (163,164,166) or by peptides from anti-DNA Ig (165), consistent with the idea that they support anti-DNA autoantibody synthesis.

$CD4^+$ ab T cells derived from lupus nephritis patients have been shown to promote pathogenic anti-DNA production *in vitro* (167). These cells also proliferate when mixed with self-B cells in a class II MHC-restricted and CD154-CD40–dependent fashion (168,169,170,171 and 172). These results indicate that anti-DNA help in human lupus also is largely cognate and contact dependent. Moreover, CD4+ T cells from patients with lupus respond to peptides of chromatin proteins (167,172,179), supporting the hypothesis that they help anti-DNA B cells. The epitopes on chromatin recognized by $CD4^+$ T cells in human lupus are similar to those epitopes recognized by $CD4^+$ T cells in murine lupus that are pathogenic on adoptive transfer and that provide help to autoreactive B cells *in vitro* (167). In addition, these T-cell epitopes are physically close to the epitopes recognized by antichromatin antibodies. Therefore, autoreactive B cells may directly activate pathogenic T cells through recognition of a similar antigenic epitope, as depicted in Fig. 39.10 [reviewed in (173)]. These data suggest that the histone-DNA complex within the nucleus drives the pathogenic response against dsDNA in both human and murine lupus. In addition, diversification of the humoral response against chromatin occurs in a sequential and stereotypic pattern. Antibodies are initially directed against the H2A–H2B subunit of the nucleosome and then, through the process of epitope spreading, develop against the H3A–H3B subunit (174).

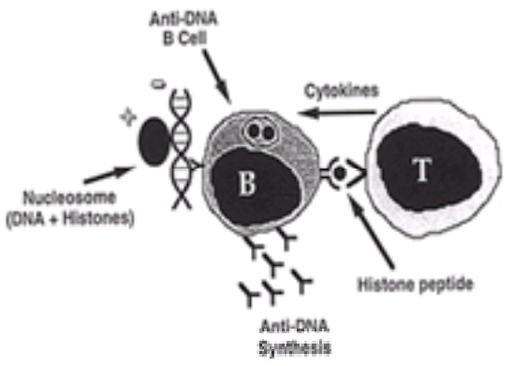

Figure 39.10. Generation of anti-dsDNA antibodies in lupus through help provided by histone-specific CD4+ T cells. In this model, surface immunoglobulin on an anti-DNA B cell can bind DNA as a component of a nucleosome, followed by internalization of the particle. Processing of histone components of the nucleosome results in presentation of histone peptides by major histocompatibility complex (MHC) class II molecules to activated, histone-specific CD4+ T cells. Cognate T-cell/B-cell help, in the setting of cytokines and costimulatory molecules (not shown), then results in the proliferation and differentiation of B cells with production of anti-dsDNA antibodies. Such T cells also could drive other clonally specific B cells capable of binding nucleosomal components to autoantibody synthesis, including those directed against chromatin, histones, or other nucleosomal components, such as high mobility group (HMG) proteins. (Adapted from Craft J, Fatenejad S. Self antigens and epitope spreading in systemic autoimmunity. *Arthritis Rheum* 1997;40:1374–1382, with permission.)

ab T-CELL HELP IN LUPUS IS AUTOANTIGEN SPECIFIC AND MHC RESTRICTED, AND MEDIATED BY CD154 (CD40 LIGAND)-CD40 INTERACTIONS

As in a normal immune response, ab T cell help in lupus is an MHC-restricted interaction between an ab T cell and B cell recognizing epitopes derived from the same antigen. This interaction is dependent on binding of CD40L (CD154) on the activated T cells to CD40 on the B-cell surface. Evidence for MHC restriction is provided by reconstitution studies of lethally irradiated lupus-prone mice in which autoantibody production depends on MHC class II matching between the donor and the recipient (175). The requirement for contact-dependent T-cell and B-cell interactions in murine lupus is further supported by the observation that disruption of ligand pairs necessary for mutual T-cell and B-cell co-stimulation results in diminished autoantibody synthesis and end-organ disease. Interruption of either CD154-CD40 or the CD28-B7.1/B7.2 ligand pair interactions in lupus-prone (NZB x NZW)F_1 and SNF_1 mice by antibodies or fusion protein (CTLA-4Ig) results in diminished autoantibody synthesis and end-organ disease (84,85,86 and 87,176). Similarly, mice with a disrupted CD154 locus on the lupus-prone MRL/Fas^{lpr} and MRL/+$^{Fas\_\ lpr}$ backgrounds have significant reductions in autoantibody levels and nephritis (177,178). Finally, soluble CD154, cleaved from the cell membrane by matrix metalloproteinases, may serve as an additional pathway to activation of both cognate and noncognate APCs (179,180). Soluble CD154 levels are elevated in lupus patients, particularly in those with active disease (182,183).

The acceleration of autoantibody production and clinical nephritis after transfer of autoantigen-specific T cells into pre-nephritic SNF or (NZB x NZW)F_1 mice indicated that these T cells are capable of promoting the lupus phenotype (163,164 and 165). To determine whether autoantigen-specific T cells are required for full disease penetrance, potentially autoreactive T cells in lupus-prone MRL/Fas^{lpr} mice were replaced with the AND TCR Va and Vb transgenes that recognize PCC in the context of $H\text{-}2^k$ (181,182). Despite transgenic T-cell activation, $TCR^{-/-}{}_a$ and TCR $b^{-/-}$ MRL/Fas^{lpr} mice lacked pathogenic autoantibody production, with absent renal, skin, and salivary gland disease (the latter two organs also are compromised in wild-type MRL mice). This study emphasized, once again, that the specificity of the responding T cell is critical for full penetrance of autoantibody production and disease in human and murine lupus.

Origin of Autoreactive T and B Cells in Lupus

The preceding studies provide a simple, concise model for lupus in which pathogenic autoantibody production by B cells requires cognate interaction between ab T cells and autoreactive B cells. The ontogeny of such cells in murine lupus has been addressed in studies of central tolerance, the process by which autoreactive T cells are deleted in the thymus. This work demonstrated that in lupus-prone animals, superantigen-induced deletion is intact (183,184 and 185) and that central deletion is comparable between Fas-deficient MRL/Fas^{lpr} and Fas-intact MRL/+ ^{Faslpr} congenic mice (186,187 and 188). A more recent study analyzed thymic deletion after administration of a conventional peptide antigen in MRL mice in comparison to a nonautoimmune strain, B10.BR, utilizing AND TCR transgenic mice (189) that recognize a pigeon cytochrome C (PCC) peptide (88,89,90,91,92,93,94,95,96,97,98,99,100,101,102,103 and 104) in the context of $H\text{-}2^k$. Identical reduction in the number of double-positive (DP) thymocytes, downregulation of the transgenic TCR, and an increase in the number of apoptotic thymocytes were observed in both the autoimmune and nonautoimmune strains (189). These experiments.suggest that negative selection to agonist antigens is intact in lupus and leads to the question of whether the initiation or regulation of T-cell activation (i.e., peripheral tolerance) is abnormal in lupus.

INTRINSIC ABNORMALITIES OF T-CELL ACTIVATION IN LUPUS

ab T cells are necessary for full penetrance of autoantibody production and disease in human and murine lupus; at present, it appears that activation of such cells in lupus is a consequence of peripheral tolerance abrogation. The events that lead to this are at present unknown. Accumulating evidence suggests that lupus T cells have intrinsic (genetic) defects that render them more susceptible to activation through their TCR–CD3 complex after contact with self-peptides. This hypothesis stems

from several observations. First, T cells from humans with SLE appear to have abnormalities in TCR signaling (190,191 and 192) and apoptosis (193,194) as well as in expression of effector molecules, including CD40 ligand (CD154) (168,171,179,180). Second, lupus-prone mice have increased numbers of activated T cells *in vivo* (195,196 and 197). Third, a recently identified genetic locus on chromosome 7 from lupus-prone New Zealand mice (NZM; New Zealand mixed) contributes to a heightened threshold of T-cell activation and a lower threshold for apoptotic death (40,198). Interpretation of studies of T cells isolated from humans and mice with lupus is complicated by the heterogeneity of such cells (for example, in the state of activation and consequences of repetitive stimulation *in vivo*). Moreover, these studies and the genetic studies of lupus mice have not shown conclusively that the identified defects are intrinsic to mature T cells rather than extrinsic (for example, in antigen presentation). Indeed, APCs, such as macrophages (199,200 and 201) and B cells (202,203), from lupus-prone mice are genetically abnormal compared with nonautoimmune controls, and such abnormalities could account for the previously identified T-cell defects. Indeed, the locus from chromosome 7 in the NZM background that contributes to enhanced T-cell activation (198) overlaps with the same locus from the Fas-deficient MRL background (MRL/Fas^{lpr}) that contributes to anti-DNA antibody production and lymphoaccumulation (204) and to renal disease (205). The latter locus is not yet known to be associated with other defects, such as in T-cell activation.

Understanding of the role of ab T cells in the etiology of lupus has been complicated by a paradox: Lupus is a disease apparently characterized by systemic T-cell activation; however, T cells isolated from lupus patients and mice have been reported to be hypoproliferative (206,207,208,209 and 210). Typically, demonstration of hypoproliferation has rested on studies in which T-cell proliferation to a nominal antigen was measured. In these studies, T cells isolated from lupus patients were hypoproliferative compared with those from healthy controls or from those with other rheumatic diseases. These conclusions are confounded, however, by the facts that (a) antigen-specific responses cannot be measured accurately without enumeration of antigen-specific T cells and equalization between groups; and (b) the proliferative response to mitogens is affected by the activation history of the T cell. It is most meaningful to compare the behavior of naive cells to naive cells and activated cells to their counterparts; however isolation of these cell populations has proved difficult. It may also be that the generalized activation of T- and B-lymphocytes seen in lupus leads to clonal expansion of self-reactive lymphocytes, skewing the lymphocyte repertoire toward a self-response and making responses to nominal antigens more difficult to detect. In any case, it will be difficult to separate the contributions of T cells and B cells to the disease process because clonal expansion of autoreactive T cells in lupus is dependent on B cells (148) and extensive T-cell and B-cell collaboration, mediated by CD154–CD40 interactions (176,178). This collaboration is enhanced by upregulated levels of CD40L on lupus T cells (168,171) and may explain the presence of chromatin- and ribonucleoprotein-specific ab T cells in the peripheral blood of human lupus patients (167,172,211,212 and 213).

The mechanism(s) underlying abnormal T-cell activation in lupus is unknown. Biochemical defects potentially affecting T-cell signaling have begun to be identified in lupus T cells, although the consequences of these abnormalities on T-cell function remain poorly understood. T cells isolated from the peripheral blood of patients with lupus show decreased activity of protein kinase A (PKA), a cyclic adenosine monophosphate (cAMP)-dependent serine/threonine kinase (214,215). Decreased PKA activity in lupus patients is due to inefficient binding of cAMP to PKA, leading to deficient phosphorylation of membrane associated proteins (214,215), among other effects. How this abnormality in such a ubiquitous and integral enzyme, which is present in most patients with lupus (216), might contribute to the development of generalized T-cell activation and systemic autoimmunity remains unknown. TCR-mediated signal transduction also has been found to be abnormal in lupus. T cells isolated from the peripheral blood of lupus patients have a greater flux of calcium from intracellular stores after TCR stimulation but, paradoxically, show deficient phosphorylation of the z chain of the CD3 complex (217). Finally, T cells from lupus patients have been reported to be deficient in the activation of the transcription factor NF-kB (218). These findings of diminished phosphorylation of the z chain of the CD3 complex and decreased induction of NFkB are surprising in light of the increasing evidence that lupus T cells are hyperresponsive to stimulation through the TCR (198).

Intrinsic Abnormalities of B-cell Activation in Lupus

Although the nature and extent of intrinsic T-cell abnormalities in lupus remain poorly defined, the case for intrinsic B-cell abnormalities is much clearer. Experimental evidence from murine and human lupus has consistently and strongly suggested that there is an intrinsic abnormality in lupus B cells that leads to dysregulated production of autoantibodies. This conclusion is supported by the demonstration that pre-B cells isolated from the fetal liver of lupus-prone (NZB x NZW) F_1 mice (NZB/W) transferred into severe combined immunodeficient (SCID) mice will lead to IgM and IgG hyperglobulinemia, production of ANAs, and, in some mice, lupuslike deposition of IgG in the kidney with significant proteinuria (219). The transfer of pre-B cells from nonautoimmune mice did not lead to these characteristic signs of autoimmunity. *In vitro* studies demonstrated that B cells in the peripheral lymphoid organs of NZB/W mice spontaneously secrete significantly more IgM from birth than control B cells (220). B cells from lupus-prone mice are also more sensitive to stimulation from T cells (221). These data are consistent with studies of human lupus that have demonstrated that B cells are hyperproliferative and produce more antibody spontaneously, including autoantibodies (222).

The molecular mechanisms responsible for this hypereffector phenotype of lupus B cells remain largely unknown. Abnormal cytokine production and expression of effector molecules on the cell surface have been investigated in both human and murine lupus. B cells and monocytes from lupus patients produce more IL-10 and are more sensitive to IL-10 stimulation (223). Further, B cells from lupus patients with active disease abnormally express CD40 ligand compared with those isolated from patients in remission or from healthy controls (168). Expression of CD40L could be induced on B cells from lupus patients in remission but not on control B cells, supporting the idea of an intrinsic difference in lupus B-cell phenotype. Taken together, these findings demonstrate that, in lupus, opportunities for T-cell and B-cell interactions exist that do not exist in unaffected persons. It seems likely that aberrant production of cytokines (such as IL-10) and expression of surface effector molecules (such as CD40L) set up a self-perpetuating cycle of lymphocyte activation that ultimately enhances disease progression.

Evidence suggests that signal transduction in B cells is abnormal in lupus. Abnormalities in both positive and negative regulation of B-cell receptor (BCR) signaling have been described. Human lupus B cells also differ in their biochemical imprint after BCR stimulation, having greater protein tyrosine phosphorylation and free calcium release than control B cells after BCR stimulation (224). The reason for this important difference is unknown. CD22 is a B-cell-specific transmembrane glycoprotein that is phosphorylated after BCR signaling and assists in the recruitment of SHP-1 phosphatase into the BCR signaling complex. It therefore serves as an important downregulator of B-cell activation (225). B cells from mice deficient in CD22 (through targeted gene knockout) are also hyperresponsive after BCR stimulation and develop high titers of IgG anti-dsDNA antibodies (225,226). The role of CD22 and other BCR-associated proteins, such as CD21, in regulating B-cell activity in lupus is unknown and is an important area for investigation.

The role of B cells as APCs also appears important to the development of lupus. MRL/Fas^{lpr} mice genetically deficient in B cells had a significantly reduced number of activated and memory T cells with a shift toward a naive phenotype compared with B-cell-intact animals (126). As a consequence, T-cell infiltration of the skin and kidney was markedly reduced. In summary, lupus B cells are intrinsically abnormal in terms of BCR signaling, with enhanced production of, and sensitivity to, cytokines trophic to B cells as well as aberrant expression of effector molecules. These abnormalities result in dysregulation of antibody production and may also lead to inappropriate activation of T cells and abnormal T-cell and B-cell collaboration.

Complement System and Fc Receptors

The complement system has a complex and paradoxical role in the pathogenesis of lupus. Activation of the classical complement pathway with local deposition of C3 is seen in the kidneys of lupus patients with proliferative glomerulonephritis. Deficiencies in the early components of the classical pathway, particularly C1q, however, are well known to predispose to lupus (227,228). This genetic correlation is particularly strong: Nearly 90% of patients completely deficient in C1q, C1r/C1s, or C4 develop SLE independent of race and ethnicity (228,229). Although still striking, the relation of C2 deficiency to disease is weaker because only approximately one third of patients with complete C2 deficiency develop lupus. This is likely due to the fact that C2 can be bypassed in the early activation of the complement system (228). Thus, complete absence of the early complement components, particularly C1q and C4, is sufficient to cause the development of autoimmunity independent of other genetic influences. Such individuals account for approximately 1% of all individuals with lupus (228). What is the link between early complement deficiency and the development of autoimmunity?

In lupus patients, particularly those with nephritis, phagocytic cells fail to clear immune complexes effectively from the peripheral lymphoid organs (230,231,232 and 233). Patients with active disease have the most pronounced impairment (232). Given the importance of immune complex deposition in the pathogenesis of nephritis and the role of C1q in binding immune complexes and facilitating their removal from the circulation, it is logical to hypothesize that patients with absent C1q will have impaired clearance of immune complexes. C1q may also bind the surface of apoptotic cells *in vitro* independent of the presence of antibody (234). Taken together, these data suggest that normal functioning of the complement system, through C1q, is necessary to remove immune complexes and apoptotic cells either with or without antibody binding. This hypothesis has not been directly tested in humans. An autoimmune syndrome characterized by the development of immune complex glomerulonephritis but with incomplete penetrance was seen in mice deficient in C1q (22). An increase in the number of apoptotic cells in the glomerulus was observed, suggesting that immune complexes of apoptotic cells with autoantibodies were being deposited in the kidney. The autoantibodies seen in these animals were directed against chromatin, the most common specificity seen in lupus. Development of autoimmunity depended on the strain studied. Glomerulonephritis was seen in 25% of the F intercross between 129 and C57BL/6 mice but not in the 129 parents. Therefore, one must be cautious in extrapolating these findings to the pathogenesis of human lupus. Given the low frequency of homozygous complement deficiency in the cohort of lupus patients, other mechanisms must account for tissue injury besides an impairment of clearance of immune complexes containing apoptotic cells.

Similarly, defects in the mechanisms for the removal or degradation of cellular debris may predispose to systemic autoimmunity. Self-antigens such as chromatin are present within the debris of apoptotic cells. An increase in the concentration of self-antigens above a certain immunologic threshold presumably breaks immunologic tolerance to these antigens. Mice engineered to be deficient in DNAse 1, the major nuclease present in the serum, develop antichromatin antibodies and immune complex–mediated glomerulonephritis (235). Lower levels of DNAse 1 were also seen in a small group of SLE patients, but how common this finding is in lupus and

whether it is primary or secondary to the disease process are unknown.

Other defects in the handling of circulating immune complexes have been described in lupus. In healthy individuals, circulating immune complexes containing complement fragment C3b bind to erythrocytes via complement receptor 1 (CR1). Red cells bearing immune complexes containing complement are then stripped of immune complexes in the spleen by phagocytic cells bearing receptors for the Fc portion of immunoglobulin. Red cells in lupus patients express lower levels of CR1 (236,237 and 238), but this is an acquired defect and not an inherited deficiency (239,240). Thus, it appears that this decrease in the ability of red cells in lupus to transport immune complexes to the spleen is not a primary event in the pathogenesis of the disease. Instead, it appears that abnormalities in expression of the Fc receptor for IgG2a may be more important as causative factors. In humans, two alleles with differing affinity for IgG2a confer either high or low affinity for the isotype. In one study, African-American lupus patients, particularly those with nephritis, appeared more likely to express only the low-affinity receptor (23), although another study reported no such association (26). In addition, a polymorphism in FcRIIIa (CD16) resulting in low binding of IgG has been associated with lupus, particularly nephritis (27). The significance of Fc receptors in the pathogenesis of lupus is illustrated in animals deficient in the ability to bind immune complexes through a targeted deletion in the common gamma chain of Fc receptors (117). Lupus-prone (NZB x NZW)F_1 mice with such a deletion were protected from the development of severe glomerulonephritis, despite the deposition of immune complexes in the kidney and the local activation of complement (117).

Vascular Injury in Lupus

The role of endothelium in the initiation and propagation of tissue injury in lupus is an increasingly important area of research (241). Endothelial cells are important mediators of inflammation and have been shown to regulate the migration of inflammatory cells into tissue via expression of adhesion molecules. They also can produce proinflammatory molecules such as nitrous oxide (NO) and the cytokines IL-6 and IL-8. Vascular endothelium is activated in lupus, as demonstrated by the increased expression of ICAM-1, VCAM-1, and E-selectin in clinically uninvolved skin in lupus patients (72). This suggests that the upregulation of adhesion molecules is an “upstream” event in lupus and occurs before the development of overt pathology. The stimuli triggering endothelial activation in lupus are largely unknown. The ligation of C1q receptors on endothelial cells leads to the upregulation of adhesion molecules *in vitro,* and immune complexes are an important ligand of C1q *in vivo*. Thus, the accumulation of immune complexes in patients with lupus nephritis could result in increased binding of C1q to endothelial cells, resulting in endothelial cell activation (242). Endothelial cells also express CD40 and are subsequently activated through interaction with CD40 ligand (CD154) (243). This raises the intriguing question of whether the aberrantly high and prolonged expression of CD40L on the surface of T and B cells in lupus (168,171,244) or elevated soluble levels in lupus (179,180) contribute to endothelial activation. The contribution of activated platelets expressing CD40L to endothelial activation via CD40L–CD40 interaction in lupus is also unknown (245). Of relevance here is the recent description of thromboembolic complications in monkeys treated with anti-CD40 ligand antibodies in an attempt to block the rejection of renal allografts (246).

Activation of vascular endothelium may be due in part to increased production of NO in lupus. Elevated production of NO has been found in both patients with active lupus (247) and lupus-prone MRL/*Fas*^{lpr} mice (248). In persons with lupus, NO levels correlate with disease activity (247). The importance of the production of NO in the pathogenesis of murine lupus was demonstrated in MRL *lpr* mice deficient in the inducible form of NO synthetase (iNOS). These mice have markedly diminished vascular disease but unchanged glomerulonephritis (249). Significant sources of NO production in lupus patients are the vascular endothelium and also keratinocytes (72), where it is produced even in clinically uninvolved skin. The clinical sequelae of vascular disease in lupus extend beyond inflammatory lesions in the skin and kidneys. Even as the prognosis for patients with lupus has improved, morbidity and mortality rates from cardiovascular disease and stroke have increased (250). The cause of the accelerated atherosclerosis remains unknown but may involve the perturbations of the vascular endothelium discussed herein.

GENETICS OF LUPUS

That SLE is a disease with a substantial genetic component is well documented by studies of monozygotic twins with lupus, with a concordance rate of 25% to 50% (16). Some of the most exciting and dramatic developments in understanding the pathogenesis of SLE have come from studies aimed at unraveling the genetics of murine lupus. Concurrent progress in understanding the genetics of human lupus has been made as well.

Advances in understanding the genetics of murine lupus come from studies of the (NZB x NZW)F_1 and New Zealand mixed (NZM) models of lupus, and, to a lesser degree, from the MRL model. The advantages of studying genetics in murine models are that (a) causal relationships between proposed susceptibility loci and disease can be identified through the introduction of candidate loci in nonautoimmune hosts (generation of congenic mice); (b) the relationships between susceptibility loci can be assessed through the use of mice congenic for multiple such loci; and (c) disease-related genes identified in lupus-prone mice can suggest mechanisms of disease and pathogenesis and can be used to screen for similar disease-associated genes in humans. Lessons from murine studies will be discussed first, followed by a review of human studies.

Disease-associated loci on chromosomes 1, 4, and 7 in both (NZB x NZW)F mice (including the NZM strain) and MRL mice have been identified by analysis of F_1 progeny backcrossed to parental strains [reviewed in (251)]. In addition, there is a weaker association with the MHC locus on chromosome 17. Using differences in short tandem repeats of DNA flanking loci of interest, mice can be bred to express selectively these loci on the host's normal genetic background (congenic mice). These studies revealed that a locus on chromosome 1 (Sle1), about 100 cM long, is sufficient to abrogate B-cell tolerance when bred into otherwise normal C57BL/6 mice (252). These mice develop ANAs directed against chromatin, specifically against the H2A/H2B component of the nucleosome. This is analogous to the process by which antibodies specific for each part of the nucleosomal complex arise sequentially in human patients. T-cell tolerance to chromatin is also lost in these animals, suggesting that expression of this locus leads to the presentation of chromatin in an immunogenic manner. Despite these gross defects in B-cell and T-cell functions, lymphocyte responses to mitogenic stimuli are normal and Sle 1 congenic mice do not develop immune complex–mediated glomerulonephritis.

A locus on chromosome 4 (Sle2) confers an intrinsic B-cell defect (204). B cells from mice congenic for this locus are hyperresponsive to stimulation through the BCR or with soluble CD40L, duplicating the phenotype of B cells in both lupus patients and in autoimmune mice. They secrete more IgM when immunized with nominal antigens but do not develop an elevated IgG response. These mice have no defects in T-cell function, nor do they develop autoimmune pathology. This strongly suggests that a T-cell defect is necessary to turn B-cell hyperresponsiveness into overt autoimmunity.

A locus on chromosome 7 (Sle3) confers an intrinsic T-cell abnormality (198). In these animals, T-cell tolerance to chromatin is broken such that T-cell reactivity against all nucleosomal components can be demonstrated. CD4+ T cells are hyperresponsive to stimulation with anti-CD3 and show a decrease in activation-induced cell death. Perhaps as a consequence of promiscuous T-cell activation and help, these mice develop low-titer ANAs but usually do not develop overt autoimmune disease. Bicongenic nonautoimmune mice bearing both susceptibility loci from chromosome 1 and chromosome 7 develop expanded pools of activated B and T cells, high-titer anti-dsDNA antibodies, and highly penetrant, lethal glomerulonephritis in female patients (40). This suggests synergistic interaction between the genes conferring intrinsic abnormalities in B- and T-cell function, leading to fulminant autoimmune disease.

Two linkage studies in Fas-deficient MRL-*Fas*^{lpr} mice also identified a centromeric region of chromosome 7 associated with disease: an (MRL/*Fas*^{lpr} x *Mus. castaneous*) x MRL/Fas^{lpr} backcross 1 analysis-linked *Lrdm2* on chromosome 7 to renal disease (205) and a more recent (MRL/*Fas*^{lpr} x C57BL/6-Fas^{lpr})F_1 cross-found linkage between *Lmb3* (from the MRL background) and lymphadenopathy and splenomegaly, with a weaker association with anti-DNA autoantibody production (254). *Lrdm2* and *Lmb3* overlap with the lupus susceptibility locus *Lbw5*, mapped using an (NZB x NZW)F_1 cross (255), and with Sle3, the susceptibility locus from the NZM background (198). Finding these overlapping susceptibility loci in different animal models of lupus suggests that a limited number of genes can interact to predispose to systemic autoimmunity.

ROLE OF APOPTOSIS IN THE INITIATION OF SYSTEMIC AUTOIMMUNITY

A rapidly growing body of work investigated the role of programmed cell death (apoptosis) in the initiation of systemic autoimmunity. The impetus of this work is the observation that nuclear and cytoplasmic (auto)antigens targeted by the adaptive immune system in lupus are generated on the surface of cells during apoptosis, exposing them to the immune system (42). The hypothesis that antigens generated during apoptosis initiate systemic autoimmunity is predicated on two ideas: (a) that tolerance to self-antigens may be broken because these antigens are generated at a high enough concentration to cross an “immunologic threshold” and (b) that self-antigens are altered during apoptosis to create new epitopes that the immune system has not seen before and therefore cannot have developed tolerance for these epitopes. Presumably, differences in the responsiveness of the adaptive immune system to these stiumli would lead to a differential adaptive immune response in individuals with lupus compared with healthy individuals (i.e., autoimmunity versus maintenance of peripheral tolerance).

Antigenic targets of lupus autoantibodies have been found on the surface of keratinocytes induced to undergo apoptosis by UVB irradiation. These include both cytoplasmic (e.g., the Ro protein, ribosomal antigens, and calreticulin) and nuclear antigens [other Ro proteins, La, snRNPs, Ku, DNA-dependent protein kinase and poly-ADP ribose polymerase (PARP)] (42). This finding is of particular interest because of the known role of UVB in initiating and exacerbating skin disease and systemic flares in those predisposed to develop lupus. In addition, many of these protein antigens appear to have been modified from their original structure by caspase-mediated cleavage, generating novel protein fragments that are now potentially immunogenic (256,257 and 258). Not all antigenic targets in lupus are cleaved during apoptosis, however.

Apoptosis is distinguished from necrosis by its ability to induce cell death without causing inflammation. This blockage of inflammation depends on the rapid clearance of apoptotic cells by phagocytic cells before the debris of apoptotic cells is recognized by circulating leukocytes. Defects in macrophage clearance of apoptotic cells *in vitro* have been reported in lupus patients (259), suggesting that the concentration of potential autoantigens may be higher in lupus. This defect alone, however, should not induce autoimmunity because B and T cells should be tolerant to autoantigens, even if they are presented more frequently. Thus, we must ask whether there are additional defects in the process of antigen processing and presentation that contribute to the abrogation of tolerance. Growing evidence supports the notion that dendritic cells capable of phagocytosing apoptotic cells can tolerize peripheral T cells (260,261). It will remain to be seen whether this pathway is fully functional in persons who have lupus.

Acknowledgment. *We thank Elizabeth Ramsburg for careful review of the manuscript. This work was in part supported by grants AR40072 and AR44076 from the National Institutes of Health, by the S.L.E. Foundation Inc., and by the Arthritis Foundation and the Lupus Foundation of America and their Connecticut chapters (J. Craft). G. Vratsanos was supported by a Physician Scientist Development Award from the American College of Rheumatology and the Arthritis Foundation.*

40 SJÖGREN'S SYNDROME

Roland Jonsson, D.M.D., Ph.D., and Karl A. Brokstad, Ph.D.

HISTORICAL FEATURES

Sjögren's syndrome is named after the Swedish ophthalmologist Henrik Sjögren (1). However, the disease was addressed during the 19th century in a number of case reports, between the years of 1882 and 1924, describing various combinations of dry mouth, dry eyes, and chronic arthritis (reviewed in 2). Mikulicz (3) reported in 1892 a man with bilateral parotid and lacrimal gland enlargement associated with massive round cell infiltration. Somewhat later Gourgerot (4), in 1925, described three patients with salivary and mucous gland atrophy and insufficiency. In 1927, Mulock Houwer (5) reported the association of filamentary keratitis, the major ocular manifestation of the syndrome, with chronic arthritis. Subsequently in 1933, Henrik Sjögren (1) reported in his classic doctoral dissertation detailed clinical and histologic findings in 19 women with xerostomia and keratoconjunctivitis sicca, of whom 13 diplayed chronic arthritis. Later on, Morgan and Castleman (6) in 1953 established that Sjögren's syndrome and Mikulicz's disease were the same entity. The link between Sjögren's syndrome and malignant lymphoma was described in a classic paper in 1964 (7). The distinction between primary and secondary Sjögren's syndrome was suggested in 1965 (8). From the diagnostic point of view, the first histologic grading assessing the infiltration of labial glands was described in 1968 (9). More recently, a set of preliminary classification criteria was identified by a European Concerted Action in 1993, and they have been widely accepted (10).

IMMUNOLOGIC HIGHLIGHTS

The salivary and lacrimal glands are the principal targets of a T-cell–mediated chronic inflammation, giving rise to deficient function and leading to dry eyes (keratoconjounctivitis sicca) and mouth (xerostomia). However, other exocrine glands including those of the pancreas, sweat glands, and mucus-secreting glands of the bowel, bronchial tree, and vagina also may be affected. The Sjögren's syndrome–associated (Ro/SSA) autoantibodies in the sera were described in 1969 (11) and were later found to be present also in secretions (12). A number of other autoantibodies have been described, but none has received significant clinical recognition (2). Gene interaction and complementation of the immune response was shown for human leukocyte antigen (HLA) and the RNA proteins Ro/SSA and La/SSB (13).

EPIDEMIOLOGY

General

Sjögren's syndrome is a worldwide disease and may occur at all ages. However, the peak incidence is in the fourth and fifth decades of life, with a female-to-male ratio of 9:1. A number of studies have shown a great variation in the frequency of Sjögren's syndrome (reviewed in 2). The prevalence studies demonstrate that sicca symptoms and primary Sjögren's syndrome affect a considerable portion of the population; precise numbers are dependent on the age group studied and on the criteria used (14). Subjects identified as having primary Sjögren's syndrome in population studies often have mild to moderate complaints, and many of them have been found not to be aware of the disease. A cautious but realistic estimate from the studies presented so far is that primary Sjögren's syndrome is a disease with a prevalence not exceeding 0.6% of the general population (six per 1,000).

For the diagnosis of Sjögren's syndrome, the most practical criterion to use is the recently modified European criteria, which include a list of exclusions (15). In addition to the subjective symptoms of dry eyes and dry mouth, the following objective items should be fulfilled: (a) ocular signs by Schirmer's I test and/or rose bengal score; (b) focal sialadenitis by histopathology; (c) salivary gland involvement by either salivary scintigraphy, parotid sialography, or unstimulated salivary flow; and (d) autoantibodies of Ro/SSA and/or La/SSB specificity.

Genetics

A prominent feature of Sjögren's syndrome is its genetic predisposition (reviewed in 16). Several families involving two or more cases of Sjögren's syndrome have been described (17), and a family history with relatives having other autoimmune diseases is common (30% to 35%) for Sjögren's syndrome patients.

The polymorphic major histocompatibility complex (MHC) genes are well-documented genetic risk factors for the development of autoimmune diseases overall (18). With regard to Sjögren's syndrome, the most relevant MHC complex genes are the class II genes, more specifically the HLA-DR and DQ alleles (19). Patients of different ethnic origin show different HLA gene associations (20). In whites of northern and western European background, including North American whites, Sjögren's syndrome is one of several autoimmune diseases associated with the haplotypes HLA-B8, DRw52, and DR3. An association with DR2 has been reported in Scandinavians (21) and DR5 in Greeks (22). All of the haplotypes are in strong linkage disequilibrium, causing difficulties in establishing which of the genes contains the locus conferring the risk.

HLA class II allele association has been reported to differ among anti-Ro/SSA positive subjects according to the presence or absence of coexisting anti-La/SSB (23). Distinct HLA haplotypes have been associated with a certain degree of autoantibody diversification in Sjögren's syndrome patients (24). Of particular importance is that a stronger correlation has been found between anti-Ro/SSA autoantibodies and DR3/DR2 than that with the disease itself (25,26). Autoantibodies to Ro/SSA and La/SSB have been found to be associated with DR3 and DQA alleles (27). Sjögren's syndrome patients with DQ1/DQ2 alleles have a much more severe autoimmune disease than do patients with any other allelic combination at HLA-DQ (13). Recently the DR3-DQ2 haplotype has been indicated as a possible marker for a more active immune response in Finnish Sjögren's patients (28).

Environment

Among the possible etiologic and triggering factors involved in Sjögren's syndrome, the discussion about a relationship between viral infections causing development of autoimmune reactions began some decades ago. The putative role of different viruses in Sjögren's syndrome can be viewed in the light that salivary glands are a site of latent viral infections. Potential viral triggers include a number of viruses including Epstein-Barr virus (EBV), widely studied in relation to Sjögren's syndrome (29). A higher prevalence of serum human herpesvirus-6 (HHV-6) specific antibodies also has been detected in patients with Sjögren's syndrome than in normal individuals (36% vs. 10%) (30). However, other studies could not confirm this finding (31,32). Difficulties in analyzing the possible role of viral infection in relation to development of Sjögren's syndrome is hampered by the high prevalence of both herpesviruses (EBV and HHV-6) in the healthy population.

Retroviruses are known to infect cells of the immune system and cause abnormalities in immune regulation. High serum titers of anti–human T lymphotropic virus type I (HTLV-I) antibodies and a high prevalence of salivary immunoglobulin A (IgA) class anti–HTLV-I antibodies in patients with Sjögren's syndrome were reported endemically in Japan (33).

Hepatitis C virus (HCV) infection has in some populations been frequently (14%) detected in patients with primary Sjögren's syndrome (34). Analysis of the association between chronic lymphocytic sialadenitis and chronic HCV liver disease showed that histologic features of Sjögren's syndrome were significantly more common in HCV-infected patients (57%) compared with controls (5%) (35).

Lymphotropic viruses have the potential to trigger the autoimmune process. Some of the immunoreactive regions within the La/SS-B protein have been found to have sequence similarities with proteins of EBV, HHV-6, and human immunodeficiency virus (HIV)-I (36). It seems reasonable that these viruses can promote autoantibody (particularly anti-La/SS-B) production through molecular mimicry or exposure of La/SS-B homolog sequences on cellular surfaces after translocation of cryptic self-determinants.

CLINICAL PRESENTATION

Signs and Symptoms

Sjögren's syndrome has a wide variety of clinical features (reviewed in 2). Onset of the disease is insidious, and patients have difficulty in determining when the disease actually started. Keratoconjunctivitis sicca and xerostomia (so-called sicca complex) are the main clinical presentations in adults, whereas bilateral parotid swelling (Fig. 40.1) can be an obvious sign at juvenile disease onset. In more than half of the patients, an extraglandular manifestation may develop during the evolution of the disease. Occasionally systemic features may lead to diagnosis.

Figure 40.1. Bilateral parotid gland enlargement in Sjögren's syndrome.

The spectrum of the disease extends from an organ-specific autoimmune disorder to a range of systemic manifestations (musculoskeletal, pulmonary, gastric, hematologic, dermatologic, renal, and nervous system involvement). Sjögren's syndrome may develop alone (primary) or in association with almost any of the autoimmune rheumatic diseases (secondary), the most frequent being rheumatoid arthritis and systemic lupus erythematosus.

Arthritis, Raynaud phenomenon, and purpuric vasculitis on the lower extremities are the most common extraglandular manifestations of primary Sjögren's syndrome. A high incidence of pulmonary involvement with functional abnormalities has been described, although they are usually subclinical and rarely progressive. A wide range of neurologic disorders has been reported, the peripheral nervous system being most frequently affected. Interstitial nephritis in a subclinical form and as a cause of renal tubular acidosis or nephritogenic diabetes insipidus occurs in about 30% of the patients.

Lymphomas, almost exclusively of B-cell lineage, are a characteristic but unusual feature of Sjögren's syndrome, occurring in about 5% of the patients (37). This complication of Sjögren's syndrome is found particularly in patients with high levels of immunoglobulins, autoantibodies, and cryoglobulins. When the lymphoma develops, the immunoglobulin levels often decrease, and the autoantibodies might disappear.

Concerning secondary Sjögren's syndrome, rheumatoid arthritis patients with sicca complex tend to have more severe disease, with frequent extraarticular manifestations including vasculitis, presenting as digital infarcts and/or cutaneous ulcers. In systemic lupus erythematosus, patients with concomitant Sjögren's syndrome have a lower frequency of glomerulonephritis and a relatively good prognosis. Primary biliary cirrhosis and scleroderma, although rare in general, are frequently complicated by Sjögren's syndrome. Other autoimmune diseases that have been described in association with Sjögren's syndrome include polymyositis, mixed connective tissue disease, chronic active hepatitis, and Hashimoto thyroiditis (38).

Laboratory Tests

The most commonly used tests for the detection of dry eyes are the Schirmer I and the rose bengal (alternatively Lissamine green dye) and subsequent scoring according to van Bijsterveld. Schirmer I is performed using standardized tear test strips. In the European classification criteria (10), Schirmer I test is positive when the wetting is less than 5 mm in 5 minutes. The scoring according to van Bijsterveld detects destroyed conjunctival epithelium induced by dryness.

Saliva-production tests are simple screening tests for salivary gland involvement in Sjögren's syndrome. Saliva, which is produced by the three major and numerous minor submucosal salivary glands, exhibits great flow variations among healthy individuals and in the same individual under diverse conditions (39,40). The test should therefore be standardized; the unstimulated whole saliva collection test is performed for 15 minutes, and the test is considered positive when 1.5 mL or less whole saliva is collected, being well below the normal mean range.

Other tests used to evaluate salivary gland involvement include parotid sialography and salivary gland scintigraphy. The sialography typically shows sialectasias in contrast to the fine arborization seen in normal parotid ductules. In the scintigraphic test, ^{99m}technetium-pertechnate is given intravenously, and in Sjögren's syndrome patients, the typical finding is decreased uptake in response to stimulation of the parotid and submandibular salivary glands. This test is a sensitive and valid method to measure abnormalities in salivary gland function in the hands of skilled personnel (41).

Anti-La/SSB antibodies were first defined by the immunodiffusion technique in association with anti-Ro60 precipitins (11). Recent studies have shown that up to 40% of anti-La–positive sera are negative on immunodiffusion and detectable only by immunoblot or enzyme-linked immunosorbent assay (ELISA). These are termed nonprecipitating anti-La antibodies (42,43). Anti-La is invariably accompanied by anti-Ro, reflecting the physical association of these molecules in Ro/La ribonucleoprotein particles (Fig. 40.2). In contrast, anti-Ro antibodies frequently occur in the absence of anti-La reactivity.

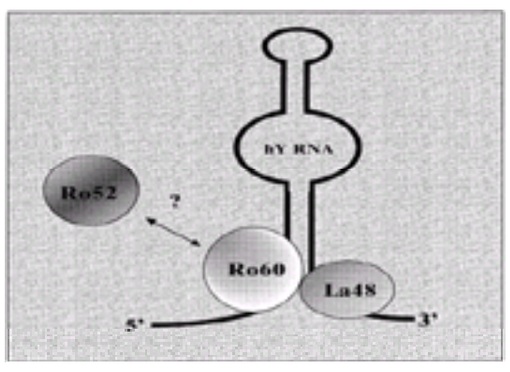

Figure 40.2. Structure of important autoantigens (Ro/SSA and La/SSB) in Sjögren's syndrome. hY RNA, human small cytoplasmic Y RNA.

The reported frequencies of anti-Ro and anti-La depend on the methods of detection and referral bias of the center performing the study. Overall, anti-Ro precipitins

occur in approximately 60% to 75% of primary Sjögren's syndrome and also are observed in cases of secondary Sjögren's syndrome, irrespective of the association with systemic lupus erythematosus, progressive systemic sclerosis, rheumatoid arthritis, or primary biliary cirrhosis (44). Anti-La antibodies were initially reported to occur in up to 40% of patients with primary Sjögren's syndrome. Even higher frequencies were reported when anti-La was analyzed by ELISA or immunoblotting (45). Further studies have shown that combined detection of anti-La and anti-Ro antibodies have a higher diagnostic specificity for primary Sjögren's syndrome than does anti-Ro alone (46).

Although the pathogenetic role of anti-Ro and anti-La in Sjögren's syndrome is not established, positive serology is associated with a high frequency of palpable purpura, leukopenia, lymphopenia, and hypergammaglobulinemia, and with more severe glandular disease (47,48 and 49). Recent studies also have found salivary enrichment of anti-Ro and anti-La in patients with Sjögren's syndrome, suggesting local autoantibody production in salivary glands (12,50) as well as presence of Ro52, Ro60, and La autoantibody-producing cells in salivary gland biopsy samples from patients with Sjögren's syndrome (51,52).

Pathology

The labial salivary gland biopsy has an important role in establishing the diagnosis of Sjögren's syndrome. It is performed preferentially according to the procedure described by Daniels (53,54). After local anesthesia, a 1.5- to 2-cm incision is made parallel to the vermilion border in the middle of the lower lip, between the midline and the corner of the mouth. At least five lobes of labial glands are then obtained by blunt dissection. After routine histologic fixation and preparation, the biopsy is evaluated according to a procedure in which an inflammatory focus is defined as an accumulation of at least 50 mononuclear leukocytes per 4 mm^2 (Fig. 40.3) (54). According to the European criteria (10), a biopsy is positive at focus score 1 or more per 4 mm^2, whereas the California criteria (55) define positive biopsy as more than one focus. Occasionally epimyoepithelial islands are seen in labial gland biopsies, but these are more common in the major glands. One differential diagnostic feature is the granulomatous inflammation as seen in connection with, for example, sarcoidosis.

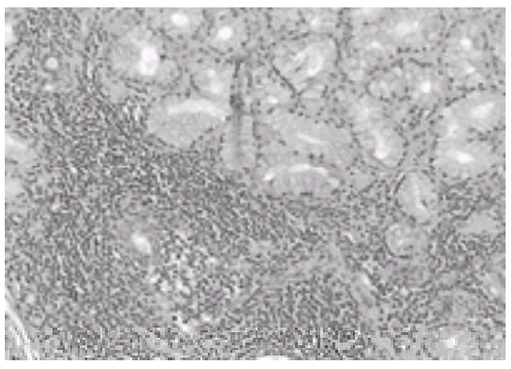

Figure 40.3. Focal sialadenitis in salivary gland with surrounding normal-appearing parenchyma in a patient with Sjögren's syndrome.

The specificity of a positive labial salivary gland biopsy is 86.2%, and the sensitivity is 82.4% in patients with primary Sjögren's syndrome diagnosed according to the European criteria (56). The focal infiltration of lymphoid cells in the salivary glands is a progressive process, as demonstrated by increase of focus score over time (57). The focus score is connected to the presence of keratoconjunctivitis sicca and autoantibodies (48,58), whereas the correlation with xerostomia is less evident (57).

Another pattern of inflammation in labial salivary gland biopsy is chronic sialadenitis, characterized by scattered mononuclear cell infiltration without focal aggregates and accompanied by degenerative changes (acinar atrophy, ductal hyperplasia, fibrosis, and/or fatty infiltration). This pattern is not considered to be typical for primary Sjögren's syndrome and often leads to glandular atrophy and xerostomia.

Treatment and Prognosis

At present, treatment for most patients is essentially symptomatic. The patient should be seen regularly by a rheumatologist as well as an ophthalmologist and dentist to prevent and treat the consequences of mucosal dryness, in addition to extraglandular manifestations and other associated complications.

Artificial tears often alleviate the patient's ocular complaints, and are of importance in preventing corneal damage and conjunctivitis (59). The use of topical steroids is not recommended because of a high risk of secondary bacterial and viral infections in the eye.

Another treatment option for dry eye is “punctal occlusion” by using a variety of “plugs” to occlude the punctal openings at the inner aspects of the eyelids (60). With this procedure, the instilled artificial tears will remain in the eye for a longer time.

The management of dry mouth aims to prevent and treat infections, gum disease, and dental caries. To reduce the risk of caries, it is necessary to keep good oral hygiene and use sugarless sweets and chewing gums to stimulate residual salivary flow. Artificial saliva products and special toothpaste may also be of benefit for certain patients, and fluoride supplementation is advocated. Eradication of oral candidiasis usually provides significant improvement of oral symptoms.

Oral pilocarpine has recently been shown to be a safe treatment and to provide significant subjective and objective benefits for patients with Sjögren's syndrome with symptoms associated with xerostomia (61). Another potential therapy includes systemic use of interferon-a (IFN-a), which may be of benefit for the symptoms associated with xerostomia (62,63). Cemiveline, a novel quinuclidine derivative of acetylcholine exhibiting high affinity for the muscarinic M_3 receptor, has long-lasting sialogogic action and few side effects (64).

Hydroxychloroquine may be useful as an immunomodulating agent reducing immune activation and lymphoproliferation and is sometimes used in patients with Sjögren's syndrome (65,66). Administration of systemic steroids also has been suggested to improve the signs and symptoms of Sjögren's syndrome, but they are mainly used for treatment of severe extraglandular complications such as pulmonary and renal involvement (67).

There are few studies on the natural course of primary Sjögren's syndrome, but it has been described as a step-wise, gradual progression from a disorder mainly in exocrine glands, to systemic extraglandular features, and finally to lymphoid neoplasia development (68). However, in general, primary Sjögren's syndrome is characterized by a stable and rather mild course of glandular and extraglandular manifestations, in contrast to the increased risk for development of malignant lymphoma (37).

Serology can be useful in predicting the subsequent outcome and complications in patients with primary Sjögren's syndrome. The presence of anti-Ro/SSA antibodies may identify patients with systemic disease (69), and in anti-Ro/SSA/anti-La/SSB–positive patients, the relative risk of developing non-Hodgkin lymphoma has been reported as high as 49.7 after 10 years' follow-up (70). The development of extraglandular manifestations seems to be influenced by a number of factors including the MHC HLA B8 and DR3 expression (71).

Spontaneous symptomatic improvement has been described in 12% of patients with primary Sjögren's syndrome, especially in elderly patients with some clinical overlap with systemic lupus erythematosus (69). In a recent study on survivorship in a population-based cohort followed up from 1976 to 1992, the authors did not demonstrate increased mortality of patients with primary Sjögren's syndrome (72).

IMMUNOPATHOLOGY

Humoral Responses

A large number of autoantibodies have been reported in both primary and secondary Sjögren's syndrome, reflecting both B-cell activation and a loss of immune tolerance in the B-cell compartment (Table 40.1) (73,74,75,76,77,78,79,80,81,82,83,84,85,86,87,88,89,90,91,92,93,94,95,96 and 97). Over the past few years, there has been significant progress in defining the fine specificity of these antibodies (Fig. 40.4) (98,99,100,101,102,103,104,105,106,107 and 108) and characterizing their target autoantigens. In some cases, the presence of these antibodies is related to the extent and severity of disease in Sjögren's syndrome.

Autoantibodies	Frequency in Primary Sjogren's Syndrome (%)	References
Non-organ-specific		
Anti-nuclear antibodies (ANA)	50–80	(73,76)
Anti-Ro/SSA	50–70	(2,73,74,75,76,77,78)
Anti-La/SSB	30–60	(2,73,74,76)
Anti-Sm	2	(74)

Anti-DNA	0	(74)
Rheumatoid factor	50–80	(2,73,79,80,81)
Anti-mitochondrial	13	(82)
Anti-neutrophil cytoplasmic	10–25	(83,84)
Anti–alfa-fodrin	55–95	(85,86)
Anti-muscarinic M3 receptor	100	(87,88,89,90,91)
Other antigens		(92,93,94)
Organ-specific		
Anti-smooth muscle	30	(74)
Anti-salivary duct	20–40	(74,95,96)
Anti-thyroid	10–50	(73,74)
Anti-gastric mucosa	5–30	(73,74)
Other tissues		(82,97)

TABLE 40.1. The Association of Autoantibodies and Sjögren's Syndrome

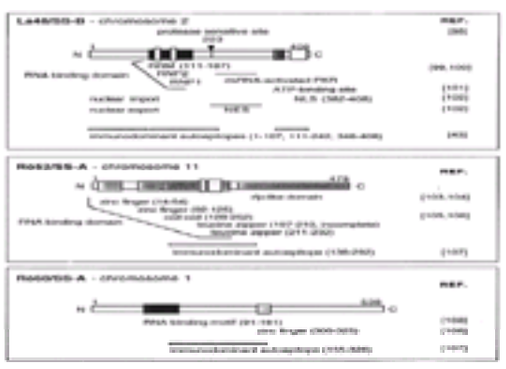

Figure 40.4. Structure, function, and immunobiology of La, Ro52, and Ro60.

The B cells make up roughly 20% of the infiltrating cell population in affected glands. The B cells produce immunoglobulins with autoantibody activity for IgG (rheumatoid factor), Ro/SSA, and La/SSB (52). A substantial number of the B cells are of $CD5^+$ phenotype (B-1 cells) (109). Production of IgG predominates in Sjögren's syndrome, whereas synthesis of IgA is more abundant in normal salivary glands.

Non–organ-specific autoantibodies anti-Ro/SSA and anti-La/SSB are the diagnostically most important and the best-characterized autoantibodies in primary Sjögren's syndrome (2). The majority of anti-Ro–positive sera also react with the denatured form of a 52-kd protein termed Ro52, which is structurally distinct from Ro60 and probably does not directly associate with the Ro ribonucleoprotein particle (Fig. 40.2) (77,78). However, the two Ro proteins colocalize to surface membrane blebs on apoptotic cells, where they may become targets of an autoimmune response (110). Human monoclonal antibodies reactive with continuous and conformation-dependent epitopes on Ro52 have recently been cloned from a patient with primary Sjögren's syndrome (111).

Anti-thyroid microsomal and anti-gastric parietal cell antibodies occur in about one third of patients with both primary and secondary Sjögren's syndrome, but other organ-specific antibodies are infrequent (38). Antibodies to salivary duct antigens were described more than 30 years ago, but they have remained poorly characterized, and their clinical significance is uncertain (95,96).

Several other autoantibodies have been reported to be frequently present in the sera of patients with primary Sjögren's syndrome, including antibodies directed against carbonic anhydrase (92,93), proteasomal subunits (94), and a-fodrin (85). These findings are intriguing but await independent confirmation in larger cohorts of Sjögren's syndrome patients. The finding of serum autoantibodies directed against the muscarinic M_3 receptor (expressed in salivary and lacrimal glands) in the majority of patients is an important advance in understanding the pathogenesis of impaired glandular function in Sjögren's syndrome (87,88). Recent studies in the nonobese diabetic (NOD) mouse have indicated that muscarinic receptor autoantibodies are directed against the agonist binding site of the molecule on the cell surface and interfere with secretory function of exocrine tissues in Sjögren's syndrome (89). Inhibitory effects of these autoantibodies on parasympathetic neurotransmission in Sjögren's syndrome has recently been experimentally shown (90). However, the clinical significance of these antibodies in Sjögren's syndrome remains to be elucidated (91).

Rheumatoid factor is detected in the serum and saliva of 60% to 80% of primary Sjögren's syndrome patients (79,80). There appears to be little role for somatic hypermutation in their generation in contrast to that of rheumatoid factor in rheumatoid arthritis (81). A significant number of patients with primary Sjögren's syndrome have mixed oligoclonal cryoglobulins, many of them having IgM rheumatoid factor activity (112). The latter frequently possess cross-reactive idiotypes, notably the 17.109 (V kappa III b related) and G-6 (VH1 related) idiotypes, which may serve as markers for lymphoma development in primary Sjögren's syndrome (113,114).

Oligoclonal or monoclonal B-cell expansion, arising mainly from salivary glands but also from visceral organs and lymph nodes, has been reported to occur in 14% to 100% of Sjögren's syndrome patients (115). In this respect, Sjögren's syndrome appears to be an intermediate between autoimmunity and malignancy, and it is suggested that patients with evidence of clonal expansions of B cells in their salivary glands are at high risk of developing malignant lymphoma (116,117 and 118). Various studies have reported that between 25% and 80% of salivary lymphoid infiltrates have morphologic and/or immunophenotypic evidence of low-grade lymphomas (119). However, there is no absolute correlation between clonality and the development of lymphoma. Although a high proportion of lymphoid cells may show evidence of immunoglobulin gene rearrangements, clonality does not necessarily predict progression to clinically overt lymphoma. The clinical benefit of immunogenotypic analysis in the clinical diagnosis of salivary gland lymphoma in Sjögren's syndrome remains to be defined (120,121). A recent study reported that a history of swollen salivary glands, lymphadenopathy, and leg ulcers predicted lymphoma development in patients with primary Sjögren's syndrome (122).

Cellular Responses

Immunohistologic analysis of lymphoid cell infiltration in exocrine glands in Sjögren's syndrome shows a predominance of T cells (Fig. 40.5A) with fewer B cells and macrophages (2) (Table 40.2). Adhesion molecules and activated lymphocyte function–associated antigen type 1 (LFA-1) promote homing and occasionally characteristic cell clustering similar to that of follicular structures of lymph nodes. Expression of the mucosal lymphocyte integrin $a^E b_7$ and its ligand E-cadherin suggest a mucosal origin of a subpopulation of the infiltrating cells (123). There is an increased expression of HLA-DR/DP/DQ molecules on acinar and ductal epithelial cells (Fig. 40.5B) (124), presumably due to local production of IFN-g by activated T cells. The majority of T cells in the lymphocytic infiltrates are $CD4^+$ T-helper cells with a CD4/CD8 ratio well over 2. Most of these T cells bear the memory phenotype $CD45RO^+$ and express the a/b T-cell receptor and LFA-1, and may contribute significantly to B-cell hyperactivity. There is indication of oligoclonal expansion of certain TCR V_b family–expressing lymphocytes (125). The peripheral blood in Sjögren's syndrome has yielded findings similar to those in salivary glands, although a difference in magnitude is occasionally evident (Table 40.3).

Infiltration of $CD3^+$ $CD4^+$ $CD45RO^+$ T cells
Mucosal lymphocyte integrin $a^E b_7^+$ cells
Activated B cells (IgG > IgM > IgA)
Production of autoantibodies and monoclonal immunoglobulins
Absence of natural killer cells
Increased expression of adhesion molecules (VCAM-1, LFA-1)
Cytokine production (IL-6, IL-10, TNF-α, IFN-γ)
Dysregulated lymphocytic apoptosis
Aberrant HLA-DR expression on glandular epithelial cells

Ig, immunoglobulin; VCAM, vascular cell adhesion molecule; LFA, leucocyte function–associated antigen; TNF, tumor necrosis factor; IFN, interferon; HLA, human leucocyte antigen.

TABLE 40.2. Immunologic Findings in Salivary Glands in Sjögren's Syndrome

Hypergammaglobuminemia
Autoantibodies (serum and actively secreting cells of ANA, RF, anti-Ro/SSA and anti-La/SSB)
Monoclonal immunoglobulins
Reduced T-cell function
Decreased natural killer cell function
Increased B-1 cells
Increased lymphocytic apoptosis

ANA, antinuclear antibody; RF, rheumatoid factor.

TABLE 40.3. Immunologic Findings in the Peripheral Blood in Sjögren's Syndrome

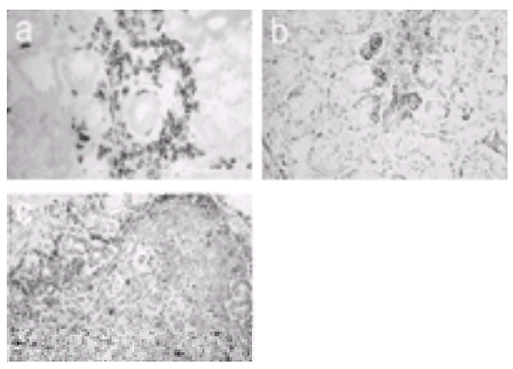

Figure 40.5. Immunohistologic features in minor salivary glands with focal sialadenitis from patients with Sjögren's syndrome disclose **(A)** a large proportion of CD3-positive T cells, **(B)** induced expression of human leukocyte antigen (HLA)-DR on glandular epithelium, and **(C)** few CD25-positive cells.

Immune-mediated Tissue Destruction

Highly upregulated expression of HLA molecules, and the more recently demonstrated B-7 costimulatory molecules (126), by salivary gland epithelium in Sjögren's syndrome (Fig. 40.5B) is a potentially effective local antigen-presenting mechanism whereby HLA antigens could be involved in exocrine glandular destruction mediated directly or indirectly by $CD4^+$ T cells. Such interaction may lead to further production of cytokines and stimulation of B-cell proliferation and differentiation. Indeed, high levels of interleukin (IL)-1b, IL-6, and tumor necrosis factor-a (TNF-a), three tissue-destructive cytokines, are produced by epithelial cells. IL-10 and IFN-g are produced mainly by infiltrating T cells, whereas IL-6 and IL-10 also are produced in increased amounts in peripheral blood (127). A low capacity to produce IL-2 in Sjögren's syndrome might be due to absence of T-cell costimulatory signals, resulting in the induction of anergy in the responding T-cell population, but other explanations also are possible.

Even though the mechanism(s) behind the characteristic glandular destruction of Sjögren's syndrome salivary glands remains obscure, immunopathologic findings demonstrate that infiltrating cytotoxic T cells (CTLs) could play a role in this event. On recognition of a proper MHC/antigen complex presented by a target cell, CTLs induce cell death through one of two main and independent pathways, the perforin-mediated or the Fas-mediated pathway. Interestingly, expression of Fas also has been detected among infiltrating mononuclear cells in salivary glands of MRL/*lpr* mice, a murine model displaying features similar to those of human systemic lupus erythematosus and Sjögren's syndrome (128).

Expression of Fas, Fas-L, Bcl-2, and other apoptosis-associated genes/proteins has been detected by reverse transcription-polymerase chain reaction (RT-PCR) and immunohistochemical staining of minor salivary glands in patients with Sjögren's syndrome (129,130). In particular, ductal and acinar epithelial cells, but to some degree also infiltrating mononuclear cells express abnormal levels of Fas and FasL, especially in cases with heavy mononuclear cell infiltration. Ductal epithelial cells expressing Fas were usually situated inside or close to a dense focus (131). Most *in situ* studies have clearly shown a low-grade or even absent apoptosis among infiltrating mononuclear cells (129,130 and 131). The presence of granzyme A in Sjögren glands (132) suggests that rather than apoptosis, the perforin pathway of CTL-mediated killing may be involved in destruction of salivary glands.

Among the salivary gland–infiltrating T cells, some express activation markers such as CD25 (Fig. 40.5C), protooncogene products, and HLA-DR, but few T cells proliferate as determined by cell-cycle studies. It seems difficult also to stimulate the T lymphocytes in Sjögren's syndrome with the autoantigens Ro/SSA and La/SSB (133). These findings suggest that many cells are of memory T-cell phenotype; either few of them are autoantigen specific, or alternatively, many of them are in a state of anergy. In both cases, lack of stimulation of T cells also will hamper the apoptotic signals.

Immunopathogenesis (Summary)

The etiology and pathogenesis of Sjögren's syndrome is still a matter of speculation, although several hypotheses prevail. Nevertheless, there is considerable evidence that some as-yet-unknown initiating factor(s) set against the appropriate genetic background may evoke immunologically mediated inflammatory mechanisms, which result in the chronic exocrine gland lesions (Fig. 40.6). T-cell–mediated autoimmune responses in the glandular tissue and dysregulated apoptosis are currently considered to be of central importance in the pathogenesis. A plethora of autoantibodies has been linked to this autoimmune exocrinopathy, although their role is not always well-defined. Accordingly, B-cell activation is a very consistent immunoregulatory abnormality in Sjögren's syndrome.

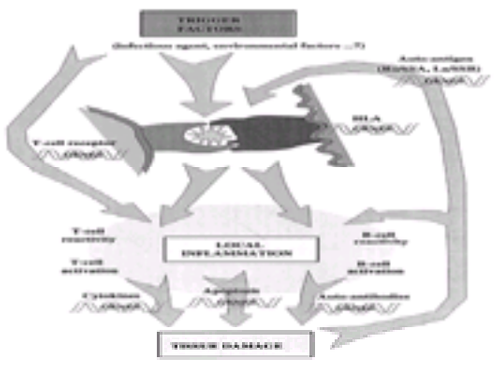

Figure 40.6. A schematic presentation of potential immune components in the pathogenesis of Sjögren's syndrome.

ANIMAL MODELS

As already alluded to, some genetic associations may predispose to Sjögren's syndrome, in particular, the genes encoding products of the MHC and immune receptors, but also other genes. It is thus natural to seek more knowledge using genetically well characterized, inbred animal models that are available for study (134). The current challenge is to find links between a particular genetic background and phenotypic expression(s) of disease.

Any proposed animal model should fulfill certain criteria and features found in the human disease. Moreover, the clinical symptoms of Sjögren's syndrome in humans usually appear relatively late in life, thus making examination of early events difficult. An animal model of the disease would make it possible to study earlier events and to identify potentially important immune reactions in the pathogenesis. Finally, both immune manipulation and the effects of drug therapy can be studied in animals (134).

The earlier attempts to induce Sjögren's syndrome in animals by injection with salivary gland extracts with or without adjuvants and/or other supplements would give rise to a transient inflammation, which was self-limiting and did not mirror the human disease in either the temporal course of events or the serologic profile. The better models of Sjögren's syndrome are the mice with spontaneous autoimmune disease with long-lasting and progressive exocrinopathy, but even in these cases, the disorder has at best represented only secondary Sjögren's syndrome (134). Both anti-Ro (135) and anti-La (136) have been recently detected in murine models of spontaneous Sjögren's syndrome. Because these autoantibodies are the dominant serologic marker in patients with primary Sjögren's syndrome, this finding is an important starting point for future work.

Interesting observations were made in the MRL/lpr mouse in which the *lpr* genotype has been identified as a mutation in the gene encoding Fas, which is a cell-surface receptor that mediates apoptosis. Apoptotic cells were absent or appeared at very low frequency among the infiltrating mononuclear cells in salivary glands. Based on the analysis of the apoptotic activity, the T cells seemed to be rescued from apoptosis because of a failure in signaling (128).

To analyze Fas and TNF receptor I apoptosis pathways in inflammatory salivary gland disease induced by murine cytomegalovirus infection, different strains of mice were infected (137). Both Fas- and TNF receptor I–mediated apoptosis were found to contribute to the clearance of murine cytomegalovirus-infected cells in salivary glands. However, because Fas-mediated apoptosis is necessary for the downmodulation of the immune response, a defect in this process can lead to a postinfectious, chronic inflammatory response that resembles Sjögren's syndrome.

To understand the role of IL-10 in Sjögren's syndrome, transgenic mice were constructed (138). The continuous overexpression of IL-10, induced apoptosis in glandular tissue and infiltration of lymphocytes consists of primarily $FasL^+$, $CD4^+$ T cells.

NOD.B10.H2b mice have been found to exhibit exocrine gland lymphocytic infiltration typical of Sjögren's syndrome–like disease and dysfunction observed in NOD mice, but without the insulitis and diabetes (139). These findings indicate that murine sicca syndrome occurs independent of autoimmune diabetes and that the congenic NOD.B10.H2b mouse represents a novel murine model of primary Sjögren's syndrome.

FUTURE DIRECTIONS

The search for susceptibility genes in families with Sjögren's syndrome is ongoing with the same approach as in the other chronic autoimmune diseases and with utilization of two major strategies: the position-independent candidate gene approach with mutation screening of suspected disease-related genes and full genome scanning (microsatellite analysis) in humans as well as in animal models to determine susceptibility chromosomal regions, which later will be used in a positional candidate gene strategy.

Another challenge in Sjögren's syndrome will be to stratify the disease process including genetic and environmental triggers (Fig. 40.6). Identification of new genetic markers and better characterization of novel autoantibodies (e.g., those directed against muscarinic receptors in exocrine glands) may lead to the development of better diagnostic and prognostic tests in Sjögren's syndrome including its systemic complications.

Sjögren's syndrome is considered to represent an ideal disease to study the mechanisms underlying autoimmunity because its manifestations are both organ specific and systemic. The significance of such studies is underlined by the high prevalence of Sjögren's syndrome as a common but often neglected systemic autoimmune disease often found in the female and aging population.

41 SYSTEMIC SCLEROSIS (SCLERODERMA)

Richard M. Silver, M.D., and Marcy B. Bolster, M.D.

Systemic sclerosis (SSc; scleroderma) is a disease of unknown etiology, the hallmark of which is induration of the skin. Although it was long regarded as a bland fibrotic process, there is now ample evidence of an active inflammatory and immunologic process underlying its pathogenesis. Characteristic microvascular and immunologic abnormalities are present in the majority of patients. It remains to be determined precisely how the immunologic and microvascular changes relate to the overproduction of connective tissue by the fibroblast, but data suggest that cytokines and growth factors derived from a prolonged immune response may influence the behavior of fibroblasts and endothelial cells, leading to overproduction of extracellular matrix proteins and to microvascular injury. In this chapter, the clinical features of scleroderma are reviewed, and the possible role of the immune response in the pathogenesis of scleroderma and related disorders is discussed.

CLASSIFICATION

Scleroderma may occur as a localized or a systemic disease. In its localized form, scleroderma is confined to the skin and adjacent tissues, where it is classified as linear scleroderma (including scleroderma *en coup de sabre*) or morphea (plaquelike, guttate, or generalized). In its systemic form (SSc), scleroderma may affect a number of visceral organs. Here the classification is somewhat controversial and is based on the extent of cutaneous involvement. One widely accepted classification is shown in Table 41.1, in which diffuse (particularly truncal) skin involvement is distinguished from limited skin involvement; the latter category encompasses the CREST [calcinosis, Raynaud phenomenon (RP), esophageal dysmotility, sclerodactyly, and telangiectasia] variant of scleroderma. Limited cutaneous SSc also includes what has been variously designated acrosclerosis, types I and II scleroderma of Barnett, types I and II of the German classification, intermediate cutaneous SSc of Giordano, and SSc *sine* scleroderma (99).

Diffuse cutaneous SSc (dSSc)[a]
Onset of Raynaud phenomenon within 1 yr of onset of skin changes (puffy or tiddebound)
Truncal and acral skin involvement
Presence of tendon friction rubs
Early and significant incidence of interstitial lung disease, oliguric renal failure, diffuse gastrointestinal disease, and myocardial involvement
Absence of anticentromere antibodies (ACAs)
Nailfold capillary dilatation and capillary dropout[b]
Antitopoisomerase (anti-Scl-70) antibodies (30% of patients) or anti-RNA polymerase antibodies (30% of patients)
Limited cutaneous SSc (lSSc)
Raynaud phenomenon for years (occasionally decades)
Skin involvement limited to hands, face, feet, and forearms (acral) or absent (no truncal involvement)
A significant late incidence of pulmonary hypertension, with or without interstitial lung disease, trigeminal neuralgia, skin calcifications, and telangiectasia
A high incidence of ACAs (70%–80%)
Dilated nailfold capillary loops, usually without capillary dropout

[a] Experienced observers note some patients with dSSc who do not develop organ insufficiency and suggest the term chronic dSSc for these patients.
[b] Nailfold capillary dilatation and destruction also may be seen in patients with dermatomyositis, overlap syndromes, and undifferentiated connective tissue disease. These syndromes may be considered part of the spectrum of scleroderma-associated disorders.
Modified from LeRoy EC, et al. Scleroderma (systemic sclerosis): Classification, subsets and pathogenesis. J Rheumatol 1988;15:202 with permission.

TABLE 41.1. Subsets of Systemic Sclerosis (ssc)

Although some have presented a conceptual framework of three subtypes of SSc [digital, proximal extremity, and truncal (110)], serologic and microvascular data now support the simpler classification shown in Table 41.1 (99). By classifying patients into subsets early in the course of the illness, one may identify patients at greater or lesser risk to develop certain visceral complications and provide more homogeneous populations of patients for studies of pathogenesis, clinical manifestations, and treatment. For example, limited cutaneous SSc tends to be a more protracted illness with a better prognosis, but late in the course of the disease, these patients may develop distinctive complications (e.g., pulmonary arterial hypertension). Diffuse cutaneous SSc is characterized by more extensive visceral organ involvement early in the course of the disease and a poorer prognosis compared with limited cutaneous SSc.

EPIDEMIOLOGY

Epidemiologic studies of scleroderma have been impeded by the lack of a specific diagnostic test and the relative rarity of the disease. Widely accepted criteria for the classification of SSc were not developed until 1980. Standardized criteria were developed to provide a uniform basis of classification and to facilitate comparison of patient groups. The American College of Rheumatology (ACR) clinical criteria for SSc are listed in Table 41.2.

Major criterion
Proximal scleroderma: typical sclerodermatous skin changes (tightness, thickening, and nonpitting induration, excluding localized forms of scleroderma) involving areas proximal to the metacarpophalangeal or metatarsophalangeal joints, affecting other parts of the extremities, face, neck, or trunk (thorax or abdomen); usually bilateral, symmetric, and almost always including similar changes in the digits (sclerodactyly)
Minor criteria
1. *Sclerodactyly*: sclerodermatous skin changes (as described above) limited to digits (fingers and/or toes)
2. *Digital pitting scars or loss of substance from the finger pad*: depressed areas at tips of digits or loss of digital-pad tissue as a result of digital ischemia rather than trauma or exogenous causes
3. *Bibasilar pulmonary fibrosis*: bilateral reticular pattern of linear or linear-nodular densities that are most pronounced in basilar portions of the lungs on standard chest roentgenogram; may assume appearance of diffuse mottling or "honeycomb lung," and should not be attributable to primary lung disease

Classification as definite systemic sclerosis requires the presence of (a) the major criterion or (b) two of three minor criteria. See (98).

TABLE 41.2. Preliminary Criteria for the Classification of Systemic Sclerosis (scleroderma)

A review of epidemiologic studies of SSc found the incidence to vary between 2 and 10 cases per million (153). Female individuals are affected more commonly than are males. The female-to-male ratio varies with age, peaking at 15:1 during the childbearing years. SSc is rare in childhood, when localized forms of scleroderma (e.g.,

morphea) are more common. The peak incidence of SSc occurs in the fifth and sixth decades (153). SSc appears to be more frequent among African-American female subjects, and African Americans have a poorer prognosis.

Few studies have been designed to investigate cases occurring in a random sample of the general population. Instead, most epidemiologic studies have relied on information obtained from hospital records and death certificates, which likely underestimate the true incidence and prevalence of SSc. In such studies, prevalence has ranged from four to 126 cases per million (153). However, a random community-based survey conducted in South Carolina estimated a prevalence of between 19 and 75 cases per 100,000 (107,108). The prevalence may be nearly 20-fold higher if one includes patients not fulfilling the ACR criteria but having substantive features of SSc [for example, RP with SSc-type capillary abnormalities (see later)].

CLINICAL FEATURES

Raynaud Phenomenon and Microvascular Disease

RP refers to episodic digital ischemia provoked by cold or emotion. Although classically described as triphasic (i.e., pallor, followed by cyanosis, and then hyperemia), a three-color response does not occur universally. Pallor appears to be the most reliable sign and hyperemia the least reliable sign in individuals lacking the classic triphasic response (106).

The establishment of the presence or absence of RP is important when evaluating a patient with thickened skin. The absence of RP should raise the possibility that one might be dealing with a disease other than SSc (Table 41.3), because 95% of SSc patients have RP.

Eosinophilic fasciitis
Chemical-induced disorders
Bleomycin fibrosis
Vinyl chloride disease
Trichloroethylene fibrosis
Toxic oil syndrome
Tryptophan-associated eosinophilia-myalgia syndrome (EMS)
Graft-versus-host disease
Digital sclerosis of diabetes mellitus (diabetic cheiroarthy)
Infiltrating carcinomas
Scleredema
Scleromyxedema (papular mucinosis)
Werner syndrome
Progeria
Rothmund syndrome
Acrodermatitis chronica atrophicans
Lichen sclerosis et atrophicus
Carcinoid syndrome
Phenylketonuria
Porphyria cutanea tarda
Congenital porphyria
Primary amyloidosis
Acromegaly

TABLE 41.3. Diseases with Cutaneous Features Resembling Scleroderma

The duration of RP before skin involvement is an important clinical point. Patients with diffuse cutaneous SSc and a tendency to early visceral organ damage usually have a brief duration of RP before the development of skin changes, whereas patients with limited cutaneous SSc usually have many years (often decades) of RP before overt skin and visceral involvement. Another important issue for the clinician is the evaluation of the individual with RP for the presence of an underlying connective tissue disease (CTD). RP per se is quite common in the general population, yet only a fraction of such individuals will develop a CTD (132). One recent survey found the prevalence of RP to be 4.6% among adults living in South Carolina (107). The prevalence may be higher in colder climates. Because RP may herald the development of serious disease, especially CTD, studies have been undertaken to test whether certain ancillary tests may be predictive of the evolution to an overt CTD. Two markers appear to have predictive value for the subsequent development of CTD (usually SSc): (a) abnormal nailfold capillaries, and (b) antinuclear antibodies (ANAs).

The nearly universal occurrence of RP and the presence of vascular lesions in all organs affected by SSc underscore the importance of the vasculature in the pathogenesis of SSc (125). Changes in the microvasculature can be observed *in vivo* in the capillary bed of nailfold skin (Fig. 41.1) (106). Two major categories of abnormalities have been identified: one is an *active* pattern, characterized by loss of capillaries and accompanied by disorganization of the capillary bed; the other is a *slow* pattern, characterized by enlargement of nailfold capillaries with minimal or no capillary loss (28). The active pattern has been shown to relate to the more rapidly progressing (diffuse cutaneous SSc) form of the disease, whereas the slow pattern is related to limited cutaneous SSc.

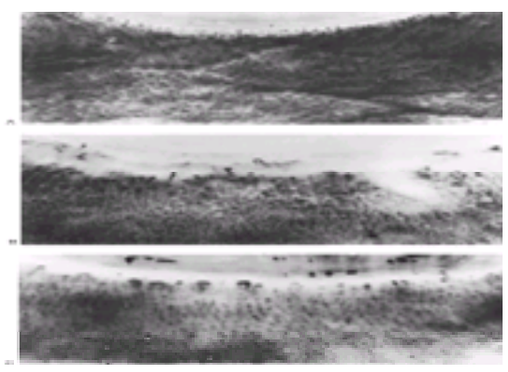

Figure 41.1. A: Normal capillaries visualized by *in vivo* nailfold capillary microscopy. **B:** "Active" pattern characterized by loss of capillaries and disorganization of the capillary bed, often seen in diffuse systemic sclerosis. **C:** "Slow" pattern characterized by enlargement of capillaries with minimal or no capillary loss, often seen in limited cutaneous systemic sclerosis. (**A:** Courtesy of Dr. H. R. Maricq. **B**, **C:** From Maricq HR. The microcirculation in scleroderma and allied diseases. (*Adv Microcirc* 1982;10:17, with permission).

An abnormal capillary pattern detected by nailfold capillary microscopy in a patient with RP indicates an increased risk for the presence of or eventual transition to a CTD (57). A prospective study of patients with RP confirmed this finding and concluded that the presence of abnormal capillaries was the most significant predictor of the subsequent development of SSc (49). In addition, the degree of capillary loss assessed by nailfold capillary microscopy may be correlated with clinical and serologic features and may assist in the subclassification of SSc, that is, diffuse cutaneous versus limited cutaneous (Table 41.1) (28).

Another marker that may be useful in predicting the presence or eventual development of CTD in the individual with RP is the presence of ANAs. Antibody specificity of ANA has been shown to be predictive of the development of specific subtypes of SSc (84,193). In a prospective study of patients with RP and undifferentiated CTD, the presence of ANAs was associated with the evolution of symptoms of CTD, usually SSc (84). Anticentromere antibody (ACA) was associated with limited cutaneous SSc (sensitivity of 60%, specificity of 98%) and anti–Scl-70 antibody was associated with diffuse cutaneous SSc (sensitivity of 38%, specificity of 100%). It is recommended that all patients with RP have a complete clinical evaluation, including nailfold capillary microscopy and ANA testing capable of detecting specific antigens associated with subsets of SSc.

Skin Involvement

Sclerosis of the skin is the hallmark of SSc, although rare patients may have typical visceral involvement in the absence of apparent skin disease (SSc *sine* scleroderma) (101). Skin thickening is the definitive diagnostic criterion of SSc in the majority of patients, and the distribution of involved skin serves as the means of classifying patients into one or another subset of SSc (Table 41.1).

Three phases of dermal involvement have been described. First, there is an edematous phase, often seen as stiff, puffy fingers and hands. In this phase, the condition is often difficult to distinguish from other CTDs or carpal tunnel syndrome; nailfold capillary microscopy and determination of the presence and type of ANAs are of greatest diagnostic utility during this phase of SSc. An indurative phase, characterized by tightness of the skin, usually follows the edematous phase. Here, sclerodactyly and the classic expressionless face with a pinched nose and puckered mouth (*mauskopf*) make the diagnosis unmistakable. Hypo- and

hyperpigmentation of the skin may occur. Ultimately an atrophic phase occurs, when the skin may actually soften.

Pitting scars over the fingertips, often accompanied by loss of substance of the finger pad, are characteristic findings in both limited and diffuse cutaneous SSc. Digital-pitting scars are one of the minor criteria for SSc and are not seen in primary RP (previously termed Raynaud disease). Telangiectasias are found on the hands and face, especially in the limited cutaneous form of SSc (Fig. 41.2). Calcinosis occurs on the volar aspect of the fingertips and over the joints, where ulceration may result in the extrusion of gritty material containing hydroxyapatite.

Figure 41.2. Face of woman with the CREST (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia) variant of systemic sclerosis.

Scleroderma skin has a thinned epidermis with loss of rete pegs and increased collagen within the dermis. In the inflammatory phase, a mononuclear cell infiltrate (lymphocytes, plasma cells, and histiocytic-type cells) is present in the dermis. During the indurative phase, there is a marked increase in thickness of the skin, accompanied by an increase in hydroxyproline content (142). The presence of fibroblasts containing well-developed rough endoplasmic reticulum and extracellular fine collagen fibrils supports the concept of increased collagen synthesis by scleroderma fibroblasts (50). The 10-nm-thick microfibrils previously thought to be early, immature collagen fibrils contain the glycoprotein fibrillin and are deposited with collagen in excessive amounts in the lower dermis of patients with localized or systemic scleroderma (51). Antifibrillin antibodies are present in both a murine model (tsk-1) and in some patients with SSc (see later).

Musculoskeletal Involvement

Musculoskeletal disease occurs in a significant percentage of patients with SSc. Autopsy studies have demonstrated muscle disease in up to 40% of patients (38), a figure that is greater than that for clinically recognized muscle disease. This discrepancy may be attributable to the occurrence of an indolent, often subclinical, myopathy that occurs with greater frequency than the more acute, inflammatory myopathy resembling polymyositis-dermatomyositis. The former is characterized by mild proximal muscle weakness and atrophy (usually without muscle tenderness), slight elevation of muscle enzyme levels (aldolase more often than creatine phosphokinase), and subtle or absent abnormalities on electromyography (35). The latter occurs in approximately 5% of SSc patients and is indistinguishable from polymyositis. Some patients with features of SSc and polymyositis have anti-PM/Scl antibodies. The PM/Scl autoantigen has been cloned and shown to encode a 75-kd acidic protein of the nucleolar complex (5). Examination of muscle biopsy specimens has revealed increased collagen deposition in interstitial and perivascular areas. Muscle fiber atrophy, degeneration, and necrosis have been observed adjacent to or far removed from areas of interstitial inflammation.

Articular complaints may be a prominent feature of SSc, particularly early in the course of the disease when arthralgia, swelling, and stiffness often occur. Later, the range of motion of joints may be limited because of overlying hidebound skin and fibrosis within the joint or tendons. Crepitus and grating sensations (tendon friction rubs) may arise from the joint or tendon sheaths. The combination of skin, joint, and tendon involvement may result in rapid development of contractures, particularly affecting the hands.

Synovial fluid analysis reveals noninflammatory joint fluid with cell counts of less than 2,000 per microliter, consisting predominantly of mononuclear cells. Radiographs usually do not reveal erosive joint disease, but in some patients, an erosive arthropathy may affect the distal and proximal interphalangeal joints and the first carpometacarpal joint. Resorption of the soft tissue at the fingertips is characteristic. Subcutaneous calcification and osseous resorption also may occur.

Gastrointestinal Tract Involvement

Gastrointestinal disease is the most commonly recognized visceral manifestation of SSc. Dysphagia for solid foods and heartburn, the most common symptoms, are due to esophageal dysmotility (distal two thirds) and esophageal reflux. Nearly 85% of SSc patients have esophageal reflux due to decreased lower esophageal sphincter pressure (198). Clinical evidence of esophageal involvement may precede cutaneous disease, particularly in patients with limited cutaneous SSc. Smooth muscle atrophy and fibrosis are the most common pathologic lesions (38). The striated muscle of the upper esophagus is spared. Inflammation, erosions, or ulcerations of the mucosa may result from reflux of gastric contents. Stricture or Barrett esophagus may occur as a complication of prolonged peptic esophagitis (Fig. 41.3).

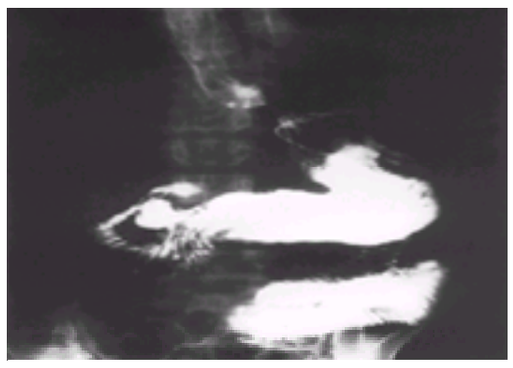

Figure 41.3. Barium esophagram showing stricture formation in the distal esophagus, secondary to chronic reflux esophagitis. (Courtesy of Dr. J. Stanley.)

Peristaltic abnormalities may delay gastric emptying and may reduce motility of the small and large intestines, giving rise to pseudoobstruction or malabsorption secondary to bacterial overgrowth. Wide-neck diverticula may be seen on barium studies, occurring especially on the antimesenteric border of the transverse and descending colon.

Liver disease is uncommon, but biliary cirrhosis may occur, usually in association with limited cutaneous SSc. Such patients usually have jaundice, pruritus, and antimitochondrial antibodies. A significant percentage of patients with primary biliary cirrhosis have features of scleroderma and ACAs (105).

Pulmonary Involvement

Lung disease ranks second to gastrointestinal tract disease in frequency of visceral involvement. Dyspnea and hypoxia may result from interstitial inflammation and fibrosis, or they may be the result of pulmonary hypertension occurring in the absence of parenchymal lung disease (23). With recent advances in the treatment of SSc-related renal disease, lung disease has become the most frequent cause of death from SSc.

Dyspnea on exertion is the most common pulmonary symptom and is often accompanied by a nonproductive cough. Examination usually reveals inspiratory “Velcro” crackles that are most prominent at the lung bases. Chest radiographs frequently show diffuse linear and nodular fibrosis in the lower two thirds of the lung fields (Fig. 41.4), but the chest radiograph is a relatively insensitive test of lung involvement in SSc. High-resolution computed tomography (HRCT) may demonstrate abnormalities before the onset of dyspnea or the detection of abnormalities by routine chest radiography (58). Tests of pulmonary function (PFTs) often reveal restrictive lung disease

with reduced lung volumes and decreased diffusing capacity. Moderate [forced vital capacity (FVC) 50% to 75% predicted] or severe (FVC less than 50% predicted) restrictive lung disease can be detected in 40% of SSc patients, and there is an increased incidence of anti–Scl-70 antibody and diffuse cutaneous skin disease in SSc patients with this degree of restrictive lung disease (170,171). HRCT findings include hazy opacification of the alveolar spaces (ground-glass opacification), irregular pleural margins, septal and subpleural fibrosis, honeycombing, subpleural cysts, and lymphadenopathy (187).

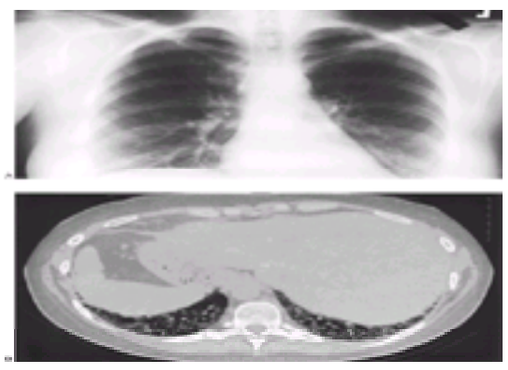

Figure 41.4. Chest radiograph **(A)** and high-resolution computed tomographic scan **(B)** of a 34-year-old woman with diffuse cutaneous systemic sclerosis of 3 years' duration.

An inflammatory component to the lung disease can be demonstrated in a significant percentage of SSc patients. Bronchoalveolar lavage (BAL) fluid reveals evidence of alveolitis, sometimes before the occurrence of dyspnea, abnormal results on PFTs, or abnormal-appearing chest radiographs (154). Most studies have shown an increased total number of cells (mostly activated alveolar macrophages) and an increased percentage and absolute number of neutrophils and eosinophils, similar to that described for idiopathic pulmonary fibrosis (129,130). A neutrophilia on BAL has been associated with symptoms of dyspnea, PFT abnormalities, and ground-glass opacification on HRCT scans (137,187,189).

The course of interstitial lung disease in patients with SSc is variable and not predicted by traditional tests, such as initial chest radiograph or PFTs, or by demographic data (149). Normal BAL findings have been associated with a stable pulmonary course, but alveolitis appears to be associated with worsening dyspnea, worsening appearance on chest radiographs, and significantly greater declines in FVC and diffusing capacity for carbon monoxide (D_{LCO}) (156).

Products of activated alveolar macrophages such as fibronectin, a glycoprotein that may serve as a chemoattractant and growth factor for fibroblasts, may play a role in the pathogenesis of SSc-related lung disease. Alveolar macrophages from patients with scleroderma release significantly more fibronectin than do those from controls, and the level of fibronectin is positively correlated with the degree of alveolitis and negatively correlated with the D_{LCO} (91). Other cytokines and growth factors of SSc patients may be important mediators of lung fibrosis (see later).

Pulmonary hypertension (in the absence of significant interstitial fibrosis) occurs in 5% to 10% of patients with limited cutaneous SSc, and only rarely in patients with diffuse cutaneous SSc. It is usually a late manifestation in patients with limited cutaneous SSc, typically occurring more than 10 years from disease onset. Patients with pulmonary hypertension experience dyspnea and fatigue, though up to one third of patients may be asymptomatic (175). Some patients with limited cutaneous SSc have an isolated decrease in the D_{LCO} on PFTs, and this has been associated with the development of severe pulmonary hypertension (169). Doppler echocardiography is a useful noninvasive means of estimating pulmonary artery pressures (117) and has a 90% sensitivity and 75% specificity for pulmonary hypertension as compared with right heart catheterization (41).

A case/control autopsy study showed that intimal thickening and luminal narrowing occur in both major subsets of SSc, but that such pulmonary vascular changes are most pronounced in patients with limited cutaneous SSc (3). Pulmonary vasospasm (visceral RP) may play a role in the pathogenesis of pulmonary arterial hypertension, but by the time that such patients are seen with dyspnea and hypoxia, significant pulmonary vascular resistance may have resulted from structural luminal narrowing.

There are other less frequent pulmonary manifestations of SSc. Pleural fibrosis is noted on HRCT scans and at autopsy more frequently than is clinically suspected (38,186). Pleural effusions also rarely occur in SSc. There is an increased frequency of lung cancer (adenocarcinoma, squamous cell carcinoma, and alveolar cell carcinoma) in scleroderma patients (178). Hemoptysis, or an enlarging infiltrate or mass lesion, suggests the presence of a malignancy and warrants appropriate evaluation. Spontaneous pneumothorax may occur because of rupture of a subpleural cystic airspace (pneumatocele). Aspiration pneumonia occurs as a result of esophageal dysmotility and the markedly reduced lower esophageal sphincter pressure. An uncommon pulmonary complication of SSc is diffuse alveolar hemorrhage. This may occur in the setting of acute renal failure or as a rare complication of lung fibrosis. Endobronchial telangiectasia also may be seen as hemoptysis and can be diagnosed by bronchoscopy.

Renal Involvement

Renal involvement is common in SSc, occurring predominantly in patients with diffuse cutaneous disease. Proteinuria (usually less than 500 mg/24 hours), azotemia, or hypertension occurs in 45% of SSc patients (26). Of all the visceral organs affected by SSc, disease of the kidney has been associated with the highest mortality. Until the introduction of dialysis and potent antihypertensive drugs, renovascular hypertension was uniformly fatal. Significant risk factors for the onset of scleroderma renal crisis include anemia, pericardial effusion, congestive heart failure, and rapid progression of skin thickening (166). Factors portending a poor prognosis in scleroderma renal crisis include (a) male gender, (b) advanced age, (c) poorly controlled blood pressure within 3 days of symptom onset, (d) congestive heart failure, and/or (e) severe renal insufficiency (creatinine greater than 3.0 mg/dL) at the time of initial therapeutic intervention (166).

The characteristic renal histopathology, similar to that seen in malignant hypertension, is concentric, subendothelial intimal proliferation affecting small arcuate and interlobular arteries (Fig. 41.5). The functional correlate of this structural abnormality is reduced renal cortical blood flow, which may be compromised further by vasospasm (visceral RP) (18). The renin-angiotensin system plays a major role in the pathogenesis of malignant hypertension secondary to SSc. Many patients have elevated plasma renin activity, which may precede or coincide with rapid deterioration in renal function, and many will respond to angiotensin-converting enzyme (ACE) inhibitor therapy. The use of captopril and other converting enzyme inhibitors has been associated with a marked reduction in mortality from SSc-related renal crisis (168), but not all patients recover renal function despite normalization of blood pressure.

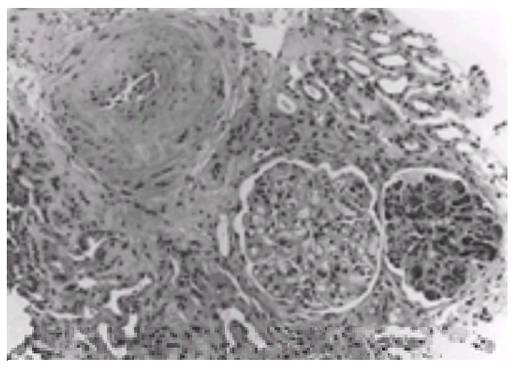

Figure 41.5. Intimal proliferation and reduplication of basement membrane and narrowing of vessel lumen in renal arteriole.

Some patients may develop acute renal failure without hypertension (65). When compared with SSc patients with hypertensive renal crisis, such patients are more likely to have microangiopathic hemolytic anemia and thrombocytopenia, and are more likely to have been treated with high doses of corticosteroids before onset of the

renal crisis. The risk of precipitating renal failure is a relative contraindication to the use of high-dose corticosteroids in SSc.

Involvement of the lower urinary tract occurs rarely, seen with microscopic hematuria with or without urinary urgency. Biopsy of the urinary bladder may reveal interstitial fibrosis (96).

Cardiac Involvement

The landmark article by Weiss et al. (188) established the entity of scleroderma heart disease. The authors set the stage for future investigation, suggesting that the pathologic changes were due to vascular disease in the setting of normal large and medium-sized coronary arteries. Heart disease may be seen as heart failure, arrhythmias, conduction disturbances, or chest pain, all of which may be the result of vascular disease and fibrosis. Pericardial effusions also occur, yet cardiac tamponade is rare. Symptoms tend to be slowly progressive and may be refractory to therapy.

Myocardial scarring in the presence of normal extramural coronary arteries is probably antedated by contraction band necrosis. This classic feature of scleroderma-associated heart disease can be produced experimentally by a transient interruption of blood flow. Evidence exists for cold-induced left ventricular dysfunction (44) and cold-induced regional perfusion defects (6). Structural lesions of the coronary microcirculation also may be a major determinant of cardiac involvement in SSc. Coronary angiograms usually appear normal, supporting the notion that myocardial dysfunction is secondary to microcirculatory disturbances. Some patients with primary scleroderma heart disease have reduced coronary blood flow and coronary reserve after maximal coronary vasodilation (124). Coronary vasospasm appears to be reversible with calcium channel blockers such as nifedipine (77).

Sjögren Syndrome

Symptoms of the sicca syndrome, particularly xerostomia and xerophthalmia, frequently occur in patients with SSc (128). Mononuclear cell infiltrates were found in biopsy tissue from labial salivary glands from nearly one third of unselected patients. An additional one third showed periglandular and interglandular fibrosis without significant inflammation. The presence of antibodies to SS-A (Ro) and SS-B (La) is correlated with histologic evidence of Sjögren syndrome, but not with salivary gland fibrosis.

Neurologic Involvement

Primary central nervous system involvement is rare in SSc. Trigeminal sensory neuralgia may occur, rarely as the presenting manifestation (182), and is more likely to occur in patients with SSc having an overlap syndrome (myositis and antiribonucleoprotein antibodies) than in those with pure SSc (47). Peripheral neuropathy occurs occasionally. Carpal tunnel syndrome may be present, particularly during the early, edematous phase of the disease.

Endocrine Involvement

Thyroid dysfunction may exist in a significant percentage of SSc patients (54). When present, hypothyroidism may be associated with high levels of antithyroid antibodies. Fibrosis of the thyroid gland may occur with or without autoimmune thyroiditis.

Erectile impotence occurs in male patients with SSc (95). It may be an early manifestation of the disease, usually with normal libido and normal testosterone and gonadotropin levels. Autonomic nervous system dysfunction and vascular abnormalities are postulated to play a role in its pathogenesis.

Fertility may be decreased in women with SSc. Scleroderma renal crisis may occur during pregnancy, accounting for maternal and fetal death. It is recommended that patients with early, diffuse cutaneous SSc (who are intrinsically at higher risk for renal crisis) delay pregnancy until their disease stabilizes (167,172). There does not appear to be an increased frequency of miscarriage, but the risk of premature and small full-term babies is increased (167,172).

ETIOLOGY AND PATHOGENESIS

Genetic Aspects

Only a few cases of familial scleroderma have been reported (25,112), and the twin concordance rate is low (56). It is interesting that asymptomatic relatives of SSc patients have a higher incidence of nonspecific ANAs than do controls (176). Because spouses also have an increased rate of ANA positivity (102), perhaps a shared environment is the dominant predisposing factor for autoantibody formation within families. A very high prevalence of SSc has been reported in Choctaw Native Americans residing in Oklahoma (10), believed to be due in part to a common ancestral founder ten generations ago (180). A candidate gene, fibrillin 1, which is defective in a mouse model of SSc (tight skin1,*tsk1*), and located on chromosome 15 in humans, was screened in Choctaw SSc cases and controls, and a 2-cM haplotype containing the fibrillin 1 gene was shown to be associated with SSc in this population (180). Choctaw SSc cases do not have the duplication of the fibrillin 1 gene seen in the *tsk1*mouse.

The resemblance of some forms of graft-versus-host disease (GVHD) to SSc, together with the observation that bidirectional cell traffic at the maternal/fetal interface can result in persistent microchimerism, has led some to speculate that microchimerism may play a role in the pathogenesis of some cases of SSc (121). Low levels of microchimerism can be detected in healthy women, but class II human leukocyte antigen (HLA) compatibility of a child appears to be more common for SSc patients, suggesting a possible role for microchimerism in the pathogenesis of SSc (13,14,120). In addition, cells containing Y-chromosome sequences were detected by *fluorescence in situ* hybridization in affected skin from some female SSc patients, but not in normal women (14). It remains to be determined whether there is a causal link between microchimerism and SSc, or whether this observation is an epiphenomenon (121).

Several population studies showed an increase in the frequency of certain class II HLA types, especially DR1, DR3, and DR5 (19), which may correlate with specific autoantibody profiles of SSc. The DR1 allele may be associated with ACAs, and hence the limited cutaneous subset of SSc, whereas DR5 may be associated with ACA or Scl-70 antibodies (4,53). The increased frequencies of HLA-DR5 and HLA-DR1 in ACA-positive patients may reflect linkage disequilibrium with DQ7 and DQ5, respectively (138). DNA typing with oligonucleotide probes suggests an important role for the presence of a DQ allele having a polar glycine or tyrosine rather than leucine at position 26 of the DQB1 domain; 100% of ACA-positive white patients with SSc, compared with 69% of ACA-negative patients with SSc, 71% of white controls, and 100% of ACA-positive nonwhite patients with SSc, had such a polar amino acid at this position (138). The second hypervariable region of the HLA-DQB1 chain may form the candidate epitope associated with the ACA response (138). Anti–Scl-70 (topoisomerase) antibodies have been found to be associated with DRw11 and a particular sequence (aa 71-77) of the DQB1 chain in white SSc patients (115), and either the DQBB1*0601 or*0301 allele in Japanese SSc patients (94).

Environmental Factors

Exposure to a variety of environmental agents has been implicated as a cause of scleroderma and scleroderma-like conditions (Table 41.4). The female preponderance normally seen in SSc is not seen in many with an environmental exposure implicated as a cause of disease, and it has been suggested that environmental exposure may be the major cause of SSc among male subjects (61).

Silica dust exposure
Silicone breast augmentation
Paraffin breast augmentation
Epoxy resins
Aromatic hydrocarbons: toluene, benzene, xylene
Aliphatic hydrocarbons: vinyl chloride, trichloroethylene, perchloroethylene
Drugs
Bleomycin
5-Hydroxy-L-tryptophan
L-Tryptophan (eosinophilia-myalgia syndrome)
Adulterated rapeseed oil (toxic oil syndrome)
Biogenic amines: appetite suppressants
Cocaine

TABLE 41.4. Chemicals and Toxins Implicated in Scleroderma and Scleroderma-Like Disorders

Exposure to silica has been implicated in some cases of SSc. This was first noted among Scottish stone masons exposed to silica dust, and later among gold miners and underground coal miners (45,141). It has been estimated that the likelihood of developing SSc is 25-fold higher in persons exposed to silica and is 110-fold higher in persons with silicosis (61). Silica-induced and idiopathic SSc appear to share similar pathophysiology, and silica *in vitro* can activate macrophages, leading to release of tumor necrosis factor (TNF)-a, interleukin (IL)-1 and IL-6, and can activate endothelial cells to express intercellular adhesion molecule (ICAM)-1 (62). Although augmentation mammoplasty with silicone or paraffin injections, or with silicone gel–filled implants, has been implicated in a number of patients with SSc (92,164), case/control and cohort studies failed to show a significant association between silicone breast implants and CTDs (144).

Exposure to vinyl chloride has been associated with the development of scleroderma-like cutaneous changes and RP, as well as acroosteolysis, pulmonary fibrosis, portal fibrosis, and hepatic hemangiosarcoma. Organic solvent exposure, either occupational or avocational, appears to be related to an increased risk of SSc (122,123).

Another illness having scleroderma-like features is the toxic oil syndrome (TOS), which affected nearly 20,000 people in Spain in 1981. It was associated with the ingestion of contaminated rapeseed oil (7). The early phase of the disease was characterized by noncardiogenic pulmonary edema, fever, skin eruptions, and eosinophilia. An intermediate phase was characterized by fasciitis and scleroderma-like skin changes, myalgia and muscle cramps, and severe peripheral neuropathy. The chronic phase was marked by softening of the affected skin, but neuropathy and muscle cramps persisted, and some patients died of pulmonary hypertension.

A very similar epidemic known as the *eosinophilia-myalgia syndrome* (EMS) occurred in the United States in 1989 (18,66,157), in association with the ingestion of L-tryptophan. One impurity in implicated batches of L-tryptophan, identified as 1,1'-ethylidenebis-(L-tryptophan) (EBT), was related to changes made in the manufacturing process (111). A similar illness was described 10 years earlier, in association with the ingestion of 5-hydroxy-L-tryptophan and carbidopa (174).

EMS patients often had acute dyspnea and cough with skin eruptions, myalgia, and eosinophilia. In many patients, fasciitis and scleroderma-like skin lesions developed, similar to what was seen in the TOS epidemic. Peripheral neuropathy was seen in both syndromes. It is unclear whether these similar epidemics share a common etiologic agent, but in each there was significant eosinophilia and evidence of altered metabolism of L-tryptophan (158). In the early phase of each syndrome, the metabolism of L-tryptophan via the L-kynurenine pathway was accentuated, perhaps by the induction of the rate-limiting enzyme, indoleamine-2,3-dioxygenase, by cytokines such as interferon-g (IFN-g) (158). This resulted in high levels of L-kynurenine and quinolinic acid, which may have played a role in the fibrosis and neuropathy seen in each syndrome.

Vascular Mechanisms

Clinical and morphologic abnormalities of the vascular system are well recognized in SSc, leading some to hypothesize that the endothelium is the major target organ (98). Morphologic abnormalities have been noted in vessels of almost every organ studied (125). Small arteries and arterioles demonstrate thickening of the intima with narrowing of the vascular lumen. The vascular media is normal or thinned, and the adventitia may be surrounded by a cuff of fibrous tissue, frequently obliterating periarterial lymphatics and capillaries. Ultrastructural studies reveal evidence of endothelial injury, with swelling and destruction of endothelial cells and reduplication of the capillary basement membrane.

Endothelin, a potent vasocontrictor, is present in increased concentrations in the plasma of patients with primary RP and SSc (195). It is tempting to speculate that in SSc, there exists a relative imbalance between endogenous vasodilators, such as nitric oxide and prostacyclin, and endogenous vasoconstrictors, such as endothelin and platelet-release products. Other vasoactive substances also may be important. For example, the presence of increased numbers of activated mast cells in skin affected by SSc suggests that histamine and other mast cell constituents may play a direct or secondary role in the vascular abnormalities (31).

Endothelial injury appears to be an early and important event in the pathogenesis of SSc, but the mechanisms leading to microvascular damage are poorly understood. Latent or persistent human cytomegalovirus (HCMV) infection has been postulated to be an accelerating factor in various autoimmune vasculopathies, including SSc (129). Elevated prevalence and levels of immunoglobulin G (IgG) HCMV antibodies have been observed in SSc patients (119).

A number of studies suggested that endothelial injury in SSc may be the result of an immune response directed against the endothelium. Antibody-dependent cell-mediated cytotoxicity (ADCC) toward endothelial cell targets has been demonstrated with some SSc sera (130). Antiendothelial cell antibodies (AECAs) present in sera of SSc patients may be pathogenic by inducing endothelial cell apoptosis (24). Studies in both an avian model of SSc and skin from patients with SSc indicated that endothelial cells undergo apoptosis early in the disease course, and suggest a role for AECAs (151). Non–antibody-mediated injury also may occur, because it has been shown that IL-2–activated lymphocytes [lymphokine-activated killer (LAK) cells] are cytotoxic to endothelial cells *in vitro*. One study found no evidence of LAK cell activity in the peripheral blood of SSc patients, but did not preclude the presence of such in the skin and other organs affected by SSc (155). In fact, the progenitor of the LAK cell [natural killer (NK) cell] adheres to endothelium and rapidly disappears from the circulation on exposure to IL-2 (12). This mechanism of endothelial cytotoxicity may be relevant, as evidence exists for enhanced production of IL-2 in patients with SSc (75). A factor resembling granzyme has been identified in SSc patients, both in sera and in skin lesions (76). Upregulation of class II major histocompatibility complex (MHC) molecule expression and other markers of endothelial cell activation, such as adhesion molecules, further supports the notion of endothelial cell perturbation in SSc (33,64,68,69,103,126,162).

Connective Tissue Aspects

The characteristic feature of SSc is excessive deposition of collagen and other extracellular matrix components (fibrillin, fibronectin, and glycosaminoglycans) in the skin and other organs. LeRoy (97) observed that SSc dermal fibroblasts synthesize excessive collagen *in vitro* and that this increased capacity to synthesize collagen persists *in vitro* for a number of passages, before declining toward normal levels. Increased synthesis of glycosaminoglycans and fibronectin also has been demonstrated. Messenger RNAs (mRNAs) of matrix proteins are increased in SSc dermal fibroblasts, largely the result of increased rates of transcription (79); increased half-lives of the mRNAs also may contribute to elevated matrix synthesis (80). Furthermore, scleroderma fibroblasts express more tissue inhibitors of metalloproteinases 1 (TIMP-1), which may contribute to excess matrix accumulation (90,93).

Studies using *in situ* hybridization showed that only a proportion of dermal fibroblasts are responsible for the high rate of connective tissue matrix synthesis (82). Another phenotypic feature of the scleroderma fibroblast is high expression of the surface molecule ICAM-1 (118). Such cells can bind to normal T lymphocytes *in vitro*, and this binding is inhibited by antibodies to ICAM-1 or to lymphocyte function-associated antigen-1 (LFA-1) (1). Circulating ICAM-1 levels are elevated in SSc, and proinflammatory cytokines enhance the release of ICAM-1 from SSc peripheral blood mononuclear cells (PBMCs) *in vitro* (68). Thus evidence is accumulating to support a physical relationship between T lymphocytes and fibroblasts, as well as cytokine-mediated effects (see later).

Transforming growth factor-b (TGF-b) enhances transcription of collagen mRNA through the activation of a promoter region of the collagen gene (70). When injected into experimental animals, TGF-b causes a mononuclear cell inflammatory response and fibrosis (140). Also of potential relevance to SSc, TGF-b induces the autocrine production of two potent fibroblast mitogens, platelet-derived growth factor (PDGF) (163), and connective tissue growth factor (CTGF) (146) and inhibits endothelial cell proliferation *in vitro* (177). Exposure to TGF-b *in vitro* leads to an increased expression of the PDGF-a receptor on dermal fibroblasts from SSc patients (194). Furthermore, exposure to TGF-b *in vitro* increases adherence of normal fibroblasts to extracellular matrix components to levels seen in scleroderma. Such an effect of TGF-b may be mediated by the cell-surface integrin b_1, which is expressed in scleroderma skin (162). TGF-b, PDGF, and CTGF have all been shown to be present in the skin of SSc patients (67), and serum CTGF levels were increased in patients with SSc and correlated with extent of skin sclerosis and pulmonary fibrosis (148). These cytokines may, therefore, play a role in the proliferation and activation of SSc fibroblasts. Such a role is bolstered by the observation that dermal fibroblasts from scleroderma patients exhibit overexpression of receptors for TGF-b as compared with normal dermal fibroblasts (87). Elevated TGF-b receptor levels correlated with elevated a 2 (I) collagen mRNA levels in scleroderma fibroblasts (87).

Immunologic Aspects

The frequent occurrence of mononuclear cell infiltrates in the dermis of early scleroderma lesions, as well as the presence of ANA in the majority of patients, suggests that cellular and humoral immunity may play a role in the pathogenesis of SSc. Additional support for such a role is the occurrence of scleroderma-like lesions in patients with chronic GVHD. Evidence suggests that SSc may be immunologically triggered and associated with expansion of fibrogenic clones of tissue fibroblasts (9). The major aspects of immune dysfunction described in patients with SSc, as well as the possible effect of the immune response on vascular and connective tissue metabolism, are discussed later.

HUMORAL IMMUNITY

Hypergammaglobulinemia occurs in a significant proportion of patients, with the largest elevation usually involving the IgG fraction (34). Immunoglobulin, C3, and fibrinogen are deposited in tissues in a variable percentage of patients. When a biopsy was performed on more than one site, and particularly if the nailfold was selected as a site for biopsy, the majority of SSc patients were noted to have deposits of immunoglobulin, C3, and fibrinogen (29). Granular deposits of IgM are present at the dermal/epidermal junction of patients with SSc. Autoantibodies from the epidermis of patients with SSc have been shown to activate complement *in vitro* (134),

and ongoing complement activation *in vivo* is suggested by elevated plasma levels of fragments C3d, C4d, and factor Ba (150), as well as the detection of activated complement C5b-9 and C5aR in SSc microvasculature (165).

ANAs occur frequently in SSc patients and their first-degree relatives, up to 95% of the former and 57% of the latter when HEp-2 is used as substrate (Fig. 41.6) (133,176). There are three major intracellular targets of ANAs in SSc. The first is ACA, which recognizes three human chromosomal antigens and is very specific for RP and limited cutaneous SSc (43). The association of ACA with certain nailfold capillary abnormalities has been noted (28). ACAs have been detected in approximately 40% of all patients with SSc, but are relatively specific for limited cutaneous SSc (50% to 96% positive) and, thus, identify a subgroup of SSc patients with less severe internal organ involvement and a more favorable prognosis.

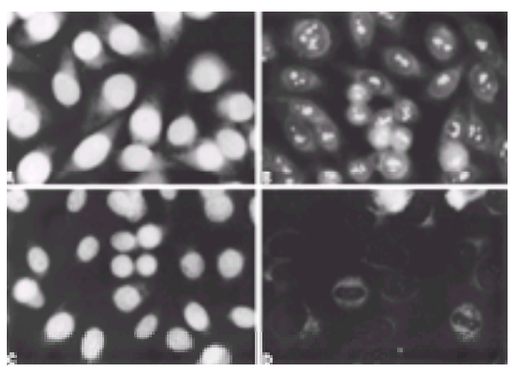

Figure 41.6. Patterns of nuclear staining seen in systemic sclerosis, using HEp-2 cells as a substrate. **A:** Homogeneous, which occurs less frequently and may be confused with diffuse, fine speckles. **B:** Nucleolar. **C:** Discrete large speckles. **D:** Centromere. (×40). (Photomicrographs courtesy of Drs. Z. Chen and S. K. Ainsworth.)

Anti–Scl-70, found in 30% to 70% of patients with diffuse cutaneous SSc, is an autoantibody directed against the nuclear enzyme DNA topoisomerase I (152). The prevalence of anti–Scl-70 antibodies varies among patients with different genetic or racial backgrounds and occurs with a relatively low frequency in scleroderma overall; nevertheless, it appears to be a highly specific marker of diffuse cutaneous SSc. Autoantibodies to RNA polymerases (RNAPs) are found in approximately half of patients with diffuse cutaneous SSc and are responsible for the speckled staining on the nucleolus in the immunofluorescence ANA test (136). Other antinucleolar antibody systems include PM-Scl, Th/To, and fibrillarin (small nucleolar U3 ribonucleoprotein) (135). Autoantibodies to the latter have been associated with high urinary mercury levels in SSc patients (11).

Although the distributions of each of the antigenic targets of SSc autoantibodies differ, they all are enriched within the nucleolus at some time during the cell cycle (179). Metals also are enriched in the nucleolus, and it has been observed that several SSc autoantigens are uniquely susceptible to cleavage by reactive oxygen species in a metal-dependent manner (27), thus potentially revealing cryptic antigenic epitopes and eliciting an MHC class II–driven autoimmune response.

Antibodies to fibrillin-1, the major structural glycoprotein of connective tissue microfibrils, are present in a significant proportion of white, Japanese, and Choctaw American Indian patients with SSc (181). This is of interest because the tsk1 mouse, a murine model of fibrosis and perhaps SSc, has a gene duplication that results in an abnormally large fibrillin-1 protein (89). These mice spontaneously produce anti–fibrillin-1 antibodies, as well as other SSc-specific autoantibodies (116). It remains to be determined whether the immune response to fibrillin or other matrix or intracellular components plays a primary role in disease pathogenesis or is a secondary phenomenon.

CELLULAR IMMUNITY

One of the earliest clinical observations suggesting a role for cell-mediated immunity in the pathogenesis of SSc was a scleroderma-like lesion in patients with GVHD (52). Scleroderma-like lesions also have been observed in a murine model of GVHD across minor histocompatibility barriers (73). The histopathology of this model is cutaneous fibrosis, loss of adipose tissue, atrophy of dermal appendages, and a T-lymphocyte and macrophage cellular infiltrate. Of interest is the observation that stainable mast cells seemingly disappear from the skin of mice with GVHD (32). Subsequent studies showed that abundant mast cells are present but not apparent with traditional staining techniques because they had lost their granules (30). By electron microscopy, these “phantom” mast cells have been shown to be highly activated.

Mast cells also are present in the skin and internal organs of patients with SSc. Granulated mast cells are increased in the skin, particularly the reticular dermis, of patients with early SSc (63). Tryptase-positive, chymase-positive mast cells have been detected in scleroderma skin specimens (72). One major product of mast cells, histamine, is elevated in the plasma of SSc patients, particularly those with diffuse cutaneous disease (46). Mast cell degranulation also has been noted in the tsk1 murine model of scleroderma (185). Mast cells are present in many fibrosing conditions besides SSc, and their exact role in fibrosis remains unclear. The mast cell may interact with both the endothelial cell and the fibroblast, each of which appears to be a critical element in the pathogenesis of SSc, but the exact role of the mast cell remains unknown (31).

The presence of perivascular lymphocytes and macrophages in the dermis of patients with SSc, particularly those with early, active skin disease, has long been appreciated (50). Studies indicate that such cells are activated, expressing class II MHC antigens (55). Macrophages from lungs of scleroderma patients exhibit a number of features indicative of *in vivo* activation, including spontaneous production and release of fibronectin (91). T lymphocytes are the predominant lymphocytic cell, with the helper/inducer phenotype ($CD4^+$) being more abundant than $CD3^+/CD8^+$ lymphocytes. The majority of the lymphocytes express HLA-DR antigen. Activated lymphocytes, predominantly $CD8^+$, are also present in lungs of SSc patients with alveolitis (196). Activated NK cells expressing CD56 and HLA-DR also are present in acute scleroderma skin lesions (55). Class II HLA antigens are expressed by dermal endothelial cells and perivascular fibroblasts in the deep dermis of acute scleroderma lesions (55), which suggests that these cells have been activated and are capable of serving as antigen-presenting cells.

Early studies reported a decreased number of circulating T lymphocytes (71,191). Flow cytometry demonstrated significantly reduced numbers and percentages of $CD8^+$ and $CD4^+$ T lymphocytes in patients with acute disease compared with those with chronic disease and normal controls (55). The $CD4^+/CD8^+$ ratio may be increased because of a diminished suppressor T-lymphocyte subset. Nonspecific suppressor cell function is diminished in some patients (71,85), but antigen-specific suppressor cell activity is usually normal and $CD4^+$ $CD45RA^+$ (suppressor-inducer) cells are not significantly different from normal (78,88). Evidence of T-cell activation includes increased expression of HLA-DR molecules and IL-2 receptors, and increased serum levels of soluble IL-2R (190).

Peripheral blood NK cell numbers and activity are reduced in patients with SSc (85,155). IL-2 stimulation of NK cells gives rise to LAK cells, which also are reduced in some SSc patients (85,155). This is enigmatic, as significantly elevated levels of IL-2 are present in sera of patients with SSc (75), and SSc serum does not contain inhibitors of LAK cells (85). One plausible explanation for the decreased LAK activity seen in SSc is that the precursors of LAK cells may have left the circulation to sites of disease activity. IL-2 induces NK-cell adhesion to endothelial cells, and NK cells promptly disappear from the circulation of cancer patients treated with high-dose IL-2 (12). Indeed, $CD16^+$ cells are increased in the skin of some SSc patients (109). Such cells not only are capable of binding to endothelial cells but also may mediate endothelial cell cytotoxicity by release of serine proteases (granzymes) (40).

The presence of mononuclear cells in the dermis of SSc patients has generated interest in the products of such cells and their potential effects on fibroblasts and endothelial cells. IFN-g is capable of downregulating fibroblast collagen synthesis *in vitro*. IFN-g exerts its action at the level of transcription, by decreasing mRNA for procollagen (42, 81). A 72-hour exposure to IFN-g reduced procollagen mRNA levels in scleroderma fibroblast cell lines to levels exhibited by control fibroblasts (81). Other cytokines also may be important in the pathogenesis of SSc. IL-1 is mitogenic to fibroblasts, as is an inhibitor to IL-1 produced by mononuclear cells from SSc patients (145). Elevated levels of IL-1 in serum, PBMC supernatant, and dermal fibroblast culture medium have been reported, and SSc fibroblasts express more IL-1R, perhaps making them more sensitive to IL-1 stimulation (86). Lymphotoxin and tumor necrosis factor-a (TNF-a), present in some SSc sera, also may be important mediators (59,74). TNF-a can injure endothelial cells *in vitro* and stimulate fibroblast proliferation (74,147). Depending on culture conditions *in vitro*, TNF-a can modulate the expression of type I and type III collagen gene expression, as well as the expression of MMP-1 and TIMP-1 by dermal fibroblasts (146). Increased levels of sTNF-a–receptor type I are detected in sera of many scleroderma patients, and seem to correlate with disease severity (104). IL-2, IL-4, IL-6, and IL-8 also are detectable in the sera and bronchoalveolar lavage fluid (BALF) of some SSc patients (22,60,190). Increased IL-4 levels may reflect activation of either T lymphocytes or mast cells. This may be relevant to the pathogenesis of SSc, because IL-4 induces proliferation of normal dermal fibroblasts in a dose-dependent fashion (48). A T-helper 2 pattern of cytokine production by T cells in blood and BALF is suggested (190), with increased IL-4 and reduced production of IFN-g.

TREATMENT

Effective treatment of SSc has been hampered by lack of knowledge regarding its etiology and pathogenesis and by difficulties in classifying patients into subsets and staging the degree of disease activity. In a study of 264 patients with SSc, overall survival was reduced, with a cumulative survival rate of less than 80% at 2 years, 50% at 8.5 years, and 30% at 12 years after entry (Fig. 41.7) (8). Factors associated with reduced survival included older age (older than 64 years), reduced renal function (blood urea nitrogen greater than 16 mg/dL), anemia (hemoglobin 11 g/dL or greater), reduced D_{LCO} (50% or less predicted), reduced total serum protein (6 g/dL or less), and reduced FVC (less than 80% predicted) (8). Nevertheless, significant improvement in outcome has been achieved, particularly with advances in supportive care. The latter is best illustrated by the improvement in survival associated with the introduction of ACE inhibitors for treating renovascular hypertension (168). Preventive and supportive treatments of this and other complications of SSc are outlined in Table 41.5.

TABLE 41.5. Supportive Measures for Treating Systemic Sclerosis

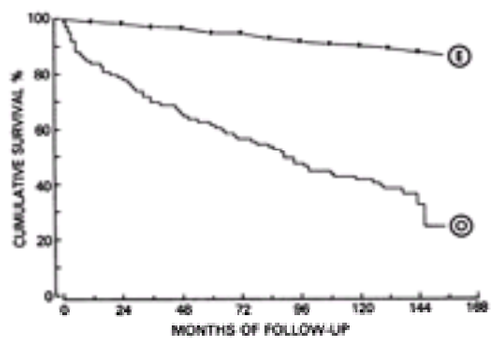

Figure 41.7. Observed survival curve for 264 patients with systemic sclerosis (*O*) and expected survival for a general population matched to the systemic sclerosis group for date of entry into the study, duration of follow-up, age, sex, and race (*E*). (From Altman RD, Medsger TA Jr, Bloch DA, et al. Predictors of survival in systemic sclerosis (scleroderma). *Arthritis Rheum* 1991;34:403, with permission)

Studies in the treatment of scleroderma lung disease have provided promising results (21). In SSc patients with alveolitis, several open studies have demonstrated the efficacy of daily oral cyclophosphamide in improving both the symptoms of dyspnea and FVC (2,17,159,171). A placebo-controlled trial, which is currently under way, is needed to assess efficacy and toxicity of oral cyclophosphamide. Single-lung transplantation has been performed in few SSc patients (100).

Isolated pulmonary hypertension, occurring predominantly in limited cutaneous SSc patients, has been historically very difficult to treat (21). Recent advances in the therapy of primary pulmonary hypertension have included the use of high-dose calcium channel blockers (139) and the prostacyclin analog epoprostenol (15,143). In SSc patients, trials have been performed using Iloprost, a prostacyclin analog (39,16,127) and inhaled nitric oxide (192), each of which demonstrated promising results. Recently a trial of epoprostenol was performed in patients with CTD and pulmonary hypertension (113), demonstrating significant improvements in pulmonary hemodynamics and exercise tolerance.

No drug has been shown in a prospective, double-blind controlled trial to be an effective treatment of SSc (160). A number of drugs and treatments have been reported to be effective, but few have withstood vigorous scrutiny (114,149). Although D-penicillamine and colchicine have been used extensively, many have found their effects to be marginal in those patients who can tolerate long-term treatment. A study comparing high-dose (750 to 1,000 mg per day) with low-dose D-penicillamine (125 mg every other day) did not demonstrate improved efficacy in terms of skin score, incidence of renal crisis, or mortality in SSc patients; however, the high-dose group had 80% of adverse reactions requiring withdrawal from the study (37). The delayed and partial response to a drug such as D-penicillamine may relate to its proposed site of action being rather distal in the pathogenetic sequence of the disease, that is, inhibition of collagen cross-links (Fig. 41.8).

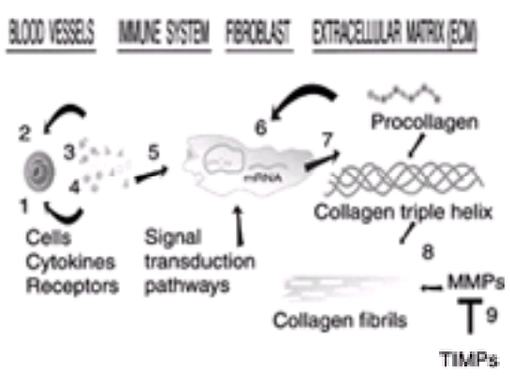

Figure 41.8. Pathogenetic basis of therapy for systemic sclerosis. Potential levels of action include (*1*) inhibit platelet aggregation; (*2*) inhibit endothelial injury; (*3*) inhibit immune cell function and cytokine production; (*4*) inhibit mast cell degranulation; (*5*) block cytokine or block cytokine receptor; (*6*) inhibit matrix protein transcription or translation; (*7*) inhibit collagen secretion assembly; (*8*) stimulate collagenase and other matrix metalloproteinase (*MMP*) activity; and (*9*) block tissue inhibitors of matrix metalloproteinases (*TIMP*).

Drugs targeted at the immune system also have been used, but results have thus far been disappointing. In a randomized double-blind placebo-controlled study of IFN-a, which inhibits collagen mRNA transcription *in vitro*, no improvement in skin score was demonstrated, and there was a significant decline in lung function (both of FVC and of D_{LCO}) (20). Short-term clinical trials of recombinant human IFNg have yielded mixed results (83,131). Open trials of cyclosporine (Cyclosporin A) suggest efficacy in some patients, but renal toxicity often precludes its use. A clinical trial using recombinant human relaxin, a hormone that inhibits TGF-b–induced fibroblast collagen synthesis and that also induces collagenase (184), was halted due to inefficacy. Autologous hematopoietic stem cell transplantation trials also are under way (36,161).

Although SSc remains an incurable disease, significant advances in supportive therapies have been made. Future therapies targeted to the immune system and to downstream steps in the process of extracellular matrix formation will likely prove to be more effective.

42 IDIOPATHIC INFLAMMATORY MYOPATHIES: DERMATOMYOSITIS, POLYMYOSITIS, AND RELATED DISORDERS

Lauren M. Pachman, M.D. and Frederick W. Miller, M.D., Ph.D.

The idiopathic inflammatory myopathies (IIMs) comprise a very diverse group of syndromes that have in common chronic muscle inflammation of unknown cause, resulting in muscular weakness. Inflammatory muscle disease was apparently not recognized until the mid-1800s. The more easily discerned disease, dermatomyositis, was first described by Unverricht (89). It was considered the major variant of inflammatory myopathy for almost 50 years until the mid-1900s, when it became clear that most myositis lacks a dermal component. In the mid-1960s Banker and Victor (2) found that dermatomyositis in the child was characterized by a greater degree of vascular inflammation and thrombosis than that seen in most other inflammatory myopathies. In the past, the use of muscle biopsies to aid in diagnosis was less frequent than it is now; therefore the extent and diversity of alterations in muscle physiology in rheumatic disease are just beginning to be appreciated. In the past 15 years there has been a concerted effort to focus on a more accurate definition of variants of IIMs. Recent histochemical, genetic, and immunologic tools have allowed investigators to divide these syndromes into more homogeneous groups.

DIAGNOSIS AND CRITERIA

The rarity and heterogeneity of the IIMs have inhibited our understanding of the range of clinical constellations and laboratory attributes that distinguish each entity from the other closely related neuromuscular and rheumatic disorders. The underlying pathology of the IIMs is chronic inflammation in muscle of unknown cause that results in the clinical features on which classification criteria have been based. Although not perfect, and in need of reassessment, five criteria (Table 42.1), proposed more than 25 years ago by Bohan and Peter (5), are still useful in sorting out the many disorders that can be confused with the IIM. Analysis of the utility of these criteria (5) suggests that their sensitivity ranges from 45% to 92%, whereas their specificity, compared with that for systemic lupus or systemic sclerosis, is 93% (48).

1. Symmetric, often progressive, proximal muscle weakness
2. Characteristic electromyographic (EMG) triad seen in myositis
   Short-duration, small, low-amplitude polyphasic potentials
   Fibrillation potentials, seen even at rest
   Bizarre high-frequency repetitive discharges
3. Elevations of serum levels of muscle-associated enzymes
   Creatine kinase (CK)
   Aldolase
   Lactate dehydrogenase (LDH)
   Transaminases (AST/SGPT and AST/SGOT)
4. Evidence of chronic inflammation in muscle biopsy
   Necrosis of type I and type II muscle fibers
   Degeneration and regeneration of myofibers with variation in myofiber size
   Interstitial or perivascular mononuclear cells
5. Characteristic rashes of dermatomyositis
   Scaly erythematous eruptions over the metacarpophalangeal or interphalangeal joints (Gottron papules)
   Periorbital purplish discoloration (heliotrope rash)
   Erythematous scaly rashes over the face, neck (V-sign), upper back and arms (shawl sign), and extensor tendons (linear extensor erythema) and other extensor surfaces

Definite disease: all criteria 1–4, except for dermatomyositis, in which any three of the first four criteria plus the rash are adequate.
Probable disease: any three of the first four criteria, except for dermatomyositis, in which only two of the first four criteria plus the rash are adequate.
Possible disease: only two of the first four criteria, except for dermatomyositis, in which only one of the first four criteria plus the rash are adequate.

TABLE 42.1. Criteria for Diagnosis of Idiopathic Inflammatory Myopathy

The first criterion is symmetric proximal muscle weakness, which is present in nearly all patients at some time during their illness. The second is electromyographic (EMG) abnormalities characteristic of inflammatory myopathy. Although most patients show one or more of these EMG abnormalities, they may be focal and present only in paraspinal muscles. Elevated serum levels of muscle-associated enzymes is the third criterion. These include creatine kinase (CK), aldolase, lactate dehydrogenase (LDH), and the transaminases. All these enzyme levels generally correlate with one another, but, despite the presence of intense focal muscle inflammation, they may be normal in some patients at all times in the disease course, close to the onset of symptoms, after the initiation of therapy, during remission, or after chronic severe myositis associated with significant muscle atrophy. The fourth criterion is histopathologic evidence of chronic muscle inflammation: a muscle biopsy specimen showing degeneration, necrosis, and regeneration of myocytes; phagocytosis; and chronic inflammatory infiltrates composed of interstitial or perivascular mononuclear cells. If not guided by magnetic resonance imaging (MRI) or ultrasound, the biopsy specimen may appear normal or be nondiagnostic (67), because of the focal distribution of the pathologic changes in the untreated patient, or because of the effects of therapy. Patients with dermatomyositis demonstrate the fifth criterion, the characteristic rashes of the disease. The classic pathognomonic signs include scaly erythematous papules overlying the metacarpophalangeal and interphalangeal joints (Gottron papules), or overlying the elbows, knees, and malleoli, and a purplish, often edematous, discoloration around the eyes (heliotrope rash) (Fig. 42.1). Other rashes that are characteristic of (but not limited to) dermatomyositis include erythematous scaly involvement of the face, neck, and anterior part of the chest (V-sign rash), of the shawl area (shawl sign rash), and over extensor tendons, particularly of the hands (linear extensor erythema). Evidence of dilated capillaries can be seen on the eyelid margins, the palate, gingiva, and edge of the nail-folds in many children and a smaller proportion of adults with dermatomyositis.

Figure 42.1. Clinical manifestations of the idiopathic inflammatory myopathies. **A:** The rash of a child with juvenile dermatomyositis, displaying periorbital erythema crossing the nasal bridge with edema and microinfarcts of the upper eyelids and the skin under the eyebrow. **B:** Linear extensor erythema and Gottron papules seen in an adult with dermatomyositis. **C:** Cuticular overgrowth and vasculitic changes at the nailbeds in an adult with dermatomyositis. **D:** Mechanic's hands: scaly, cracking skin over the lateral and palmar aspects of the fingers are commonly seen in adult patients with myositis associated with antisynthetase autoantibodies.

Inasmuch as a number of disorders may satisfy one or more of these criteria, the history and physical examination must be carefully performed to exclude the many entities that can closely mimic IIM (Table 42.2). Some of these diseases can be differentiated based on the clinical setting in which they occur, and others, by laboratory and muscle biopsy findings. Many of these disorders have an inflammatory myopathic component, but one of the pathologic features distinguishing IIM and its mimics is that in the latter, the inflammation is secondary to another cause of myopathy. In general, this secondary inflammation is indicated by the presence of polymorphonuclear cells or macrophages surrounding previously damaged myocytes in muscle biopsy specimens. In contrast, inflammation in IIMs appears as the primary event, with mononuclear cells surrounding and invading otherwise normal-appearing muscle cells.

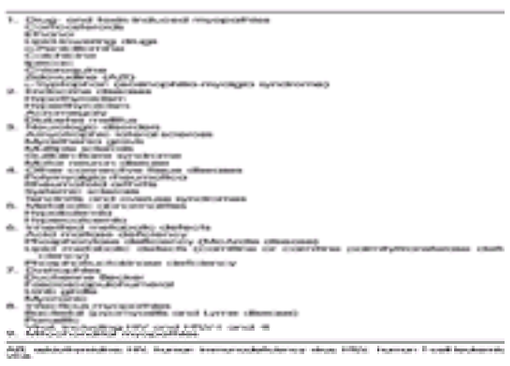

TABLE 42.2. Differential Diagnosis of Idiopathic Inflammatory Myopathy

The recent discovery of a group of autoantibodies only seen in myositis patients (the *myositis-specific autoantibodies*) (MSAs) (42) and the information that MRI provides in assessment of muscle inflammation and damage (75) have improved our capacity to diagnose and treat certain individuals with IIM. These findings, as well as other aspects of the IIM, including genetic testing, markers of immune activation and tissue damage, should undergo assessment of their usefulness in the development of new, more sensitive and specific classification criteria for the IIM (87). Recent advances in understanding the genetic basis for many of the metabolic and dystrophic myopathies should allow development of more accurate genetic diagnostic tools to help distinguish the IIMs from these other often difficult to diagnose disorders.

EPIDEMIOLOGY

In a global sense, the IIM syndromes are some of the most rare causes of myopathy and are far less common than the inflammatory myopathies that occur as a result of bacterial or parasitic infection and are prevalent worldwide. Although many epidemiologic studies of IIM combine polymyositis and dermatomyositis, recognition of some of the rarer variants, particularly inclusion body myositis (IBM), has occurred only recently. Nonetheless, IBM is likely the most common form of idiopathic myositis in persons older than 50 years (19). There appears to be a bimodal age distribution of onset in individuals with IIM. One peak occurs at ages 5 to 14 years, and the other at 45 to 64 years (48). In 1970, the incidence of these diseases was estimated to be 1.0 to 3.2 cases per year per 1 million white Americans and 7.7 for black Americans (48), but more recent data suggest that the incidence and prevalence have been increasing over the last three decades (56). Mortality appears to be influenced by age and gender; nonwhite females seem to have the highest mortality, and children with IIM seem to have a low mortality rate (30,31).

The incidence of juvenile dermatomyositis has just been established as 3.1 per million children per year for white, Hispanic, and African-Americans (50); it is 10 to 20 times more common than polymyositis. The child with juvenile dermatomyositis tends to have a more acute and severe onset (24), after an antecedent infection, which is often upper respiratory (66). The rash precedes identification of weakness in 50% (67). Seasonal factors may be related to the onset of symptoms in adults with polymyositis, as suggested by one study from Greece (45). In both the pediatric and adult myositis populations overall, there is a female predominance of about 2:1, although this may vary with specific ethnic background.

CLASSIFICATION

Once the heterogeneity of these patients was recognized, attempts were made to categorize them into more understandable groups. Although many classifications have been proposed, we have found that the most useful one incorporates both clinical and serologic information (Table 42.3). As helpful as the clinical classification of IIM has been, recent data suggest that dividing patients into serologic groups based on the presence or absence of certain autoantibodies found only in myositis patients, the MSAs, results in even more homogeneous patient groups (41).

Clinical classification
Primary idiopathic polymyositis
Primary idiopathic dermatomyositis
Myositis associated with another connective tissue disease (overlap myositis)
Myositis associated with cancer
Juvenile myositis
Inclusion body myositis
Miscellaneous myositis (eosinophilic, granulomatous, focal nodular, ocular, and others)
Serologic classification[a]
Myositis associated with antisynthetase autoantibodies
Myositis associated with anti-M-2 autoantibodies
Myositis associated with anti-signal recognition particle autoantibodies
Myositis associated with other myositis-specific autoantibodies[b]
Myositis without any of the above-mentioned autoantibodies

[a] See Table 42.6.
[b] Including anti-MAS, anti-PL12, and other autoantibodies (see Table 42.6)

TABLE 42.3. Classifications of the Idiopathic Inflammatory Myopathies

The MSAs are directed against and inhibit the function of translational components, proteins, and ribonucleic acids involved in the process of protein synthesis (51). Members of this family of autoantibodies include autoantibodies directed against one of five aminoacyl-transfer RNA (tRNA) synthetases, alanyl-tRNA, elongation factors, proteins of the signal-recognition particle (SRP), nuclear helicases, and several RNAs and proteins not yet identified. In addition to their interesting immunologic aspects, the myositis-specific autoantibodies have clinical utility in helping to assess the diverse signs and symptoms of patients with myositis and by assisting in their therapy. This is because each of these autoantibodies is associated with particular epidemiologic, clinical, immunogenetic, therapeutic, and prognostic features. Thus patients with each of these autoantibodies can be considered to have different syndromes that share the common feature of chronic inflammation in muscle.

CLINICAL FEATURES

Primary Idiopathic Polymyositis

Patients with myositis have many nonspecific symptoms that may complicate and delay diagnosis and treatment. Symmetric, progressive, proximal muscle weakness, however, is the primary clinical finding in polymyositis. It most often develops subacutely over weeks to months, but can develop acutely over days or insidiously over years. Patients often complain of an inability to climb stairs, arise from a seated position, reach for heavy objects, or comb their hair. Although proximal muscles of the neck, shoulders, and hips are more commonly and more severely affected, distal muscles of the limbs also can be involved. Some patients have fatigability of muscle function, and others have myalgias that limit their activity and that make assessment of true weakness difficult. As a group, patients with polymyositis have the most severe myositis and have the poorest response to therapy, compared with all other clinical subsets (41).

Myositis patients may have involvement of other organ systems that can alter the presentation and prognosis (Table 42.4). The systemic nature of these diseases is seen in general symptoms such as fatigue, fever, and malaise, or by pathology in specific organ systems. Cardiopulmonary involvement, with arrhythmias, dyspnea, or interstitial pulmonary infiltrates, is an especially worrisome, poor prognostic sign. Dysphagia or vasculitis affecting the gastrointestinal tract may be so severe as to require nasogastric feeding or parenteral nutrition, but is more commonly reflected in nasal speech, reflux symptoms (which may associated with change in the quality

of the voice), or gastrointestinal bleeding.

TABLE 42.4. Systemic Manifestations of Idiopathic Inflammatory Myopathy

Primary Idiopathic Dermatomyositis

Patients with dermatomyositis are distinguished from those with polymyositis by the skin changes described previously. The rash can precede, develop concurrent with, or follow the development of muscle weakness. Furthermore, the rashes can change over time. Occasional patients have classic dermatomyositis rashes and some other organ manifestations of connective tissue disease such as arthritis or interstitial lung disease, but clinical muscle weakness does not develop. This condition has been referred to as *amyopathic dermatomyositis* or *dermatomyositis sine myositis*. A number of these patients do have evidence of mild myositis, as demonstrated by minor enzyme elevations, by mild EMG or histologic changes (17), or by the appearance of the muscles on MRI scans (21). They may develop other symptoms of chronic disease (e.g., loss of range of motion) over time. The disease severity and responsiveness of dermatomyositis patients as a group tend to be intermediate between those of polymyositis and myositis-overlap patients.

Myositis Associated with Another Connective Tissue Disease

Patients may meet all the criteria for IIM and those for another connective tissue disease. These patients, sometimes referred to as having *overlap myositis*, most frequently have myositis in association with systemic sclerosis, systemic lupus erythematosus, or rheumatoid arthritis (adult patients who are rheumatoid factor positive or negative as well as seronegative patients with systemic-onset juvenile rheumatoid arthritis can be seen in this category). In addition, virtually any of the many rheumatic and autoimmune disease syndromes may be present (70). Because the myositis in these patients is generally the mildest of all the clinical myositis groups and most easily treated, these patients have a relatively good prognosis (41).

Myositis Associated with Cancer

Patients with both myositis and cancer have been recognized for more than 70 years, and the incidence of malignancy in these patients has been estimated to be up to 5 times that of the general population. Patients older than 40 years who have dermatomyositis appear to be at the greatest risk of cancer. A recent large population-based study estimated the risk of cancer to be 1.8 times higher in people with polymyositis and 2.4 times higher in those with dermatomyositis, although all forms of malignancy were reported to be roughly in the same proportion as in the general population (84). Although cancer can precede, develop concurrently, or follow the myositis, most cases occur within 2 years of the onset of myositis. Further evidence that the cancer is associated with the pathogenesis of myositis is provided by the finding that in some patients, surgical removal of the cancer can result in complete resolution of all signs and symptoms of myositis, and conversely, the return of the cancer is often heralded by the recurrence of myositis. The prognosis of these patients depends greatly on the prognosis of their cancer, as this is the primary cause of their death.

Although the association between cancer and myositis is well established, the more important question is how to approach the new patient with myositis in this regard. Our experience is that a thorough history and physical examination, with careful attention to any abnormalities suggestive of malignancy, will detect most cancers. The most useful tests include chest radiograph films; stool guaiac studies; mammography; careful lymph node, breast, and pelvic examinations; and in women with risk factors for ovarian cancer, abdominal ultrasound with serum levels of CA-125 antigen. Multiple x-ray studies or invasive procedures screening for cancer without a clinical reason are unlikely to be beneficial.

Juvenile Myositis

In children, acute infectious myositis can be distinguished from a chronic inflammatory process by the propensity of the former to be characterized by severe pain in calf muscles, which rapidly resolves in 1 to 4 weeks (49). This acute myositis, often accompanied by myoglobinuria, EMG changes, and CK elevations, is frequently associated with identification of influenza A and B on viral culture (14) and muscle biopsy specimens (22). In contrast, the onset of myositis in juvenile dermatomyositis is often insidious and may be preceded by a recurrent photosensitive dermatitis (92), low-grade fever, or both. Prominent physical findings include soft palatal weakness, resulting in a nasal tonality in speech that often has a raspy quality, and a positive Gower sign in addition to symmetric proximal muscle weakness. Vasculitis is the hallmark of this illness and is reflected by abnormal nail-fold capillaries (85), capillary thrombosis (2), and dropout (7), with occasional subsequent infarction of affected tissue, including skin, muscle, and gastrointestinal tract (11). The focal distribution of disease is revealed by MRI (Fig. 42.2) (34), which may assist in identification of a biopsy site and may explain cases with obvious symptoms but normal histology. Studies of lung function may show only a restrictive ventilatory defect (64), without impairment of perfusion or evidence of pulmonary fibrosis. One of the most useful associations with a global assessment of disease activity is the increased proportion of peripheral blood B cells (percentage CD19) (60), which are not activated (61). The increased %$CD19^+$ is frequently associated with a decrease in circulating $CD8^+$ cells, often resulting in an increased CD4/CD8 ratio. The extent of vasculitis may be associated with elevated plasma levels of von Willebrand factor antigen (82); the inflammatory component may be reflected by elevated neopterin, a macrophage-derived cytokine (91). Levels of one or all the muscle-associated enzymes may be elevated. An increased erythrocyte sedimentation rate and leukocytosis occasionally are seen, and immunoglobulin M (IgM) may be increased early in the disease (62). The most common autoimmune serologic marker is an antinuclear antigen (ANA), which is seen in a speckled pattern in more than 60% of patients with juvenile dermatomyositis (65). The specific antigens to which these antibodies bind have been identified in only 10% of children (20); the most common identified autoantibody in these patients, known as anti–Mi-2, is directed against a 220-kd nuclear helicase that is a component of a complex of nuclear proteins. This serologic subgroup appears to have a milder disease course (88). In addition to anti–Mi-2 autoantibodies, all the other MSAs, including anti-SRP and the anti-synthetases that were originally identified in adults, also occur in children (80).

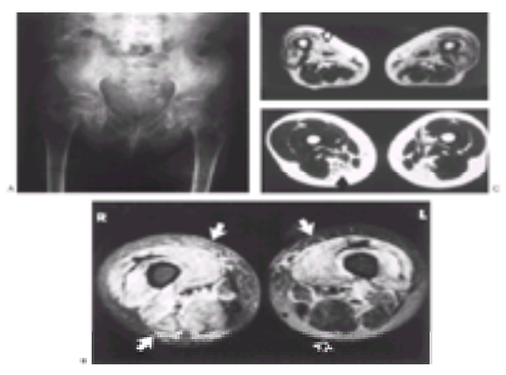

Figure 42.2. Radiographic findings in the idiopathic inflammatory myopathies. **A:** Radiographic evidence of extensive soft tissue calcification in a child with active juvenile dermatomyositis (JDM), which continued over several years. There is marked osteopenia. **B:** Magnetic resonance image (MRI) (T_2-weighted with fat suppression) through midthigh of a child with JDM. There is diffuse abnormal high signal within the quadriceps muscle group and the hamstring muscle group on the right (*arrows*). There is normal signal and relative sparing of the hamstring muscles on the left (*open arrow*). **C:** MRI (T_1-weighted) of long-standing inclusion body myositis. **Top:** Significant symmetric atrophy of the anterior thigh muscles and fatty replacement of many of the other muscle groups. **Bottom:** Clinically active adult dermatomyositis showing involvement of the posterior thigh muscles. (From Fraser DD, Frank JA, Dalakas M, et al. MRI in inflammatory myopathies. *J Rheumatol*

1991;8:1693, with permission.)

Delay in diagnosis and therapy with the consequent increase in disease duration and severity is associated with an increased frequency of soft tissue calcifications, usually at pressure points (6), which occur in 20% to 30% of affected children (67). The calcifications in patients with juvenile dermatomyositis have the same crystalline structure as those seen in patients with scleroderma. g-Carboxyglutamic acid, a component of the vitamin K–dependent pathway, is present in these calcifications; children with dermatomyositis have an increased urinary excretion of this compound (39). Early recognition of the symptoms of juvenile dermatomyositis and the prompt institution of aggressive therapy have decreased the occurrence of this serious complication. A prolonged disease course as well as the presence of pathologic calcinosis is associated with increased mononuclear cell production of tumor necrosis factor (TNF)-a and TNF-a–308A polymorphism at –308 in the promoter region of the TNFa allele in white children with juvenile dermatomyositis (68).

Inclusion Body Myositis

IBM is a recently described form of IIM affecting primarily older white men. It is characterized by: an insidious onset and progression; more distal and asymmetric muscle weakness than that seen in polymyositis; a tendency for atrophy of the anterior thigh muscles, which results in frequent falling; little extramuscular involvement; and a poor response to therapy (12,13,41). Patients with IBM generally meet the criteria for definite IIM, although the serum CK levels are seldom more than 5 to 6 times the upper limits of normal, and the EMGs often show evidence of both myopathy and neuropathy. The diagnosis is confirmed by the histologic finding of distinctive rimmed vacuoles in myofibers (Fig. 42.3). Without therapy, these patients gradually become restricted to the use of a wheelchair, and soon thereafter, they are bed bound. Possibly because they do not have the severe cardiac and pulmonary disease of other patients with myositis, deaths directly as a result of this disease are infrequent. As is the case for polymyositis and dermatomyositis, a few families appear to have a familial form of IBM (76). Another myopathy, not a member of the IIM group, is a related illness without muscle inflammation known as inclusion body myopathy. The inclusion body myopathy syndromes can be either sporadic or familial, and in the latter case, genetic diagnostic methods may be available in the not too distant future (15).

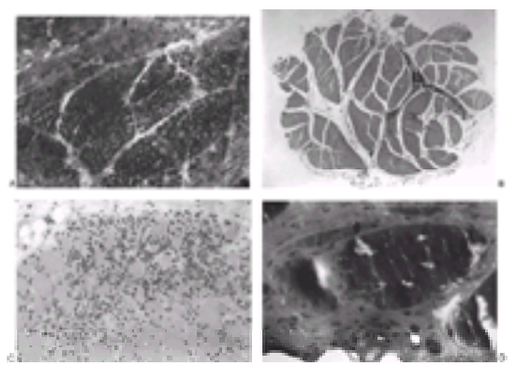

Figure 42.3. Histopathologic findings in muscle in the idiopathic inflammatory myopathies. **A:** A biopsy specimen of skeletal muscle from a child with dermatomyositis (trichrome stain) demonstrating perifascicular atrophy, fiber-size variation, vascular occlusion, and a perivascular infiltrate composed primarily of mononuclear cells. **B:** Adult dermatomyositis (trichrome stain) showing variation of myofiber size (reflecting degeneration and regeneration), perifascicular atrophy, increased interstitium, and scattered perivascular mononuclear infiltrate. **C:** Adult polymyositis (hematoxylin and eosin stain) showing variation of myofiber size and focal endomysial inflammation. **D:** Inclusion body myositis (high power, trichrome) showing the characteristic, purplish staining, rimmed vacuoles within the myocyte. (From Farid NR, Bona CA, eds. *The molecular aspects of autoimmunity.* Langhorne, PA: Harwood Academic, 1990.)

Myositis Associated with Antisynthetase Autoantibodies

Patients with autoantibodies directed against one of five aminoacyl-tRNA synthetases, enzymes that bind amino acids to tRNA in one of the early steps in protein synthesis, have been associated with what is known as the *antisynthetase syndrome*. The antisynthetase syndrome is characterized by myositis in association with a high frequency of interstitial lung disease, symmetric polyarthritis (which frequently mimics rheumatoid arthritis and involves the small joints of the hands, the wrists, and the knees), fevers, Raynaud phenomenon, and mechanic's hands (a scaling and cracking rash over the lateral and palmar aspects of the fingers; see Fig. 42.1). These patients tend to have an acute onset in the spring (38), a moderate response to therapy, but persistent disease and a flare of disease with taper of therapy, and a relatively poor prognosis (41). These patients can have polymyositis, dermatomyositis, or overlap myositis. Anti-Jo-1 autoantibodies, which are directed against histidyl-tRNA synthetase and are found in 20% to 30% of myositis patients (Table 42.5), are the most common antisynthetase autoantibodies.

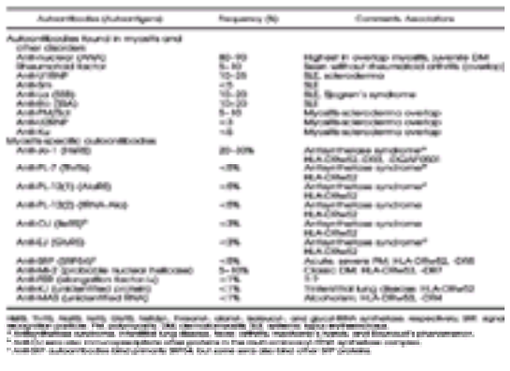

TABLE 42.5. Serologic Abnormalities in the Idiopathic Inflammatory Myopathies

Myositis Associated with Anti–Signal-Recognition Particle Autoantibodies

A different MSA binds to proteins of the SRP, a complex of six proteins and 7SL RNA that interacts with newly formed polypeptides on the polyribosome and moves them to the endoplasmic reticulum for processing. As a group, patients with anti-SRP autoantibodies have the most acute and severe myositis, usually beginning in the autumn, and the poorest response to therapy. These patients tend to have severe myalgias and, partly because of the high frequency of cardiac involvement, the poorest prognosis of all the serologic subsets (41). All patients with anti-SRP autoantibodies reported to date have been categorized in the clinical group of polymyositis (86).

Myositis Associated with Anti–Mi-2 Autoantibodies

In contrast to those of patients in the synthetase or SRP groups, the anti–Mi-2 autoantibody is directed against a nuclear protein, which is a helicase that is involved in regulating transcription, rather than a cytoplasmic protein involved in translation (83). They also differ from the other MSA groups in having relatively mild disease, with a good response to therapy. Patients in the Mi-2 group tend to have an acute disease onset; classic dermatomyositis clinically; an increased incidence of the V-sign rash, shawl sign rash, and cuticular overgrowth; a good response to therapy; and little extramuscular involvement (41).

CLINICAL EVALUATION

Because the differential diagnosis of muscle pain and weakness is extensive, it is important to be aware of a wide range of medical disorders that can result in muscle symptoms when evaluating these patients. First, it is important to define clearly the patient's problems. Is the patient actually weak or suffering from fatigue or pain that prevents performance of daily tasks? The characteristics and distribution of the weakness are often helpful. Is the weakness of acute to subacute onset, proximal, and

symmetric, as is usually seen in polymyositis and dermatomyositis; or slowly progressive and distal, as seen in several dystrophies and inclusion body myositis; or more focal and asymmetric, as can occur in other dystrophies? Is the weakness relatively constant, as in the IIMs, or is it intermittent and related to fasting or excessive activity, as in the case of certain metabolic myopathies? Weakness of the proximal leg muscles often results in difficulty climbing stairs, rising from a chair, and walking long distances. Proximal arm weakness usually causes problems in lifting objects, putting on heavy clothing, and combing or styling hair. The facial muscles are rarely involved in the IIMs affecting adults; in juvenile dermatomyositis, hoarseness, masseter involvement and atrophy can be seen (62), and the presence of difficulty in swallowing (often with penetration of the airway) indicates severe disease.

A review of systems may identify involvement of other organs, as manifested by pulmonary, cardiac, gastrointestinal, and skin symptoms. In children it is especially important to obtain a detailed family history to exclude the familial patterns associated with the various dystrophies and metabolic and mitochondrial myopathies. A careful history should be able to help the physician identify drug, toxin, or other exposures associated with myopathies (42). Symptoms and signs of endocrine disorders or infections should be confirmed by appropriate diagnostic testing.

The physical examination should focus on objectively defining the weakness and disability of the patient, by using a semiquantitative grading system. The cardiac, pulmonary, and gastrointestinal systems should be carefully examined for signs of involvement, and the skin and nail-beds checked for evidence of vasculitis or other abnormalities. The presence of pain on muscle compression should be noted.

Laboratory testing should include a complete blood cell count, measurement of electrolytes and CK and aldolase, as well as a general chemical survey that includes aspartate aminotransferase (SGOT), LDH, alanine aminotransferase (SGPT), and urinalysis. Testing for autoantibodies is often useful in evaluating patients with muscle weakness. The majority of adult patients with IIM have one or more autoantibodies (Table 42.5), and this distinguishes the IIMs from all the other forms of myopathy, in which autoantibodies are infrequent. ANAs are most common in IIM (41), usually seen in a coarse speckled nuclear pattern. In juvenile dermatomyositis, in addition to the positive speckled ANA, evidence of immune dysregulation is obtained by assessment of peripheral lymphocyte phenotype, which usually documents a lymphopenia, with an increased %$CD19^+$ B cells and increased CD4/CD8 ratio (60). EMG is frequently used to differentiate myopathic from neuropathic states.

A muscle biopsy with histochemical analysis is almost always indicated to confirm the diagnosis of IIM, as it provides critical information when the procedure is properly performed and the specimen properly processed. In addition to ruling out many of the mimics of the IIMs, different abnormalities and different distributions of inflammatory cells are seen in the various clinical groups. In dermatomyositis, the most characteristic finding is that the mononuclear cell infiltrate tends to be perivascular or perifascicular; in children with this disorder, occlusion of capillaries is prominent, and interfascicular fibrosis may be present. In both adults and children, atrophy of the myofibers at the periphery of the fascicle (perifascicular atrophy) is a characteristic finding, and in very severe cases, is associated with infarction of muscle. In polymyositis, in contrast, the leukocytes tend to be located within scattered, single myofibers, although sometimes the inflammatory infiltrate is extensive; perivascular inflammation and perifascicular atrophy are not usually present. Inclusion body myositis is diagnosed in a patient with myositis by the presence in trichrome-stained frozen muscle sections of characteristic reddish inclusions and vacuoles, which are rimmed by purplish granules (Fig. 42.3). Additional features include endomysial fibrosis, variation in myofiber diameter, and the presence of angulated fibers.

THERAPY

Corticosteroids are the mainstay of therapy for IIM. The timing, dose, and route of administration should be based on disease severity. Several factors are important in achieving responses to corticosteroids. In addition to the patient's clinical and autoantibody status, these include adequate initial dose (1 mg/kg/day or more) and continuation of prednisone until or after the serum CK level becomes normal in adults. In children, higher doses of corticosteroids are often used initially, and reduction of dose is guided by both the muscle enzymes and the immunologic data (normalization of neopterin, von Willebrand factor antigen, %CD19 cells). Children should be treated with a very slow rate of prednisone tapering. In adults, the reduction of prednisone therapy should average about 10 mg per month from the first reduction to the time that a maintenance dose is achieved (57). It is important to remember that corticosteroid responses in patients with myositis are generally slower and less dramatic than those seen in patients with systemic lupus erythematosus or rheumatoid arthritis, and improvement in strength may lag behind normalization of serum levels of muscle-derived enzymes by weeks to months. In the treatment of juvenile dermatomyositis, the dose, route, and duration of therapy are still controversial (44). Children with very active vasculitis often experience a decreased absorption of orally administered prednisolone, with less bioavailability compared with the same dose of methylprednisolone given by the intravenous route. Some data indicate that in this group of patients, in which vasculitis is a prominent feature, high-dose intravenous steroid therapy is associated with a more rapid resolution of disease and fewer adverse consequences of therapy (compression fracture, growth retardation, glaucoma). However, it remains unclear whether bolus corticosteroids and alternate-day steroid administration are useful in the majority of patients with IIM. The adverse effects of high-dose intermittent-pulse methylprednisolone have been identified in children and are variable (36). In children, osteopenia associated with decreased osteocalcin levels and bone mineral density (72) is found before therapy and can be exacerbated by administration of steroids, which suppress calcium absorption. In these children, administration of exogenous vitamin D and a calcium-sufficient diet, in addition to effective control of the inflammatory process, will increase bone mineral density and decrease the frequency of bone fracture (72). An eye examination is needed to evaluate the possibility of glaucoma, and to document the presence of cataracts, which may improve as the daily dose of corticosteroids is decreased.

Rehabilitation and physical therapy are very important in maintaining range of motion and preventing contractures during active disease. Exercise probably improves strength and endurance when initiated in a graded way during disease remission (29). Other immunosuppressive regimens have been tried in corticosteroid-resistant patients. Oral methotrexate and azathioprine are the major therapeutic options for corticosteroid-resistant patients. Which alternative is to be chosen is determined by the individual risk factors of each patient. Once patients are in remission, our experience with adults is that corticosteroid maintenance for periods of 6 to 12 months at 0.25 mg/kg every other day decreases the frequency of later flares of disease. In children with dermatomyositis, however, alternate-day steroid therapy does not appear effective either in the control of disease or in the prevention of flares. Methotrexate (intravenous or subcutaneously) given in conjunction with folic acid is helpful in moderately acute disease, whereas intravenous cyclophosphamide may be needed in critical conditions. Cyclosporine (28), intravenous gamma globulin (80), tacrolimus (58), or combinations of cytotoxics, particularly methotrexate and azathioprine (59), may be beneficial in some patients. A randomized double-blind, sham-controlled trial of apheresis failed to show any significant benefit after plasma exchange or leukapheresis in steroid-resistant patients with myositis not taking cytotoxic drugs (52). In patients with cutaneous involvement, hydroxychloroquine (7 mg/kg/day; maximal dose, 400 mg/day) and sunscreens with a sun protection factor (SPF) higher than 15, along with decreased sun exposure, can be useful for the treatment of the rash of dermatomyositis and the prevention of sun-induced disease exacerbation. No specific treatment besides therapy for the underlying myositis is known to improve the other systemic manifestations of the IIM. Patients in poor prognostic groups (patients with delays in diagnosis, older patients with acute severe myositis, cardiopulmonary disease, or dysphagia associated with myositis; the clinical group with polymyositis; or the serologic groups with antisynthetase or anti-SRP autoantibodies) should be considered for earlier and more aggressive therapy.

Part of the difficulty in defining appropriate therapy for myositis patients relates to the few reliable and objective measures of disease activity and damage (79). Although serum CK levels are often associated with levels of the other myositis-associated enzymes (aldolase, LDH, transaminases), all of these enzymes may not be elevated at the same time, and do not always accurately reflect disease activity (66). For example, they are not highly associated with the degree of weakness, rash and other extramuscular manifestations, or inflammation on biopsy specimens in some patients. This may be due to circulating inhibitors of CK enzyme activity (33), the focal nature of the inflammation, the effects of prior episodes of myositis on residual strength, the concurrent development of another cause of muscle weakness, and differences in rates of change with time among these factors. Serum CK levels, for example, often increase a few weeks to months before myositis flares are clinically evident, and often decrease before clinical improvement is recognized. The development of validated disease activity and damage-assessment tools for the IIM is an important step toward better future therapies (43).

ETIOLOGY AND PATHOGENESIS

The etiology of the IIM is by definition unknown, and the pathogeneses are still poorly understood, but intriguing findings suggest that environmental factors acting on groups of genetically predisposed individuals lead to immunologic activation and subsequent tissue damage. Predisposing genetic factors for all clinical forms of IIM in whites include human leukocyte antigen (HLA)-DR3 and -*DQA1*0501* (41,51,73,74). The relative risk for juvenile dermatomyositis is 3.8 for the white population with DR3 and 18.2 for those with *DQA1*0501*(73) and is similar for adult IIM (41, 51). The presence of TNF-a-308A in whites with juvenile dermatomyositis is associated with disease of a longer duration, and an increased frequency of pathologic calcifications (68). Immunogenetic risk factors, however, appear to differ in the different autoantibody groups (Table 42.5) (41) and in some ethnic groups (78). Further evidence for the importance of genetic susceptibility comes from the rare cases of monozygotic twins, siblings, and other family members with myositis, who can even share a common clinical group and autoantibody response (51). Newer molecular genetic methods that involve whole genome scanning (3), combined with family linkage studies (23), suggest that perhaps the same 20 or more regions located over the entire genome may be common risk factors for many autoimmune diseases. It is likely that these regions encode polymorphic genes regulating immune responses (immunogenetic markers) and the metabolism of environmental exposures (pharmacogenetic markers).

Anecdotal reports of the clustering in onset of myositis cases, as well as temporal associations with a growing list of infectious and noninfectious agents, have suggested strong environmental influences in the development of IIM. Environmental factors of interest include picornaviruses, for which there are supporting serologic, ultrastructural, animal model, and unconfirmed molecular hybridization data, and retroviruses, notably human immunodeficiency virus (HIV) and human T-cell lymphotropic virus type I (HTLV-I) (70). The different seasons of myositis onset in different clinical and autoantibody groups also suggest different environmental influences in different subgroups of patients (38). In juvenile dermatomyositis, case-control data document the presence of antecedent illness in the 3 months before the first definite symptom (rash/weakness) of disease (66); streptococcal exposure can induce disease flares (46). A growing list of noninfectious agents, including

foods and dietary supplements, drugs, biologic agents, excessive ultraviolet light exposure, and a number of occupational and other exposures have been reported in individual cases to be temporally associated with the onset of myositis. Much more work is needed in this area to confirm a true etiologic role of any of these agents (42). Cases of drug-associated myositis are the best-documented examples of environmentally associated myositis syndromes. The prototypic example of penicillamine-induced myositis is well-described entity that can exhibit similar clinical, serologic, laboratory, and pathologic findings as idiopathic myositis and usually resolves after discontinuing the medication. Of interest, the immunogenetic risk factors for the development of myositis after penicillamine exposure appear to differ from those of idiopathic myositis, suggesting that gene/environment interactions are likely important in the development of the environmental myositis syndromes (42).

Whatever the primary genetic and environmental risk factors are for the initiation of myositis, a growing body of evidence suggests that immunologic processes are central to the later aspects of pathogenesis. Many lines of evidence point to both humoral and cellular immune abnormalities in IIM patients (Table 42.6). Pathogenic mechanisms may be different in the different clinical groups. Muscle biopsy specimens from dermatomyositis patients show an early invasion of mononuclear cells, with prominent B cells present, with associated changes in the vascular endothelia, occlusion of capillaries, and deposition of components of the complement membrane attack complex (35). In contrast, patients with polymyositis or inclusion body myositis are characterized by higher proportions of activated T cells in their systemic circulation and within myofibers in muscle specimens (18,53). Both $CD8^+$ (suppressor/cytotoxic) T cells and DR^+ (activated) cells are seen surrounding and invading otherwise normal-appearing myocytes. However, there is evidence of peripheral blood T-cell activation [hypoxanthine-guanine phosphoribosyltransferase (HPRT) studies] (1) and oligoclonality of CRD3 region of the Vb8 T-cell receptor in muscle biopsies of untreated children (69), suggesting an antigen-driven response.

Autoantibodies (see Table 42.6)
Immunoglobulin and complement deposition in muscle
Hypergammaglobulinemia, hypogammaglobulinemia, and agammaglobulinemia
Circulating immune complexes
Cellular abnormalities
Activated MNCs and T cells expressing restricted receptors (TCR) in muscle
Altered peripheral MNC immunophenotypes
Altered peripheral MNC trafficking to muscle
Decreased autologous mixed lymphocyte and MNC mitogenic response
Proliferative responses of MNCs to autologous muscle
Increased cytokine expression in the periphery and target organs
Increased circulating levels of soluble cell markers (sIL-2R, sCD4, sCD8)
Altered expression of costimulatory molecules in target tissues

MNC, mononuclear cell; TCR, T-cell receptor; IL, interleukin.

TABLE 42.6. Immunologic Abnormalities in the Idiopathic Inflammatory Myopathies

Additional evidence for the role of T cells in the pathogenesis of IIM comes from *in vitro* stimulation studies that show that T cells from myositis subjects preferentially respond to autologous muscle. Studies of T-cell receptors in muscle biopsies demonstrate expression of restricted families of receptors with common motifs in different forms of IIM. Investigations of costimulatory molecules on the surface of myocytes suggest that the target cells themselves may act as efficient antigen-presenting cells for T cells that appear to traffic to and invade histologically normal myocytes (4,55,59,69).

The roles of the wide array of autoantibodies seen in myositis patients (Table 42.5) remain unclear, and there is no direct evidence to support a pathogenic role. However, indirect evidence for the involvement of some MSAs in disease pathogenesis includes the findings that they can be detected months before myositis onset, appear to be induced and sustained by conformational epitopes on the human autoantigen they target, and vary in titer with disease activity, sometimes becoming negative after prolonged remission (54).

Animal models are imperfect in reproducing the human IIM syndromes and provide limited insight into the susceptibility and pathogenesis of IIM. Familial canine dermatomyositis, first reported in 1984, affects collies and Shetland sheep dogs (25); skin and muscle involvement occurs in young animals and is preceded by circulating IgG-containing immune complexes (27). These dogs do not develop ANAs, but muscle specimens show a vasculitis and crystalline structures compatible with enterovirus in endothelial cells (26). Genetic susceptibility is suggested by some preference for DLA-D15 in these animals (27). In some murine strains, newborn animals develop myositis after injection with coxsackievirus B (32,70). This model is dependent on the presence of live virus and an intact immune response involving T cells (93). In addition, when myocarditis secondary to coxsackievirus was investigated, focal lesions were produced by $CD4^+$ T helper cells (9); the genetic background of the host appears to modulate the extent of damage seen on passive transfer (40). A model of adult polymyositis has been developed by using a myopathic variant of the encephalomyocarditis virus, a member of the cardiovirus subgroup of picornavirus (10).

CURRENT PROBLEMS AND FUTURE DIRECTIONS

Whereas advances in technology have afforded new insights into the pathophysiology of IIMs, they also have raised questions about the diagnostic criteria and classifications of these syndromes. For example, because the MSAs appear to define more homogeneous subsets of IIM patients, should these tests be added as an additional diagnostic criterion, and should they be performed routinely as part of the clinical evaluation? Should MRI also be part of the diagnostic evaluation of myositis patients? This radiologic approach permits a noninvasive *in vivo* functional analysis of large areas of muscle not possible by other methods and may help in defining clinical subgroups and in directing the site of biopsy (21). If so, what is the level of sensitivity and specificity of this procedure? The rate of change on MRI scans with clinical response to therapy and the correlation of MRI data with muscle histologic findings remain to be determined. MR spectroscopy, a noninvasive technology related to MRI, can measure the *in vivo* concentration of compounds in a given tissue. By analysis of the distribution of phosphate groups on different molecules involved in energy metabolism in muscle, biochemical abnormalities can be quantitated. These may relate to disease activity and may be different in various clinical subsets of patients.

Although both human and animal model data suggest that histocompatibility antigens play a role in disease susceptibility as well as in severity, there is no prospective evidence that disease severity or expression is also under immunogenetic control. If immunogenetics does play a role, then to what extent can this information be used in defining risk factors and potential immunotherapeutic approaches? Finally, at the heart of a current controversy, are infectious or noninfectious environmental agents responsible for IIM in some patients, and what is the relationship of these agents to the cardiomyopathies in humans? Studies of molecular mimicry in other conditions raise the question of whether shared epitopes between these environmental agents and muscle or skin targets in myositis might incite immunoreactivity.

We need to have better ways to assess disease activity, persistence, and outcome. In the future, various mediators of inflammation such as cytokines, cell-surface activation markers, hormones, and receptor levels may prove useful as adjuncts to traditional disease measures. We need better measures of disease outcome. Additionally, the effect of this group of diseases on socioeconomic, emotional, educational, and marital status has not yet been evaluated.

The establishment of national or international registries of newly diagnosed cases could provide important data on these rare diseases and could serve as a basis for multicenter studies. A registry including serum and tissue banking would add significantly to information available in areas ranging from genetic susceptibility to immune responses. As new knowledge emerges, this database could be accessed to validate and test new concepts and hypotheses.

Effective therapeutic options are quite limited. The optimal dose, route, and duration of therapy for all the current agents have yet to be well studied. Biologic agents may be useful in future therapy if inflammatory pathways in each disease subset can be characterized. Newer therapeutic approaches are urgently needed in these diseases that cause significant morbidity and mortality. These future modalities may include biologic mediators, monoclonal and antiidiotypic antibodies, cytokines, peptides, or autoantigen therapy.
