For many pollens, the relationship between the pollen count and symptoms of hay fever provides strong evidence for a causal nature and demonstrates that airborne allergen levels are relevant to whether symptoms will be present in allergic individuals (158,159,186,223,279). For the role of indoor allergens in asthma, where there is no clear seasonal variation, the evidence for a causal relationship is less direct. In 1965 Hill (92) listed the evidence that was needed to conclude that exposure to an environmental dust was causally related to a respiratory disease (Table 61.7). The association between dust mite allergens and asthma is complicated because there are two distinct phases to the relationship: sensitization and the subsequent development of bronchial hyperreactivity and symptomatic asthma (Fig. 61.7). For some of the criteria listed in Table 61.7, the evidence relates to the relationship between sensitization and asthma, whereas for others (e.g., the dose/response relationship), the evidence is about the relationship of allergen exposure to sensitization. Perhaps the most convincing evidence comes from what Hill referred to as experimental (i.e., provocation and avoidance studies). Given the increasing evidence that asthma is an inflammatory disease, it is striking that the only challenge to the lung that consistently induces this kind of eosinophil-rich inflammation is inhalation of allergen by an allergic patient. Challenges with sulfur dioxide, passive smoke, ozone, and viruses can produce changes in lung function but do not on their own produce an eosinophilic infiltrate (129), although there may be important interactions between the effects of these substances and the effects of allergen exposure. Thus exposures to rhinovirus and to ozone have been reported to enhance the subsequent response to allergen provocation. Studies now show that reducing the exposure to allergen of patients with asthma who are allergic to mites can reduce symptoms and decrease bronchial hyperreactivity. The studies are categorized as (a) those in which the patients are moved to a sanatorium (116,183,212,263,272) or a hospital room, and (b) those in which avoidance measures are carried out in the patient's house (64,151,268). These studies have indirectly provided evidence about the levels of mite allergen in a house at which symptoms and bronchial hyperreactivity are maintained. To be effective in a controlled trial, allergen must be decreased by about 90%, and the levels should be decreased below 2 µg group 1 mite allergen per gram of dust if possible. With these criteria for effective reduction, good evidence for efficacy is available for covering mattresses, washing bedding at 130°F, removing carpets, and treating carpets chemically with either benzyl benzoate or 3% tannic acid (86,135,165).

Criterion	Evidence
Strength of association	Odds ratios ≥ 7 (and ≤ 30) have been reported in many studies
Consistency of association	Dust-mite sensitization has been demonstrated among individuals with asthma in the Netherlands, United Kingdom, Denmark, Japan, Australia, Brazil, and United States
Specificity	Asthma is the only lung disease associated with exposure to mite (or cat) allergens
Dose response relation	At least four studies have shown a dose-response relation between mite allergen levels and the prevalence of sensitization
Temporality	In a prospective study, exposure to high levels of mite allergen preceded evidence of sensitization and asthma
Experimental evidence	
Challenge studies	Bronchial provocation of allergic individuals can produce bronchospasm, increased bronchial hyperreactivity, and eosinophil infiltrate
Avoidance studies	Sanatoria and hospitals; patients' houses

TABLE 61.7. Evidence for a Causal Relation between Dust-Mite Allergen Exposure and Sensitization and Asthma: Criteria of Hill

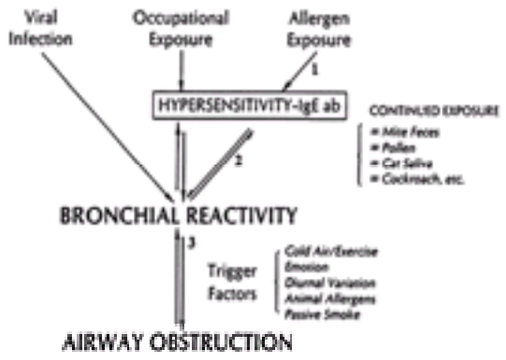

Figure 61.7. Role played by allergens in chronic asthma. The initial role of allergen exposure is in sensitization, including the production of immunoglobulin E (IgE) antibodies. For this phase (*1*), there is extensive evidence for a dose/response relationship. Patients who are sensitized are at increased risk for the development of such symptoms as rhinitis, asthma, and atopic dermatitis. However, the level of exposure necessary to induce symptoms or bronchial reactivity (*2*) varies widely among patients. Some individuals who have IgE antibodies are not aware of symptoms. Most of the triggers of acute asthma (*3*) are nonspecific, but some allergens can cause acute bronchospasm. The latter appears to be more common with allergens that are airborne on small particles (e.g., cat dander or rat allergens).

Threshold values have been proposed for several allergens. It is important to recognize the difference between these “thresholds” and those used for toxic chemicals. For chemical exposure, a threshold value is the level below which there is considered to be no risk. For allergens, the threshold value is a level below which 10% or fewer of the at-risk population develop sensitization (176,177,182,189). The other distinction is that with toxic gases (e.g., radon and formaldehyde), it is assumed that the whole population is at risk and that the risk of disease increases progressively with a dose above threshold. In contrast, with allergen exposure, “nonatopic” individuals are at low risk of sensitization or disease, even with high levels. Moreover, thresholds for sensitization may be different from thresholds for causing disease among sensitized individuals. It was initially proposed that 2 µg group 1 allergen per gram of dust was the threshold for sensitization to mite allergens (note: sensitization is not necessarily restricted to group 1 allergens), and that 10 µg group 1 allergen per gram of dust was a level above which individuals allergic to mites were more likely to have acute attacks (176,177,182). The proposed threshold for sensitization to mite allergens has been supported by numerous studies (40,127,218,226). In contrast, evidence for a simple relationship to symptoms is less clear. The fact that many allergic individuals do not develop asthma implies that for these individuals, the dose necessary to induce symptoms in the lungs is higher than that necessary to sensitize them. For other patients, including those with severe symptoms, the level of exposure necessary to induce symptoms is *lower* than that necessary to induce sensitization. Thus a simple threshold for symptoms may be less appropriate than one for sensitization. Indeed, the 10 µg/g level of mite exposure may be regarded more appropriately as a level above which those patients allergic to mites who are going to have symptoms do have symptoms.

THE MODIFIED Th2 RESPONSE TO ALLERGENS AS A MODEL OF TOLERANCE AND TARGET FOR IMMUNOTHERAPY

Allergic disease has increased dramatically in the last few decades and for reasons that remain largely unclear. Despite extensive speculation about a shift from Th1 responses early in life to those of a Th2 type, the evidence for Th1 responses to common allergens is limited to *in vitro* T-cell data. Thus there is very little evidence for high-titer IgG antibodies, delayed hypersensitivity skin tests, or lung diseases other than asthma. By contrast, there are now several clinical situations in which “tolerance” to an allergen has been demonstrated in the presence of an IgG4 antibody response. These include bee venom, rat urinary allergen, the response to immunotherapy, and most recently, the response to Fel d 1 among children living in a house with a cat. Among a cohort of children living in the United States, those children whose houses had more than 20 µg Fel d 1 per gram of dust were *less* likely to be sensitized to cat allergen (228). In this study, the prevalence of IgG antibodies correlated closely with exposure, and was predominantly of the IgG4 isotype; in contrast, the prevalence of IgE antibodies was decreased at higher allergen levels. These findings are in keeping with a “modified Th2” response (184). As mentioned earlier, previous evidence from Aalberse et al. (1) showed that the immune response to immunotherapy and the response of beekeepers to phospholipase A_2 is characterized by a predominance of IgG4 antibodies. Inducing a modified Th2 response with increased IgG4 and decreased IgE antibodies may be a more attractive immunotherapeutic strategy than stimulation of a cell-mediated Th1 response that has the potential to induce tissue damage.

CONCLUSIONS

Allergens are those antigens that commonly give rise to an IgE antibody response in humans. In keeping with animal models, this form of immune response is most often induced by repeated “low-dose” exposure to allergens such as pollens, fungal spores, cat dander, and mite fecal pellets. The word “allergen” is commonly used to describe either the source (e.g., ragweed pollen) or the purified protein (e.g., Amb a 1). Studies with purified allergens have shown that the immune response to allergens includes IgG and IgA antibodies, a T-cell response, and IgE antibody. With the development of protein and DNA sequencing, it has become possible to study the nature of allergens and the epitopes that react with T cells and IgE antibodies. In keeping with their sources, allergens are a very diverse group of proteins. Although many allergens are enzymes and several groups of related proteins have been defined, no characteristic features that relate to allergenicity have appeared. An allergen is best defined as a soluble foreign protein of 5 to 80 kd that is inhaled (or ingested) repeatedly, so that it commonly gives rise to IgE antibody responses in individuals who are genetically predisposed.

The purification of allergens has made it possible not only to study the properties of the allergen but also to measure the concentrations in extracts and in the environment. For the indoor allergens, in which none of the airborne particles can be identified microscopically, measurement of major allergens has proved important for quantitating exposure and analyzing the particle sizes of airborne allergens. This technique in turn has provided better understanding of the ways in which allergens contribute to asthma and of the appropriate measures to control exposure. Measurement of mite, cat, and cockroach allergens in houses has provided quantitative data about the relationship between exposure and sensitization. For dust mite allergens, these measurements have suggested a threshold for exposure above which the risk of sensitization is increased. These results provide important evidence about the role of allergens in asthma. By contrast, for cat allergen exposure, the dose/response relationship is not simple, and high exposure can induce a form of tolerance. Thus threshold levels cannot be simply applied to cat exposure. Understanding the role of allergens in allergic disease is directly relevant to several aspects of treatment; evidence about exposure has provided a scientific basis for evaluating methods of allergen avoidance in the treatment of asthma. In addition, the measurement of major allergens provides an objective method for standardizing allergen extracts, using micrograms of allergen per milliliter. Methods of this kind are increasingly being adopted in Europe. Finally, with molecular biology techniques, it is now possible to define epitopes on allergens that interact with T cells and B cells, thereby allowing the design of peptides or altered molecules as treatments that act selectively on T cells. Thus advances in understanding the proteins that give rise to immediate hypersensitivity have provided a cornerstone for investigating allergic disease.

62 GENETICS OF ALLERGIC DISEASE

Deborah A. Meyers, Ph.D., Timothy D. Howard, Ph.D., and Eugene R. Bleecker, M.D.

It is now generally accepted that there exists a genetic component to many common chronic disorders, including both allergy (atopy) and asthma. Studies are in progress to determine which genes, and which polymorphisms within these genes, are responsible for increasing an individual's susceptibility to allergic diseases. Most likely, multiple genes interact with each other and with environmental factors to produce atopic disease (Fig. 62.1). Additionally, individuals with symptomatic allergies may have specific gene variants that influence the progression (or severity) of the disease and even the response to treatment (pharmacogenetics).

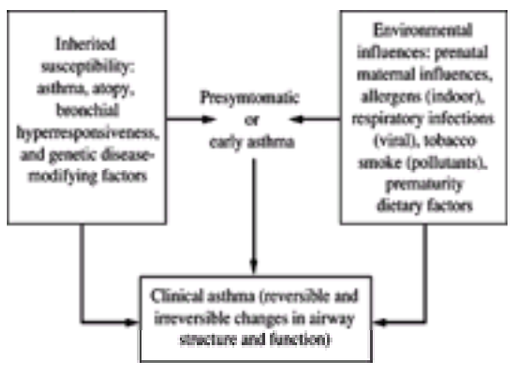

Figure 62.1. Gene/environment interactions in the development of childhood asthma.

Delineation of the role of genetics in allergy and asthma will further our understanding of the pathogenesis of these disorders (Table 62.1). Genetic tests in conjunction with phenotypic information in a specific family may be useful in early disease diagnosis, possibly even before symptoms occur, when preventive strategies may be appropriate. Better understanding of the disease process and the nature of the genes in the development and expression of atopic disorders involved also may lead to new therapeutic approaches. Thus these studies have widespread public health implications, given the high frequency of allergies in the general population.

• To understand the heritable component of the disease or trait and gene-environment interactions
• Elucidate important disease mechanisms
• Develop new therapeutic interventions
• Develop methods for early diagnosis and disease prevention

TABLE 62.1. Benefits of Genetic Studies in Allergy and Asthma

PHENOTYPE DEFINITION

In performing genetic studies, it is first necessary to clearly define the phenotype(s) (trait or disease) that will be studied; such definition as this is an important part of the overall experimental design (Table 62.2). It is reasonable to ascertain populations (e.g., families) through one or multiple index cases, or probands, who are affected by recognized standards, which should be clearly defined by standardized methods. Issues often arise regarding the affection status of relatives who have only some of the disease characteristics. For example, the “allergic” phenotype can be defined in several ways, ranging from a definition based solely on symptoms or objective measures such as total serum or specific immunoglobulin E (IgE) levels and/or response to allergen skin tests, to the combination of both subjective (symptoms) and objective traits. Multiple accepted definitions may exist, but a clear definition must be provided so that the results and potential differences between studies can be distinguished.

• Identification of a population
• Clinical assessment
• Linkage analysis: genome screen
• Fine mapping and gene localization
• Identification of the gene and the relevant sequence variant
• Gene-association studies
• Gene function and expression

TABLE 62.2. Steps Toward Finding a Susceptibility Gene for Allergy and Asthma

In studies of common disorders such as allergy and asthma, where interactions between genes and environmental factors are involved, associated phenotypes, which may be easier to measure objectively, are often used. For example, high total serum IgE levels have been shown to correlate with the clinical expression of allergy and bronchial hyperresponsiveness, which is an important component of allergic and asthmatic phenotypes (1,2,3 and 4). Therefore the results from positional cloning studies of total serum IgE levels may provide important information on susceptibility genes for both allergy and asthma. Identifying gene(s) and sequence variants for the regulation of total serum IgE levels represents one component (possibly a very important component) in the overall complicated processes involved in the development of allergic diseases.

In addition to total serum IgE levels, other measures can be evaluated as associated phenotypes in genetic studies of allergy and asthma (Table 62.3). Often laboratory measurements such as total serum IgE, specific IgE levels, or skin-test responsiveness to common allergens are used in studies of allergy, and bronchial hyperresponsiveness is used in studies of asthma. The advantages of these measures are the ease in which they may be obtained in all family members or individuals in a specific population and the possibility of analyzing these traits as quantitative measures without having to specify a specific clinical cut point. In addition, it may be possible to define the overall allergic phenotype based on the various clinical and laboratory measures with statistical techniques such as principal component analysis. This analysis simultaneously incorporates data from multiple measures such as clinical history, skin-test responses, and specific and total serum IgE levels into one outcome measure (5).

Atopic parameters
Total serum IgE
Specific IgE
Allergen skin tests
Bronchial hyperresponsiveness
Direct (methacholine, histamine)
Indirect (adenosine, exercise, etc.)
Asthma
Physician diagnosis
Symptoms and laboratory results
Severity classification
Airflow obstruction and reversibility
Combinations of "atopic" and "asthmatic" parameters

IgE, immunoglobulin E.

TABLE 62.3. Possible Phenotypes

GENETIC EPIDEMIOLOGY

Twin Studies

For both allergy and asthma, twin studies have been performed to estimate the extent of the genetic contribution. Comparison of frequencies of different allergic and asthmatic phenotypes in monozygotic (MZ) versus dizygotic (DZ) twins suggests the presence of a strong heritable component because MZ twins have the same phenotype more often than do DZ twins (6,7). However, twin studies are not useful for gene mapping or positional cloning studies because MZ twins share identical genotypes; DZ twin families may be used, but these twins are equivalent to full siblings, who are usually easier to ascertain.

The observed difference in the level of a quantitative trait in members of MZ versus DZ twin pairs provides information on the degree of heritability, whereas the difference observed between members of a MZ twin pair is more reflective of environmental influences. For example, in a study by Hopp et al. (8), the intrapair correlation coefficient for total serum IgE levels was 82% in 61 MZ twin pairs and 52% in 46 DZ twin pairs, giving a heritability estimate (the ratio of genetic variance to the observed total variance) of 0.61. This result provides strong evidence for a genetic component; however, the nongenetic component caused by environmental factors is still substantial. These estimates should be interpreted with caution, because the extent of the environmental components may vary in different individuals and populations. For example, in families or in a population that is exposed to a homogeneous environment, the estimate of heritability will be higher (smaller environmental component) than that in those exposed to a less homogeneous environment, even if the genetic component is the same.

Risk to Relatives

Significant evidence of familial aggregation also provides evidence for a genetic component to the phenotype, although aggregation also is influenced by common environmental factors or by an interaction of environmental and genetic factors. The risk ratio (l), which is the relative's risk compared with the prevalence of the disease or trait within the general population, is often used to estimate the degree of familial aggregation. These risk ratios can also be used to estimate the number of chromosomal loci involved in the disorder (9). However, the accuracy of these odds ratios is sensitive to the accuracy of the overall population prevalence (which may differ significantly between populations and is dependent on phenotype definition). In common disorders, such as allergies, risk ratios may show only a two- to threefold increased risk to a relative of an affected individual, supporting the presence of multiple genes.

Another method for evaluating evidence for a genetic component is to determine the correlation between family members for a quantitative trait. For example, a significant correlation between parents and offspring and between offspring was observed for total serum IgE levels in a study of more than 1,000 individuals from 200 Dutch families (10). An even stronger correlation was observed among siblings (p .001), supporting the presence of a strange genetic component for atopic phenotypes. A portion of this correlation was probably caused by environmental factors, although a significant correlation between parents (unrelated individuals) was not found. An interactive effect between genes and the environment also may be important.

Segregation Analysis

Segregation analysis may be performed to determine whether a specific genetic or environmental model explains the observed familial aggregation and may provide specific information on the mode of inheritance. The observed number of family members with the trait is compared with the expected number by using various models of inheritance, such as recessive, dominant, polygenic, codominant, and an environmental model. For example, the observation that children of two parents with elevated IgE levels also have high IgE levels suggests recessive inheritance of this trait. The frequency of children in such families with low levels would reflect the degree of incomplete penetrance of the susceptibility gene. To perform segregation analysis, families have to be ascertained in a standard manner that may need to be adjusted for in the segregation analysis. For example, all families in a specific study may be ascertained through one affected parent, but if they were selected though an affected parent and an affected child, the results will be biased in favor of a dominant model of inheritance. For genetic linkage studies, families are usually selected because of multiple affected members and are, usually, not appropriate for segregation analysis.

Another significant problem with segregation analysis is that usually only one- or two-locus models are fitted to the data, which are poor approximations to the true situation in common disorders that involve multiple genes (11). Therefore most recent studies concentrate on linkage analysis instead of segregation analysis.

When segregation analysis can be performed, it yields useful information pertinent to linkage analysis and gene identification. In segregation analysis, the best-fitting or most likely model of inheritance is determined by comparing the likelihoods from the different models tested (dominant, recessive, polygenic, or environmental) with the likelihood of the general model. Models that differ significantly from the general model can be rejected. Estimates of gene frequency and the frequency of each genotype as well as the degree of penetrance are obtained. The best-fitting model and parameter estimates are useful in subsequent linkage analysis. In numerous family studies, total serum IgE levels have been examined as a quantitative trait with segregation analysis (10,12,13,14,15,16,17,19 and 20), but there have been few segregation studies for other allergic or asthmatic phenotypes.

An analysis of data from 200 Dutch families is described as an example of segregation analysis for total serum IgE levels (10). These 200 families (1,171 family members) were ascertained through a parent (proband) who was initially evaluated between 1962 and 1975 at Beatrixoord Hospital, Haren, the Netherlands (a regional referral center for patients with asthma and other obstructive airways diseases). Patients with symptomatic asthma without a current asthma exacerbation were referred to this hospital and admitted for a standardized allergy and pulmonary evaluation. At the time of initial testing, all probands had asthma symptoms, were hyperresponsive to histamine (PC_{20} FEV_1 histamine £32 mg/mL, 30-second method), and were younger than 45 years. Among the 200 families, 166 families consisted of two generations, 33 families of three generations, and one family of four generations. Total serum IgE (IU) was measured by solid-phase immunoassay (Pharmacia IgE EIA: Pharmacia Diagnostics). Log (total serum IgE levels) were used because they are approximately normally distributed. Because log(IgE) values were higher in male subjects and in younger individuals, the effect of sex and age was included in the segregation analyses.

In the one-locus segregation analysis, both the sporadic model and mixed environmental model were rejected. Although single-gene models were rejected, several mixed mendelian models (major gene plus a residual effect) were not rejected. The mixed recessive model (i.e., a major recessive gene and with significant residual genetic effects) was the best-fitting (p = .75) and the most parsimonious model, although only slightly better than the mixed additive model. The estimate of the gene frequency q_a (corresponding to a high IgE level) under the mixed recessive model was 0.57, which results in genotype frequencies of 0.68 for *AA/Aa*, and 0.32 for genotype *aa* (assuming Hardy-Weinberg equilibrium). This recessive gene had a large effect on IgE levels and was responsible for 32.4% of the adjusted $\log_{10}$(IgE) levels in these families. The mean IgE level for genotype *aa* (μ_{aa}) was estimated to be 209 IU/mL, significantly higher than the mean (29 IU/mL) for the other genotypes (μ_{AA}, μ_{Aa}) and a clinically relevant value.

Because the control of IgE is probably regulated by more than one gene, a two-locus segregation analysis was performed; in this analysis, the mixed two major gene models (i.e., two major genes and residual genetic effects) fit the data significantly better than the one major gene model. Among the several mixed two major gene models that were tested, a model with a major recessive gene and a dominant modifier gene was the most parsimonious model. The estimate of the gene frequency for the first recessive gene (q_a) was 0.55, similar to the gene frequency of the mixed recessive model under one-locus segregation analysis. The estimate of gene frequency for the second dominant gene (q_b) was 0.8. The second gene modifies the effect of the first recessive gene so that a portion of the individuals who were homozygous for the high-risk allele at the first gene did not have high IgE levels. Individuals with genotype *aaBB* (homozygous for the high-risk allele at the first gene and homozygous for the low-risk allele at the second locus) had normal IgE levels (mean = 23 IU/mL), whereas individuals with genotypes *aaBb* and *aabb* (29.6% of the total sample) had high IgE levels (mean = 282 IU/mL). The two major genes were responsible for 51.3% of the adjusted $\log_{10}$(IgE) variance. The first gene was responsible for 40.6%, and the second gene was responsible for 9.0% of the observed $\log_{10}$(IgE) variance in these families.

In several other one-locus segregation studies, evidence for recessive inheritance of high total serum IgE levels has been observed (12,14,17,20). In a one-locus study of several large pedigrees, evidence also was obtained suggesting genetic heterogeneity in the mode of inheritance; the most parsimonious genetic model was different in the different pedigrees (19). From a study of the Amish community, which is genetically isolated and inbred, evidence for codominant inheritance was observed in an early study (18), whereas it was difficult to distinguish between models in a later study (21). Evidence for polygenic inheritance was obtained from a study of large Mormon families (22), who are more representative of the general population than are the Amish.

In each study, evidence was observed for a strong familial component to the inheritance of total serum IgE levels. The differences in the best-fitting model of inheritance and estimates of mean IgE levels and allele frequencies are not unexpected. They reflect differences between populations, ascertainment schemes, and analytic methodology for a trait, where there is substantial overlap between the distributions for individuals with low and high IgE levels. For example, in the one-locus study by Xu et al. (10), the recessive model was the most parsimonious, although the codominant model had a very similar likelihood. However, in a larger study, Martinez et al. (15) were able to estimate means and variances for three distributions, resulting in a codominant model of inheritance. Basically, this result reflects the difficulty in distinguishing between gene carriers (heterozygous individuals, “LH”) and homozygous family members (“LL” or “HH”).

Segregation studies also have been performed in nonwhite populations. A test for genetic heterogeneity across Hispanic and non-Hispanic white families was not significant; there was no evidence for a difference in the mode of inheritance between the two racial groups (15). Although a difference in gene frequency may be observed because of genetic variability in the founding populations, it was not surprising that no difference was found for this common trait.

The fact that evidence for a major gene was obtained from multiple single-locus segregation analysis does not mean that only one locus is involved in regulation of total serum IgE levels. Significant residual variance has been observed, suggesting an additional genetic influence. Two-locus segregation analysis was performed in the Dutch family study, and evidence for a second gene (dominant) was obtained (10).

There have been few segregation studies of allergic or asthmatic phenotypes besides studies involving total serum IgE levels. The evidence for a major gene for bronchial hyperresponsiveness (BHR) is less clear. In a family study of bronchial responsiveness to methacholine, evidence for a major gene was not found, but neither the genetic nor the environmental models could be excluded (23). In another study of the response to inhaled carbachol in 80 families with children with asthma, suggestive evidence for autosomal dominant inheritance with incomplete penetrance was observed (a formal segregation analysis was not performed) (24). In a sample of Dutch families, segregation analysis was performed for BHR to histamine (25). Ninety-two families ascertained through a parent, the proband, with asthma diagnosed approximately 25 years ago, were included in the analysis. Initially, no evidence for a major gene was observed; however, when IgE levels were included as a covariate, evidence for mendelian inheritance of a susceptibility gene for BHR with high penetrance was found. These data suggest that separate, yet interacting, genes for BHR and serum IgE levels may exist.

For the asthma phenotype, segregation analysis based on questionnaire data was performed and showed a strong familial polygenic component, suggesting the presence of multiple genes (26). This finding is not surprising and supports the complex genetic regulation in asthma and allergy. Unfortunately, there are limitations for segregation analysis in common disorders, because modeling three or four loci is not computationally feasible with currently available methods.

GENE IDENTIFICATION

General Approaches

Positional cloning has become easier to perform because of technologic developments that facilitate rapid and accurate large-scale genotyping at a reasonable cost (Fig. 62.2). However, identifying susceptibility genes for common disorders is still a major undertaking. Multiple study designs may be used in linkage studies in which families are used for positional cloning and gene identification. These approaches range from studies of only affected siblings to studies of multigenerational pedigrees. Families may be from a general heterogeneous population or a more genetically homogeneous or isolated population (possibly inbred) with a recent or more distant founder effect. As previously discussed, it may be useful to study associated phenotypes, such as total serum IgE levels, in all family members, as well as to evaluate the presence of symptomatic allergic disease. It also is important to consider the effect of age on the phenotype when studies are performed on individuals from different generations. For example, a young child may not have developed these disorders or traits, or it may not be possible to phenotype accurately a parent with a history of childhood asthma, who is now a smoker with evidence of chronic obstructive lung disease.

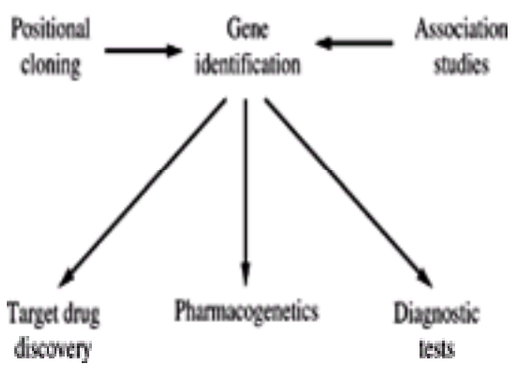

Figure 62.2. Approaches to identifying genes in allergic disorders.

A commonly used approach for gene-mapping studies is to ascertain and characterize affected siblings (or other types of relative pairs). In this study design, parents do not have to be phenotyped, and it is optional as to whether DNA samples are obtained from them. This design is often used for genome screening to identify chromosomal regions likely to contain susceptibility genes. For genomic screening, a large number (usually more than 300) of informative polymorphic DNA markers that span each chromosome at regular intervals (approximately 10 cM) are genotyped and used to define chromosomal regions linked to allergic or asthmatic phenotypes. This study design is useful because siblings are of a similar age and share similar environmental exposures compared with other types of relatives. It may be difficult to phenotype a parent because of other confounding factors or loss of phenotypic expression with age; and the environmental influences present when a parent developed the disorder may be quite different from the children's environmental exposures. This approach has been used by the U.S. Collaborative Study on the Genetics of Asthma (CSGA), in which families were ascertained through an affected sib pair [both with a doctor's diagnosis of asthma, the presence of asthma symptoms, and BHR (or reversibility if it was not appropriate to perform hyperresponsiveness testing)]. This was not strictly a sib-pair design because parents and other siblings were phenotyped and genotyped, and some families were extended to include additional relatives (27).

Large multigenerational pedigrees also may be studied and ascertained through one or more probands. For common disorders, different susceptibility genes may enter the pedigree through multiple individuals (spouses as well as the original founders). For example, a nuclear family (parents and children) may be extended to include a first cousin with asthma; however, it is possible that the genetic susceptibility is different in the first cousin and is due to genes transmitted from the parent married into the pedigree. Although these families are still useful in practice, it is difficult to allow for bilineal families in the analysis.

Studies of isolated and inbred populations, in which the relationships between the nuclear families are known and may be traced back to a small number of founders, are very useful; for example, the Old Order Amish in Pennsylvania (21) and the Hutterites in South Dakota (28). A subpopulation of the Hutterite community has been studied for asthma, atopy, and related phenotypes by Ober et al. (28). The family relationships are well documented, and, although individuals may leave the community, no one enters it. Thus the gene pool has remained closed over multiple generations. However, even in a closed population, multiple genes may be segregating for common diseases. The Pennsylvania Amish are a similar inbred population who have been studied for atopy and total serum IgE levels (21).

It also may be useful to study nuclear families from homogeneous populations with a known founder effect, even if the actual relationships between the families are not known. For example, homogeneous populations have been studied in northern Holland (29). These populations are especially useful for fine mapping studies, because it is more likely that a shared haplotype (small chromosomal region around a disease gene) will be detected over a small region, limiting the number of potential genes to be examined. Similar to genetic studies in inbred populations, the susceptibility genes that are present in a homogeneous population may be less common in larger heterogeneous populations. Thus it is essential to study different populations to replicate findings and to determine differences in gene frequencies.

Results of Genome Screens

In one of the first genomewide screens, 80 white families were studied and genotyped for 253 autosomal markers. Analyses were performed for multiple phenotypes related to atopy and asthma (30). Both log IgE and skin-test response showed evidence for linkage to chromosome 11, and log IgE levels showed linkage to chromosome 16. Evidence for linkage to log of the slope of bronchial responsiveness to methacholine was observed for chromosomes 4 and 7, with *p* values <.0005 (D4S426, D7S484). Evidence for linkage for log IgE levels also was obtained for chromosome 7, but none of the measures of the atopic phenotype (total serum IgE levels, skin tests, or total eosinophil count) showed evidence for linkage to chromosome 4. Both log IgE and skin-test response were linked to chromosome 11, and log IgE levels showed linkage to chromosome 16. The marker spacing used in this early study was broader, and the sample size was smaller (80 families) than those used in some of the later studies and, thus, may have decreased the power to detect genes with smaller effects.

A genome screen to map loci for asthma was performed by the Collaborative Study of the Genetics of Asthma using 320 markers at approximately 10-cM spacing in 261 affected sib pairs from different racial groups (African Americans, whites, and Hispanics) ascertained through two siblings with asthma (27). Affected family members met the same criteria for asthma as the probands, which included a physician's prior diagnosis of asthma, the presence of asthma symptoms, and evidence of BHR or reversibility of airflow obstruction. Evidence for linkage was seen in the African-American families for 5p15 (p = .001) and 17p11.1-q11.2 (p = .0015). In the Hispanic families, evidence for linkage to 2q33 (p = .0005) and 21q21 (p = .004) was seen, with preliminary evidence for 12q14-24.2 (p = .03). In the observed white families, the following regions were detected with *p* values <.01: 11p15, 12q14-24.2, 12q21.3-qter, 14q11.2-13, and 19q13. Two other regions had *p* values <.02: 5q23-31 and 6p21.3-23. Although multiple regions were detected in the white families, none had *p* values <.001. It is important to note that these are the results from the first 40% of the sib total sample and must be verified in the total sample.

A genome screen for asthma and BHR (approximately 300 markers) was performed in the inbred Hutterite population (361 individuals as the primary sample and 292 individuals in a replication sample) (28). The analysis was performed for four phenotypes: “strict” asthma, BHR, asthma symptoms and “loose” asthma (symptoms and/or BHR). Evidence for linkage was observed in both the primary sample and the replication sample for four chromosomal regions: 5q23-q31, 12q15-q24, 19q13, and 21q21 (p = .00091 for D5S1480, .0025 for D12S375, .010 for D19S178, and .033 for D21S1440 for the total sample).

In a multicenter German study, a genomewide scan with 351 markers was performed for 97 families with 156 affected sib pairs (31). Evidence of linkage to four regions of the genome (chromosome 2pter, 6p21.3, 9q, and 12q13) was obtained for clinical asthma D2S2298 (p = .0074), D6S291 (p = .0081), D9S1784 (p = .0073), and D12S351 (p = .0103). For BHR, similar results were found for chromosomes 2 and 9.

In the sample of 200 Dutch families, one- and two-locus segregation analysis was performed and provided evidence for at least two major genes that regulate total serum IgE levels. A genomewide screen was performed in these families for log IgE with variance component analysis, a method appropriate for quantitative trait mapping. LOD scores greater than 2 were obtained for chromosomes 3, 5q, 7, and 12 (10). In addition, a genomewide screen was performed for the BHR phenotype. The strongest evidence for linkage was observed on chromosome 5q in the same area reported previously with a candidate gene approach. Evidence for linkage also was observed for chromosome 3p (LOD = 2.8). Preliminary evidence was seen for three other chromosomes (1, 2, and 7) (32).

Multiple regions of the genome have been observed in several of the genomewide screens, and some of these regions also have been found in candidate gene studies. Replication of results is important because few studies are of adequate size to detect the multiple genes probably present for genetic susceptibility to asthma and allergy. Linkage to chromosomes 5q, 11, and 12q has been observed in multiple studies. Additional regions, including 6p and several others, have been observed but not replicated in other studies. However, even for replicated findings, it is not clear that the same regions are being detected in the different studies. For some chromosomes, the markers reported in different studies are at a significant distance from each other (for example, 30 cM). Possibly there are multiple susceptibility genes in a region. In addition, because of the genetic complexity of these diseases, it is difficult to model the disease accurately in the analysis, which makes it difficult to map the gene location accurately (Table 62.4).

Chromosome 5q	
	Total serum IgE and bronchial hyperresponsiveness mapping to 5q, a region with multiple proinflammatory candidate genes
Chromosome 6p	
	Associations between responses to specific allergens and HLA haplotypes
	Linkage of the asthma phenotype

	Patented gene isolated from small inbred island population
Chromosome 12q	
	Linkage of allergic and asthma phenotypes to multiple chromosomal regions

HLA, human leukocyte antigen.

TABLE 62.4. Proposed Chromosomal Locations for Susceptibility Genes for Asthma and Allergy

Chromosome 5q

Multiple studies, including studies in the Amish, Hutterite, and Dutch populations, have shown evidence for linkage to 5q for allergic and asthmatic phenotypes. This region on 5q contains many candidate genes involved in the regulation of IgE and the development or progression of inflammation associated with allergy and asthma [cytokines interleukin (IL)-3, IL-4, IL-5, IL-9, IL-13, and granulocyte/macrophage colony-stimulating factor (GM-CSF); b_2-adrenergic receptor; glucocorticoid receptor]. In the inbred and Amish population, linkage to chromosome 5q in the region of several of the cytokines was observed for regulation of total serum IgE levels (21). In the Dutch study, significant evidence for linkage was observed for total serum IgE levels, BHR, and asthma. In the white families in the CSGA study, preliminary evidence for linkage to this region of 5q was observed for the asthma phenotype (27). Strong evidence for linkage to 5q (D5S1480) was observed in the Hutterites (another inbred population) for the “loose” definition of asthma, which included individuals with asthma, BHR, or symptoms of asthma (28). Mapping to a region that contains many candidate genes makes it difficult to perform fine mapping studies because polymorphisms in several of these genes may have small effects.

Chromosome 6p

Multiple HLA haplotypes have been correlated with several measures of the allergic phenotype in a number of studies (33,34). Linkage to chromosome 6p has been obtained for a related phenotype (eosinophil count) in a genome screen of atopic families (30). In the CSGA white population, there was evidence for linkage to 6p for the asthma phenotype (27). The German genomewide screen for asthma-susceptibility loci also detected evidence for linkage to this region (31). Because many individuals with asthma are allergic, it is not clear whether the evidence for linkage to this region is due to the major histocompatibility complex (MHC) and its influence

on the allergic response or whether other susceptibility genes for atopy and asthma map to this region.

Chromosome 11q

Evidence for linkage of a broadly defined allergic phenotype to markers on chromosome 11q was first described in 1989 (35). In a later study, evidence was obtained that sequence variants in the FceRIb gene on 11q increases the risk for developing allergy and possibly even asthma (36). The sequence variant detected in their families (Leu181) has not been observed in several other studies including the Dutch family studies (37). However, there is continued evidence for linkage of the atopic phenotype to this region. Recently a patent was released reporting linkage to chromosome 11p (near the centromere) and the identification of two novel susceptibility genes found in an isolated inbred population of approximately 350 individuals living on a small south Atlantic island (Tristan da Cuhna). These genes are similar to members of the *ets* family of transcription factors. According to this patent, at least one polymorphism in one of these genes is associated with asthma. Until this finding is evaluated in other, more heterogeneous populations, it is not clear whether variations in this gene may explain the published linkage to this chromosome. This discussion illustrates the difficulties in accurately mapping the susceptibility gene and determining sequence variants that may confer a moderate increase in susceptibility.

Chromosome 12q

There is a broad region (possibly two regions) on 12q with strong evidence for linkage in multiple studies for several phenotypes associated with allergy and asthma, as well as for clinical asthma. Evidence for linkage for both asthma and total serum IgE levels was found in an Afro-Caribbean population, and for total IgE levels, in the Amish population (38). In the CSGA, evidence for linkage was observed for the asthma phenotype in whites (p = .004) and Hispanics (p = .026) but not in African Americans (27). In a sample of randomly ascertained families and a sample of families ascertained for multiple members with asthma, evidence for linkage was seen for both asthma and allergic phenotypes (39). Although several candidate genes map to this region, including interferon-g, nitric oxide synthase 1, and mast cell growth factor, polymorphisms in these genes do not appear responsible for the observed linkage. As with the other chromosomal regions, evidence for linkage is found over a very wide region of the chromosome, and possibly there are two linked regions and multiple susceptibility genes.

Candidate Gene Associations

Association studies are performed to compare the frequency of a specific polymorphism (sequence variant) in a candidate gene in individuals with and without the disease phenotype. It is important to determine *a priori* the rationale for performing such a study, because there are many candidate genes for most of the common disorders. For example, it is reasonable to test for an association with a sequence variant with a known function that is biologically important. It is also important to demonstrate significant evidence at an appropriate statistical level. For most candidate gene studies, conflicting reports make it difficult to determine the significance of the findings. To add to this complexity, another explanation of an observed association is linkage disequilibrium (i.e., the observed polymorphism is physically close to the sequence variant important in the disorder, and there is co-inheritance of both polymorphisms). Therefore the polymorphism tested may not be the relevant functional polymorphism.

Two candidate genes (CD14 and IL13) that have significant evidence for association to allergic phenotypes map to the region of 5q where linkage has been detected. CD14 is a multifunctional receptor expressed primarily on the surface of monocytes, macrophages, and neutrophils. It also is present in soluble form in serum and in bronchoalveolar lavage fluid after segmental allergen challenge (40). Baldini et al. (41) identified a polymorphism in the promoter region of the CD14 gene (C to T transition at position –159) and found that among 317 whites, TT homozygotes had lower total serum IgE levels than did the CT and CC genotypes together. However, the difference was significant only among skin-test–positive individuals (p = .004; n = 163). In addition, the mean number of skin tests was significantly decreased in TT homozygotes compared with the mean number in the combined CC/CT groups (p = .001). No association was observed among skin-test–positive Hispanics, although the sample size was considerably smaller (n = 43). In the Dutch population, a similar association was found (42). The C allele acting in a recessive manner (CC vs. CT or TT) was associated with an increased number of skin tests in all probands and spouses (p = .008) (42). These data suggest that CD14 may have a role as a modifier gene by modulating allergic phenotypes that affect disease expression (severity), but this gene is probably not involved in genetic susceptibility to allergy.

IL-13 is a cytokine produced by T-helper subtype 2 (Th2) cells capable of inducing isotype class-switching of B cells to IgE (43). Association studies with IL-13 polymorphisms have been performed with various atopic phenotypes in several populations. A promoter polymorphism was identified at position –1055 adjacent to the nuclear factor of activated T cells (NFAT) site and reported to be associated with allergic asthma in a Dutch population (44). In addition, an Arg130Gln polymorphism in exon 4 has been shown to be associated with high total serum IgE levels (45,46), atopic dermatitis (45), and asthma (47) in German (45,46), American (46), British (47), and Japanese (47) populations. Results in the Dutch population reveal significant associations between either asthmatic or atopic phenotypes for the two single-nucleotide polymorphisms described earlier, plus a single-nucleotide polymorphism in the 3' untranslated region (UTR) of the gene (46).

Other examples of association studies with allergic phenotypes are the studies of the IL-4 receptor and its multiple polymorphisms (48,49,50,51 and 52). In the first study, an association for the Gln551Arg polymorphism with atopy (defined as an elevation in total serum IgE levels) was observed (48). This variation also was reported to produce a gain of receptor function. It has now become evident that multiple polymorphisms in this gene are in strong linkage disequilibrium with each other. From studies on the Hutterite population, the 406Cys allele was strongly associated with atopy based on skin-test responsiveness (52). Multiple pair-wise haplotypes were strongly associated with asthma; because the Hutterites are an inbred founder population, there is strong linkage disequilibrium between many of the polymorphisms. Even in the families from the United States CSGA, strong linkage disequilibrium and different haplotypes from those in the Hutterite population provided significant evidence for an association with asthma and atopy (52). Results in our Dutch population revealed a significant association between three polymorphisms (E375A, C406R, and S478P) and allergic phenotypes such as increased levels of total serum IgE levels (³100 IU/mL) and more than one positive skin test. In each case, the common allele (E375, C406, and S478) was associated with the allergic phenotype (p = .001–.04). The most significant results were observed with the E375A, C406R, and S478P polymorphisms in individuals with at least one positive skin test and total serum IgE levels ³100 IU/mL, presumably the “most allergic” group in this population (unpublished data). Because it is not clear from the multiple studies which polymorphism or combination of polymorphisms is responsible for the observed association, t here may be additional important variants in the gene that are in linkage disequilibrium with those already studied. Because polymorphisms within a gene are often in linkage disequilibrium, this example illustrates the difficulty in determining the role of a given polymorphism in a candidate gene that has a modest effect on risk.

Candidate gene studies may be performed to determine the effect of a postulated susceptibility gene or to examine the potential effect of a disease modifier gene. An important example of an association study with clinical implications is in the area of pharmacogenetics. The response to a given therapy varies among patients with asthma, and part of this difference may be due to genetic variability. For example, there are differences in response to b-agonist therapy among patients with asthma, which may be partially due to genotypic differences for polymorphisms in the b_2-adrenergic receptor gene (53). There are several known functional polymorphisms in this gene, which maps to chromosome 5q, including those at codons 16, 27, and 164 (54,55 and 56). b_2-Agonists are the most common therapeutic agent used to treat asthma. It has been suggested that regular use of inhaled b-agonists may be associated with adverse events in asthma. It is possible that differences in pharmacologic responses to b-agonist therapy among individuals with asthma may be affected by polymorphisms in this receptor. Israel et al. (55) reported that individuals who are homozygous for arginine at position 16 (Arg/Arg) showed a decline in respiratory function when treated with regular b_2-agonist therapy. This decline increased during a 4-week run-out period. Findings such as these are important because they may explain clinical observations related to adverse pharmacologic responses and may be used to identify a subgroup of individuals who are likely not to respond as well as others to a specific therapy.

SUMMARY OF PROGRESS

Once linkage is confirmed in complex genetic disorders such as asthma or clinical allergic disease, finding the actual gene is a complex process (11). It remains to be seen whether there are single mutations that have a major effect on genetic susceptibility to asthma, or whether even within a major gene, there are multiple common sequence variants. Clearly, multiple genes influence the atopic and asthmatic phenotype (Table 62.5). This is expected, given the frequency of the disease and the failure to detect a strong major gene effect in family studies. Nevertheless, significant progress has been made in the last decade. Several regions of the genome have been identified for susceptibility loci to asthma and BHR (Table 62.4). Future research will be focused in five major areas: (a) completion of genomewide searches in different populations, (b) replication of previously reported linkages, (c) development of multilocus models to investigate the role of multiple susceptibility loci, (d) fine mapping of all the region(s) of interest, and (e) studies of candidate gene association. Determining the specific role of each gene in the development of atopy and asthma, as well as closely associated phenotypes, will result in improved understanding of phenotype-to-genotype correlations. These combined genetic, molecular, and clinical studies will lead to improved therapies and better techniques for early diagnosis of allergy and asthma. By understanding the basic genetic mechanisms that lead to the development of allergy and asthma, new therapeutic interventions will be developed that will modify the development and clinical progression of these common disorders.

• Evidence for multiple susceptibility genes with ethnic differences. Similar regions detected in a restricted and an inbred population
• Different types of populations are useful to narrow regions for positional cloning and gene identification
• Conditional analyses show evidence for regions similar to those previously reported and for gene/gene interaction
• Multiple susceptibility genes probably have sequence polymorphisms (common variants), probably not severe mutations, that influence the phenotype
• Current challenge is to identify these genes and investigate gene-environment interactions

63 ALLERGIC DISEASES

Philip S. Norman, M.D.

Allergic rhinitis is caused by mucous membrane exposure to inhaled allergenic materials and is mediated by specific immunologic mechanisms. The characteristic symptom complex includes sneezing, nasal congestion, and watery discharge as well as conjunctival itching. Bronchoconstriction may accompany these symptoms. This discussion of allergic rhinitis is concerned mainly with the airborne allergens described in Chapter 61. These reactions are triggered initially by immunoglobulin E (IgE) antibodies. There follows a late-phase inflammation, presumably directed by cytokines secreted by T-helper type 2 (Th2) lymphocytes.

ALLERGEN EXPOSURE

The nose is an efficient (nearly 100%) filter for particles 10 µm or greater in diameter. Efficiency drops progressively with particle size; removal is 80% for 5-µm particles and approaches zero for 1- to 2-µm particles (1). The epithelium is squamous at the entrance but changes to ciliary just posterior to the anterior tips of the nasal turbinates. A large portion of large particulate matter deposits in the anterior nonciliated area as a result of high linear velocity, a change in direction of flow, and filtration by hairs. Smaller particles are removed on the ciliary epithelium by impingement against bends in the air stream created by the convoluted passages and also are removed to some unknown degree by electrostatic precipitation (2). Particles deposited on the ciliary epithelium become entrapped in the mucus blanket and are moved to the pharynx for swallowing in 2 to 15 minutes.

Particulate allergens such as pollens vary in size from 10 to 100 µm, making them ideal for filtration by the nose. Mucosal response to deposited allergens is rapid; sneezing often occurs 30 to 60 seconds after inhalation of pollen, because presensitized cells are readily accessible to pollen antigens (3). Mast cell–basophil mediators are readily found in nasal secretions within minutes of exposure, concomitant with symptoms. The mediators identified include histamine, mast cell tryptase (4), prostaglandin D_2 (PGD_2), and leukotrienes (5); there is significant concordance among the mediators. The amount of mediators generated is proportional to the amount of allergen in the challenge. Vascular permeability increases rapidly, as mediators are accompanied by serum proteins including albumin and kininogen (a substrate for kinin formation) (6). Kinins concomitantly found in secretions are generated from this source. Mast cells are the main source of mediators on new exposure. Whereas many of these mediators can come from several cell types, mast cell tryptase measured by radioimmunoassay is specific and can be found regularly in nasal secretions shortly after antigen challenge (4,7).

Mediators are no longer detectable in secretions 30 minutes after a single challenge (3). After the early reaction, symptoms return in many patients 3 to 11 hours later, and most of the mediators reappear in secretions for a time (8). Among mast cell mediators, PGD_2 is notably absent in this “late-phase” reaction, suggesting basophils as a prime source.

CELLULAR FINDINGS

Twenty-four hours after challenge, large numbers of neutrophils and eosinophils have accumulated in the tissues (9) and secretions (10). Intraepithelial mast cells increase in number in the mucosa but not in the secretions (11). Basophils also increase in number in secretions (12) as well as during natural exposure (11,13). One day after challenge, $CD4^+$ T-helper cells are increased in number in the submucosa (9). At the same time, the number of cells expressing messenger RNA (mRNA) for interleukin (IL)-3, IL-4, IL-5, IL-13, and granulocyte/macrophage colony-stimulating factor (GM-CSF) are increased (14,15). The likely sources of these proinflammatory cytokines are T cells of the Th2 type, which are polarized to secrete IL-4, IL-5, IL-6, IL-9, IL-10, and IL-13 (16). The principal cells expressing IL-4 and IL-5 have been identified as $CD3^+$ T cells (17,18). Fourteen percent to 22% of clones of T cells from nasal and bronchial biopsy sites after challenge showed allergen specificity and exhibited a Th2 profile (16). Presumably, they are stimulated by antigen-presenting cells presenting peptide sequences from the antigen to specific receptors on these T-cell clones. Cells that can process antigen for presentation to T cells are abundant in the nose. CD-1 (T6), human leukocyte antigen (HLA)-DR–expressing dendritic cells are readily found in the mucosa (19). They increase in number during seasonal rhinitis (20). Macrophages positive for CD68/EBM11 and HLA-DR, and thus capable of presenting antigen, also are found in the submucosa and increase in number during seasonal rhinitis and after allergen challenge (21).

Granulocytes enter tissues by sticking to vascular endothelium and subsequent diapedesis. In nasal biopsies 24 hours after allergen challenge, leukocyte adhesion molecules on vascular endothelium, E-selectin, and vascular cell adhesion molecule 1 (VCAM-1) are increased. VCAM-1 has corresponding ligands on eosinophils, basophils, lymphocytes, and monocytes but not on neutrophils (22). Epithelial cells also generate chemokines, particularly the CC chemokines (23,24) with chemotactic activity for eosinophils and T lymphocytes. After challenge, mRNA coding for RANTES (regulated on activation, normal T-cell expressed and secreted), monocyte chemotactic protein (MCP)-3, MCP-4, and eotaxin is expressed mainly by macrophages, T cells, and eosinophils (25). Furthermore, IL-16, a specific chemoattractant for $CD4^+$ cells (T cells, eosinophils, and macrophages) is upregulated after allergen challenge (26). Presumably, the ingress of effector cells into challenged tissue is the result of secretion of these cytokines by resident Th2 lymphocytes. The specific effector substances secreted by eosinophils, basophils, and T lymphocytes are discussed in Chapter 22, Chapter 23, and Chapter 18, respectively, along with their roles in disease.

RELATIONSHIP OF IMMUNOLOGIC REACTIVITY TO SYMPTOMS

There is a strong correlation between the sensitivity of mediator-containing cells and the severity of disease during natural pollen exposure. The antigen concentration required for 50% histamine release from the basophils of an allergic individual defines the cell sensitivity, which is stable from season to season in most untreated adults. It varies, however, 10,000-fold from patient to patient. The severity of a patient's allergic symptoms during the ragweed season is directly related to the sensitivity of his or her cells to ragweed Amb a 1 (27,28). Thus the leukocyte system provides a prognostic measure of the severity of the disease that is useful in selecting matched groups for clinical trials. Serum levels of specific IgE antibodies also parallel the severity of symptoms on natural exposure in untreated ragweed-sensitive patients; and leukocyte histamine release and serum levels of IgE antibodies also have a close correlation (29,30).

NONSPECIFIC ENHANCEMENT OF ALLERGIC REACTIONS

Immunologic mechanisms explain many of the manifestations of simple allergic rhinitis. Nevertheless, mucosal hyperemia, swelling, and hypersecretion can be induced by noxious stimuli that have nothing to do with allergy. Additional processes, both physical and emotional, can therefore contribute to the picture of allergic rhinitis.

Some of these stimuli may act through mediator release triggered by nonimmunologic mechanisms. For instance, Togias et al. (31) found that patients subject to nasal stuffiness and hypersecretion on exposure to cold reacted in the laboratory to nasal challenge with cold (3 to 10°C), dry (10% relative humidity) air not only with characteristic symptoms but also with the appearance of mast cell–basophil mediators in secretions.

A ragweed-sensitive patient with normal nasal function responds to pollen exposure out of season with modest swelling and hyperemia. During the hay fever season, when the mucosa is already swollen and hyperemic, an additional exposure to pollen elicits a severe reaction (32). Exposure of ragweed-sensitive patients on successive days to pollen in sufficient amount to invoke symptoms induces reactions similar in severity with less pollen each day. This *priming* effect is nonspecific and local; repeated exposure to one pollen induces overreactivity to another immunologically unrelated pollen; and if only one nostril is exposed, the unexposed nostril does not become primed. Biopsies of the mucosa after such repeated exposures show eosinophil infiltration and basement membrane changes (33,34). The increased symptomatic response is accompanied by an increase in the level of histamine in secretions, but not of PGD_2, suggesting that an increased number of basophils may contribute to the response (35).

Emotional stimuli act in the same way. Persons exhibiting nasal hyperfunction in response to pollen exposure respond with further reactions when subjected to a

conflict situation. The nose can react in only one way to a variety of stimuli, and these stimuli may act in concert (32,36).

Nevertheless, the severity of seasonal rhinitis is clearly related to allergen exposure. In the laboratory, inhalation of ragweed pollen produces both symptomatic responses and inflammatory mediators in secretions in proportion to the amount of pollen inhaled. The minimal amount of pollen required to elicit a response varies from 10^3 to 5×10^5 pollen grains, depending on the patient (37). A similar quantitative relationship between exposure and severity of symptoms may be demonstrated during natural pollen exposure. As a season of exposure progresses, the severity of symptoms gradually increases in relation to airborne pollen concentration. Although sometimes attributed to the appearance of other allergens (such as mold spores), this phenomenon may equally well represent either specific immunologic enhancement of sensitivity or nonspecific priming.

Over a 4- or 5-year period, annual monitoring of patients' seasonal disease with symptom diaries shows little change if there is no immunologic intervention. The symptoms may gradually fade in severity with aging. Spontaneous remissions are uncommon but well documented. We have observed a small number of young and middle-aged adults who spontaneously lost clinical sensitivity to ragweed pollen as well as histamine-releasing activity of basophils and skin test reactivity despite continuing seasonal exposure to ragweed during treatment with only antihistamines.

CHRONIC RHINITIS, HYPERPLASTIC SINUSITIS, AND NASAL POLYPS

Symptoms of rhinitis can occur year round because of exposure to dust mites, animal danders, mold spores, and other allergens perennially present in the environment, but in many cases, no relationship can be established between allergic exposure and symptoms. Hyperfunctioning noses present a similar appearance; hence, pale, swollen membranes do not establish the diagnosis of allergy. Patients with perennial rhinitis frequently have chronic thickening of the sinus membranes (hyperplastic sinusitis) and polyps of the nose or sinuses (38). With hyperplastic sinusitis, the pathologic change is an irregular thickening of the antral membrane, frequently associated with mucous polyps within the sinus or with cysts containing mucoid fluid. The epithelium loses its cilia and is thickened and hyalinized, and the tunica propria is edematous and infiltrated by lymphocytes, plasma cells, and eosinophils (39). Nasal polyps most frequently arise from within the ethmoid or maxillary sinuses and project into the nasal cavity. The polyp is made up chiefly of edema fluid with sparse fibrous cells and few mucous glands. There is infiltration by eosinophils, mononuclear cells, and plasma cells.

Associated allergic diseases are common. Among 200 patients with hyperplastic sinusitis; 165 patients had asthma, 25 had hay fever, 33 had eczema, and some had other allergic conditions. One half of the patients showed positive wheal and erythema skin reactions to recognized allergens, but many of these reactions were not considered clinically significant. A considerable number of patients were sensitive to aspirin (40).

mRNAs for some of the same cytokines present in tissues of individuals with seasonal allergic rhinitis have been found in patients with chronic rhinitis and sinusitis. These include GM-CSF, IL-3, IL-4, IL-5, and IL-13 in patients with allergies. Individuals with nonatopic sinus disease have increases in mRNA for the same cytokines with the exception of IL-4 (41,42). Furthermore, they have less IL-5 and more GM-CSF than do allergic individuals (43). VCAM-1 is upregulated in both groups. Increased numbers of B cells accompanied by increased IgE heavy-chain transcripts are found only in allergic patients (44). These studies appear to confirm the allergic pathogenesis of many cases of sinus disease. There remain many patients with disease that is not demonstrably allergic and has an obscure pathogenesis, even though it involves some of the same pathways.

Nonallergic sinus disease may be a common term for a number of conditions. Two genetic disorders, cystic fibrosis and primary ciliary dyskinesia (Kartagener syndrome), are associated with persistent sinus disease. Furthermore, a survey of 147 consecutive patients with chronic rhinosinusitis found 11 to carry a mutation in the cystic fibrosis gene, an incidence significantly higher than that of the general population (45). Whether other mutations may confer susceptibility to chronic rhinitis or sinusitis is unknown. Patients with antibody deficiencies usually have sinus disease, along with infections elsewhere.

DIAGNOSIS

Most important in diagnosis is the skill of the physician in eliciting the history (time, place, and circumstances of occurrence of symptoms) and correlating it with the biology of allergens (46,47 and 48). A suspected diagnosis should be confirmed with an objective test for specific immediate sensitivity conferred by IgE antibodies. The long-accepted method is direct skin testing with diluted extracts of the suspected allergens. The two principal means used are (a) the intradermal method, in which 0.01 to 0.05 mL is introduced with a fine hypodermic needle between layers of the skin; and (b) the prick test, in which a superficial wound or scratch in the outermost layer of the skin is overlaid with a drop of antigen solution. A positive reaction is revealed by a wheal with a surrounding flare developing over a 15- to 30-minute period. The intradermal test yields positive reactions at lower concentrations, as a greater volume of antigen is introduced. A study of *Bacillus subtilis* antigen revealed a 1,000-fold difference in sensitivity between the two methods; when this factor was applied, there was excellent correlation between the two tests (49).

Skin tests have been criticized on several counts: (a) They are at times positive to one or more common allergens in the absence of allergic symptoms or are negative when the clinical impression is positive or when provocative tests with the allergen evoke a reaction; (b) The degree of positivity may vary from one anatomic site to another; (c) The range of error is no less than threefold and may be tenfold in clinical practice; (d) Extracts may vary in potency from one batch to another or may deteriorate on storage; and (e) Use of antihistamines or sympathomimetics may influence the outcome. Many of these problems are solvable by adequate attention to technique and to the quality of reagents used (50,51 and 52).

In vitro methods of detecting IgE-mediated reactions include both immunoassays for serum IgE antibodies, such as the radioallergosorbent test (RAST), and biologic tests, such as histamine release from isolated, washed, viable leukocytes. Several studies attest to their diagnostic usefulness in hay fever, asthma, and anaphylaxis (53). Only a few patients with positive RAST and skin tests have leukocytes that do not release histamine *in vitro* (51).

TREATMENT

Three principal therapeutic methods are used to alleviate allergic rhinitis: avoidance of exposure; pharmacologic treatment to minimize or counteract symptoms; and immunologic treatment, which attempts to alter the immune response to allergens.

Avoidance of Exposure

Avoidance of exposure to specific allergens is a simple and direct concept that is often difficult for patients to carry out. Patients with hay fever may take vacations to areas free from pollen for the duration of pollen exposure. The ragweed plant, for instance, occurs principally in central and eastern North America and is not present in high mountains, on the West Coast, or in southern Florida.

House dust mites are a major allergen for perennial rhinitis as well as asthma. When the degree of exposure is uncertain, dust samples should be collected from the mattress and bedroom and sent to a laboratory for determination of dust-mite allergen. Levels >2µg allergen per gram of dust indicate that control measures are in order. The measures commonly recommended to decrease mite exposure in the home involve mostly the sleeping room and are listed in Table 63.1.

House pets are another source of allergen that can be eliminated, although removal of a dog or cat from the home does not result in rapid reduction of allergen exposure. Cat allergen levels, for instance, may remain elevated for 20 weeks or more. Aggressive cleaning can cause allergen levels to decline more rapidly (54).

Enclose pillows, mattresses, and box springs in zippered mite-proof (vinyl) covers
Remove carpeting
Avoid heavy curtains or venetian blinds; launder curtains frequently
Substitute wooden or plastic furniture for upholstered furniture
Wash blankets in hot (>130°F 55°C) water every 2 weeks
Avoid wall pennants, macrame hangings, and other items that collect dust
Clean drawers and closets with a damp cloth
Clean floors with an oiled or damp dust mop
Keep all clothing in a closet with the door shut

TABLE 63.1. Techniques for Dust-Mite Reduction

Mold growth is controlled mainly by keeping humidity low (less than 50% relative humidity), particularly in cellars, and eliminating point sources of moisture such as plumbing leaks. Cockroaches are controlled by extermination. The effectiveness of the measures taken may be checked by laboratory analysis of a dust sample (55).

Inhaled air can be efficiently cleaned of allergens. A laboratory worker sensitive to animal dander may almost eliminate exposure by wearing a mask with an adequate filter. Mechanical filters associated with a blower clean the air in closed environments if they have sufficient capacity to recirculate the air frequently, as multiple passes are required for effective cleaning. Electrostatic precipitators and high-efficiency particulate air (HEPA) filters are more efficient, effectively cleaning the air of 99% or more of particulates in a single passage through the device. Even so, adequate recirculation is needed because of the inevitable addition of outside air. Such air cleaners do not remove allergens from the dust in carpets or furniture, which provide reservoirs of fresh allergen whenever they are disturbed (56).

Drug Treatment

The antihistamines in use for rhinitis are H_1-receptor antagonists, which inhibit the smooth muscle and blood vessel effects of histamine but do not inhibit H_2 effects, such as gastric secretion. These drugs antagonize the manifestations attributable to histamine but not those due to other mediators. They are most often administered orally, but preparations for topical administration in the eye or nose also are available. Antihistamines may be categorized in two classes: the classic antihistamines and the newer, nonsedating antihistamines. Classic antihistamines also are anticholinergic, antiserotoninergic, and anti-a-adrenergic. In addition, they are highly liposoluble and readily cross the blood–brain barrier. As histamine may be a neurotransmitter, antihistamines may cause sedation by inhibition of central nervous system histamine. They may, however, cause occasional patients to become restless, nervous, and sleepless; overdoses may cause seizures. The newer antihistamines are more strict H_1 inhibitors and penetrate the central nervous system less readily; they therefore do not cause sedation in therapeutic doses. They have prolonged half-lives and require less frequent dosing.

Somnolence and incoordination are common side effects of classic antihistamines, but can be an advantage for nighttime use when the discomforts of rhinitis cause sleeplessness. Parasympatholytic activity accounts for the occasional undesirable side effects of dry mouth, difficulty in voiding, and impotence, but is useful in the treatment of hay fever, as it tends to reduce nasal hypersecretion (57). The newer, nonsedating antihistamines rarely cause side effects.

Patients with seasonal allergic rhinitis may have a gratifying initial response to antihistamine treatment, particularly early in the season when pollen counts are low. However, as the season progresses and the exposure to higher concentrations of pollen is prolonged, symptoms are often inadequately controlled. Nasal itching and rhinorrhea tend to be relieved better than nasal obstruction or headache due to sinus congestion. Perennial rhinitis is less successfully relieved by antihistaminics than is the seasonal condition. When antihistamines are unsatisfactory, other methods of treatment are needed.

Orally administered sympathomimetic drugs such as ephedrine, phenylpropanolamine hydrochloride, and pseudoephedrine hydrochloride are sometimes useful in relieving nasal obstruction. These drugs occasionally increase blood pressure levels in hypertensive patients; they may also increase the heart rate and cause excitement. They are often used in combination with antihistamines to control nasal congestion better and to counteract partially the drowsiness produced by antihistamines. Topical use of sympathomimetic amines with a-adrenergic action causes vasoconstriction and shrinkage of edematous nasal mucosa. Their disadvantage is rebound vasodilatation (“aftercongestion”) when the vasoconstriction effect has worn off; and prolonged topical use may result in chronic rhinitis.

An atropine-like drug (ipratropium) applied locally limits the portion of the hypersecretion of mucus that is under neural control. In some patients, it may lead to excessive dryness of the mucous membranes; in others, it is a useful but minor addition to management.

Glucocorticoids in sufficient doses ordinarily effect complete relief of allergic rhinitis in 12 to 36 hours. Although the antiinflammatory action in the allergic reaction is incompletely understood, glucocorticoids are able to inhibit basophil (but not mast cell) mediator release *in vitro*, inhibit expression of adhesion molecules important in granulocyte migration, and inhibit the late phase of a nasal-challenge reaction to pollen extract more readily than the immediate phase (58,59). Oral prednisone in daily doses of 15 to 25 mg nearly always produces amelioration of symptoms in seasonal rhinitis. Once improvement is achieved, the smallest dose that will continue to keep the patient comfortable is commonly 5 to 15 milligrams per day or every other day. When allergen exposure becomes minimal, the drug may be discontinued. The relatively short period of administration (4 to 6 weeks) and the small doses required in most instances avoid the commonly feared side effects of prolonged steroid administration. Doses of 10 to 25 mg of prednisone per day often relieve chronic perennial rhinitis and shrink nasal polyps, sometimes completely. Recurrence of obstruction and recrudescence of polyps are usual when the drug is stopped, however. Prolonged, continuous use of glucocorticoids to control symptoms introduces undesirable side effects.

Nasal sprays of steroids active locally on mucous membranes appear to be a suitable alternative. The steroids (beclomethasone, flunisolide, triamcinolone, budesonide, fluticasone, and mometasone) ameliorate the symptoms of both seasonal and perennial rhinitis without detectable suppression of adrenal activity. If the dose is increased to several times the recommended dose, evidence of mild adrenal suppression appears. Minimal local side effects consist of transitory nasal burning after instillation and infrequent nosebleeds. Although originally recommended for twice-daily use, many of these agents are available in forms that are effective when used once daily. Some patients with severe disease (either acute or chronic) find that twice-daily use is necessary for relief (60).

Cromolyn sodium instilled nasally 5 or 6 times a day as a 4% solution ameliorates the symptoms of allergic rhinitis without side effects. A related compound, nedocromil, in a 1% solution appears to be more effective (61). Comparisons of the efficacy of topical steroids and cromolyn sodium for the treatment of allergic rhinitis showed the steroids to have a modest advantage (62,63). A locally sprayed antihistamine solution (azelastine) used twice daily can also produce some symptomatic relief. Eyedrops that relieve conjunctival symptoms include mast cell stabilizers (cromolyn, lodoximide, ketotifen), antihistamines (pheniramine, levocobastine, emedastine), and nonsteroidal antiinflammatory drugs (keterolac).

Immunologic Therapy

Immunologic treatment for hay fever was introduced in 1911 by Noon (64) and Freeman (65). They used subcutaneous injections of sterilized grass pollen extracts and gradually increased doses in advance of the expected season. Although often referred to as hyposensitization or desensitization, *immunotherapy* is a more appropriate term for this procedure.

Immunotherapy uses aqueous sterile filtered extracts of the specific allergens that cause symptoms in the patient. The extract is first administered in minute doses in weekly or biweekly injections, and the dose is gradually increased as tolerated by the patient. The end point of the dosage is commonly determined by the occurrence of local or systemic allergic reactions to the injections or by patient satisfaction with relief of symptoms. Reduction of mucous membrane or skin sensitivity has been little used in practice as an indicator of adequacy of dosage. Maintenance doses are continued every 2 to 6 weeks for 3 years or more.

EFFICACY

With unaltered aqueous extracts, satisfactory relief of symptoms has been obtained in allergic rhinitis due to grass pollen, ragweed pollen, birch pollen, mountain cedar pollen, cat dander, and house dust mites (66,67). Immunotherapy with extracts of other pollens, molds, danders, and inhalant allergens may be clinically effective by analogy but has not been subjected to controlled study.

Where studied, clinical efficacy depends on dose. With ragweed pollen extract, hay fever symptoms are progressively less severe as the dose is increased up to an, as yet, poorly defined maximum (68). A final dose of whole extract equivalent to about 10 to 20 µg Amb a 1 per injection is near the maximum. Larger doses probably provide little additional protection. From both clinical and immunologic evidence, it seems likely that the maximal or final dose is more meaningful than the cumulative annual dose. Controlled studies of the efficacy of ragweed pollen (37,69), grass pollen (70,71), cat (72,73), and dust-mite (74,75) extracts have been performed with extracts whose content of major allergen has been estimated. The final (or maximal) dose that demonstrated efficacy was similar for these disparate allergens and ranged from 5 to 20 µg of allergen. These numbers provide a rough guide to the target dosage of an immunotherapy regimen. Although major allergen content is not ordinarily included on the label in the United States, data can often be obtained from the manufacturer.

Symptoms are alleviated but are infrequently completely cured. Clinical relief is specific for the allergen administered and does little or nothing for symptoms from immunologically unrelated allergens (76). Accurate and complete diagnosis is therefore mandatory for best results, as a good result with treatment with one or several species of allergens could be overshadowed by continuing symptoms from an allergen not included. Highly purified major allergens have been effective in immunotherapy trials (68,77). Recombinant allergenic proteins, although biologically active, have yet to be tried in controlled trials.

In two studies, some patients relapsed within 6 months to a year after discontinuation of immunotherapy, providing a rationale for long-term administration of booster injections (78,79). How long to continue immunotherapy, however, has been studied rarely. In a study of continuing immunotherapy for grass pollen hay fever, treatment was stopped after 3 to 4 years. Amelioration of symptoms continued through 3 additional years, and there was a sustained reduction in late-phase skin

responses (80).

MODE OF ACTION

During immunotherapy, carefully performed assays to determine titers show the intradermal skin test wheal and erythema to be somewhat suppressed (81,82). Immediate mediator responses to nasal challenges are suppressed in both the magnitude of response and the threshold for any response (37,83). More striking are changes in the late-phase response, particularly in the skin. Nearly every person receiving immunotherapy has an almost complete suppression of the late-phase response to intradermally administered allergen (83,84,85 and 86). With mountain cedar pollinosis, suppression of the late cutaneous response correlated significantly with dose of extract, postseasonal levels of IgG1 and IgG2 antibodies, and improvement in symptoms (85). Although not everyone with ragweed pollinosis has a late-phase mediator response to nasal challenge as it is usually carried out, those individuals who did have a late-phase response no longer exhibited one after immunotherapy (83).

These changes are accompanied by multiple immunologic changes. Whereas exposure by the transmucosal route leads mostly to antibodies of the IgE type, adequate parenteral immunization results in a striking increase in IgG antibodies (28,87). These antibodies block histamine release from basophils (88). There is a significant correlation between the dose of allergen administered and the IgG antibody response (28,87). Although patients with high serum IgG antibody levels more often have less severe symptoms after immunotherapy than do patients with low IgG antibody levels ($p < .02$), the correlation is not useful for predicting the clinical response in a particular individual (87). With prolonged immunotherapy, there is an IgG antibody subclass switch from IgG1 to IgG4. IgG4 antibodies form small, nonprecipitating immune complexes because of functional monovalency (89,90), which may help to account for the lack of immune complex disease during immunotherapy.

Specific IgG and secretory IgA antibodies in nasal secretions also have increased levels after immunotherapy and appear to be locally generated. Levels of IgA or IgG antibody in secretions showed no correlation with symptoms reported after natural exposure (91).

Immunotherapy by the usual regimen raises the level of serum IgE antibodies before IgG antibody levels begin to increase. This increase in IgE may be associated with the higher incidence of untoward reactions while the dose of allergen is being increased. Eventually IgE antibodies decline to levels below baseline after a year or more (92). With allergens such as ragweed that involve seasonal exposure, the usual postseasonal increase in IgE antibody levels no longer occurs (30,93). At best, however, the specific IgE antibody levels remain in the range found in sensitive patients, so that it is difficult to attribute improvement to these modest changes.

Basophil reactivity to *in vitro* antigen challenge may decline dramatically in some patients and become almost nonexistent. This change has no relationship to serum IgE and may represent a nonspecific change in cell reactivity (94). Although this change may be significant for the patients who develop it, it is not induced in many patients and cannot account for the effects of immunotherapy in most people.

Various indirect measures of lymphocyte activity in the presence of allergen are reduced in patients undergoing immunotherapy in comparison with those in untreated control subjects (95,96). These activities are now attributed to T cells. In cultures of CD4 lymphocytes from peripheral blood, IL-4 production is reduced after antigen stimulation (97), even though it may be temporarily increased early in the course of treatment (98). This finding indicates eventual downregulation of antigenically specific Th2 activity.

Biopsies of late-phase skin reactions from untreated patients show infiltrating T cells with CD3 and CD4 markers. These cells are significantly reduced in number in biopsies from patients receiving clinically efficacious immunotherapy. Eosinophil infiltration in these biopsies was less in the treated patients but not significantly so (99). The increased number of eosinophils in nasal secretions after a nasal allergen challenge also is reduced but not to a significant degree (83). The number of eosinophils in nasal secretions during natural seasonal exposure is, however, significantly reduced in treated patients (100). In patients successfully treated for grass pollen allergy, biopsies of skin and nasal mucosa 24 hours after a challenge show increased mRNA for interferon-g (IFN-g) and IL-2 but no change in mRNA for IL-4 or IL-5 (101). Another study of skin biopsies showed increased numbers of macrophages positive for IL-12 mRNA (102). Because IL-12 is an inducer of Th1 activity, these studies indicate an upregulation of Th1 lymphocytes. The change in balance between Th2- and Th1-lymphocyte–directed activities could explain the considerable increase in IgG antibodies and the modest decline in IgE antibodies.

UNTOWARD REACTIONS

There are three types of allergic reactions to pollen extracts administered subcutaneously. Early in treatment, there is usually a local reaction: a wheal and erythema at the site of injection that resembles a positive reaction to a skin test. It appears in 10 to 30 minutes and subsides in a few hours. A second kind of local reaction appears as an itching erythematous swelling of the subcutaneous tissues without wheal formation, beginning 2 to 4 hours after the injection. These reactions commonly reach a maximum in 18 to 24 hours, without necrosis, and subside in a day or two. IgE antibodies participate in late (2 to 24 hours) skin reactions. Such reactions are a minor problem unless a too rapid progression in dosage leads to a large, uncomfortable swelling (103).

In contrast, “systemic” reactions, although relatively uncommon and usually mild, are a potentially serious consequence of therapy, as they represent anaphylaxis and may be fatal (104). They require prompt management with epinephrine and other measures (Chapter 64). Administration of glucocorticoids for several days after a severe systemic reaction may prevent recurrences of hives and angioedematous swellings, but these drugs have no effect on the immediate anaphylactic response itself. Long-term ill effects such as immune complex disease or polyarteritis have been suspected in individual cases, but two prospective studies failed to find that circulating immune complexes are any more common in patients receiving immunotherapy than in patients with similar allergies who are not receiving immunotherapy (105,106).

STANDARDIZATION OF ALLERGENIC EXTRACTS

The two historic methods used for labeling extracts for therapy are wt/vol (dry weight of starting material/volume of extracting fluid) and the protein nitrogen unit (1 PNU = 0.00001 mg protein nitrogen, as determined by precipitating protein with phosphotungstic acid and performing a Kjeldahl nitrogen analysis on the precipitate) (107). Neither is necessarily related to allergenic activity or immunizing activity in immunotherapy, and, in practice, neither provides adequate information to the physician (108,109).

Direct skin testing of allergic patients is often used for setting units of direct biologic relevance. Two methods have achieved acceptance: (a) In the histamine equivalent in prick testing (HEP) system, the concentration of allergen extract is adjusted to elicit a wheal in the skin-prick test equivalent to that produced by a histamine hydrochloride solution of 1 milligram per milliliter. A preparation of this strength is said to contain 1,000 biologic units (BU) per milliliter (110). The HEP system is used in the European Union. (b) An intradermal bioassay uses testing of allergic patients with threefold dilutions and establishes a best-fit linear regression line from four serial dilutions. In each patient, the dilution producing a 50-mL sum of erythema response (D_{50}) is calculated. The mean D_{50} in a population of 15 maximally sensitive individuals defines the potency of a reference. Potency is denominated in Bioequivalent Allergy Units (BAU) (111). The Center for Biologics Evaluation and Research of the U.S. Food and Drug Administration has prepared standards labeled in BAU that can be compared with commercial materials by RAST inhibition. Mite, grass pollen, and cat extracts are currently standardized in this way. In addition, for ragweed and cat, in which major allergens have been identified and isolated, standard sera are furnished for a radial immunodiffusion assay of the allergen. A ragweed pollen extract labeled 100,000 U/mL must contain 200 to 400 µg Amb a 1 per milliliter. A combination of RAST inhibition, isoelectric focusing, and crossed immunoelectrophoresis also serves as laboratory controls for allergenic products.

An Allergen Standardization Subcommittee of the International Union of Immunologic Societies has developed standard extracts of short ragweed, timothy grass, dog dander, birch, and *Dermatophagoides pteronyssinus*, and has prepared large batches of glass-sealed ampules labeled in arbitrary units. These materials have been accepted by the World Health Organization as international standard preparations (ISPs).

Isolation, cloning, and production of recombinant proteins representing specific allergenic components along with development of monoclonal antibodies make it possible to quantitate specific active proteins in crude extracts and to offer an additional opportunity for accurate standardization in mass units of one or more major allergens (see Chapter 61).

ALTERNATE METHODS

Techniques to shorten the time required to reach full doses or to reduce the risk of serious allergic reactions have been tried repeatedly. A “clustered” regimen gives several injections at about 30-minute intervals at each visit. The number of visits is reduced, but the time required to reach a therapeutic dose and the rate of systemic reactions are not changed (112). A “rush” program reaches full doses in 4 days with a rate of systemic reactions not dissimilar to that noted with slower programs (113). The administration of concentrated aqueous extracts orally in the form of capsules containing extract or drops diluted with water produces a low rate of systemic reactions. The controlled studies that have demonstrated satisfactory efficacy with birch and ragweed extracts required very large doses, about 100 times that used in injection regimens (114,115).

Extracts may be physically or chemically modified to delay absorption or reduce allergenicity. In the United States, only alum-precipitated extracts are available to

physicians; these extracts offer a modest advantage in achieving effective doses with fewer injections (116). In Europe, clinically significant results have been obtained with stabilized alum-precipitated preparations of grass pollen and cat extracts (117,118). Modification by cross-linking protein molecules with aldehydes increases the average molecular weight of the constituents of a crude extract greatly and results in reduced allergenic activity (119,120). “Allergoids,” extracts modified by formaldehyde, are in common use outside the United States (121) and have been introduced in an alum-precipitated form. Other modifications include conjugation of the extract to alginate, methoxy-polyethylene glycol coupling, and tyrosine-precipitated, glutaraldehyde-modified extract.

64 ANAPHYLACTIC SYNDROME

Alexandra S. Worobec, M.D., and Dean D. Metcalfe, M.D.

Systemic anaphylaxis is an acute allergic reaction that involves the release of mediators from mast cells, basophils, and secondarily recruited inflammatory cells, which may occur within a few minutes to a few hours after exposure to a triggering agent. The discovery of anaphylaxis (155) is an instructive example of the manner in which scientific advances occur when a curious fact is interpreted by a prepared mind. The story of how Portier and Richet discovered, during a Mediterranean cruise, that injection of an extract of “sea anemone” (the tentacles of jellyfish) into a dog was tolerated the first time but induced death when reinjected in the same amount several weeks later is part of the early folklore of immunology. The term *anaphylaxis*, as proposed by Portier and Richet, means loss of “protection”; but these investigators (155) also recognized that (a) anaphylaxis is acquired and (b) it is the opposite of “prophylaxis.” A further step was taken by Arthus (6), who realized that the “toxin” does not have to be a toxin; any nontoxic foreign protein can induce anaphylaxis.

Over the last century, numerous antigens have been reported to be associated with anaphylaxis. These include serum therapy used in the treatment of diphtheria, tetanus, meningococcemia, and tuberculosis and that used for treatment of renal and hepatic allograft rejection (14,24,97,132,157,203,205), antibiotics such as penicillin (3,45,64,66,76,90,94,95,96,101,102,103,105,116,151,164,214), therapeutic proteins and biologics (35,82,113,202), polysaccharides (9,55,120), and ingested antigens (12,22,43,48,57,80,83,127,138,146,169,217).

Exposure to environmental allergens, such as latex, seminal fluid, and insect or crotalid venoms accounts for additional cases of anaphylaxis (65,104,134,152,189,191,218). Anaphylaxis resulting from stings by insects of the order Hymenoptera (see Chapter 69) is a persistent problem: serious systemic reactions have been estimated to occur in 0.4% of the population (13,106,195). The appearance of systemic reactions to the sting of the imported fire ant has expanded the significance of sensitivity in the order Hymenoptera (114,159). The diverse group of proteins and haptens that elicit the typical clinical sequence of anaphylaxis is continually increasing with the introduction of new diagnostic and therapeutic agents. One estimate places the rate of fatal anaphylaxis among treated patients at 0.001% (204) and another at 0.002% (76).

Because the life-threatening clinical manifestations of anaphylactic shock in humans can arise from obstruction of the upper or lower airways with secondary vascular collapse, or from primary circulatory failure without antecedent respiratory difficulty, the anaphylactic response is best considered a syndrome. Defining anaphylaxis as an adverse immunologic syndrome not limited to an immunoglobulin E (IgE)-mediated event avoids the need for the term *anaphylactoid reaction,* which sometimes is used to describe shock-like reactions from presumed non-IgE-dependent mechanisms. Indeed, studies with IgE-deficient mice are consistent with the hypothesis that non-IgE-mediated signal pathways also can initiate systemic reactions resembling anaphylaxis (140). Although presently the mechanism is unknown in humans, in the mouse, this process possibly may be mediated through IgG1 and the Fc receptor III for IgG1 (Fcg RIII) (31,36,131).

CONSTITUTIONAL FACTORS AND ETIOLOGY

Whether underlying factors such as age, sex, race, occupation, or geographic location predispose a person to anaphylaxis is unclear and remains controversial, except insofar as they may provide exposure to a particular antigen. The atopic diathesis may represent a risk factor for anaphylaxis, although there is room for disagreement (82). In one study, 5 of 17 patients who died of anaphylaxis after penicillin treatment had asthma (94); in another study, skin-sensitizing antibodies to penicillin developed in 12 of 15 atopic patients after penicillin treatment compared with 31 of 110 nonatopic persons (102). In a familial drug study, children of parents known to be allergic to an antibiotic were found to have a 15-fold higher relative risk for allergic reactions to antibiotics than children without such histories (35). In contrast, a multicenter study with more than 1,000 patients disclosed no correlation between penicillin reactions and a family or personal history of allergy (60,74). With respect to age differences, the risk for drug allergy and the concomitant risk for anaphylaxis appear less common and less severe in infants and in elderly persons; perhaps because of immaturity and involution of the immune system, respectively, at these two extremes of human development (35). Women appear to have an approximately 35% higher incidence and an approximately 20-fold higher risk for adverse cutaneous reactions to different agents and for systemic reactions to radiocontrast media, aspirin, muscle relaxants, and latex than men (35,108). A syndrome has been described entitled *multiple drug allergy* in which patients report allergic reactions to multiple antibiotics (209). This entity may reflect an underlying predisposition—genetic or otherwise—to respond immunologically to *haptens*, simple chemicals that are not antigenic in themselves but become antigenic after the chemical or one of its metabolites forms a stable bond with a host protein rather than an underlying predisposition to react to specific classes of drugs (108).

The dose, duration, frequency, and route of administration may affect the propensity to develop sensitization. Although sensitization may occur by any route, topical and oral routes of exposure appear to have the greatest and lowest risks, respectively. In the sensitized person, however, reexposure to antigen through the oral route may lead to prolonged and potentially severe symptoms as a result of slow or delayed absorption of antigen. Single, intermittent doses are less likely to induce an allergic response than high doses with prolonged parenteral exposure. More frequent exposures are more likely to result in sensitization than those separated by years.

Proteins, polysaccharides, and haptens (Table 64.1) are known to elicit systemic anaphylactic reactions in humans as defined by one or more of the following criteria: (a) a confirmatory postmortem examination that reveals laryngeal edema, acute pulmonary hyperinflation, or a positive wheal-and-flare response; (b) *in vitro* demonstration of IgE to the eliciting material; and/or (c) hypotension, concomitant with other manifestations of anaphylaxis, such as characteristic cutaneous, respiratory, or gastrointestinal involvement. Primary hypotensive responses without antecedent respiratory problems are a predominant reaction pattern with certain agents such as protein hormones or penicillins (81,110).

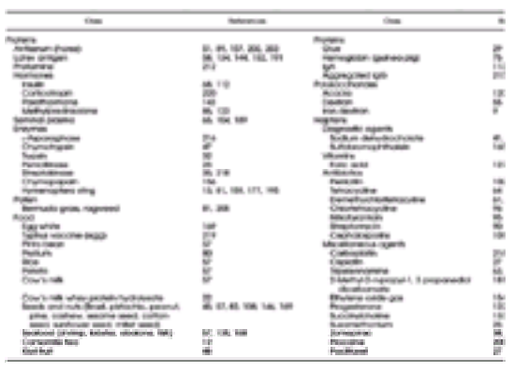

TABLE 64.1. Materials Producing Anaphylactic Reactions in Humans

Substances that cause anaphylaxis are diverse, and some of the more common and clinically prevalent etiologic agents are summarized here. A historically noteworthy protein class known to elicit anaphylaxis is exemplified by horse antihuman lymphocyte globulin (ALG) used as an adjunct for immunosuppression of allograft recipients. ALG elicited systemic anaphylactic reactions in 11 of 53 patients (89) and in 6 of 48 patients (24) treated by two groups. The high incidence of systemic reactions as well as the augmentation of immediate-type skin test reactivity during treatment with ALG (24) is particularly relevant in view of the virtual absence of serum sickness in this patient population (132,202). In these studies, nearly all recipients of ALG had an antibody response of the IgM class to horse proteins. It may be that the failure of these patients to make such a response in the IgG class accounts for their lack of serum sickness as well as for their propensity to demonstrate an IgE-type response.

Food allergens are a common cause of anaphylaxis and are responsible for up to one third of cases in some series (108). Food allergy and anaphylaxis resulting from food reactions appear to be more prevalent in the pediatric population. The most frequent offenders are peanuts, true nuts, fish, shellfish, milk, and eggs (82). Cross-reactivity with other foods in the same group is possible. Anaphylactic reactions to foods almost always occur within 1 hour of ingestion. Symptoms may involve

the gastrointestinal, cutaneous, ocular, respiratory, and/or cardiovascular systems.

Of the heterologous proteins in clinical use, the most significant addition of anaphylactogenic agents in the past decade may be the latex antigens (82,152,191) (see Chapter 73). These water-soluble allergens are proteins in latex sap used to make latex rubber articles. Anaphylaxis has been reported after intraoperative contact with rubber gloves (58,134) or contact with latex catheters used during a barium enema (144). The incidence of anaphylaxis to latex allergens is increased in health care personnel, in children with spina bifida and genitourinary abnormalities, and in workers with occupational exposure to latex. Reactions appear to be more common in atopic persons. The incidence of reactions to latex appears to have increased over the last decade, although it is not clear whether this increase is due in part to better reporting and diagnosis of the problem, to changes in the manufacture of latex, or to an overall increase in the number of persons with atopy. Evidence of IgE-mediated sensitivity to foods (as evidenced by skin prick testing or *in vitro* tests) is common in latex-sensitive patients (> 50% of patients in some series). Nonetheless, only a small fraction of patients allergic to latex have clinical reactions on food ingestion (27% of patients with positive skin test responses in one series) (10). Clinical and *in vitro* cross-reactivity has been reported between latex and avocado, banana, chestnut, potato, tomato, and kiwi fruit.

Anaphylactic reactions to purified heterologous proteins such as hormones (35,68,112,220) can be attributed to unrecognized contaminants or denaturation when positive skin tests are obtained with natural but not synthetic materials (163), but this is not invariably the case. The best studied example addresses recombinant human insulin. Antibody of the IgE class in patients experiencing anaphylaxis to insulin has been shown to react against human synthetic insulin and insulin prepared from recombination of polypeptide subunits (149). Patients are more likely to experience anaphylaxis if therapy is interrupted.

An unusual association of recurrent unexplained anaphylaxis with menses has been reported. These episodes are observed in some women before the onset of menses and appear to be due to hypersensitivity to progesterone. The term *catamenial anaphylaxis* has been applied to this form of anaphylaxis (122,192).

Systemic anaphylactic reactions from insect stings of the order Hymenoptera (see Chapter 69), contained in the superfamilies Apoidea (bees), Vespoidea (wasps, hornets, yellow jackets), and Sphecoidea (solitary wasps), are well recognized. Identical reactions secondary to ant stings of the superfamily Formicoidea have been documented. Two South American species of fire ants introduced into the southern United States early in the twentieth century, *Solenopsis invicta* and *Solenopsis richteri*, are known for their aggressive behavior, and their stings also elicit a reaction (114,159). Other biting insects, such as deer ticks and mosquitos, occasionally cause anaphylaxis (218). Triatoma, indigenous to the American Southwest, is a nocturnal blood-sucking arthropod whose bite also may produce anaphylaxis.

Among the haptens, benzylpenicillin, semisynthetic penicillins, and cephalosporins are best characterized and continue to be problematic clinically. Penicillin reactions occur at a frequency of 1 to 5 per 10,000 administrations of penicillin, and fatalities occur at a rate of approximately 1 per 50,000 to 100,000 courses (108). The benzylpenicilloyl group of benzylpenicillin has been established as a major (in abundance only but not in terms of predisposition to immediate hypersensitivity reactions) haptenic determinant (145), and there is extensive cross-reactivity with a-aminobenzyl (ampicillin) penicilloyl haptens. Only slight cross-reactivity is observed with dimethoxyphenyl (methicillin) or oxacilloyl (oxacillin) penicilloyl haptens (101). Allergenicity to the major determinant is less predictive of immediate hypersensitivity reactions than that to the minor determinant (35). In addition to benzylpenicilloyl-specific antibody, penicillin therapy thus may induce the formation of antibodies for minor determinants derived from benzylpenicillin (103). These penicillin minor determinants constitute the remaining 5% of penicillin metabolites and include penicilloate, penicilloyl-amine, benzylpenicilloyl-*N*-prophylamine, and penilloate. IgE antibodies to penicillin minor determinants are responsible for most anaphylactic reactions associated with penicillin use (35,82,108). If skin test results for penicillin with both major (penicilloyl) and minor determinants (penicillin G and others) are negative, 97% to 99% of patients (depending on the reagents used) will tolerate penicillin administration without risk of an immediate reaction (82). Conversely, a patient with a positive history and a positive skin test response to penicillin has a 50% or greater chance of an immediate reaction if penicillin is readministered.

Four reaction patterns associated with penicillin hypersensitivity have been described. These patterns—immediate, accelerated, late, and recurrent—are characterized by urticaria with or without systemic manifestations and skin-sensitizing IgE antibodies of varying specificities (102,106). By definition, only the immediate reaction associated with skin-sensitizing antibody to minor determinants of benzylpenicillin would ordinarily be recognized as anaphylactic, that is, according to the criteria of rapidity of onset after antigen exposure and association with vascular and respiratory difficulties. The less spectacular nature of the response associated with skin-sensitizing antibodies of benzylpenicilloyl specificity (i.e., accelerated and late urticarial reactions) is possibly due to modification by neutralizing antibody or to the requirement for metabolism to the eliciting determinant or both. IgG and IgM anti-penicillin antibodies appear responsible for penicillin-associated hemolytic anemia, nephritis, and serum sickness.

Cephalosporins also give rise to a major determinant, the cephaloyl group (66), and to minor determinants that cross-react with those of benzylpenicillin (101). First-generation cephalosporins may pose a greater risk than second- or third-generation cephalosporins. Indeed, patients with a history of urticaria or anaphylaxis to penicillin are three to four times more likely to react to a cephalosporin, although the risk of a reaction to a cephalosporin in this setting is less than 10% (3,82). For related antibiotic classes, carbapenems (e.g., imipenem) should be considered cross-reactive with penicillin. Aztreonam, a monobactam, rarely cross-reacts with penicillin (35,82).

Aspirin and nonsteroidal antiinflammatory drugs (NSAIDs) and radiographic dyes are two common classes of agents that can elicit adverse reactions reminiscent of systemic anaphylaxis. Both groups, however, can act through non-IgE mediated mechanisms. The lack of skin-test reactivity to *N*-acetylsalicyloyl or salicyloyl determinants (175) in persons who react to aspirin and their clinical intolerance to structurally unrelated NSAIDs (170) indicate a need to identify the non-IgE-dependent mechanism(s) involved. For iodinated organic contrast agents, although some adverse reactions have been indistinguishable from anaphylaxis by clinicopathologic criteria (28,139,150), skin testing has not yielded predictable results (49), and adverse responders have not been shown to have specific IgE. Severe reactions are noted in about 0.01% of patients undergoing urographic studies (4); such reactions may occur more frequently with the doses used for angiography (139) and less frequently when agents of lower osmolarity are employed (109). Risk factors for adverse reactions to radiocontrast materials (RCM) consist of a history of asthma or atopy, cardiovascular disease, and use of b-adrenergic blocking agents or angiotensin-converting enzyme (ACE) inhibitors (82). Clinically, these reactions tend to be characterized by hypotension with pruritic urticaria rather than by primary respiratory distress. Patients who have experienced previous adverse reactions from administration of RCM are at increased risk for a repeat reaction, with estimates of this risk ranging from 16% to 44% for procedures with high osmolality RCM (82). Direct histamine release may be responsible in part for the reaction because RCMs, such as methylglucamine diatrizoate, release histamine from suspensions of human peripheral leukocytes (126) and degranulate mast cells in the hamster cheek pouch after topical application (99). The presumption that adverse reactors are unduly susceptible to direct histamine release has not been substantiated by analysis of plasma histamine levels (20). The capacity of radiographic dyes to activate the alternative complement pathway *in vitro* and even *in vivo* suggests another mechanism for the adverse reactions, but the *in vivo* hypocomplementemia has not been associated with clinical manifestations (5).

In addition to RCM, adverse systemic reactions experienced during diagnostic or surgical procedures may be caused by a number of other etiologic agents, which can make identification of the inciting factor(s) difficult. Furthermore, it may be difficult to differentiate between immune and nonimmune mast cell-mediated reactions and pharmacologic effects. Although anaphylactic reactions to local anesthetics have been reported, IgE-mediated systemic anaphylaxis to these agents appears unusual. Local anesthetics are classified into groups: esters (aminobenzoate and benzoic acid subtypes), amides, ethers, and ketones. In patients who have had reactions to an ester-type anesthetic, an amide should be considered for provocative or graded dose testing; however, in those with a reaction to an amide, another amide should be tested because cross-reactivity among amides has not been documented. Other etiologic agents of adverse reactions during operative procedures include thiopental (IgE-mediated), opioid analgesics (direct mast cell mediator release), neuromuscular blocking agents such as *d*-tubocurarine or succinylcholine (IgE-mediated in some cases; also histamine release by direct cross-linking of mast cell surface IgE molecules), protamine (both IgE-mediated and non-IgE-mediated reactions), ethylene oxide (IgE-mediated), methylmethacrylate (bone cement, nonimmunologic mechanism), and, far less frequently, additives such as parabens or sulfites.

Transfusion reactions characterized by hypotension on receipt of a few milliliters of whole blood or intravenous immune globulin have been noted in IgA-deficient persons and are attributed to the presence of IgG or IgE antibodies that recognize IgA (113,176,207). Selective IgA deficiency occurs with a frequency of about 1:700 (121), and about 40% of those affected manifest such class-specific anti-IgA (176). These patients are skin test-negative to plasma, buffy-coat cells, erythrocytes (176), and even IgA (137). The acquired hypocomplementemia in some patients with agammaglobulinemia during an adverse reaction to g-globulin administration has been attributed in some instances to the direct action of aggregates in the preparation. Newer preparations of intravenous g-globulin are relatively free of this complication. Complement activation is also thought to follow the formation of complexes of recipient IgG and donor IgA (215). Urticaria and fever have been noted in transfusion reactions to allotype-specific antibodies (53).

Anaphylaxis has been described in the setting of administration of avian-based vaccines and has been attributed to the egg protein in the vaccine as well as to hydrolyzed gelatin, sorbitol, and neomycin (82). True anaphylactic reactions to vaccines, however, are rare, including vaccines that may have minute quantities of avian protein (measles, mumps, yellow fever, and influenza). Two studies performed in egg-allergic children (n = 140 and n = 54, respectively) who received the measles, mumps, and rubella (MMR) vaccine indicated that at least 97.5% of these children tolerated the vaccine without significant difficulty (44,79). Furthermore, in a total of 17 studies, MMR vaccine was safely given as single dose to 1,209 patients with a positive skin test to egg. Whether the same safety profile would be seen in patients with underlying asthma is unknown, although asthmatic children with a positive skin test to influenza vaccine and a history of egg sensitivity were safely given influenza vaccine with use of a desensitization procedure (78).

The incidence of anaphylaxis during allergy skin testing or immunotherapy is low. The risk factors for the development of systemic reactions to allergen immunotherapy have been identified. As summarized in the American Academy of Allergy, Asthma and Immunology's Joint Task Force on Practice Parameters for “The Diagnosis and Management of Anaphylaxis,” these risk factors consist of the following: (a) unstable glucocorticoid-dependent asthma; (b) strong allergic reactivity, based on diagnostic tests such as immediate hypersensitivity skin tests; (c) a history of previous systemic reactions to allergen immunotherapy; (d) starting a new vial of allergen

extract; (e) asthmatic symptoms immediately before receiving an injection of allergenic extract; (f) concomitant treatment with b-adrenergic blocking agents; (g) administration of pollen extracts, especially during high environmental exposure periods to aeroallergens; and (h) a rate of increase in the dose of allergenic extract that is too rapid for the patient's degree of sensitivity (82). Other factors that may impact on increased risk for immediate hypersensitivity are use of nonstandardized extracts that may have significant lot-to-lot potency differences; administration of extract at the time of exacerbation of allergy symptoms, asthma symptoms, or during an upper respiratory infection; or administration of extract in the setting of fever from any cause. Patients receiving ACE inhibitors may be at increased risk for anaphylaxis (173,187), with at-risk patients having significantly lower levels of renin and of angiotensin I and II than those who do not experience repeated episodes of anaphylaxis with immunotherapy (70,71 and 72).

CLINICOPATHOLOGIC CHARACTERISTICS

The time course of appearance and the perception of symptoms and signs differ among individual patients, but the hallmark of the anaphylactic reaction is the onset of an associated manifestation within seconds to minutes after introduction of the antigen, generally by ingestion or injection. In general, the magnitude of the anaphylactic response parallels the magnitude of the stimulus. Thus, more severe reactions occur closer temporally to the time of exposure to the inciting agent. Respiratory distress may originate in the upper or lower airway or both. Laryngeal edema may be experienced as a “lump” in the throat or hoarseness of voice or stridor. Bronchial obstruction is associated with a feeling of tightness in the chest or even audible wheezing.

A particularly characteristic feature of anaphylaxis is an eruption of well-circumscribed, discrete, cutaneous wheals with erythematous, raised, serpiginous borders and blanched centers. These urticarial eruptions are intensely pruritic, diffusely distributed or localized, and may coalesce to form giant hives. These lesions seldom persist beyond 48 hours. A localized, nonpitting, deeper edematous cutaneous process—angioedema—also may be present asymptomatically or with a burning or stinging sensation. Flushing, headache, and rhinitis represent bothersome, but non–life-threatening symptoms. Gastrointestinal manifestations include nausea, vomiting, cramping abdominal pain, and diarrhea that is occasionally bloody. Uterine cramping also may occur. Reactions may be more severe in patients receiving b-adrenergic-blocking drugs (201).

Life-threatening manifestations most commonly involve respiratory distress secondary to upper airway obstruction from angioedema of the tongue, oropharynx, or larynx or secondary lower airway obstruction from bronchospasm. In fatal cases with bronchial obstruction, the lungs are greatly hyperinflated (15,81,185,205). The microscopic findings in the bronchi, however, are limited to increased luminal secretions, peribronchial congestion, submucosal edema, and eosinophilic infiltration. The angioedema associated with death by mechanical obstruction occurs in the epiglottis and larynx (81,205), but the process also may occur in the hypopharynx and to some extent in the trachea. Upper airway edema and bronchial obstruction with hyperinflation of the lungs can be found in about 60% and 50% of deaths, respectively, from anaphylaxis. On microscopic examination, edema is presumed by the wide separation of the collagen fibers and the glandular elements, with vascular congestion and eosinophilic infiltration also present. In some fatal cases, both upper and lower airway involvement may be marked. A tissue feature that may distinguish persons who die of systemic anaphylaxis from other mechanisms of acute death consists of a prominence of eosinophils in pulmonary capillaries, splenic and liver sinusoids, and lamina propria of the respiratory tract (34,81,205).

Cardiovascular symptoms, which are often severe and refractory to treatment, include hypotension, arrhythmias, and hypovolemic shock. The major factors causing cardiovascular abnormalities include an initial loss of intravascular fluid and vasodilation. These events may be followed shortly thereafter by vasoconstriction and myocardial depression. Persons who die of vascular collapse without antecedent hypoxia caused by respiratory insufficiency exhibit visceral congestion (34,81,164) but no major shift in the distribution of blood volume. Whether the associated electrocardiographic (ECG) abnormalities (151), with or without infarction, noted in such patients reflect a primary cardiac event or are secondary to a critical reduction in plasma volume (67) is not established. Left ventricular contractility, however, is depressed with IgE-mediated anaphylaxis (30). Involvement of the cardiovascular system constitutes the second most common cause of death in anaphylactic syndromes (218).

Increased peripheral vascular resistance represents a normal hemodynamic response to improve cardiac output during anaphylaxis. This physiologic change involves both secretion of catecholamines, such as epinephrine and norepinephrine, and activation of the angiotensin system, resulting in conversion of angiotensin I to angiotensin II and increased secretion of these two agents. In some patients experiencing anaphylaxis, peripheral resistance is abnormally elevated because of this response. In other patients, despite elevated levels of these vasopressor substances, systemic vascular resistance falls. Indeed, it has been suggested that a failure to mobilize these compensatory mechanisms may place individuals at risk for anaphylaxis and perhaps a worse outcome from such an event. This hypothesis appears to be supported by at least one study in which Hymenoptera-sensitive patients were shown to have lower levels of baseline plasma angiotensin I and II than normal controls (71). An inverse correlation between angiotensin levels and the severity of anaphylaxis was noted, with more severe symptoms in patients with lower levels.

IMMUNOPHARMACOLOGIC FEATURES

The Prausnitz–Küstner reaction is a classic observation used to illustrate the importance of the role of IgE in the pathogenesis of at least some types of anaphylaxis. An example of this reaction was observed after serum obtained from the heart blood of a patient dying of systemic anaphylaxis was transferred intradermally into a normal recipient. Rechallenge of the recipient 24 hours later with the original antigenic reagent at the same site resulted in the development of the wheal-and-flare reaction (75). Indeed, antigen-specific IgE has been identified in the serum of the patients who have undergone a systemic anaphylactic reaction (Table 64.1) using a number of different laboratory methods (149,189,195). Fixation of IgE to human basophils has been demonstrated by autoradiography (77), and the presence of IgE on mast cells in human skin and respiratory tissues has been established by immunofluorescence with specific anti-human IgE (91). The presence of functional IgE on mast cells of human lung (91) and nasal polyp (84) tissues has been demonstrated by the capacity of anti-IgE to generate and release the mediators of immediate hypersensitivity from these tissues. The location of mast cells in the perivenular areas of connective tissues, as well as intraepithelially in the portio vaginalis uteri and the gastrointestinal and respiratory systems, affords their membrane-bound IgE ready access to potential antigens and makes their products available to a wide variety of cell types, including fibroblasts, vascular endothelial cells, nerve cells, glandular epithelial cells, smooth muscle cells, and other cells of the immune system (46,222).

A wealth of signal transduction research in the area of IgE-mediated immediate hypersensitivity reactions has shed light on important molecular signaling events that regulate the various downstream pathways that ultimately result in mast cell mediator release and cytokine production. Cross-linking of the high-affinity Fc receptor for IgE (FceRI) has been generally thought to occur between the Fab portions of IgE and multivalent antigens. The possibility of additional mechanisms resulting in FceRI aggregation also have been discussed, namely, that anaphylaxis may be triggered through antibodies directed against the a chain of FceRI or through antibodies directed against IgE or IgG-IgE complexes bound to FceRI (118). Regardless of the specific site(s) on FceRI involved, and regardless of the mechanism, aggregation of FceRI initiates intracellular signaling cascades, leading to mast cell degranulation, *de novo* synthesis, release of phospholipid and arachidonic acid-derived mediators, and induction of cytosolic gene expression (59). Tyrosine phosphorylation of the FceRIb and FceRIg immunoreceptor tyrosine activation motifs (ITAMs) on the b and g chains of FceRI is the first molecular alteration observed after receptor aggregation. This event is followed by an increased association of $p56^{lyn}$ with FceRIb and binding of $p72^{syk}$ to FceRIg. Subsequent transphosphorylation of FceRIg-bound $p72^{syk}$ produces an increase in $p72^{syk}$ catalytic activity with resultant activation of multiple downstream signaling pathways, including activation of phospholipases (PLCg1 and PLCg2) and of G proteins (Ras and Pyk2), regulation of protein phosphorylation [phosphokinase (PK) A, PKC, PI-3-kinase, mitogen-activated protein (MAP) kinase], and dephosphorylation [src homology 2 domain-containing phosphatase 1 (SHP-1), SHP-2, *src* homology 2 domain-containing polyinositol 5-phosphatase (SHIP), CD45, protein tyrosine phosphatase (PTP) 1C, PTP1D], and ultimately calcium mobilization. Enzymatic activity of Janus kinase 3 (JAK3), a member of the Janus family of protein-tyrosine kinases that is expressed in mast cells, is enhanced by IgE receptor/FceRI cross-linking (117).

Evidence indicates that there is a divergence of downstream pathways with respect to activation of molecules necessary for the rapid release of mediators during degranulation, such as histamine and heparin; pathways involved in the synthesis of newly formed lipid mediators, such as arachidonic acid metabolites; and pathways that regulate gene expression of cytokines. The biologic sequelae of these events (see Chapter 27) include the release and generation of mediators, some preformed and stored in secretory granules and others synthesized *de novo*. These include histamine, tryptase, chymase, heparin, prostaglandin D_2 (PGD_2), leukotriene C4 $(LTC)_4$, thromboxane B_2, platelet-activating factor (PAF), cytokines [interleukin (IL)-1, IL-2, IL-3, IL-4, IL-5, IL-6, IL-8, IL-13, IL-16; tumor necrosis factor-a (TNF-a)], growth factors [granulocyte–macrophage colony-stimulating factor (GM-CSF)], stem cell factor (SCF), and chemotactic factors [macrophage inflammatory protein (MIP-1a, MIP-1b), and monocyte chemoattractant protein (MCP-1)] (18,26,56). Many of these mediators play an important role in increasing vascular permeability, inducing smooth muscle contraction, promoting tissue edema and mucus secretion, and regulating the influx of inflammatory cells. In addition, many of these mediators activate other inflammatory pathways. Tryptase has kallikrein activity and can activate the complement cascade as well as cleave fibrinogen. PAF can activate the clotting cascade and promote disseminated intravascular coagulation. Heparin inhibits clotting. Chemotactic factors have the ability to induce migration of eosinophils and other inflammatory cells and thus to intensify and prolong reactions. Resulting cytokine production by T-lymphocytes may drive or predispose an individual to future anaphylactic episodes. This possibility has been illustrated both in an ovalbumin (OVA)-specific T-cell receptor transgenic mouse model, where orally ingested antigen was shown to elicit a T-helper cell type 2 (Th2) response from a subpopulation of T cells that produced high levels of IL-4 and promoted IgE secretion (186) and also by IL-4 mRNA induction by peripheral blood lymphocytes specific for b-lactam antibiotics in a patient with immediate hypersensitivity to b-lactam antibiotics (54). Taken together, these various physiologic processes result in the acute clinical sequelae pathognomonic of anaphylaxis and may be associated with protracted symptoms and/or multiphasic responses.

The physiologic effects of individual chemical mediators released during anaphylaxis overlap. It is thus difficult to attribute specific clinical manifestations to any one substance. Because histamine infusions produce many of the symptoms seen during anaphylaxis, histamine is generally recognized as one of the principal mediators of anaphylaxis. Vascular collapse after the sting of a Hymenoptera occurs with an elevation of blood histamine and mast cell tryptase (177,193). Elevations in blood

histamine occur with experimentally induced episodes of physical allergy in patients with cold-induced urticaria–angioedema (88), exercise-induced cholinergic urticaria (196), and exercise-induced anaphylaxis (limited) (183). In the latter case, cutaneous mast cell degranulation also was demonstrated with detailed ultrastructural studies (184). Although clinically important, histamine release is insufficient to account for the vascular collapse in patients with systemic mastocytosis, and H1 and H2 antihistaminics fail to prevent all such attacks. Also, attacks of vascular collapse appear to subside with administration of aspirin. It has been suggested that this occurs via inhibition of the formation of PGD_2 (161).

In vivo systemic histamine administration (213) and endogenous release by chemical histamine releasers (100) lead to urticaria and angioedema. These manifestations of the anaphylactic syndrome thus are customarily attributed to histamine. Thus, vascular collapse without antecedent hypoxia or myocardial ischemia may be due principally to the release of histamine and the generation of PGD_2.

Similarly, the sulfidopeptide leukotrienes are considered the most likely mediators of the marked peripheral airway effects, which present as “acute emphysema.” In normal humans, the potencies of LTC_4 and LTD4 are 3 logs greater than that of histamine, and that of LTE_4 is 1 log greater in terms of compromising airflow as assessed by expiration from 30% of vital capacity, a measurement reflecting the effects on peripheral airways in preference to central airways (210,211). In experimental animal models, the sulfidopeptide leukotrienes are potent constrictors of coronary arteries (8), and thus they also may be involved in instances of vascular collapse of central origin with ECG findings of myocardial ischemia. The mast cell degranulation associated with a wheal-and-flare response to specific antigen in atopic persons is followed by the incremental local accumulation of eosinophils (7), presumably through the action of factors chemotactic for eosinophils or those that promote eosinophil adhesion (91). Logically, the same mechanism would account for the tissue eosinophilia observed at postmortem examination of persons who died of systemic anaphylaxis (81).

Whereas the importance of other mast cell and basophil mediators has not been as clearly shown in anaphylaxis, recent data indicate that nitric oxide (NO) may play a role in this acute inflammatory reaction. NO is constitutively produced by vascular endothelium, and both mast cells and vascular smooth-muscle cells can be stimulated to produce this molecule (107). NO synthesis is induced by numerous factors, including histamine, LTC_4, bradykinin, substance P, and hypoxia (119). NO acts on the peripheral vasculature to increase permeability and induce smooth-muscle relaxation, resulting in hypotension (86,129). Animal models of anaphylaxis indicate that NO may play an important role as a signaling molecule between chemical mediators produced early in the anaphylactic response and the cardiovascular system (128,130,166).

DIFFERENTIAL DIAGNOSIS

The diagnosis of an anaphylactic reaction depends largely on an accurate history revealing the onset of the appropriate signs and symptoms within minutes after the responsible material is encountered. Various disorders may present with clinical manifestations not unlike anaphylaxis and hence constitute the differential diagnostic list for this syndrome (Table 64.2) (52,125,160,218). The vasovagal reaction is perhaps the most common diagnosis that is confused with anaphylaxis. It presents with symptoms of pallor, profuse sweating, weakness, bradycardia, hypotension, and occasionally syncope (218). Because bradycardia is an early manifestation of hypovolemic shock, heart rate cannot be used reliably to differentiate a vasovagal reaction from anaphylaxis. Indeed, the heart rate has been reported to be low, normal, or elevated during anaphylaxis.

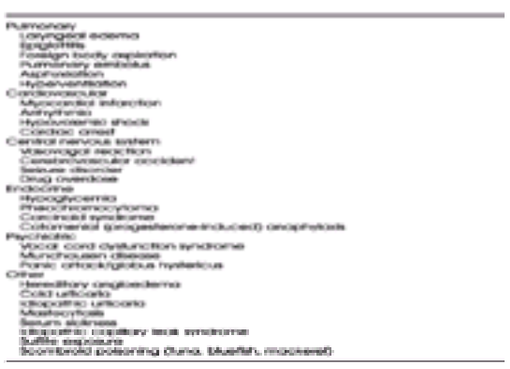

TABLE 64.2. Differential Diagnosis of Anaphylaxis

When only a portion of the full syndrome is present, such as isolated urticaria, sudden bronchospasm in a patient with asthma, or vascular collapse after intravenous administration of an agent, it is difficult to exclude a nonimmunologic, toxicologic, or idiosyncratic response. Even the presence of the full syndrome does not ensure an IgE-dependent mechanism. Intravenous administration of chemical mast cell–degranulating agents (100) can elicit generalized pruritic urticaria, angioedema, and a sensation of retrosternal oppression. In patients receiving an intravenous infusion of morphine, a drug known to release histamine from mast cells, peripheral vasodilation, hypotension, and a marked elevation in blood histamine have been noted (162). NSAIDs such as indomethacin sometimes precipitate a life-threatening episode of obstruction of the upper or lower airways in persons with asthma or an attack of urticaria and angioedema in atopic persons without asthma accompanied by occasional vascular collapse, which is clinically reminiscent of anaphylaxis. The mechanism does not appear to represent an acquired immunologic response, however, in that the patients experience similar episodes on ingesting NSAIDs that do not possess common antigenic determinants and do not stimulate production of detectable specific IgE (170). NSAIDs inhibit the enzyme cyclooxygenase with a potency that parallels their ability to provoke an adverse reaction resulting from increasing arachidonic acid metabolism by lipoxygenase-dependent pathways. Mast cells may be involved in an idiosyncratic activation, as evidenced by the documentation of mast cell tryptase and histamine release in aspirin-sensitive individuals with asthma after oral challenge with aspirin (17), so as to include leukotriene generation.

It is still not clear whether the systemic reaction to iodinated contrast agents is by direct mast cell or basophil degranulation or by a non-IgE immunologic mechanism. Adverse reactions to the contrast agents generally lack the post-event febrile period characteristic of a transfusion reaction, however. Patients with recurring systemic anaphylaxis that clinically is not due to a recognized antigen, including food allergens (199), and in whom the non-IgE-mediated causes of similar reactions have been excluded, are labeled as manifesting idiopathic anaphylaxis (39,111,182). Regardless of the mechanism, each of the previously discussed acute adverse responses is best managed by therapy appropriate for IgE-mediated anaphylaxis.

Other differential diagnostic possibilities may require alternative or additional maneuvers. Low levels or abnormal function of C1 inhibitor, a plasma regulatory protein, is associated in hereditary angioedema with episodic attacks of nonpitting edema that may involve any external body surface as well as mucosal surfaces. Attacks may affect the airway with respiratory obstruction. In the absence of oropharyngeal angioedema or other diagnostic historical facts, the diagnosis of laryngeal edema should be confirmed by visualization and the exclusion of laryngeal spasm, foreign-body aspiration, and tumor (148). The diagnosis of a carcinoid syndrome, caused by enterochromaffin cell tumors that secrete vasoactive substances such as serotonin, is favored by the finding of excessive 5-hydroxyindoleacetic acid (5-HIAA) in the urine, right-sided valvular disease, and blockade of flushing by administration of somatostatin (octreotide) (125). The superimposition of a myocardial infarction on an anaphylactic reaction also has been recognized (106,177,218) and requires an approach appropriate for that condition. Detection of skin-sensitizing antibodies, as evaluated by direct skin testing, is a sensitive, often useful method for the diagnosis of IgE hypersensitivity to a given moiety but carries the small risk of inducing an anaphylactic reaction in the patient being tested (69). Furthermore, the finding that IgE may be produced mucosally and exported to the lumen under the control of IL-4 indicates that serum and skin-based assays occasionally may be inadequate for investigating the role of IgE in hypersensitivity syndromes (31). This possibility needs to be taken into account in skin test–negative patients with a strongly positive recent history for anaphylaxis. Accordingly, several other approaches are available for evaluating hypersensitivity to an allergen. Active histamine release from peripheral leukocytes of patients has been used to confirm anaphylactic sensitivity to nuts, seafoods, and other foods (57) and to Hymenoptera venoms (195). Passive sensitization of peripheral leukocytes from normal donors has been used to establish that the antibody of the Hymenoptera-sensitive donor was of the IgE class (195). These latter approaches, however, often are available only at research centers and thus are rarely routinely used. If purified antigen is available, a solid-phase immunoadsorbent radioimmunoassay or enzymatic assay may be used to demonstrate the presence of specific IgE (143,149). For patients with suspected food allergy, double- or single-blinded, placebo-controlled food challenges may be performed with the suspected food. Such testing should be performed in a medical facility where personnel are experienced in this procedure and are prepared to treat anaphylaxis (82). Finally, elevated plasma histamine, urinary histamine metabolites, or plasma/serum tryptase levels are retrospective supportive findings in favor of a mast cell–mediated disorder such as anaphylaxis (42,52,73,82). Plasma histamine levels are maximal 5 to 15 minutes after an anaphylactic episode and return to baseline by 30 to 60 minutes. Use of plasma histamine levels may be clinically problematic because blood specimens must be processed immediately to prevent spontaneous basophil histamine release and the resulting artifactually elevated histamine levels in unseparated blood. Urinary histamine and its metabolites are elevated for a longer time, and measurements of these levels may be useful (82).

b-Tryptase is a neutral protease stored in mast cell secretory granules that is secreted by human mast cells after activation (87,177,178,179 and 180). b-Tryptase is usually undetectable in serum at baseline (< 1 ng/mL), but the level increases to reflect the severity of mast cell activation. During anaphylactic reactions, serum levels of b-tryptase have been reported to peak 30 to 60 minutes after the onset of symptoms and then decline, with a half-life of about 2 hours. Lack of correlation between

histamine and tryptase levels has been reported, with some patients exhibiting elevations of only one of these mediators (98). Unlike b-tryptase, a-tryptase is not stored in secretory granules of mast cells but appears to be produced constitutively. In systemic mastocytosis, there is a baseline increase in a-tryptase production (180). Commercially available tryptase assays (UniCAP System, Pharmacia-Upjohn) currently detect both a- and b-tryptase, with a normal range below 11 ng per milliliter. b-Tryptase alone may be detected with the G5 monoclonal antibody; however, this assay system is not currently available for commercial use. The total tryptase (a and b) assay system appears to be less sensitive than the b-tryptase assay for detecting elevated tryptase levels during anaphylaxis. If, however, baseline and acute blood samples are compared, a twofold or greater increase in total tryptase during the acute event provides at least as high a sensitivity as the b-tryptase specific assay (82,87,178,179).

The use of tryptase levels in postmortem sera as an indicator of anaphylaxis may contribute to the exclusion of anaphylaxis as the underlying cause of death in unexplained cases, but caution is warranted because serum b-tryptase levels occasionally are elevated in cases where anaphylaxis is not expected (40,87). In addition, several reports suggest that tryptase levels are more consistently increased in IgE-mediated anaphylaxis and less consistently so in non-IgE–mediated reactions and thus may be contemplated as a surrogate marker to distinguish the two (50,87,158,167). In all these situations, interpretation of serum tryptase levels must take into account the severity of the reaction because milder anaphylactic reactions are not always associated with significantly higher tryptase levels (82,87,142,177).

Other potential surrogate markers to distinguish anaphylaxis from mastocytosis eventually may include soluble CD25 (sCD25) and soluble kit (sKIT, CD117) levels. Both of these shed receptors are increased only modestly during anaphylactic episodes as detected by enzyme-linked immunosorbent assay (ELISA) and are markedly increased in systemic mastocytosis (2). The cellular source of sCD25 in anaphylaxis is likely to be activated T-lymphocytes, in line with the demonstration of activated T cells in Hymenoptera hypersensitivity (16) and downregulation of their surface IL-2 receptors after rush hyposensitization (200). Whether these surrogate markers will be clinically useful or will remain interesting research findings remains to be determined.

PREVENTION AND TREATMENT

A negative history of a previous adverse effect is no guarantee that administration of a pharmaceutical agent will not produce anaphylaxis. Subclinical sensitization may result from a previous uneventful clinical exposure (81), for example, as with the presence of the material in food (102,214) or with contact of a cross-reacting antigen (103,157). In a study of six fatal cases of systemic anaphylaxis (81), no instance was found in which serious difficulty would have been predictable on historical grounds. Yet the constitutional reaction began within minutes of antigen administration, and the patients were dead within 16 to 120 minutes despite emergency medical attention in four cases.

Prevention of the anaphylactic syndrome must take into account the sensitivity of the recipient, the dose and character of the diagnostic or therapeutic agent, and the effect of the administration route on the rate of absorption. Identification and avoidance of causative agents, as feasible, remain the most important steps in the management of susceptible persons. If there is a definite history of an anaphylactic reaction with a particular treatment, even though mild, it is advisable to select another agent or procedure. A skin test should be performed before the administration of certain materials that produce a high incidence of anaphylactic reactions (e.g., horse serum or allergenic extracts) or when the nature of a past adverse reaction is unclear. Patients with known sensitivities, such as to foods or stinging insects, should be taught to recognize the clinical signals of impending anaphylaxis (i.e., a lump in throat, difficulty breathing, lightheadedness, feeling of impending doom) and feel comfortable and skilled in the technique of self-administration of epinephrine. Epinephrine in a syringe or in an autoinjector device should be carried by the patient at all times, with several spares in convenient locations (e.g., at home and at work), and these kits should be renewed on a yearly basis.

In the case of penicillin, not all urticarial reactions imply the same hazard. Thus, skin testing to determine the presence and haptenic specificity of skin-sensitizing antibody may be justified if penicillin is clearly the drug of choice. If the skin-sensitizing antibody has minor determinant specificity to benzylpenicillin, penicillin should be avoided, whereas isolated major determinant specificity to benzylpenicilloyl generally would not contradict penicillin therapy if the clinical indication exclusively warranted treatment with penicillin. An occasional patient with skin-sensitizing antibody of benzylpenicilloyl specificity can manifest immediate reactions (45). In these situations, the skin-sensitizing antibody was of high concentration and binding avidity, whereas the titer of IgG antibody was relatively low.

Because even an intradermal or conjunctival test may produce a serious reaction, a prick test should precede these tests in any high-risk situation. In the event an agent is to be used despite a positive history, a positive skin test, or both, precautionary measures should include the following: (a) having present an intravenous infusion, intubation equipment, and a tracheostomy set; and (b) administration of the material first by prick test or intradermally into the distal portion of an extremity. If this test is tolerated, injection of material intradermally, subcutaneously, intramuscularly, or intravenously may be considered with increasing doses at 20- to 30-minute intervals such that the initial dose by the next route does not exceed the final dose by the previous route. Even with this technique, it may be difficult to be certain when target cell exhaustion has been reached and how long it will persist; in several instances (14,62,203), parenteral injection of the therapeutic dose of the agent has been lethal despite painstaking previous “acute desensitization.” With such “exhaustion” or “pharmacologic” desensitization, it is critical to give the therapeutic agent at regular intervals to prevent reestablishing a sensitized cell pool of hazardous size. Otherwise, because this procedure constitutes a form of “controlled anaphylaxis,” patients are likely to require repeat desensitization in the event of a future requirement for readministration of the known agent.

A different form of response involves the development of antibody of the IgG class that appears protective against anaphylaxis induced by Hymenoptera group venom by interacting with the antigen so that less of it reaches the sensitized tissue mast cells. Indeed, immunotherapy is often efficacious and indicated for the treatment of Hymenoptera hypersensitivity.

The hazards of anaphylactic transfusion reactions in IgA-deficient patients have been circumvented by using extensively washed erythrocytes, whole blood from IgA-deficient persons (113), and even autotransfusion. The protective role of pretreatment with glucocorticoids and H_1 and H_2 antihistamines with or without ephedrine (126, 221) at least 2 hours before radiographic studies in patients with a history of a previous reaction is well documented. Even under such conditions, studies should use a test dose, contrast agents of lower osmolarity; and, in the case of pyelography, a retrograde rather than an intravenous route when possible.

Patients with idiopathic anaphylaxis who experience frequent attacks should be placed on maintenance therapy with oral antihistamines and, in some severe cases, glucocorticoids (e.g., oral prednisone, 20–40 mg daily) until the episodes abate. Glucocorticoids may be tapered thereafter. High-risk patients on b-blocker therapy, including topical medications used in the treatment of glaucoma, should be continued on these medications only if feasible alternatives are unavailable and the drug is medically indicated.

Early recognition of an anaphylactic reaction is essential because death can occur within minutes to hours after the first symptoms appear (81,92). The immediate treatment of anaphylaxis begins with a rapid assessment of the patient's level of consciousness, along with the patient's airway, breathing, and circulation (ABCs). The management of anaphylaxis should take into consideration the severity of the reaction. Epinephrine is the initial drug of choice (Table 64.3) (124). The recommended dose of epinephrine in adults is usually 0.3 mL of 1:1,000 aqueous epinephrine injected subcutaneously, although the dosage may need to be decreased in elderly patients (to perhaps 0.2 mL) or increased in patients receiving b-adrenergic blockers (to 0.5 mL). Epinephrine dosages in children are based on weight, that is, 0.01 mL per kilogram of a 1:1,000 dilution up to a maximum of 0.3 mL of epinephrine injected subcutaneously. If the antigenic material has been injected into an extremity, the rate of absorption may be reduced by prompt application of a tourniquet proximal to the reaction area, administration of 0.2 mL 1:1,000 epinephrine into the site, and removal of an insect stinger, if present, without compression. One study of 17 children with a history of anaphylaxis to food, Hymenoptera venom, or other substances (188) concluded that intramuscular administration of epinephrine may afford greater bioavailability. The mean maximum epinephrine concentration was slightly greater after intramuscular injection, and the time to maximum concentration was almost five times longer with subcutaneous than with intramuscular injection (approximately 30 and 7 minutes, respectively) (141,188). In addition, more than 70% of patients who received intramuscular epinephrine achieved peak epinephrine levels within 5 minutes, compared with only 20% of those who received epinephrine subcutaneously.

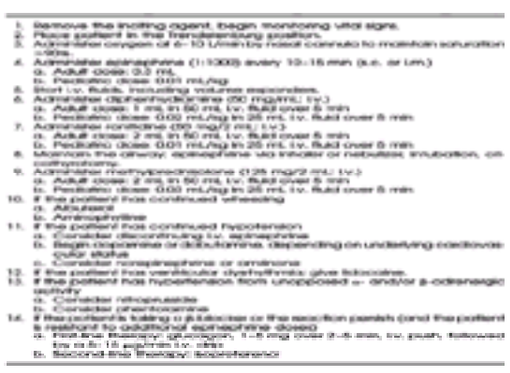

TABLE 64.3. Treatment of Anaphylaxis

Supportive measures also should include establishment of an intravenous infusion to provide for the administration of volume expanders and other medications (21,218). Oxygen via a nasal cannula or intermittent positive-pressure breathing of oxygen with epinephrine via nebulizer or inhaler may be helpful, but either endotracheal intubation or a tracheostomy is required for progressive hypoxia. Ancillary agents such as the H_1 antihistamine, diphenhydramine, or aminophylline are appropriate for urticaria–angioedema and bronchospasm, respectively. H_1 and H_2 actions of histamine may lead to arrhythmias and a widened pulse pressure, suggesting a beneficial effect of H_2 antihistamines (110). Clinical and experimental evidence suggests that treatment with a combination of H_1 and H_2 receptor antagonists may be more effective than treatment with an H_1 antihistamine alone in preventing histamine-induced hypotension (21,42,82,218). Intravenous glucocorticoids are not efficacious for the acute event but should be considered in instances in which amelioration is not complete and subacute bronchospasm or hypotension persists (218).

In addition to fluid resuscitative measures, treatment of refractory hypotension and shock may require pharmacologic intervention. Replacement of serial subcutaneous and intramuscular epinephrine injections with an intravenous bolus, followed by a continuous infusion of a 1:10,000 epinephrine drip, is generally recommended as first-line therapy (21,218). Lack of response to this measure may warrant the addition of an intravenous continuous infusion of dopamine or dobutamine, depending on the patient's underlying cardiovascular status, followed by norepinephrine or amrinone. Established dosages of these vasoactive inotropic medications are provided by the American Heart Association (AHA) guidelines (33). Hypertension resulting from unopposed b-adrenergic and a-adrenergic activity may require prompt treatment with nitroprusside or phentolamine until blood pressure stabilizes. Even with close cardiac monitoring and titration, myocardial infarction is a known associated sequela of systemic anaphylaxis, either from the initial hypotensive insult to the myocardium or from a- or b-adrenergic effects on an already compromised cardiovascular system.

Occasionally, apparent “biphasic reactions” occur; that is, reactions recur hours after the initial reaction (19,37,197). It is therefore recommended that patients experiencing anaphylaxis be kept under observation for up to 24 hours and that glucocorticoids be administered in instances of moderate or severe anaphylaxis to help prevent such delayed-onset reactions. Whether epinephrine acts to prevent mediator release, reverse the action of mediators on target tissues, or both is not established, but its early administration appears to be critical. Epinephrine is still the drug of choice when anaphylaxis occurs in a patient on a b-adrenergic blocker (82,201,218) or in pregnant women experiencing anaphylaxis (218). It is also an important strategy to prevent or lessen the severity of anaphylactic reactions by early self-intervention in high-risk patients.

65 ASTHMA

Mark D. Steel, M.D. and Stephen T. Holgate, M.D.

HISTORY

The word *asthma* was first introduced in ancient Greece. It originally referred to the symptom of breathlessness rather than to the disease that is recognized today. Mild breathlessness was termed *dyspnea*; moderate breathlessness, *asthma*; and severe breathlessness, *orthopnea* (1). Hippocrates (460–380 BC) believed that ill health arose from an imbalance among the four humors (body fluids): blood, phlegm, yellow bile, and black bile. Phlegm was thought to originate in the brain, from where it condensed in the nasal cavities via the pituitary gland. Asthma was considered to result from excess phlegm flowing down into the lung (1). Claudius Galen of Pergamum (129–216 AD) elaborated on the hippocratic concept of the humors and dominated medical thinking about the causation of ill health throughout the Middle Ages (1).

Unlike Galen and Hippocrates, a number of early physicians did appear to appreciate at least some of the clinical features of asthma, attempting to differentiate it from other diseases that cause breathlessness. Aretaeus of Cappadocia (81–131 AD) referred to asthma as a disease characterized by paroxysms of breathlessness induced by exercise and associated with cough. His writings were not discovered until 1554 and are considered the best description of asthma from ancient times (2). Moses Maimonides (1130–1204) also referred to the paroxysms of breathlessness in his *Treatise on Asthma* (1190), the earliest known monograph on the condition, and recognized that the disease often improved during adolescence (1).

Galenic dogma was eventually challenged during the Renaissance period by Paracelsus (1493–1541), who vigorously denied the ancient humoral theories and burned Galen's works. His ideas led to the gradual liberation of European medical thinking about the pathogenesis of disease. Johannes Baptiste van Helmont (1579–1644) argued against the ancient humoral theory of asthma on the basis that coughing prevented the descent of phlegm into the lungs. Although he reasoned that the production of phlegm occurred in the airways, he argued that the onset of a paroxysm of breathlessness was too rapid to be explained by the accumulation of phlegm within the lung (3).

Early descriptions of asthma overlap to varying degrees with descriptions of other respiratory and cardiac diseases that cause breathlessness and cough. Sir John Floyer (1649–1734) is generally considered the first to describe clearly and to differentiate asthma from these other conditions in his *Treatise of the Asthma* (1698), the first monograph on the subject written in English (4). In it, he describes the periodic nature of the disease, the typical worsening of symptoms during the night, and the expectoration of bronchial casts of viscid phlegm. He refers to the clinical signs of airflow obstruction, noting hyperinflation of the chest and prolonged expiration associated with wheeze. Like van Helmont, Floyer also regarded asthma as a nervous disorder, and he postulated that involuntary spasms of the bronchi resulted from the contraction of muscle fibers under the influence of the vagus nerve. Opposition to the *spasm* theory of asthma, however, came from those who continued to argue that phlegm was the cause of airflow obstruction in the disease. These opponents included Giovanni Battista Morgagni (1682–1771), who observed thick mucus obstructing the airways in a case of presumed fatal asthma (2).

In 1808, Franz Reisseinen identified the circular smooth-muscle layer in the bronchial wall (1); and in 1830, Eberle postulated that bronchoconstriction was not the result of a convulsion but was instead a reflex action in response to irritating stimuli in the lungs or elsewhere (5). In 1842, Francois Longet demonstrated that electrical stimulation of the vagus nerve could indeed induce bronchoconstriction (1); by the mid-nineteenth century, the spasm theory of asthma prevailed. This conclusion is evident in the writings of Henry Hyde Salter (1823–1871), the greatest authority on asthma in Victorian England. In his treatise *On Asthma: Its Pathology and Treatment* (1860) (6), Salter reinforced the concept of asthma as a disease of the nervous system causing paroxysms of bronchial spasm, grouping cases according to whether he considered them a reflex phenomenon or a nonreflex disorder originating in the brain. He dismissed mucosal edema and tenacious mucus plugs as additional causes of bronchial obstruction on the basis that he could find no evidence of these in the lungs of persons with asthma who had died of other causes. In 1875, Karl Stoerk directly observed the rapid development of mucosal edema and hyperemia throughout the trachea in a patient during an attack of asthma. In 1886, Sir Andrew Clark challenged the spasm theory of asthma, arguing that episodes of mucosal edema with associated increased mucus production could cause paroxysms of airflow obstruction in the absence of bronchial smooth muscle contraction (7). By the end of the nineteenth century, asthma still was considered a nervous disorder, but opinion differed as to whether the cause of bronchial obstruction was bronchospasm or neurogenic vasodilatation.

The observation that many individuals with asthma react to specific environmental factors in an idiosyncratic manner has been documented since the Renaissance period, when increasing recognition was given to the influence of external factors on health. In 1547, Geromo Cardano advised the asthmatic Archbishop of St. Andrews, Scotland, to avoid feather bedding. This resulted in symptomatic improvement and is often cited as the first example of therapeutic allergen avoidance (1). Both van Helmont and Floyer recognized that the inhalation of dust and the ingestion of certain foods could induce asthma in susceptible individuals, and Barnadino Ramazzini (1633–1714) gave the first clear account of occupational asthma in bakers and millers (8). Although the influence of seasonal changes on the disease was appreciated by Floyer, it was John Elliotson who, in 1831, first proposed that pollen might be the environmental factor responsible for inducing asthma in association with hay fever (1). In 1873, Charles Blackley confirmed this idea, postulating that other “proteids” might be important in other forms of the disease (9). By the end of the nineteenth century, the *nervous* theory of asthma suggested that certain inhaled or ingested environmental irritants and proteids could stimulate either reflex bronchospasm or mucosal vasodilatation in susceptible individuals. Recognizing the idiosyncratic nature of the disease, Salter argued that the susceptibility of the individual to asthma reflected an abnormal increase in the irritability of the part of the nervous system affected (6).

Immunologic Highlights

In 1902, Charles Richet and Paul Portier reported that, whereas the extract from sea anemone tentacles had no effect on dogs when given as a single injection, a second injection after a few weeks caused a rapid and fatal reaction. Richet gave the term *anaphylaxis* to this phenomenon, suggesting that the initial injection of toxin had somehow weakened the dog's defense mechanisms and increased its susceptibility to toxin on subsequent exposure (9). In 1904, Theobold Smith reported that fatal anaphylactic shock could be induced by repeated injections of horse serum into guinea pigs, suggesting that nontoxic proteins also could cause anaphylaxis (9).

The following year, Clement von Pirquet and Bela Schick reported the occurrence of a transient fever, rash, and polyarthritis in patients given antiserum for the treatment of major infection. They termed this clinical syndrome *serum sickness* and noticed that a repeated injection of antiserum could induce an immediate and sometimes fatal reaction (9). On the basis of similarities between this observation and the anaphylactic shock described in animals, they argued that serum sickness was a form of anaphylactic reaction in humans. In 1907, von Pirquet introduced the term *allergy* to refer to the altered state of reactivity induced by repeated exposure to foreign substances that is responsible for anaphylaxis. In 1910, John Auer and Paul Lewis demonstrated bronchospasm to be a key feature of anaphylactic shock in guinea pigs, leading Samuel Meltzer to propose the *anaphylactic* theory of asthma later the same year, thus classifying asthma not as a nervous disorder but as an allergic disease (10).

The following year, Leonard Noon demonstrated that persons who were sensitized to grass pollen developed a wheal-and-flare reaction after receiving an injection of a grass pollen extract into the skin, thereby introducing allergen skin testing (9). In 1919, Maximilian Ramirez reported the case of a man who developed asthmatic symptoms on contact with horses shortly after being transfused with blood from a horse-sensitive donor. This condition was associated with a positive skin test to horse antigen, and Ramirez concluded that “anaphylactic bodies,” responsible for mediating anaphylaxis, had been passively transferred via the donor's blood (11). Two years later, Carl Prausnitz and Heinz Küstner renamed this transferable factor *reagin* (9). On the basis of positive skin testing, Coca and Cooke introduced the term *atopy* in 1923 to denote the sensitization of persons to one or more environmental allergens (12). It had already become apparent, however, that not all persons with asthma had positive skin tests, leading to the classification of asthma into *extrinsic* (allergic) and *intrinsic* (nonallergic) groups by Walker in 1918 (13). Nonetheless, the anaphylactic theory continued to dominate the field of asthma research.

In 1929, Sir Henry Dale demonstrated that intravenous administration of histamine could induce an anaphylactic-like syndrome in guinea pigs and rabbits, and he postulated that histamine played a key role in the anaphylactic reaction (9). Evidence in support of Dale's hypothesis came when increased serum levels of histamine were shown to be associated with anaphylaxis in guinea pigs. Furthermore, the newly developed histamine receptor antagonists significantly reduced the severity of the anaphylactic reaction in this animal model (9). In 1952, Riley demonstrated the source of histamine to be the tissue mast cell (14), and the mast cell hypothesis of anaphylaxis and asthma was subsequently proposed. It soon became evident, however, that histamine was not the only soluble factor mediating anaphylaxis. Using the isolated organ bath preparation of sensitized guinea pig lung, Brocklehurst demonstrated that antihistamines failed to prevent a sustained smooth muscle contraction in response to allergen challenge. In 1960, on the basis of the time course of this contractile response, he termed the soluble mediators responsible the slow-reacting substance of anaphylaxis (SRS-A) (15).

Kimishige and Teruko Ishizaka identified reagin as the immunoglobulin E (IgE) subclass of antibody in 1967 (16), and Johansson reported an association between allergic asthma and elevated levels of serum IgE the same year (17). In 1971, Tomoika and Kimishige Ishizaka demonstrated the presence of receptors for IgE on mast cells, later shown to be high-affinity receptors for the Fc portion of the IgE molecule (FceRI). By 1979, the Ishazakas had reported mast cell activation after the cross-linking of these receptors by allergen-IgE antibody complexes, resulting in the release of histamine and SRS-A (18). SRS-A subsequently was identified as the cysteinyl leukotrienes-leukotriene (LT)C_4 LTD_4, and LTE_4, whose structures and synthetic pathways were elucidated in 1983 (19).

In 1986, Mossman et al. (20) published data from a study in mice, which has since had a major influence on our thinking about the cellular and molecular mechanisms underlying allergy. On the basis of differences in patterns of cytokine expression *in vitro*, two distinct subsets of T helper memory cells, termed T helper type 1 (Th1) and Th2, were identified within the $CD4^+$ lymphocyte population. Murine Th1 cells were found to express interleukin-2 (IL-2) and interferon-g (IFN-g), whereas Th2 cells expressed IL-4 and IL-5. Both subsets produced IL-3 and granulocyte–macrophage colony-stimulating factor (GM-CSF). Subsequent studies in humans demonstrated similar subsets of T helper cells (21), termed Th1-like (IFN-g) and Th2-like (IL-3, -4, -5, -6, -9,-13; GM-CSF). Because IL-4 upregulates IgE production (22) and IL-5 promotes eosinophil recruitment (23), Th2-like and Th1-like cells were considered to orchestrate allergic and nonallergic immune responses, respectively. Consequently, the mast cell hypothesis was superseded by the postulated pivotal role of the T cell in asthma.

EPIDEMIOLOGY

Population-based studies provide data on the prevalence, geographic distribution, and natural history of disease. In addition, they play a key role in directing research on the etiology of disease by focusing attention on genetic and environmental risk factors. The outcomes and conclusions drawn from such studies are critically dependent, however, on how the disease has been defined.

Definition of Asthma

The lack of an objective definition for asthma, allowing the unequivocal differentiation of the asthmatic from the nonasthmatic phenotype, remains a fundamental problem (24,25), reflecting the phenotypic heterogeneity of the disease and the current lack of understanding of the processes involved. Such heterogeneity is suggested by the various clinical subgroups (subphenotypes) of asthma that are recognized, including atopic asthma, aspirin-intolerant asthma (AIA), exercise-induced asthma (EIA), occupational non-IgE-dependent asthma, intrinsic asthma, brittle asthma, and cough-variant asthma. This complexity is further increased when variations in disease chronicity, severity, and response to treatment are considered. Thus, far from being a single disease entity, asthma is probably best considered a clinical syndrome comprising multiple variants.

The original clinical definition of asthma can be found in Salter's treatise of 1860, in which he describes the condition as “paroxysmal dyspnea, generally periodic, with healthy respiration between attacks” (6). In 1959, the Ciba Foundation guest symposium redefined asthma as “a widespread narrowing of the bronchial airways which changes in severity over short periods of time, either spontaneously or under treatment” (26). This definition drew a distinction between “reversible” airflow obstruction, corresponding to asthma, and “irreversible” airflow obstruction, subsequently synonymous with chronic obstructive pulmonary disease (COPD). Longitudinal studies have since shown that a significant proportion of persons who have chronic asthma exhibit an increased rate of decline in lung function over time, leading to the progressive acquisition of a fixed component of airflow obstruction (27). Furthermore, asthmatic and COPD populations overlap in peak expiratory flow (PEF) variability (28). Thus, similarities in lung function in the clinical syndromes of chronic asthma and COPD have added to the diagnostic difficulty.

Bronchial responsiveness refers to a change in airway caliber in response to a variety of nonspecific physical or chemical stimuli; it was first introduced as a concept by Dautrebande and Philpott in 1941. An exaggerated bronchoconstrictor response, termed *bronchial hyperresponsiveness* (BHR), subsequently was found to be a feature of asthma, leading to the incorporation of BHR into the definition of the disease by the American Thoracic Society in 1962 (29). More recently, fiberoptic bronchoscopy has allowed new insights into the pathogenesis of asthma, with the recognition that persistent airway inflammation is a consistent feature of all forms of the disease (30,31). Consequently, the combined World Health Organization (WHO) and National Heart, Lung, and Blood Institute (NHLBI) working group of 1995 defined asthma as “a chronic inflammatory disorder of the airways giving rise to recurrent respiratory symptoms associated with widespread, variable, and reversible airflow obstruction and bronchial hyperresponsiveness” (32). Chronic Th2-mediated airway inflammation has since been shown to be a feature of both atopic and nonatopic asthma (33,34 and 35).

In clinical practice, the diagnosis of asthma equates to a medical opinion that is based on a balance of probabilities, taking account of the medical history, physical examination, measures of lung function, and response to treatment. Although such an assessment may be feasible for each subject in a small-scale study, this is generally not the case when the study is population-based. Thus, epidemiologists have used symptom questionnaires, but the validity of this method continues to be a subject for debate (24). In attempting to improve diagnostic accuracy, many epidemiologists have combined symptom questionnaires with “objective” measures of bronchial responsiveness or PEF variability.

Bronchial Hyperresponsiveness and Peak Expiratory Flow Variability

The measure of lung function that has received the greatest attention as an objective diagnostic marker for asthma has been BHR. Physical stimuli used to assess bronchial responsiveness include exercise and cold (dry) air; chemical stimuli include histamine, methacholine, and adenosine monophosphate. The histamine challenge and methacholine challenge are the methods most widely used to provide a measure of bronchial responsiveness; they are expressed as the concentration (or dose), termed the PC_{20} (or PD_{20}), of histamine or methacholine that is required to produce a 20% fall in FEV_1 (forced expiratory volume in 1 second). The threshold used to define BHR is arbitrary, but values of 8 mg per milliliter or less are generally used, and both chemicals give comparable results. When defined this way with histamine, one study (36) found BHR to have a sensitivity of 97% for physician-diagnosed asthma, suggesting that 97% of the asthmatic population have BHR. The specificity of the test was only 71%, however, suggesting that 29% of the nonasthmatic population also have BHR by this definition. Others have reported similar results (37). Thus, a negative test may be considered useful for excluding asthma, but a positive test has limited use as a diagnostic marker for the disease because BHR is also associated with atopy, COPD, increasing age, and female gender in the nonasthmatic population (24). Although some authorities advocate a measure of bronchial hyperresponsiveness in addition to a standardized symptom questionnaire when defining asthma in population-based studies (38), others argue that the diagnostic accuracy of a standardized symptom questionnaire *alone* is probably little different (24,25).

In contrast, there has been relatively little interest in the measure of airflow variability as an objective diagnostic marker for asthma, despite the fact that the various definitions of asthma have variable airflow obstruction as a unifying feature. When defined as PEF variability exceeding the 90th percentile of a distribution, one study (39) involving children found variable airflow obstruction to have a specificity of 91% for physician-diagnosed asthma but a sensitivity of only 36%. Similar levels of sensitivity have been found when 90% specificity is taken as a cutoff in other studies involving children and adults (37,40). Numerous issues relating to the

measurement and analysis of airflow variability have yet to be resolved (41).

The correlation between PEF variability and bronchial responsiveness is not strong (28,40), perhaps indicating that these two measures of lung function relate to different pathophysiologic processes in the diseased lung. Whereas PEF variability exhibits a stronger correlation than BHR with respect to cough and wheeze in the past week, BHR shows a stronger correlation than PEF variability with respect to such symptoms over a period of 12 months (37), and exacerbations of asthma do not appear to be associated with changes in BHR (42). Furthermore, BHR not only correlates with reduced FEV_1 (24), but it also is associated with impaired growth in FEV_1 in children and accelerated decline in FEV_1 in adults (27). Thus, BHR might be of use as a prognostic marker, helping to identify persons with asthma who are at increased risk of chronic and severe disease, whereas PEF variability might simply be a marker of current disease activity. Longitudinal studies also indicate that asymptomatic BHR is an independent risk factor for the development of asthma (43,44), suggesting that BHR may represent an intermediate phenotype between normality and the clinical disease (45). The debate surrounding the significance of BHR probably will continue until its underlying mechanisms are better understood.

Prevalence, Morbidity, and Mortality

Despite difficulties relating to the definition of asthma and changes in the International Classification of Diseases (ICD), it is generally agreed that prevalence rates for early-onset asthma and atopy have increased throughout the world since the 1960s, probably twofold or threefold (46). In contrast, the prevalence of late-onset disease, presenting for the first time at age 40 or older, appears not to have increased over the last 20 years, at least in elderly persons (47).

To obtain data allowing for more reliable comparisons between countries, as well as with future time points, efforts have been made to establish international collaborative studies with standardized methodology. These include the International Study of Asthma and Allergies in Childhood (ISAAC) (48) and The European Community Respiratory Health Survey (ECRHS) (49), which focused on adults between the ages of 20 and 44 years. ISAAC phase 1 assessed 721,601 children, aged 6 to 7 and 13 to 14 years, from 56 countries throughout the world. The results indicate a prevalence of asthmalike symptoms in the past 12 months of 2% to 32% and a previous history of physician-diagnosed asthma of 1.5% to 28%, with little difference between the two age groups. Countries with a prevalence of less than 10% were found mainly in Asia, North Africa, Eastern Europe, and the Eastern Mediterranean regions. In contrast, countries with a prevalence of more than 20% included the United States, the United Kingdom, New Zealand, Australia, and Latin America.

Although asthma can present at any age (50), 80% to 90% of all cases are thought to present with symptoms before the age of 5 years (51), and the mean annual incidence for wheezy illness in childhood is believed to be greatest before the age of 3 years (52). Longitudinal studies have shown that, of the cases of wheezy illness presenting under the age of 5 years, only a third persist into later childhood as established cases of asthma (52,53), and up to half of these cases resolve by adulthood (54). These studies suggest that, although persistent asthma appears to affect between 5% and 12% of the general population, at least three times as many people experience sporadic asthmalike symptoms at some point during their lives. During childhood, the male-to-female ratio for physician-diagnosed asthma is approximately 2:1. After puberty, however, the disease is more common in the female population, suggesting that hormonal factors may play an important role (55).

The ISAAC study found that the proportion of children with severe asthma compared with the total number of children with asthmalike symptoms varied little between countries, suggesting that factors influencing the prevalence of the disease might also affect the severity. This finding is consistent with observed increases in hospital admission rates (56), reflecting the rise in the prevalence of asthma in westernized societies. In the United States alone, the cost of treating asthma is an estimated $6 billion per annum, half of which is spent on hospital care and 80% of which is spent on the 20% of patients at the severe end of the disease spectrum (57). There is also concern relating to the apparent increase in asthma-related deaths observed in most developed countries, with mortality rates presently standing at between 1.0 and 1.5 per 100,000 of the general population. This increase in the asthma mortality rate appears to be real and cannot be explained by changes in ICD coding or death certification (58).

Role of Atopy

Since 1910, the anaphylactic theory of asthma has dominated research into the disease, largely supported by data from population-based studies. These data suggest that about 90% of persons under the age of 30 years who have asthma are atopic and that atopy is the strongest risk factor for the disease, with an odds ratio of between 10 and 20 (59). Furthermore, longitudinal studies have shown atopy to be a risk factor for the persistence of early childhood wheeze into late childhood (52,53) and for the persistence of childhood asthma into adulthood (54).

Although originally atopy was defined on the basis of positive skin testing to allergen, it was recognized that a negative test did not necessarily exclude atopy because it was still possible to be allergic to proteins not present on the panel of test allergens. After the introduction of tests allowing the measurement of total serum IgE, the definition of atopy was revised. Consequently, population-based studies challenged the traditional classification of asthma into extrinsic and intrinsic groups by demonstrating an association between elevated levels of total serum IgE and all forms of asthma, irrespective of skin-prick test results (60,61). This finding led to the suggestion that atopy and allergic airway inflammation were in fact pathognomonic for asthma, further supporting the anaphylactic theory. In the case of “intrinsic” asthma, it was suggested that the allergens responsible were unidentified environmental or endogenous proteins (60). Consequently, the pathogenesis of asthma was viewed in terms of a serial model for allergic disease in which the exposure of genetically susceptible individuals to allergen induces a presymptomatic state of atopic sensitization, characterized by a Th2-mediated inflammatory response to allergen, with progression to clinical asthma on continued allergen exposure. This model, however, raises a fundamental question: What are the mechanisms whereby Th1 and Th2 immune responses are programmed into long-term immunologic memory? Furthermore, it fails to take into account the observation that only 20% of the atopic population develop asthma, with additional subsets presenting with atopic eczema or allergic rhinitis. This finding raises a second fundamental question: What are the mechanisms by which the Th2-mediated inflammatory response to allergen localizes to a mucosal surface? In the case of asthma, it is postulated that gene-environment interactions not only skew the programming of immunologic memory toward the Th2 phenotype but also determine target-organ selectivity, localizing the allergic inflammatory response to the airway mucosa. The persistence of asthma in lungs transplanted from asthmatic donors to nonasthmatic recipients, but not the converse, strongly suggests that determinants of target-organ localization reside within the target organ itself (62).

Although it is generally accepted that atopy plays an important role in asthma pathogenesis, a number of epidemiologic observations have challenged the dominance of the anaphylactic theory, questioning the contribution made by IgE-dependent mechanisms to the development of the disease. In parallel with asthma, evidence suggests that the prevalence of atopy has increased throughout the world since the 1960s and that almost 50% of the population from westernized societies demonstrate sensitization to one or more environmental allergens, with lower prevalence rates observed in less developed countries (59). Most epidemiologic studies, however, found no evidence to suggest an association between the prevalence of asthma and atopy (defined as skin-prick test positivity) when measured in the same population at different times or in two or more different populations at the same time (63).

There is also concern about the validity of using total serum IgE to define atopy. Although levels of total serum IgE correlate with skin-prick test positivity, this correlation is stronger if measures of allergen-specific serum IgE radioallergosorbent test (RAST) are used instead. Furthermore, because the level of serum IgE used to define atopy is purely arbitrary, it is considered likely that the prevalence of atopy has been overestimated significantly in many population-based studies (63). Indeed, many epidemiologists now argue that atopy should be defined either in terms of RAST or skin-prick test positivity to common environmental allergens (64). By this definition, the correlation observed between elevated levels of total serum IgE and nonatopic asthma led to the suggestion that coinherited genetic factors might increase a person's susceptibility to both asthma and increased IgE production (65). In this case, IgE may not necessarily play a causal role in asthma, but it may simply be a marker of the chronic Th2-mediated airway inflammation that underlies the disease. Family-based studies suggest, however, that the tendency to produce increased amounts of IgE is just one of a number of inherited factors associated with the inheritance of asthma, and its ability to predict the development of asthma is limited (66). In cases of late-onset asthma, the prevalence of atopy is no greater than that in the age-matched nonasthmatic population, and atopy diminishes as a risk factor, especially toward the severe end of the disease spectrum (67). Thus, factors other than atopy are likely to play an important role in the development of asthma.

Intermediate Phenotypes

Population-based studies provided data on which hypothetical models of asthma pathogenesis have been based. These models suggest that, as a consequence of gene-environment interactions, chronic Th2-mediated airway inflammation and BHR develop, giving rise to an asymptomatic “asthmatic state.” This state then provides the context in which progression to clinical asthma might occur (45). Exactly how these two intermediate phenotypes interact with one another is not completely understood (Fig. 65.1). Although airway inflammation is considered an important mechanism underlying BHR, asymptomatic BHR and markers of allergic inflammation are independent risk factors for the development of asthma (43). It is postulated that children who “outgrow” their asthma retain the asthmatic state and are at risk of asthma relapse in later life, as lung function declines. Failure to recollect the childhood illness may give rise to the diagnostic label of late-onset asthma (55).

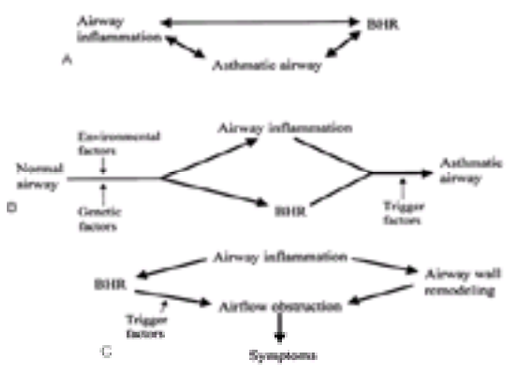

Figure 65.1. Hypothetical models of asthma. **(A)** Airway inflammation and BHR interdependence.**(B)** Steps involved in transforming a normal airway into an asthmatic airway.**(C)** Airway inflammation as the dominant driving force in the creation of the asthmatic state. (Reprinted from Banik AN, Holgate ST. Problems and progress in measuring methacholine metacholine bronchial reactivity. *Clin Exp Allergy* 1998;28(Suppl 1):15–19, with permission.)

In the absence of an objective definition for asthma, epidemiologists and geneticists have used intermediate phenotypes in the design of their studies, using atopy (RAST and skin test positivity) and total serum IgE as surrogate markers for chronic Th2-mediated airway inflammation. Despite the close relationships between BHR, skin test positivity, RAST, total serum IgE, and asthma (60,61), these phenotypes are not interchangeable, and it cannot be assumed that the gene–environment interactions responsible for the intermediate phenotypes are the same as those responsible for asthma. Thus, reliance on intermediate phenotypes carries with it a risk that important etiologic factors other than atopy might go unrecognized.

Genetics of Asthma and Atopy

The tendency for asthma to cluster within families was recognized by Salter in his treatise of 1860 (6) and later was confirmed by familial aggregation studies (68). Although suggestive of a genetic basis for asthma, these studies are not conclusive because an alternative explanation could be the familial sharing of environmental factors. Stronger evidence for a genetic contribution to the etiology of asthma has come from the study of inheritance in twins. Twin studies are based on the fact that monozygotic twins have identical genotypes, whereas dizygotic twins share on average only half their genes. Thus, diseases with a genetic component show higher rates of concordance in twins that are monozygotic than in those that are dizygotic. This pattern of inheritance is observed not only for asthma but also for BHR, atopy, and increased levels of total serum IgE, strongly suggesting a genetic basis for both the disease and intermediate phenotypes (69). In the case of atopy, the genetic component appears to be independent from that determining the target-organ selectivity of allergic disease (68) as well as from that determining BHR (70). This finding is consistent with data from segregation studies that indicate that asthma is a complex multigenic disorder, probably involving a number of subtle polymorphisms whose expressions are dependent on interactions with other genes (epistasis) as well as with the environment (69). Estimates of the contribution that genetic factors make to asthma susceptibility range from 35% to 70%, depending on the population and design of study (71). The two main methods used in attempts to identify asthma and atopy susceptibility genes are the *genome scan* (positional cloning) and *candidate gene approach* (fine mapping) (69,71).

Genome Scan

Genome scans use a panel of microsatellite DNA markers that label the entire human genome at known positions, typically 5 to 10 cM apart. Linkage studies are conducted within families or inbred populations, correlating the inheritance of genetic material, identified by the markers, with the phenotype of interest. The closer a microsatellite marker is to a disease-related gene, the less chance there is that they will be separated at meiosis. Linkage is measured by the lod score (log of the odds ratio of the probability of linkage to the probability of no linkage), and a lod score greater than 3.6 is considered significant (72). Thus, genome scans identify candidate susceptibility loci, within which susceptibility genes might reside. It is currently not possible, however, to narrow the focus to less than 1 cM (1 million base pairs), corresponding close to 100 genes. Numerous genome scans for asthma and atopy have now been completed (Table 65.1) (73,74,75,76 and 77), each reporting evidence for linkage to multiple loci. Most of these studies suggest candidate susceptibility loci within chromosomal regions 5q, 6p, 11q, 12q, and 13q. Although other regions have been highlighted by one or two studies, there is concern regarding statistical power because all these studies involved relatively small numbers of families (i.e., 100–500) (72). In an attempt to address this problem, efforts have been made to pool data (78); however, no candidate susceptibility genes for asthma or atopy have emerged from genome scans to date.

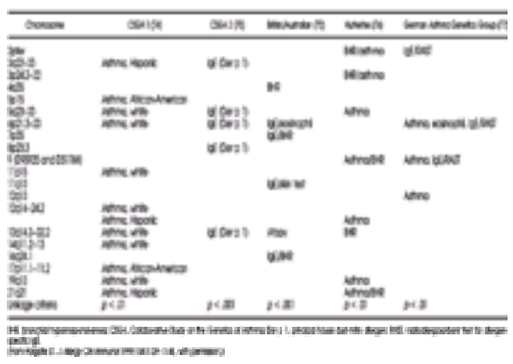

TABLE 65.1. Summary of Results from Published Whole-Genome Scans in Asthma

Candidate Gene Approach

The candidate gene approach involves direct testing for linkage or association between the allele (gene polymorphism) and phenotype of interest. Whereas linkage studies are performed on families or inbred populations, association studies generally are undertaken on populations of unrelated persons and compare the frequency of the candidate allele in those expressing the phenotype of interest with its frequency in those not affected. Candidate genes are chosen on the basis of cell and molecular models of asthma and the considered likelihood that they are important determinants of disease susceptibility, disease modification (chronicity and severity), or response to drug therapy (*pharmacogenetics*). A positive association does not necessarily imply a causal relationship because the candidate gene might be in linkage disequilibrium with a genuine disease-causing gene. Alternatively, a positive association might also occur if the candidate gene and disease both occur with increased frequency in an ethnic group. Thus, to prevent false-positive results, association studies should be performed in relatively homogeneous populations. Although numerous candidate genes have been described (Table 65.2), no gene has yet been identified as being involved in the inheritance of asthma with any certainty. Much interest has focused on the IL-4 gene cluster on chromosome 5q31-33, encoding the Th2 cytokine array, IL-3, IL-4, IL-5, IL-6, IL-9, IL-13, and GM-CSF. Importantly, the promoter regions of all human Th2-like genes share a common motif (CTTGG|.|.|. CCAAG), which is not present in the IFN-g promoter (79). This fact would be consistent with a mechanism for coexpression of Th2-like genes and has stimulated interest in the transcription factors involved.

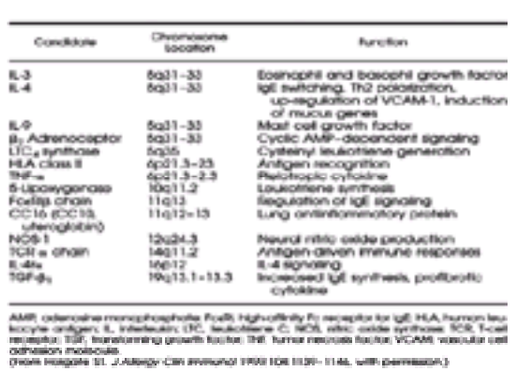

TABLE 65.2. Candidate Genes in Asthma and Allergy and Their Chromosomal Locations

Environmental Factors

Although genetic factors, at least in part, might account for geographic and racial differences in the prevalence of asthma and atopy, they fail to explain the rate of increase in the prevalence of these conditions over the past three to four decades, strongly suggesting that environmental changes are primarily responsible. When considering which environmental factors are involved, it is important to determine whether they increase the risk of developing asthma, influence disease chronicity and severity, or trigger acute exacerbations. The gradient of increasing prevalence observed for asthma and atopy from developing to developed countries led to the *westernization hypothesis* (80), suggesting that environmental factors predisposing to the development of asthma might be identified from among those closely associated with westernized living conditions.

Aeroallergens

Historically, allergens received greatest attention in asthma research. Population-based studies indicated that of all environmental allergens, common indoor aeroallergens are most closely associated with asthma (81). In temperate climes, the principal allergen is the fecal protein excreted by house dust mites (82), *Dermatophagoides pteronyssinus* and *Dermatophagoides farinae*. In regions with low humidity, other indoor allergens predominate and are more closely associated with the disease. These include aeroallergens derived from domestic pets (83), cockroaches (84), and the fungal spores of *Alternaria alternata* (85). Food allergens (86) and pollens (81) are rarely associated with asthma.

Population-based studies suggest that infancy is the optimum time for aeroallergen exposure to induce atopy in later life, supporting the concept of a “sensitization window” (87). Although the risk of developing atopy is dependent on allergen dose and duration of exposure, individual susceptibility varies, and no minimum dose threshold has yet been identified (88). Repeated inhalation of low-dose allergen increases bronchial responsiveness in atopic, nonasthmatic persons (89) and induces asthmatic symptoms in atopic persons who have preexisting asymptomatic BHR (44). In addition, Sporik et al. (90) demonstrated a dose-dependent relationship between exposure to house dust-mite allergen (Der p 1) during the first 2 years of life and the likelihood of developing asthma up to the age of 11 years. These observations were used to support the hypothesis that aeroallergens play a causal role in the pathogenesis of asthma. Increased disease prevalence reflects, at least in part, higher levels of exposure to house dust mites associated with westernized housing (91), characterized by wall-to-wall carpeting, central heating, and energy-conservation measures. Martinez (92) argued against this hypothesis, suggesting that if a causal relationship between aeroallergens and asthma existed, the likelihood of developing asthma should not be dependent on the age at which prior sensitization occurs. He cited a study by Peat et al. (93) in which children who had become atopic to aeroallergens after the age of 8 years were shown to be at less risk of developing asthma or BHR than those who had become sensitized before this age. These children were at no greater risk than their nonatopic peers were over a 4-year period. The epidemiologic evidence used to support the allergen hypothesis was recently critically reviewed and considered to be equivocal (94), adding to the argument that factors other than atopy are likely to play an important role in the development of the disease.

In established asthma, allergen exposure can increase BHR and clinical disease activity (95). Numerous studies also indicate a positive correlation between the level of allergen sensitization and the degree of asthma chronicity and severity (88). Aeroallergens may precipitate acute exacerbations of the disease (96).

Infection

A major achievement of modern society has been a steady reduction in childhood infection rates. Smaller family size, improved sanitation, vaccination programs, and antibiotics have all contributed. Along with the use of detergents and antiseptics, these measures have made the westernized environment relatively sterile. The inverse correlation observed over time between infection rates and the prevalence of asthma and atopy (97,98) led to the *hygiene hypothesis* (99), which postulates that exposure to certain infectious agents during infancy reduces the risk of allergy by promoting the maturation of Th1-like responses, shortening the sensitization window. A gradient of infection rate might therefore explain why the risk of allergy declines in the last-born child as sibling numbers increase (100). In addition, the hygiene hypothesis, at least in part, might account for the observed gradients of increasing allergy prevalence from low to high socioeconomic class (101), from rural to urban regions in Africa (102), and from East to West Germany shortly after reunification in 1989 (103). Evidence in support of this hypothesis includes the finding that the level of childhood exposure to lipopolysaccharide (LPS, endotoxin), a component of the gram-negative bacterial cell wall, is inversely related to the risk of allergic disease (104). Furthermore, a reduced risk of allergy has been associated with measles infection during infancy in Africa (105) and with strongly positive tuberculin tests, indicative of exposure to *Mycobacterium tuberculosis* in Japanese children (106). The hygiene hypothesis, however, is more closely associated with atopy than it is with asthma (107). For example, despite increases in the prevalence of atopy and hay fever associated with the westernization of former East Germany from 1991/1992 through 1995/1996, prevalence rates for asthma and BHR have remained essentially unchanged (46). Thus, other environmental factors are likely to be responsible for localizing Th2-like responses to the airway mucosa in genetically susceptible persons.

Wheezy illness, usually the result of a viral respiratory tract infection (RTI), affects up to 30% of all children under the age of 5 years, and one third of these children will develop atopic asthma in later childhood (52). In children under the age of 3 years, the respiratory syncytial virus (RSV) is the most common cause of lower RTI (108), and the minority of young children who have elevated levels of serum IgE and RSV-specific IgE at the time of infection are at greatest risk of persistent wheeze into late childhood (109). Some studies suggest that RSV bronchiolitis in early life is associated with an increased risk of developing atopy (110), and it is postulated that such infection also may induce asthma by promoting airway mucosal Th2-like responses in genetically susceptible persons (111). A recent cohort study of children in the community, however, found that lower RTI with RSV before the age of 3 years did not increase the risk of developing atopy (108). Furthermore, although RSV infection in early childhood increased the risk of developing persistent wheeze during the first 10 years of life, no difference in asthma prevalence was observed at age 13 years between children who had and had not been infected with RSV before the age of 3 years. These researchers concluded that RSV plays no role in the causation of atopy and argue that the virus is unlikely to be causal factor for atopic asthma because this condition most commonly affects older children and adolescents (108). Children infected with RSV in early life had a significantly reduced FEV_1 at age 11 years. This reduction occurred independently of asthmalike symptoms and reversed to a nonsignificant value with bronchodilator therapy, suggesting an association between RSV infection in early life and altered regulation of airway smooth muscle tone. The significance of this finding is presently unclear (108). Although some studies suggest that RSV bronchiolitis in early life is a risk factor for the development of BHR, others argue that this risk is dependent on the coexistence of atopy (112). Other respiratory tract viruses, however, can induce BHR in persons who do not have asthma (113), and a history of viral RTI in the previous 5 years is reported to be a risk factor for the development of asthma in persons with preexisting BHR (44).

In established asthma, viral RTI is the most common cause of acute exacerbation, accounting for 80% to 85% of childhood cases (114) and 44% of cases in adults (115). In both groups, the common cold virus (*rhinovirus*) is most frequently responsible (114,115). Viral respiratory tract infection also has been implicated in most asthma deaths (58).

Air Pollution

Epidemiologic studies fail to support a causal role for outdoor oxidant air pollutants (sulfur dioxide, nitrogen dioxide, ozone) in the pathogenesis of asthma or atopy. No evidence of an increase in the levels of these pollutants has been found in the United Kingdom since the 1970s (80). Furthermore, although prevalence rates for asthma and atopy were greater in West Germany at the start of reunification, air pollution levels were higher in East Germany (103). Some evidence suggests that diesel exhaust particles may increase the risk of sensitization to aeroallergens (116), and this finding may be of relevance in view of the increasing numbers of diesel cars on European roads. In established asthma, there is little doubt that outdoor air pollution increases asthma morbidity rates (80), in association with increased airway inflammation and BHR (117,118). This fact, at least in part, reflects a synergistic interaction between air pollutants and aeroallergens (119,120).

Tobacco smoke is the most common indoor air pollutant, and there is evidence to suggest an increased risk of atopy and asthma in children whose mothers smoked during pregnancy (91). Maternal smoking during pregnancy is associated with reduced lung function, increased bronchial responsiveness, and higher risks of wheezy illness in infancy (91). In children with wheezy illness in early life, continued cigarette smoke exposure is associated with a progressive deterioration in lung function and increased bronchial responsiveness (91). Other studies, however, suggest that maternal cigarette smoking is *not* a risk factor for the persistence of wheeze into late childhood (52). Although active cigarette smoking in adolescence and adulthood increases bronchial responsiveness (121), no studies have directly linked this increase to the development of late-onset asthma. Active cigarette smoking is associated with an increased risk of asthma relapse at age 33 years, after a prolonged period without symptoms (122).

Diet

The westernization hypothesis postulates that dietary changes contributed to the rising prevalence of asthma (80). Epidemiologic studies demonstrated a general decline in consumption of antioxidant vitamins A, C, and E; and it is suggested that this circumstance increased the susceptibility of the airway mucosa to oxidant

stress from air pollutants and activated inflammatory cells (80). In addition, there has also been a trend toward the increased consumption of w-6 fatty acids, found in vegetable oil, relative to the consumption of w-3 fatty acids, found in fish oil and butter (91). In view of evidence suggesting proinflammatory and antiinflammatory actions for w-6 and w-3 fatty acids, respectively, it is postulated that an altered balance in their consumption increased the susceptibility of the airway mucosa to the damaging effects of allergens, viruses, and air pollutants (91). Finally, a decline in breast-feeding and the increased use of formula feeds have been postulated to play a causal role in asthma and atopy (91). Evidence in support of all these dietary hypotheses remains controversial.

Occupation

About 200 workplace-related compounds are now known to be capable of inducing asthma in susceptible persons (Table 65.3), and it is estimated that occupational asthma accounts for up to 7% of late-onset disease (50). The responsible compounds are inhaled, and they may be divided into two groups based on their molecular weight (50). The high-molecular-weight compounds are proteins that induce asthma through immunologic mechanisms that generally involve the production of antigen-specific IgE. Such compounds are more likely to induce asthma in persons who have preexisting atopy. In contrast, the low-molecular-weight compounds act as haptens (chemical sensitizers), promoting an immunologic response against self-antigens within the airway mucosa. Generally, this is not associated with increased IgE production, and preexisting atopy appears not to be a risk factor (50). The prevalence of occupational asthma in workers exposed to these chemical sensitizers depends on the compound involved and the level of exposure. For example, whereas 5% of workers exposed to toluene diisocyanate develop asthma (123), more that 50% of workers exposed to complex platinum salts are affected, with greatest risk observed among cigarette smokers (124).

Compounds	Industry/Personnel
Metal salts	
Platinum	Metal refining
Wood dusts and vegetables	
Oak	Carpenters, woodmill workers
Mahogany	
Western red cedar (plicatic acid)	
Grain (mites, fungi)	Millers, bakers
Flour	
Industrial chemicals	
Isocyanates	Polyurethane, paint, adhesives
Phthalic acid anhydride, trimellitic anhydride	Epoxy resins
Aminoethylethanolamine and colophony	Soldering
Ethylenediamine	Rubber industry
Paraphenylenediamine	Dye industry
Persulfates	Hair bleach
Pharmaceutical agents	
Penicillins	Pharmacists
Cimetidine	
Biologic enzymes	
Bacillus subtilis	Washing powder
Pancreatic enzymes	Pharmacists
Animal secretions	
α-Globulin in rat urine	Laboratory workers, veterinarians
Parathymin in mouse urine	
Locusts	
Animal dander	

TABLE 65.3. Examples of Compounds that Induce Occupational Asthma

CLINICAL PRESENTATION

Symptoms and Signs

The clinical syndrome of asthma is characterized by paroxysms of breathlessness, wheeze, chest tightness, and cough. Physical signs include tachypnea, a prolonged expiratory phase, and diffuse polyphonic wheeze on auscultation. If the patient is asymptomatic, clinical examination may be unremarkable. As the severity of chronic asthma increases, daytime and nocturnal symptoms become more frequent. In the minority of patients who have chronic severe disease, symptoms are continuous, activities of daily living are limited, and acute exacerbations are common.

Factors that suggest atopic asthma include onset of symptoms before the age of 30 years, a personal or family history of eczema or hay fever, and the recognition that paroxysms are triggered by allergen exposure. About 80% of patients also experience exercise-induced symptoms, and exercise may be the only trigger in a minority of cases. Symptoms typically develop 5 to 10 minutes after the exercise is stopped and resolve within half an hour. A refractory period of 1 hour may follow, during which further exercise fails to induce more symptoms.

Patients who develop symptoms after the age of 40 years are likely to have intrinsic disease, although occupational asthma should be considered if symptoms relate to the workplace. Of patients with asthma, 5% to 30% experience symptoms within 2 hours of ingesting aspirin or other nonsteroidal antiinflammatory drugs (NSAIDs). AIA classically occurs in female patients with late-onset, nonatopic disease, associated with nasal polyps and vasomotor rhinitis. In cough-variant asthma, cough is the predominant or only symptom.

Pathophysiology

Widespread, variable, and reversible airflow obstruction characterize asthma. Spirometry provides a measure of FEV_1 and forced vital capacity (FVC), and airflow obstruction is objectively defined as an FEV_1:FVC ratio of less than 70%. Although PEF correlates with FEV_1, its measurement tends to underestimate the degree of airflow obstruction and fails to differentiate obstructive from restrictive ventilatory defects. The severity of airflow obstruction is objectively assessed by comparing measured FEV_1 or PEF with predicted values, based on the normal distribution of lung function in the population, taking into account age, height, gender, and ethnicity. If FEV_1 is 80% or less of the predicted value, the degree of reversibility can be assessed by repeating the measurement 10 to 15 minutes after inhalation of a standard dose of short-acting b_2-agonist. Provided the increase in FEV_1 exceeds 200 mL, reversibility of 15% or more is generally accepted as being diagnostic for asthma (32). If airflow obstruction is present and reversibility in response to short-acting b-agonist is not observed, however, reversibility in response to a course of systemic glucocorticoids (prednisolone, 30–40 mg daily for 14 days) should be assessed in an attempt to differentiate chronic asthma from COPD. This course also allows the personal best FEV_1 and PEF to be identified.

In chronic asthma, moderate disease is defined as an FEV_1 or PEF 60% to 80% of that predicted, with mild disease above 80% and severe disease below 60% (32). In cases of acute asthma, it is recommended that measured FEV_1 or PEF be compared with the patient's personal best value, if this is known. An acute moderate exacerbation then is defined as a percentage best (or predicted) FEV_1 or PEF of 60% to 80%, with acute severe disease below 60% (32). The cutoff percentage values for FEV_1 and PEF used to define mild, moderate, and severe asthma are arbitrary, and the correlation that exists between perceived severity of asthma symptoms and degree of underlying airflow obstruction is poor (125).

If spirometry is normal, assessment of daily PEF variability may help to confirm a diagnosis of asthma. PEF is measured at least twice a day (morning and night), before and 10 to 15 minutes after a standard dose of short-acting b-agonist. Daily PEF variability of 20% or more, typically with dips in the early morning, is generally accepted as being diagnostic for asthma (126). Monitoring of PEF has its limitations (41), however, and PEF variability may not be present in cases of mild intermittent asthma. Nonetheless, the degree of PEF variability tends to reflect disease severity, with mild persistent asthma associated with values of 20% to 30% and moderate to severe disease associated with PEF variability greater than 30% (32). In severe chronic disease, PEF variability may be lost. In contrast, brittle asthma is characterized by extreme variability in PEF, with precipitous drops in lung function increasing the risk of severe and life-threatening exacerbations (127). PEF monitoring may help with the diagnosis of occupational asthma (128).

For safety reasons, challenge tests are generally not used in routine clinical practice. Exercise testing may be of value in the diagnosis of EIA. In a standard 6-minute running protocol, falls in FEV_1 or PEF of at least 15% and 20%, respectively, measured 5 to 15 minutes after exercise, are considered diagnostic (32). Measurement of airway responsiveness by histamine or methacholine challenge may help to exclude asthma, but its use is largely confined to research.

In asthma, airflow obstruction occurs as a consequence of airway lumen narrowing. Turbulent airflow generates wheeze, and breathlessness results from increased gas trapping and decreased dynamic lung compliance, increasing the work of breathing. In severe disease, the situation is further complicated by hypoxemia due to ventilation–perfusion mismatch (129). Narrowing of the airway lumen results from a combination of bronchial smooth-muscle constriction, airway-wall thickening, and mucus hypersecretion.

Allergen Challenge Model

After its introduction by Lowell and Schiller in 1948, the inhaled-allergen challenge test became a model for the study of allergen-induced airflow obstruction and allergic airway inflammation. In response to an inhaled dose of allergen, sensitized persons with asthma exhibit a decline in FEV_1 during the first 20 minutes, with

gradual recovery over the following 2 hours. This marks the early asthmatic response (EAR). Approximately half of the persons who have asthma also exhibit a late asthmatic response (LAR), corresponding to a second fall in FEV_1 at 6 hours (Fig. 65.2). Although this usually resolves within 12 hours, an associated increase in BHR may last several days or weeks (130).

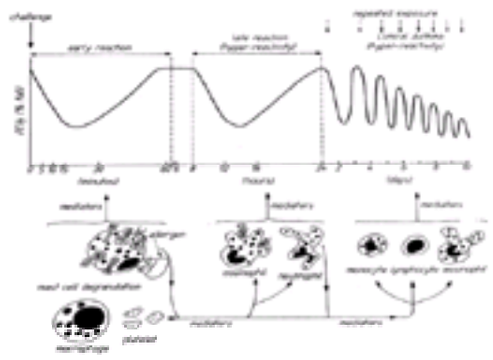

Figure 65.2. Mechanisms of the allergen-produced early and late reactions and the acquired increase in bronchial responsiveness.

Early Asthmatic Response

Inhibition of the EAR by inhaled disodium cromoglycate (131) suggests that this response is primarily mediated by mast cells, resident in the airways. Cross-linking of FceRI by allergen-IgE antibody complex induces mast cell activation (18), resulting in the release of preformed mediators, most notably histamine, tryptase, and chymase (132). Mast cell tryptase liberates secondary mediators, C3a and bradykinin, from precursor proteins. In addition, activated mast cells synthesize and release platelet-activating factor (PAF) and metabolites of arachidonic acid, including LTA_4, LTB_4, and prostanoids (prostaglandin D_2, thromboxane A_2) (133,134). LTA_4 gives rise to the cysteinyl leukotriene LTC_4, which is rapidly metabolized to LTD_4 and then to LTE_4 (19).

Evidence suggests that mast cell–derived cysteinyl leukotrienes are the principal mediators that cause airflow obstruction during the EAR. Cysteinyl leukotrienes induce contraction of isolated human bronchial smooth muscle with 1,000- to 5,000-fold more potency than histamine, and antagonists of the LTD_4/LTE_4 ($CysLT_1$) receptor inhibit the EAR by 50% to 90% (135). Significant reductions in the EAR by antagonists of the H_1-receptor and thromboxane receptor suggest that histamine is the principal mediator during the first 7 minutes of the EAR, whereas prostanoids act synergistically with the cysteinyl leukotrienes during the remainder of the EAR (136). The contributions of PAF, C3a, and bradykinin to early allergen-induced bronchoconstriction appear to be relatively minor, and the role of LTB activity in asthma is questionable (137).

During the EAR, airway mucosal edema and mucus hypersecretion augment airflow obstruction. The cysteinyl leukotrienes, prostanoids, histamine, PAF, C3a, and bradykinin are all vasoactive mediators, increasing capillary permeability and local blood flow and causing plasma exudation and airway wall thickening. In addition, the cysteinyl leukotrienes (138), prostanoids (139), histamine (140), and PAF and chymase (141) stimulate the secretion of mucus by glands in the submucosa. Mucus and exuded plasma not only tend to occlude the airway lumen, but they also may cross-react and increase mucus viscosity (142), thereby promoting mucostasis. Thus, the EAR can be accounted for by allergen-induced mast cell activation and mediator release.

Late Asthmatic Response

In contrast to the EAR, the LAR is associated with increased numbers of activated eosinophils in both the bronchial mucosa (143) and bronchoalveolar lavage (BAL) fluid (144), suggesting an influx of eosinophils from the vascular compartment to the airway lumen. Activated eosinophils release the cysteinyl leukotrienes (145), and CysLT receptor antagonists inhibit the LAR by 25% to 90% (135). These observations suggest that principal mediators causing airflow obstruction during the LAR include eosinophil-derived cysteinyl leukotrienes.

Exercise-induced Asthma

Non-IgE-mediated mast cell activation may also account for EIA, reproduced by hyperventilation. Increasing inspired air humidity reduces the severity of hyperventilation-induced airflow obstruction, whereas changes in inspired air temperature have no effect, provided humidity is kept constant (146). This finding suggests that the stimulus for EIA is airway water loss. It is postulated that, as a consequence, transient hyperosmolarity of the epithelial lining fluid triggers local mast cell activation (147). Observations in support of this hypothesis include hyperosmolar-induced mast cell activation *in vitro* and increased urinary levels of LTE shortly after exercise-induced bronchoconstriction (136). In addition, antagonists of the H_1-receptor and the $CysLT_1$ receptor inhibit exercise-induced bronchoconstriction by 30% to 50% and 60% to 70%, respectively (136). Why certain persons should be susceptible to exercise-induced airway water loss is not clear, but it is suggested that this circumstance may reflect an inability of the airway epithelium to condition-inspired air as minute volume increases (147).

Aspirin-intolerant Asthma

Evidence suggests that the cysteinyl leukotrienes also play a major role in AIA. In activated mast cells and eosinophils, arachidonic acid metabolism may take one of two main pathways. Arachidonic acid may be converted by 5-lipoxygenase (5-LO) to LTA_4 and LTB_4. LTA_4 is then converted by LTC_4 synthase (LTC_4S) to the cysteinyl leukotrienes. Alternatively, prostanoids are generated from arachidonic acid by cyclooxygenase. The expression of LTC_4S by mast cells and eosinophils of persons with AIA is increased fivefold above that of persons with aspirin-tolerant asthma, correlating with increased production of cysteinyl leukotrienes (148). The gene for LTC_4S resides on 5q35, and studies suggest an association between AIA and a polymorphism for the LTC_4S promoter (149). It is postulated that by inhibiting cyclooxygenase, NSAIDs promote metabolism of arachidonic acid via the lipoxygenase pathway, augmenting the production of cysteinyl leukotrienes, especially in cases of AIA with overexpressed LTC_4S. This hypothesis is consistent with observed increases in urinary levels of LTE_4 after NSAID ingestion (150) and inhibition of AIA by $CysLT_1$ receptor antagonists (135).

Bronchial Hyperresponsiveness

Although allergen, exercise, hyperventilation, and aspirin challenge models all have provided some insight into the mechanisms underlying acute airflow obstruction in asthma, epidemiologic evidence suggests that variable and reversible airflow obstruction, characteristic of chronic asthma, occurs in the context of an exaggerated bronchoconstrictor response to nonspecific stimulation, that is, BHR. Postulated models for BHR remain controversial, and mechanisms underlying this disorder of airway function are likely to be multiple and complex, involving neuromuscular, inflammatory, and geometric factors.

The caliber of the airway lumen is dependent on a balance between the force generated by airway smooth muscle (ASM) and the opposing mechanical load from structural elements of the airway wall and surrounding lung parenchyma (151). It is postulated that BHR results from a primary abnormality of asthmatic ASM, giving rise to the generation of excessive force when stimulated. *In vitro* studies, however, failed to demonstrate an intrinsic difference in length–tension properties between asthmatic and nonasthmatic ASM (152). Despite this, ASM hypertrophy and hyperplasia still might be capable of generating excessive force *in vivo* (153,154).

Whereas deep inspiration fully reverses induced bronchoconstriction in persons without asthma, this response is only partial or absent in persons who have asthma, suggesting that resting ASM tone may be abnormally increased in asthma (155). In addition, airway responsiveness can be increased in persons without asthma simply by changing the pattern of breathing and avoiding deep inspiration (156). Thus, BHR may be more a problem of limited ASM relaxation than of exaggerated ASM contraction (156). Either way, it is postulated that BHR results from altered autonomic regulation of ASM tone (157).

Autonomic Regulation of Airway Function

Airway smooth muscle tone is primarily regulated by the parasympathetic nervous system. Cholinergic nerves innervate ASM, and muscarinic receptor activation by acetylcholine induces ASM contraction and bronchoconstriction (157). Airway cholinergic nerves also release cotransmitters, including vasoactive intestinal polypeptide (VIP) and nitric oxide (NO). These provide the inhibitory limb of the nonadrenergic, noncholinergic (i-NANC) nervous system and attenuate cholinergic neural

bronchoconstriction by functionally antagonizing acetylcholine (158). Indeed, the i-NANC nervous system is the only neural bronchodilator pathway known within the human airway because ASM lacks direct sympathetic innervation (157). b_2-adrenergic receptor (b_2-AR) activation by circulating catecholamines or inhaled b2-agonists can induce ASM relaxation and bronchodilation. In addition to regulating ASM tone, parasympathetic nerves also innervate submucosal glands, stimulating mucus secretion (157).

Sensory autonomic nerves relay signals from C-fiber and rapidly adapting receptors (RARs), intimately associated with the airway epithelium (159). These polymodal irritant receptors respond to a range of stimuli, including air pollutants, epithelial lining fluid hyperosmolarity, bradykinin, histamine, PAF, and prostanoids; and they mediate protective vagal reflexes, including cough (159), mucus hypersecretion, and increased ASM tone (bronchial responsiveness) (160). Stimulation of RARs and C-fiber receptors is thought to account for the sensation of chest tightness (157), and neural sensitivity to epithelial lining fluid hyperosmolarity is postulated to be a parallel mechanism for the induction of EIA (147).

The neurotransmitters of sensory C-fibers are tachykinin neuropeptides, including substance P and neurokinin A. In addition to conducting signals to the central nervous system, C-fiber stimulation can also elicit a local axon reflex, releasing substance P and neurokinin A within the airway wall. This provides the excitatory limb of the NANC nervous system (e-NANC) and augments cholinergic neural bronchoconstriction by stimulating tachykinin receptors expressed on ASM (157). Thus, the NANC nervous system appears to modulate parasympathetic function, and it is postulated that increased ASM tone and BHR result from low i-NANC and/or high e-NANC activity (157).

Role of Airway Inflammation

A large body of evidence supports the hypothesis that BHR is a direct consequence of airway inflammation. In the allergen challenge model, increased bronchial responsiveness develops between the EAR and LAR (130) in association with eosinophil recruitment into the airways (143,144). Positive correlations have been reported between the degree of bronchial responsiveness and the numbers of (a) eosinophils in induced sputum (161); (b) activated eosinophils, mast cells, and Th2-memory cells in BAL fluid (162,163 and 164); and (c) activated eosinophils, mast cells, $CD4^+$ T-memory cells, and $CD8^+$ T cells in bronchial biopsies (165,166). In addition, airway inflammation and increased bronchial responsiveness can be induced by inhalation of IL-5 (167), tumor necrosis factor-a (TNF-a) (167), sulfur dioxide (117), nitrogen dioxide (118), ozone (168), toluene diisocyanate (169), and rhinovirus (170). Whereas IL-5 inhalation induces airway eosinophilia, inhalation of TNF-a, ozone, or toluene diisocyanate induces airway neutrophilia.

Increased i-NANC neurotransmitter degradation as a consequence of airway inflammation might account for reduced i-NANC activity and exaggerated cholinergic reflex bronchoconstriction in asthma. Mast cell tryptase degrades VIP, and inflammatory cell-derived reactive oxygen intermediates may increase the clearance of NO. A complete absence of VIP immunoreactivity has been described in asthmatic airways, but no reduction in the i-NANC bronchodilator reflex is observed in persons who have mild asthma (157). Despite this, low i-NANC activity still may play a role in more severe disease.

Normally, tachykinins of the e-NANC system are inactivated by neutral endopeptidase (NEP, CD10), a membrane-bound metallopeptidase predominantly expressed by airway epithelial cells. Increased epithelial damage (171,172) and shedding (173) are characteristic features of asthma, correlating with BHR; and associated loss of NEP is postulated to cause increased e-NANC activity and exaggerated cholinergic reflex bronchoconstriction in asthma (157). Alternatively, viral RTI, oxidant air pollutants, and IL-1b may downregulate airway epithelial NEP expression (157). This hypothesis is supported by the observed inverse relationship between airway epithelial NEP expression and bronchial responsiveness in persons with asthma (174) and increased levels of substance P in BAL fluid and induced sputum from persons with asthma compared with levels in normal controls (157). In addition, increased numbers of substance P-immunoreactive nerves have been observed in asthmatic airways (175).

It is also postulated that increased e-NANC activity mediates so-called *neurogenic inflammation* (157). Animal models have shown that tachykinins can increase capillary permeability and local blood flow, causing plasma exudation. In addition, the e-NANC nervous system may modulate inflammatory cell recruitment and activity (176). The contribution of neurogenic mechanisms to chronic airway inflammation in asthma remains unclear, but the limited evidence available suggests that it is not important in mild asthma (157). Neurogenic inflammation could play a more significant role in severe disease, however, including brittle asthma.

Bronchial hyperresponsiveness might result from increased cholinergic and NANC neural activity resulting from higher levels of RAR and C-fiber receptor activation. This may result from greater exposure to inhaled stimuli as a consequence of airway epithelial damage and tight junction disruption (177). Alternatively, the threshold for activation of these irritant receptors might be reduced by inflammatory mediators, such as PAF (157). The ability of inhaled bradykinin to induce asthma symptoms in asthmatic individuals suggests that this inflammatory mediator may be an important activator of RAR and C-fiber receptors in the disease. Indeed, inhibition of the bronchoconstrictor response to inhaled bradykinin by antagonists of the tachykinin receptor suggests that the actions of bradykinin occur largely via stimulation of cholinergic and NANC reflexes (178).

Models also have been proposed in which airway inflammation induces BHR through mechanisms that do not involve altered autonomic neural function. For example, endothelin-1 is a potent bronchoconstrictor, and its release by airway epithelial cells is increased in association with airway inflammation in asthma (179). Alternatively, airway epithelial damage and tight junction disruption could promote allergen access to mast cells and antigen-presenting cells (APCs) (177), inducing a stronger inflammatory response with the release of greater amounts of cysteinyl leukotrienes, IL-5, and TNF-a. In addition, TNF-a and IL-1b may directly increase the contractile response of ASM (180), and airway edema may unload (mechanically uncouple) ASM, allowing greater contraction for the same degree of stimulation (151).

Geometric Factors

It is postulated that BHR is the consequence of increased airway wall thickness, with a greater reduction in airway caliber occurring for the same degree of ASM shortening (181). In addition, partial occlusion of the airway lumen with mucus and inflammatory exudate could further amplify the bronchoconstrictor response. In cases of fatal asthma, postmortem studies consistently demonstrate prominent thickening of the airway wall (182). High-resolution computed tomography (HRCT) has shown that airway wall thickening also occurs in milder forms of the disease (183,184). In chronic moderate to severe asthma, characterized by a fixed component of airflow obstruction, a positive correlation has been observed between airway wall thickness and the degree of BHR (185). In addition, airway wall thickness has been shown to correlate with the severity of chronic asthma, including a decline in FEV_1 (183). Increased airway wall thickness might therefore account for the associations observed in epidemiologic studies between BHR, reduced FEV_1, asthma chronicity, and disease severity (24). Other studies, however, found no correlation between airway wall thickness and bronchial responsiveness or asthma severity (184).

Despite the large number of studies that support the hypothesis that BHR is a direct consequence of airway inflammation, an almost equal number of reports demonstrated no significant correlation between airway responsiveness and airway inflammation (186). Indeed, BHR has been reported in persons with asthma in the absence of any demonstrable airway inflammation (187). Thus, chronic Th2-mediated airway inflammation alone cannot account for BHR in chronic asthma. Although glucocorticoid therapy tends to normalize airway responsiveness in association with suppressed airway inflammation, complete normalization of airway responsiveness is unusual, suggesting that BHR results from a combination of steroid-responsive and steroid-nonresponsive mechanisms (188). The latter may relate to the noninflammatory component of asthmatic airway wall thickening resulting from the relatively fixed structural changes, termed *airway wall remodeling* (189).

Laboratory Tests

Asthma is associated with blood eosinophilia and elevated total serum IgE, but neither of these is diagnostic. Tests for atopy (skin-prick testing and RAST IgE) also add little to the diagnosis but may be of use in the management of asthma, helping to confirm potential allergenic triggers. A positive skin or RAST test does not necessarily imply that an allergen is a trigger for asthma. The likelihood of this must be judged from the patient's history.

Pathology

Fatal Asthma

Postmortem examination of the lungs of patients who have died of acute severe asthma reveals prominent airway wall thickening, a markedly edematous airway mucosa, and occlusion of bronchial lumen with plugs of viscid mucus (182,190). Microscopic examination reveals vasodilatation and marked inflammatory cell infiltration, extending from the airway lumen to the submucosa (Fig. 65.3). The predominant inflammatory cell types are neutrophils (191) and eosinophils, but lymphocytes are also present. Structural alterations are present throughout the airway wall, including extensive airway epithelial damage, goblet cell hyperplasia, subbasement membrane (SBM) thickening (190), ASM hypertrophy and hyperplasia (153), and submucosal mucus gland hypertrophy (192). These structural changes of airway wall remodeling contribute to the increased thickness of the asthmatic airway wall.

Figure 65.3. Cross-section of peripheral bronchus from a person dying of asthma. The sample was immunostained with a monoclonal antibody to eosinophil cationic protein. Marked eosinophil infiltrate, thickening of the subbasement membrane, and a plug of mucus containing cellular debris filling the airway are present.

Mild to Moderate Asthma

Fiberoptic bronchoscopy allows sampling of the bronchial mucosa in persons with asthma. Limitations of the technique include the small size of biopsy and the restricted number of sites that can be sampled. In addition, the depth of biopsy precludes assessment of ASM and deeper structures and provides no measure of airway wall thickness. Despite these limitations, fiberoptic bronchoscopy has revolutionized research in asthma.

Chronic airway inflammation and airway wall remodeling are consistent features of all forms of asthma. Inflammatory cell infiltration of the bronchial mucosa is characterized by a predominance of activated eosinophils (30), but T-lymphocytes (193) and mast cells (194) are also present. Numbers of activated eosinophils, mast cells, and T cells are also increased in BAL fluid from individuals with chronic stable asthma compared with normal controls (195). Disease severity correlates with the numbers of activated eosinophils and $CD4^+$ T cells in the airway lumen (161,196). In contrast, disease severity does not correlate with the numbers of eosinophils in the bronchial mucosa (166,187,194,197). Furthermore, in chronic severe asthma, eosinophil numbers may be increased only marginally in the bronchial mucosa compared with normal controls (198). This finding suggests rapid eosinophil migration through the bronchial mucosa and airway epithelium and has stimulated research into the eosinophil chemotactic activity of sputum (161). In acute severe exacerbations (199) or severe chronic disease (200), the predominant inflammatory cell type may be the neutrophil, but this may be, at least in part, an effect of high-dose glucocorticoid therapy (201).

Features of airway wall remodeling in asthmatic bronchial biopsies include airway epithelial damage (171,172), SBM thickening (171,202), increased numbers of myofibroblasts (203), neovascularization (204), and new autonomic nerve growth (175). Evidence suggests that airway epithelial damage is a consistent feature of asthma and is characterized by the selective loss of columnar cells, leaving the underlying basal cell layer adherent to the basement membrane (171). This circumstance is consistent with the greater degree of epithelial shedding in asthma, with clusters of desquamated columnar epithelial cells forming creola bodies (173). Until recently, it has not been possible to differentiate confidently artifactual epithelial damage from biopsy forceps and tissue processing from true epithelial damage. Recent findings of upregulated expression of CD44 (205) and the epidermal growth factor receptor (EGFR, c-erbB1) (206) in asthmatic epithelium provide evidence of a response to true injury.

Thickening of SBM is characterized by the deposition of types I, III, and IV collagen, fibronectin, and tenascin into the lamina reticularis (202,207). SBM thickness positively correlates with the number of underlying myofibroblasts (203), and these cells are thought to be the source of deposited collagen. In addition, there is evidence of increased collagen deposition into the submucosa of asthmatic airways compared with airways of normal controls (208). Because of the limited depth of bronchial biopsy, SBM thickness has come to be used as a marker of the remodeling process. Relationships between SBM thickness and other structural changes of airway wall remodeling, including airway wall thickness, remain unclear.

Pathologic observations raise a fundamental question: What is the relationship between chronic airway inflammation and airway wall remodeling? It is postulated that airway wall remodeling occurs as part of the repair response to repeated epithelial injury resulting from chronic airway inflammation and insults from environmental factors, including aeroallergens, oxidant air pollutants, and viruses (209). Furthermore, airway epithelial cells have the potential of signaling to inflammatory cells. This finding led to a model of the asthmatic airway in which the damaged and stressed airway epithelium functions as a key regulator not only of the remodeling process but also of inflammatory cell recruitment and local T-cell responses, driving sustained Th2-immune deviation and disease chronicity (209).

Pathologic observations raise a second fundamental question: What is the consequence of airway wall remodeling on lung function, including airway responsiveness? Indirect evidence suggesting alterations in airway function in association with airway wall remodeling already have been hinted at from previously mentioned HRCT studies. In addition, positive correlations have been reported between SBM thickness and both (a) bronchial responsiveness (210,211) and (b) disease severity and increased decline in FEV_1 (210,212). These observations, however, have not been confirmed in other studies (197,202,203). Thus, the functional significance of SBM thickening and airway wall remodeling in asthma remains controversial, but its importance may be reflected in the observation that SBM thickening occurs in childhood (190), even before the development of asthma symptoms (213).

MANAGEMENT

The aims of asthma management are (a) to achieve and maintain symptom control with minimal (ideally no) short-acting b_2-agonist requirement; (b) to prevent acute exacerbations; (c) to maintain (near) normal lung function, with daily PEF variability below 20%; (d) to maintain normal activities, including exercise; and (e) to avoid adverse drug effects. To achieve these objectives, groups of leading respiratory physicians have published national and international guidelines for the management of chronic and acute asthma in children and adults. Guidelines for the management of chronic asthma are based on a stepwise approach (Fig. 65.4) to drug treatment according to disease severity (32). Six classes of asthma drug therapy are currently available: b_2-agonists, anticholinergics, and methylxanthines are bronchodilators, acting primarily on ASM. In contrast, glucocorticoids, chromones, and leukotriene receptor antagonists are antiinflammatory agents. Recognition that asthma is a chronic inflammatory disorder of the airways has promoted early intervention with antiinflammatory drug therapy at step two. The place for leukotriene receptor antagonists in the stepwise approach to asthma management has yet to be determined.

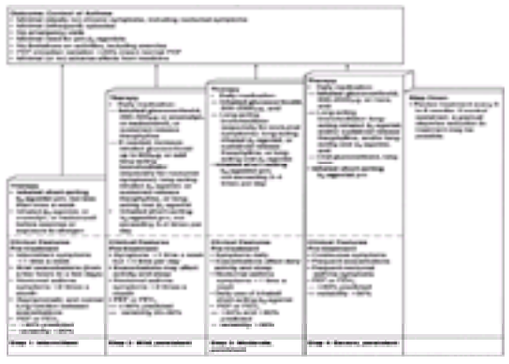

Figure 65.4. Stepwise approach to the treatment of asthma as recommended by the National Heart, Lung, and Blood Institute/World Health Organization (NHLBI/WHO) workshop report. The presence of any one of the features of severity is sufficient to place a patient in that category. Patients should start treatment at the step most appropriate to the initial severity of their condition. Step-up treatment is initiated if control is not achieved at the current step, but first the inhaler technique, compliance, and environmental control (i.e., avoidance of allergens or other trigger factors) should be reviewed. A rescue course of prednisolone may be needed at any time and at any step. Preferred treatments are in bold. (Adapted from *Global Initiative for Asthma (GINA)*. ISBN 91-3042. NHLBI/WHO Workshop Report, 1995, with permission.)

Because asthma is a dynamic condition, with relapses and remissions (Fig. 65.5), drug treatment needs to be stepped up or down as required. Asthma control is achieved most effectively through patient education and guidance, with the development of a partnership in which comanagement is encouraged. This involves a

personalized asthma-management plan (32) and domiciliary PEF monitoring. Objective measurement of airflow obstruction is desirable because subjective perception of asthma severity may be inaccurate. Informed patients then can step up their treatment at the first signs of an exacerbation and seek medical attention in good time. These signs include increased symptom frequency, nocturnal symptoms, a decline in PEF, and increased PEF variability.

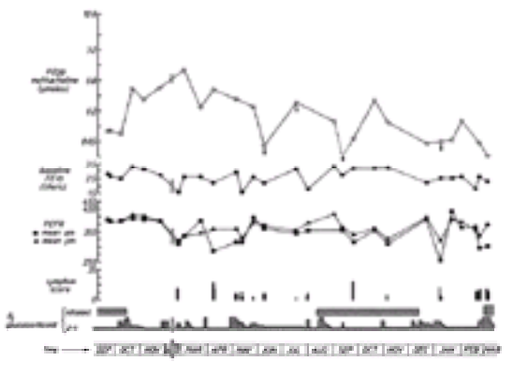

Figure 65.5. One-year diary of symptoms, peak expiratory flow rates (PEFR), forced expiratory volume (FEV), methacholine response (PD_{20}), and treatment in a 16-year-old girl with moderately severe asthma. Although asthma is perceived by the patients as “episodes,” there is evidence for continuous airway dysfunction.

Regular follow-up allows the opportunity to reinforce patient education and guidance, check inhaler technique, monitor lung function, and step down treatment when appropriate. Explaining the rationale behind the various treatment options promotes compliance, especially with inhaled glucocorticoid therapy. Referral to a respiratory physician is indicated when there is diagnostic doubt or difficulty achieving symptom control or maintaining lung function.

Avoidance of Triggers

Identification and avoidance of exacerbating triggers (such as allergens, cigarette smoke, and other air pollutants), drugs (NSAIDs, b-blockers), workplace-related compounds, and psychological stress play an important role in asthma management. Avoiding exercise and cold (dry) air generally imposes inappropriate restrictions, however, and it is often preferable to adjust drug treatment accordingly. Although studies have demonstrated improved symptom control and lung function as well as reduced airway responsiveness resulting from allergen avoidance measures (91,96), a recent metaanalysis failed to find any improvement in lung function in house dust mite–sensitive asthmatic persons (214). This analysis may have overlooked improvements in symptoms and airway responsiveness, however, and it may have included studies in which allergen avoidance was not achieved (215).

Acute Asthma

Acute moderate to severe exacerbations are most commonly the consequence of a rhinovirus RTI (114,115). Although moderate exacerbations (PEF or FEV_1 60%–80% of personal best or predicted) may be managed in the community under close medical supervision, severe exacerbations require hospitalization (Fig. 65.6). Treatment of acute moderate to severe asthma exacerbations involves repeated administration of inhaled b_2-agonist and early introduction of systemic glucocorticoid rescue therapy (216). In acute severe asthma, supplemental oxygen should be given to maintain oxygen saturations above 90% (95% in children). In addition, inhaled anticholinergic (217) and parenteral b_2-agonist (218) therapies should be considered, although the latter may worsen ventilation–perfusion mismatch (219). Intravenous aminophylline provides no additional bronchodilator effect over adequate doses of b_2-agonist (220). It may benefit respiratory drive or respiratory muscle function, however, and prolong or sustain the response to b_2-agonist between doses. Cases of life-threatening asthma should be closely observed in the intensive care unit, where immediate ventilatory support can be provided if necessary.

Drug Therapies

Glucocorticoids

This class of drug remains the most effective therapy available for asthma. Glucocorticoids reduce symptoms, increase lung function, decrease bronchial responsiveness, and reduce the frequency of acute exacerbations (221,222). In addition, they also can reduce asthma-related mortality (223). The beneficial effects of glucocorticoids are associated with reductions in the numbers of eosinophils and T cells in BAL fluid (224) and of eosinophils, T cells, and mast cells in the bronchial biopsies (225). In addition, glucocorticoid therapy reduces the number of cells expressing mRNA for IL-4 and IL-5 in BAL fluid (224,226) and for IL-4, IL-5, and IL-13 in bronchial biopsies (225,227). In contrast, they increase the number of cells expressing mRNA for IFN-g (225,226) and IL-12 (227) and have no influence on cysteinyl leukotriene production (228).

Glucocorticoids act by binding to the glucocorticoid receptor (GCR), a transcription factor that translocates from the cytoplasm to the nucleus; they bind to specific regulatory DNA sequences, termed *glucocorticoid responsive elements* (GREs), within the promoter regions of target genes (79). Mutual repression of transcriptional activity may occur as a consequence of GCR binding to proinflammatory transcription factors, including nuclear factor-kB (NF-kB), activator protein-1 (AP-1), nuclear factor of activated T cells (NF-AT), and cyclic AMP response element binding protein (CREB) (79). Gene expression is therefore likely to be dependent on the ratio of interacting GCRs and proinflammatory transcription factors present in the nucleus of the cell.

Moderate to severe chronic asthma is characterized by reduced responsiveness to glucocorticoid therapy (229). A spectrum of glucocorticoid responsiveness probably exists, with glucocorticoid-sensitive and glucocorticoid-resistant asthma at opposite ends. True glucocorticoid-resistant asthma, defined as the failure to exhibit significant reversibility in response to high-dose systemic glucocorticoid therapy despite demonstrable reversibility in response to short-acting b_2-agonist, is rare. Instead, most moderate to severe asthmatic persons exhibit relative glucocorticoid resistance, with the term *steroid-dependent asthma* referring to those with severe disease requiring long-term oral glucocorticoid therapy. Glucocorticoid resistance results, at least in part, from a failure of glucocorticoid therapy to suppress Th2-like responses and airway inflammation (224,227). The mechanism that underlies glucocorticoid resistance remains unclear, however (229).

The gene encoding the GCR resides on chromosome 5q31-33, and polymorphisms might play a role in glucocorticoid-resistant disease. One study of six glucocorticoid-sensitive and six glucocorticoid-resistant asthmatic persons, however, found no evidence to support this possibility (230). Reduced GCR binding affinity for glucocorticoids in T cells was reported in a subgroup of glucocorticoid-resistant asthmatic persons and could be induced *in vitro* with a combination of IL-2 and IL-4 (229). In a second subgroup of glucocorticoid-resistant asthmatic persons, GCR binding affinity was normal, but the numbers of glucocorticoid binding sites were reduced (229). Other studies showed glucocorticoid-resistant asthma to be associated with an altered ability of the GCR to bind to GRE (229). Increased expression of

AP-1 in glucocorticoid-resistant asthma led to the hypothesis that excessive stimulation of cells by proinflammatory cytokines induces reduced steroid responsiveness through the interference of GCR function by increased levels of proinflammatory transcription factors (79). Thus, reduced glucocorticoid responsiveness might be expected in cases of more established Th2-mediated airway inflammation. Indeed, it has been observed that delay in the introduction of glucocorticoid therapy for chronic asthma is associated with reduced improvement in lung function and airway responsiveness (231,232). An alternative hypothesis to explain this observation is that early introduction of glucocorticoid therapy prevents the decline in lung function due to airway wall remodeling, secondary to chronic airway inflammation. This hypothesis would be consistent with the finding that glucocorticoid therapy can partially reverse the deposition of collagen, fibronectin, and tenascin into the SBM (207). These observations and hypotheses led to the recommendation that effective antiinflammatory therapy be introduced early in an attempt to prevent or even reverse the development of fixed airflow obstruction. Improvements in lung function and airway responsiveness, however, usually are lost on withdrawal of glucocorticoid treatment (231), and it remains unclear as to whether antiinflammatory therapy simply suppresses asthma or actually modifies its natural history.

Long-term inhaled glucocorticoid therapy (>800 µg daily of beclomethasone or budesonide, and > 400 µg daily of fluticasone) is associated with an increased risk of cataracts, glaucoma, osteoporosis, skin bruising, and adrenal suppression (233). Hence, it is important to prescribe the lowest dose that achieves asthma control. There is no evidence that inhaled glucocorticoid therapy retards growth in children with asthma (233). The use of a spacer device combined with mouth rinsing after glucocorticoid administration may prevent oropharyngeal candidiasis.

Leukotriene Receptor Antagonists

The contributions made by the cysteinyl leukotrienes to many of the features of asthma have been discussed already. Leukotriene receptor antagonists reduce the numbers of T cells, mast cells, and eosinophils in asthmatic bronchial mucosa (234). This class of drug is particularly effective in the treatment of EIA and AIA (135). Clinical trials showed that leukotriene receptor antagonists provide added benefit over glucocorticoid therapy in the treatment of chronic asthma, reflecting the apparent lack of glucocorticoid influence on cysteinyl leukotriene production (135,228). The response to leukotriene receptor antagonists therapy is variable, however, and evidence suggests that this situation may reflect a pharmacogenetic interaction involving 5-LO (235) and LTC_4S (149) promoter polymorphisms. A Churg-Strauss–like syndrome has been reported in association with leukotriene receptor antagonists use, but it probably represents unmasking of this condition as a result of the reduction or cessation of oral glucocorticoid therapy (233).

b_2-Agonists

This class of asthma drug acts primarily on airway smooth muscle, inducing relaxation via activation of the adenylyl cyclase. Although *in vitro* studies suggest that b_2-agonists also have potential antiinflammatory activity (236), there is little evidence of this *in vivo* (237). The gene encoding the b_2-adrenoceptor (b_2-AR) resides on chromosome 5q31-33, and several polymorphisms have been identified (238). Of these, the Gly16 polymorphism has been associated with features of moderate to severe asthma, including nocturnal symptoms, reduced bronchodilator response, and increased airway responsiveness (71). In addition, the Gly16 polymorphism is particularly susceptible to agonist-induced receptor downregulation *in vitro* and may be associated with tachyphylaxis, although this finding is not supported by other clinical studies (71). The Glu27 polymorphism has been associated with childhood asthma and elevated serum IgE levels in asthmatic families; however, the evidence of linkage between b_2-AR polymorphisms and asthma remains controversial (71).

Other Asthma Drugs

Chromones appear to act predominantly by stabilizing mast cells (239) but also may suppress other inflammatory cells, including eosinophils, neutrophils, monocytes, and macrophages (240). Oral theophylline is a relatively weak bronchodilator with a low toxic:therapeutic ratio, requiring monitoring of plasma levels. Like b_2-agonists, there is interest in its antiinflammatory activity, which led to a reappraisal of its role in asthma (241). It is argued that antihistamines, in combination with leukotriene receptor antagonists, are also worthy of reappraisal (136). Methotrexate, cyclosporin, and gold have some glucocorticoid-sparing effect (242), but their use in asthma should be restricted to selected patients who are under the supervision of a respiratory physician.

Specific Immunotherapy

There is uncertainty about the value of specific injection immunotherapy (SIT) in the management of asthma. First, evidence suggests that the role of allergy in the pathogenesis of chronic asthma is less important than once thought. Second, SIT is specific for the allergen injected, and patients with atopic asthma are often multiply sensitized. Third, and most important, patients with asthma are at increased risk of severe adverse reactions with SIT. In a confidential inquiry by the American Academy of Allergy and Immunology into deaths associated with SIT, almost all those who died were being treated for asthma, and the mode of death was catastrophic bronchospasm (243). For these reasons, SIT is not currently recommended for asthma.

PROGNOSIS

Longitudinal studies showed that, of children with established asthma, up to 50% will become asymptomatic by adulthood (54). Factors predisposing to the persistence of childhood asthma into later life include moderate to severe chronic disease, parental history of asthma, strong signs of atopy (including atopic dermatitis or allergic rhinitis), female gender, and active cigarette smoking (54).

Population-based studies suggest that of adults with chronic asthma, 60% have mild, 20% moderate, and 20% severe disease (244). Furthermore, longitudinal studies suggest that 12% of adults with chronic asthma become asymptomatic, with normal lung function, within 25 years (245). Thus, most patients with asthma have a good prognosis. Poor prognostic indicators, associated with an accelerated decline in FEV_1, include moderate to severe chronic disease at presentation, active cigarette smoking, and BHR but not atopy (27). There is no evidence that any of the current asthma therapies can modify the natural history of asthma.

In cases of occupational asthma, more than 50% of patients remain symptomatic or maintain lung function abnormalities despite cessation of exposure to the responsible agent. Interestingly, cessation of exposure is associated with resolution of airway inflammation and reversal of SBM thickening, both in patients who improve clinically and in those who do not (50).

IMMUNOPATHOLOGY

In vivo evidence for Th2-mediated airway inflammation in asthma has come from the investigation of BAL fluid and bronchial biopsies obtained using the fiberoptic bronchoscope. Compared with normal controls, BAL fluid from atopic asthmatic patients contains greater numbers of cells expressing mRNA for IL-3, IL-4, IL-5, and GM-CSF, and these cells are predominantly T-lymphocytes (246). Similarly, bronchial biopsies from atopic asthmatics exhibit increased cellular expression of mRNA for IL-4, IL-5 (247), and IL-13 (34). Once again, these cells are predominantly $CD4^+$ T cells (Th2-like) but also include $CD8^+$ (cytotoxic) T cells (Tc2-like) (35). Unlike the expression of IL-5, that of IL-4 is also increased in individuals who are atopic and nonasthmatic (33,247), suggesting that IL-5 may be associated more closely with the asthma phenotype. As mentioned previously, chronic airway inflammation associated with a Th2/Tc2-deviated cytokine profile is also a feature of nonatopic asthma (33,34 and 35), including the nonatopic occupational form of the disease (248).

Airway Mucosal $CD4^+$ T-cell Activation

Activation of a $CD4^+$ T cell within the airway mucosa requires cognate interaction with a professional APC (249). The principal APC is considered the dendritic cell, which differentiates from a $CD34^+$ bone marrow precursor in the presence of GM-CSF and TNF-a, losing its monocyte marker (CD14) while gaining the dendritic cell marker (CD1a) (250). In the airway mucosa of patients with asthma, dendritic cell numbers are increased but fall in response to glucocorticoid therapy (251). Dendritic cells reside primarily within the airway epithelium, optimally positioned for making contact with inhaled antigen. If antigen does make contact, it is internalized, processed into short peptide sequences, and expressed on the APC surface in conjunction with human leukocyte antigen (HLA) class II (Fig. 65.7). Recognition of this HLA class II-peptide complex by the antigen-specific T-cell receptor (TCR) of a $CD4^+$ T cell provides the first of three signals necessary for maximal activation of the lymphocyte (249). The second, costimulatory signal is not antigen-specific and is generated when CD28, constitutively expressed on the $CD4^+$ T cell, binds to its ligands, CD80 (B7-1) and CD86 (B7-2), expressed on the APC (252). The third signal results from the secretion of IL-1b by the APC, enhancing T-cell responsiveness. Consequently, the activated T-lymphocyte expresses the IL-2 receptor (IL-2R, CD25), proliferates under the autocrine influence of IL-2 (clonal expansion), and produces Th1- or Th2-like cytokines. $CD4^+$ T cells that are activated by dendritic cells may be naive ($CD45RA^+$) or Th-memory cells ($CD45RO^+$). The latter arise from clonal expansion and provide long-term, antigen-specific immunologic memory, generating a more rapid and intense T-helper cell response on subsequent antigen exposure. Evidence suggests that when a naive $CD4^+$ T cell is activated, the Th1- or Th2-like phenotype becomes programmed into the daughter Th-memory cells (21). Although such programming of Th1- or Th2-like responses into long-term immunologic memory appears to be irreversible in mice, this may not be the case in humans (79). The mechanism directing the differentiation of activated airway mucosal $CD4^+$ T cells to a Th2-like phenotype remains a fundamental question in asthma

research, and attempts to answer this question have implicated all three signaling steps in the T-cell activation process.

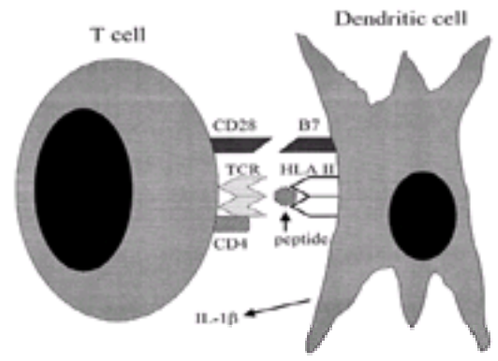

Figure 65.7. Dendritic cell–T cell interactions. Dendritic cells capture allergen and present processed peptide sequences, in conjunction with human leukocyte antigen (HLA) class II, to the T-cell receptor (TCR) of allergen-specific $CD4^+$ T cells. Costimulatory signals required for maximal T-cell activation include CD28/B7 and interleukin-1 (IL-1b).

Both HLA class II and the TCR have been proposed as candidate susceptibility genes for atopy and asthma, although most reported associations between HLA class II or TCR genotypes and the asthmatic phenotype have been controversial (71). Relatively strong associations with HLA class II genes have been observed with occupational asthma and AIA (71).

The role of CD28/B7 costimulation has been investigated with the human bronchial explant model, in which bronchial biopsy specimens from persons with mild atopic asthma and from normal controls were challenged with allergen *in vitro* (253). In biopsies from persons with asthma, transcription and release of IL-5 and IL-13 were augmented by allergen exposure. In contrast, these Th2 cytokines were not detected in normal biopsies. CTLA-4-Ig, a fusion protein that binds to CD80 and CD86, thereby blocking CD28/B7 signaling, almost totally inhibited the allergen-induced secretion of IL-5 and IL-13 in asthmatic biopsies (253). This finding suggests that CD28/B7 costimulation plays an important role in the activation of Th2-like cells by APCs and that this process occurs within the asthmatic bronchial mucosa. Additional studies with blocking antibodies to CD80 or CD86 demonstrated that Th2-like cell activation requires signals from both these costimulatory molecules (254). This finding is consistent with observations in the murine model of asthma, suggesting that CD28/CD86 costimulation is required for the induction of a Th2 phenotype (255), whereas CD28/CD80 costimulation is necessary for T-cell activation (256).

Interest also focused on the influence of the local cytokine milieu on the phenotype of activated $CD4^+$ T cells (79). As well as releasing IL-1b, normal mature dendritic cells also secrete IL-12, a cytokine that promotes the differentiation of naive $CD4^+$ T cells to a Th-1 like phenotype when activated *in vitro* (167). In addition, $CD4^+$ T-cell differentiation also appears to be dependent on the relative balance between Th1 (IFN-g) and Th2 (IL-4 and IL-10) cytokines present in the microenvironment at the time of T-cell activation. Whereas T cells are unable to differentiate into Th2-like cells in the absence of IL-4, IFN-g tends to prevent the development of this phenotype (167). Evidence suggests that IFN-g exerts its effect by inhibiting IL-4-induced downregulation of the IL-12 receptor b-chain, thereby reducing the sensitivity of the $CD4^+$ T cell to the Th1-promoting influence of IL-12 (257). IL-10 facilitates $CD4^+$ T-cell differentiation to a Th2-like phenotype by suppressing the production of IL-12 by APCs (258). The finding that IL-12 can induce the production of IFN-g in human Th2-like-memory cells *in vitro* (259) suggests that this cytokine might also be capable of changing a Th2-like cell to either a Th1-like or a Th0 cell (79), the latter characterized by a mixed cytokine profile that remains associated with the allergic response (260). Thus, programming of Th1- and Th2-like immune responses into long-term immunologic memory may be potentially reversible in humans, being strongly influenced by the local cytokine milieu at the time of $CD4^+$ T-cell activation (Fig. 65.8). Evidence therefore suggests that Th2-like immune responses are more likely to prevail in a microenvironment relatively deficient in IL-12 and IFN-g. This is consistent with the finding that the cellular expression of IL-12 mRNA (227) is decreased in bronchial biopsies from persons with asthma compared with normal controls; IFN-g mRNA is reduced in both groups (247). Finally, the ability of dendritic cells to direct the cytokine response of T cells led to the suggestion that there are two types of dendritic cell, designated DC_1 and DC_2 (261).

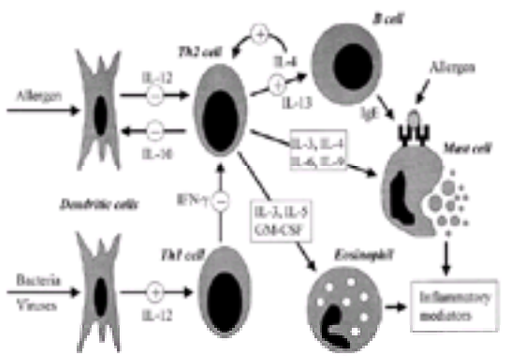

Figure 65.8. Proposed cellular and molecular mechanisms of allergy. Both soluble mediator and cognate interactions between dendritic cells and naive $CD4^+$ T cells direct their differentiation to the T helper cell type 2 (Th2) phenotype. Th2 polarization is effectively suppressed if T cells are driven along the Th1 pathway by interleukin-12 (IL-12) to produce increased interferon-g (IFN-g). It is postulated that exposure to bacteria, and possibly viruses, at a critical time during immune development in early childhood enhances Th1 at the expense of Th2 responses, thereby protecting against allergy. (Redrawn from Holgate ST. *Nature* 402(Suppl): B2–B4, with permission.)

Early Life Origins of Atopy and Asthma

The programming of cytokine responses into immunologic memory is greatly influenced by the maturity of the adaptive immune system at the time of antigen exposure (87). Studies suggest that exposure of the fetus to environmental allergens *in utero* is a normal phenomenon, probably involving the transfer of allergen across the placenta, and that fetal $CD4^+$ T-cell activation with allergen-specific Th-memory cell formation commonly occurs as early as the second trimester of pregnancy (262). Furthermore, neonatal cord blood mononuclear cells (CBMCs) universally exhibit a Th2-like response when challenged with allergen *in vitro* (263). The reason for this is not clear, but it is postulated that a Th1-like response is detrimental to pregnancy, reducing immunologic tolerance between mother and fetus, and that the Th2-like phenotype is the default response of the fetal immune system (99). This, at least in part, may reflect the influence of IL-10 on fetal APCs because IL-10 is produced by the placenta throughout pregnancy and is detectable in amniotic fluid (264).

At birth, the *in vitro* responses of CBMCs from neonates who become atopic in later life differ from those of CBMCs from neonates who do not become atopic. CBMCs in the atopic group not only exhibit a reduced IFN-g response to mitogen (PHA) but also show a weaker Th2-like response to allergen, suggesting that atopic persons have a generalized maturational defect in adaptive immune function at birth (263). During the first year of life, peripheral blood mononuclear cells (PBMCs) in the nonatopic group rapidly downregulate their Th2-like response to allergen but maintain a relatively weak IFN-g response. In contrast, PBMCs in the atopic group exhibit an age-related upregulation of both Th2-like and IFN-g responses, thereby adopting a Th0 phenotype. Between 2 and 5 years of age, further maturation of the Th1-like response occurs in the nonatopic group, corresponding to the upregulation of IFN-g, whereas downregulation of this cytokine occurs in the atopic group (263). Thus, the programming of cytokine responses into long-term immunologic memory appears to depend on the process of immune maturation during early life. To what extent this is influenced by maternal and infant allergen exposure is unclear. It is postulated that by increasing maternal Th2-like cytokine production, maternal atopy has the potential to cause a maturational defect in the adaptive immune system of the fetus, and continued allergen exposure during infancy reinforces a Th2/Th0 response in children so affected (262). This could explain why the inherited risk of atopy is greatest if the mother rather than the father is atopic (265). Furthermore, it is consistent with the finding that levels of IL-10 in amniotic fluid are higher in atopic mothers than in nonatopic controls (262). Studies are under way to assess whether the risk of developing atopy can be reduced through allergen avoidance strategies during the second trimester of pregnancy and the first year of life (266). Studies already showed that allergen avoidance measures taken during the first year of life in young children from atopic parents reduce the prevalence of wheezy illness, but only up to the age of 4 years (267), but these studies did not include allergen avoidance during pregnancy.

Although CBMCs exhibit a universal Th2-like phenotype in response to allergen, the ability of mitogen to induce IFN-g synthesis led to the suggestion and

demonstration that fetal Th2-like responses are, at least in part, the consequence of APC immaturity, characterized by reduced IL-12 production (268). Factors that facilitate postnatal APC maturation and IL-12 production might therefore promote Th1-type responses during infancy, thus reducing the risk of allergen-specific Th2-memory consolidation. The principal environmental stimulus for normal postnatal APC maturation is bacterial exposure (99). Both LPS (269) and components of the cell wall *of M. tuberculosis* (270) activate dendritic cells via the CD14 receptor, thereby inducing the production of IL-12. This mechanism might, at least in part, explain the inverse correlation between childhood infection rates and the prevalence of allergic disease (97,98), providing a mechanistic model in support of the hygiene hypothesis (99). A polymorphism of the CD14 gene, which resides on chromosome 5q31-33, is associated with total serum IgE (271). As mentioned previously, however, the hygiene hypothesis is more closely associated with atopy than with asthma (107), suggesting that other gene–environment interactions are likely to be responsible for localizing Th2-like responses to the airway mucosa. Based on epidemiologic evidence, candidate environmental factors would include aeroallergens, certain viruses, and air pollutants. For example, Martinez postulated that, instead of consolidating airway mucosal Th1-like responses, RSV bronchiolitis in early childhood might promote a Th2-like response in genetically susceptible persons, involving natural killer type 2 (NK2) and Tc2 cells (111).

Isotype Switching to IgE

Antigen-specific IgE production requires cognate interaction between Th2-like memory and B cells (272). The B cell acts as an antigen-specific APC, internalizing antigen recognized by its surface immunoglobulin. Subsequent Th2-like memory cell activation results from HLA class II–peptide complex recognition by the TCR in association with CD28/B7 costimulation. The switching of antibody synthesis from the IgM to IgE class then requires two signals. The first is generated when the costimulatory molecule, CD40, expressed by the B cell on antigen recognition, binds to its ligand, CD40L (CD154), expressed on the Th2-like cell (Fig. 65.9). The second signal results from the secretion of IL-4 and its homolog, IL-13, by the activated Th2-like cell (272). The IL-4 receptor (IL-4R) shares its a-chain (IL-4Ra) with the IL-13 receptor (IL-13R) (273), and activation of either of these receptors on the B cell leads to downstream activation of signal transducer and activator of transcription-6 (STAT-6) (274), initiating the isotype switch to IgE. IL-4 and IL-13, however, also activate different intracellular pathways, explaining why IL-13 cannot support differentiation of T cells to the Th2-like phenotype (275). Candidate genes for asthma and atopy include IL-4 and IL-13 on 5q31-33, and the IL-4Ra on chromosome 16p12.1 (71). Polymorphisms of the IL-4 gene promoter, causing increased IL-4 gene transcription, have been associated with elevated serum IgE levels and asthma, although this finding has not been confirmed by other studies (71). Polymorphisms of the IL-13 gene have been associated with elevated serum IgE levels (276), and polymorphisms of the IL-4Ra gene, giving rise to enhanced activation of STAT-6, have been associated with increased risk of atopy (71).

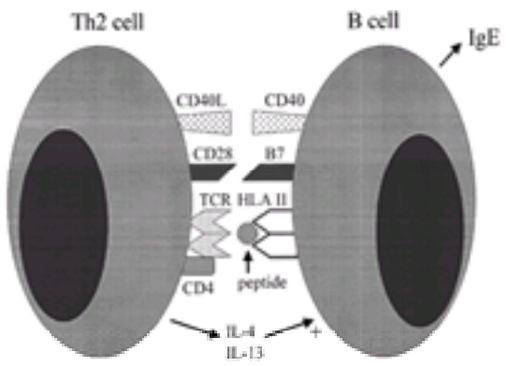

Figure 65.9. T-helper cell type 2 (Th2) cell–B-cell interactions involved in isotype switching to immunoglobulin E (IgE). Allergen-specific B cells can capture, process, and present allergen to Th2-memory cells. Costimulatory signals required by B cells for isotype switching to IgE include CD40/CD40L and interleukin-4 (IL-4)/IL-13.

In vitro studies show that isotype switching to IgE can also occur in the absence of Th2-like cells. Both mast cells and basophils can provide the necessary signals, expressing CD40L and releasing IL-4 in response to the activation of FceRI by IgE–allergen complexes (272). The mast cell–mediated induction of IgE synthesis by B cells requires additional, exogenous IL-4, however (272). In the absence of cognate interaction with allergen-specific Th2-like cells, B cells produce nonspecific, polyclonal IgE in the presence of basophils or mast cells *in vitro*.

When stimulated by IL-4 and IL-13, expression of the low-affinity IgE receptor (FceRII, CD23) is induced in the B cell (277). Activation of CD23 by IgE–allergen complex suppresses IgE production by the B cell, thereby acting as a feedback inhibition mechanism. Not only is Der p 1 an allergen, it also has cysteine protease activity (278) capable of cleaving CD23. Resulting disruption of feedback inhibition might explain, at least in part, why house dust mite allergen is relatively potent at inducing IgE responses in atopic persons (277). Inhibition of IgE production also has been shown to occur with IFN-g through a direct action on B cells (167).

Allergen Challenge Model

As a consequence of the anaphylactic theory of asthma, a great deal of research has been done with the allergen challenge model to elucidate the cellular and molecular mechanisms underlying the airway inflammatory response to aeroallergen exposure. Mast cell activation by allergen–IgE antibody complex already has been discussed, and this section focuses on mechanisms of inflammatory cell recruitment into the airway, characterizing the LAR. Because of associated eosinophilic inflammation and BHR, the LAR has been considered a better model of chronic asthma than the EAR. Although less pronounced, increased numbers of other inflammatory cells are also observed in BAL fluid during the LAR, including activated $CD4^+$ T cells (279), macrophages (280), neutrophils (281), and basophils (163).

The mechanism of inflammatory cell recruitment into the airways involves signals from cell adhesion molecules and chemotactic factors. During the EAR, histamine and the cysteinyl leukotrienes induce the expression of the P-selectin on vascular endothelial cells. The ligands for this cell adhesion molecule are specific oligosaccharides (lectins) expressed by all leukocytes, and interactions between these and P-selectin give rise to rolling and margination of leukocytes along the vascular endothelial wall (282). Activated mast cells also release a number of cytokines, including IL-3, IL-4, IL-5, IL-16, GM-CSF, and TNF-a (134,167). Within 6 hours of acute allergen challenge, TNF-a induces the expression of additional cell adhesion molecules on vascular endothelial cells, including E-selectin, intercellular adhesion molecule-1 (ICAM-1), and vascular cell adhesion molecule-1 (VCAM-1) (283,284), the last of which is also upregulated by IL-4 (167). The ligands for E-selectin are lectins, and those for ICAM-1 include the integrins, leukocyte functional antigen-1 (LFA-1), and Mac-1 (CD11b/CD18 integrin). Although these ligands are expressed on all leukocytes, IL-5 induced up-regulation of LFA-1 and membrane attack complex-1 (MAC-1) on eosinophils facilitates the selective recruitment of this inflammatory cell (285). In addition, VCAM-1 promotes eosinophilic inflammation because its ligand, very late antigen-4 (VLA-4), is expressed by eosinophils and basophils, but not by neutrophils (286). Furthermore, whereas E-selectin and ICAM-1 are downregulated at 24 hours after allergen challenge, VCAM-1 remains upregulated (287).

Chemotactic factors cause leukocytes adherent to the vascular endothelium to migrate across the vessel wall (*diapedesis*) and bronchial mucosa. The cysteinyl leukotrienes are potent, selective chemoattractants for eosinophils, and they increase eosinophil recruitment into the airway when inhaled by persons who have asthma (288). *In vitro* studies show LTB_4 and PAF to be chemoattractants for eosinophils and neutrophils (289); however, inhaled PAF fails to induce recruitment of eosinophils into the airways of atopic persons, casting doubt on its chemotactic function *in vivo* (290). IL-3, IL-5, and GM-CSF are selectively chemotactic for eosinophils (167). In addition, these cytokines prime eosinophils for activation and prolong their survival (167). IL-16 (lymphocyte chemoattractant factor) is chemotactic for $CD4^+$ T cells and eosinophils, and TNF-a is chemotactic for neutrophils and monocytes (167).

In addition to inhibiting the EAR, disodium cromoglycate also prevents the LAR (131), suggesting that mast cell activation at least initiates the recruitment of inflammatory cells into the airways. The continued recruitment of inflammatory cells probably occurs under the influence of activated Th2-like cells and eosinophils (143). Like mast cells, activated Th2-like cells and eosinophils contribute to the cytokine milieu by releasing IL-3, IL-4, IL-5, GM-CSF, and TNF-a (145,167,246,291). In addition, activated eosinophils release the cysteinyl leukotrienes (145) and IL-16 (167), whereas Th2-like cells are a source of IL-13, capable of upregulating VCAM-1 on vascular endothelial cells, like IL-4 (292). Activated Th2-like cells and eosinophils also release members of the CC chemokine (chemotactic cytokine) family, including RANTES (regulated on activation normal T cell expressed and secreted) and eotaxin (167). Eotaxin is chemotactic for eosinophils and basophils. RANTES is chemotactic for eosinophils and Th-memory cells. Because the receptor for RANTES, CCR3, is expressed by Th2-like but not Th1-like cells, it is postulated that this CC chemokine selectively recruits Th2-memory cells and therefore may play an important role in the target-organ localization of allergic responses (167,293). Allergen challenge is associated with increased BAL fluid levels of IL-4, IL-5, IL-13, IL-16, GM-CSF, RANTES, and eotaxin in atopic persons with asthma (279,294,295 and 296). Inhibition of the eosinophil chemotactic activity of BAL fluid by monoclonal antibodies against RANTES and IL-5 suggests that these two cytokines are the major eosinophil chemoattractants in asthmatic airways (297).

Doubts about the Allergen Challenge Model for Chronic Asthma

In the late 1960s, reported correlation between the inhibitory action of disodium cromoglycate on the EAR (131) and the clinical efficacy of the drug in asthma (298) helped to reinforce the mast cell theory of anaphylaxis and asthma. Consequently, the allergen challenge model became used as a screening test in the development

of novel asthma therapies. During the 1980s, it became increasingly apparent that the ability of a drug to suppress the EAR and LAR did not predict its clinical efficacy (299). For example, although nedocromil sodium inhibits the EAR and LAR, clinical trials have shown it to be no better than placebo in the treatment of chronic asthma (300). In addition, cellular and molecular discrepancies are observed between the LAR and clinical disease. Whereas BAL fluid cell counts in the LAR typically reveal an eosinophilia of 30% to 70%, with associated neutrophils and basophils, BAL fluids from patients with chronic asthma exhibit eosinophil counts of 5% to 8%, with neutrophils an inconsistent feature and basophils rarely seen (299). Furthermore, upregulation of E-selectin, ICAM-1, and VCAM-1 expression on vascular endothelial cells is not observed in chronic stable disease (301). Thus, doubt has been cast on the validity of the allergen challenge model and mast cell hypothesis with respect to chronic asthma.

T-cell Hypothesis

Over the past decade, after the discovery of the Th1/Th2 paradigm, several observations led to, and supported, the T-cell hypothesis of asthma (302). This hypothesis postulates that chronically activated Th2-memory cells, resident in the airways, play a pivotal role in the disease, orchestrating eosinophil recruitment and activation and associated IgE synthesis through the release of Th2-like cytokines. Supporting evidence includes the predominance of chronically activated Th2-memory cells as the major source of IL-4 and IL-5 in bronchial biopsies (193,247) and BAL fluid (303) from atopic and nonatopic (35) asthmatic persons. In addition, positive correlations have been demonstrated between the number of activated Th2-memory cells and (a) the number of eosinophils in bronchial biopsies (304), (b) the number of eosinophils in BAL fluid (303), and (c) the clinical severity of the disease (305). Furthermore, clinical response to glucocorticoid therapy is associated with a reduction in T-cell numbers in the bronchial mucosa (225).

Why Th2-memory cells should become chronically active remains unclear. Persistent low-grade exposure to aeroallergens may be one explanation in cases of atopic asthma. Studies have shown that airway dendritic cells express the a-subunit of the FceRI (306), and IgE-mediated capture and internalization of allergen increase the effectiveness of allergen presentation by 100- to 500-fold (307). b-chain polymorphisms of the FceRI (FceRI-b), which resides on chromosome 11q13, have been associated with atopy, BHR, and asthma; and it has been postulated that certain polymorphisms might enhance FceRI function and mast cell activation (71). No *in vitro* evidence in support of this hypothesis has been shown, however, and other population-based studies have failed to confirm the associations (71).

In nonatopic asthma, IgE-facilitated antigen presentation also may play a role in the induction and maintenance of chronic Th2-memory cell activation, perhaps involving unknown allergens, self-antigens, or persistent low-grade viral infection (308). In clinical trials, however, a humanized anti-IgE monoclonal antibody (rhuMAb-E25), which inhibits both EAR and LAR to acute allergen challenge (309), had only limited efficacy when administered for 12 weeks to patients with moderate-to-severe atopic asthma (310), despite causing marked reductions in serum levels of total and allergen-specific IgE. Thus, although IgE-dependent mechanisms may contribute to chronic Th2-mediated airway inflammation, non-IgE-dependent mechanisms are likely to be operating in parallel. This reiterates the conclusion drawn from epidemiologic data that factors other than atopy are likely to play an important role in asthma pathogenesis.

At 48 hours postactivation, the $CD4^+$ T cell normally expresses CTLA-4 (CD152), which binds to B7 (CD80 and CD86) on the APC. In contrast to the CD28/B7 signal, however, binding of CTLA-4 to B7 generates a negative signal, and it is postulated that this serves to downregulate the T-cell response (293). Studies showed that if the CTLA-4/B7 signal is blocked, Th2 cytokine production is increased, and the period of cytokine production is prolonged (293). Furthermore, some evidence suggests that CTLA-4 expression on T cells is both reduced and delayed in atopic persons compared with normal controls, and this may predispose to prolonged Th2-memory cell activation (293). Other studies suggest that CTLA-4 is also capable of generating a positive signal (311).

T helper-like cells are not the only source of proallergic cytokines (167). The contribution of Tc2-like cells, mast cells, eosinophils, and basophils to the cytokine network already has been mentioned. In addition, the structural cells of the airways are also potential sources of proinflammatory mediators, cytokines, chemokines, adhesion molecules, and growth factors (Table 65.4) (167). Furthermore, as mentioned, it is postulated that the damaged and stressed airway epithelium functions as a key regulator of inflammatory cell recruitment, airway wall remodeling, and local T-cell responses, driving sustained Th2-immune deviation and disease chronicity (209). Thus, the pivotal role of T cells in asthma remains controversial.

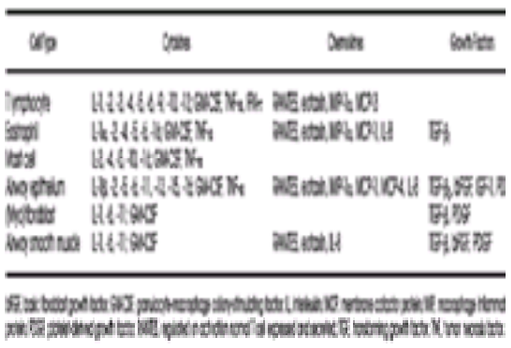

TABLE 65.4. Cell Sources of Cytokines, Chemokines, and Growth Factors

Role of the Airway Epithelium

The airway epithelium can respond to the inhalation of potentially damaging environmental agents by defensively adopting a stress phenotype, which normally functions to initiate the local recruitment of inflammatory cells and prepare the airway to clear the insult and respond to injury. Bronchial biopsies from asthmatic individuals provide evidence of widespread epithelial stress, characterized by the upregulated expression of proinflammatory transcription factors, including NF-kB (312), AP-1 (313), and STAT-1 (314). Target genes for NF-kB include proinflammatory cytokines (IL-1b, IL-6, GM-CSF, TNF-a), CC chemokines [RANTES, eotaxin, membrane cofactor protein (MCP-1), macrophage inflammatory protein (MIP-1)a], CXC chemokines [IL-8, growth-related oncogene (GRO)-a], cell adhesion molecules (ICAM-1, VCAM-1), cyclooxygenase-2 (COX-2), and inducible nitric oxide synthase (iNOS) (315). Target genes for STAT-1 include ICAM-1 (314), and many of those for NF-kB are also shared by AP-1 (316).

Normally, STAT-1 is activated by IFN-g, but levels of this Th1-like cytokine are not increased in asthma (314); however, STAT-1 is also downstream of the epidermal growth factor receptor (EGFR) (317), the expression of which is upregulated throughout the airway epithelium in relation to the severity of chronic disease (206). Because ligand-independent EGFR activation can occur in response to oxidant stress from air pollutants or inflammatory cells, or through transactivation by G-protein-coupled receptors, including protease-activated receptors, it is suggested that the EGFR is likely to play a key role in the induction of epithelial stress responses in asthma (209).

Known activators of NF-kB, many of which also activate AP-1, include Der p 1 (318), rhinovirus (319), proinflammatory cytokines (IL-1k, IL-6, TNF-a), PAF, and oxidant stress (315,316). Although there is potential for positive feedback to occur between epithelial stress responses and inflammatory cell recruitment, these events are normally self-limiting. Epithelial stress and airway inflammation are sustained in asthma, however, and it is postulated that this results, at least in part, from an airway epithelium that is intrinsically more susceptible to stress when exposed to potentially damaging environmental or inflammatory agents (209). This hypothesis is consistent with the *in vitro* observation that airway epithelial cells from persons with asthma produce greater quantities of GM-CSF, RANTES, and IL-8 both at baseline and in response to diesel exhaust particle exposure than cells from normal controls (320).

In addition to promoting the local recruitment of inflammatory cells, the airway epithelium has the potential to modulate T-cell responses, driving Th2-immune deviation. COX-2 catalyzes the production of PGE_2, which inhibits IL-12 production by dendritic cells *in vitro* (321). Airway epithelial cells may directly influence the phenotype of local T cells through the release of IL-5 (322), IL-13 (323), and IL-15 (167).

Airway Wall Remodeling

Although the precise mechanisms that underlie the remodeling process in asthma have yet to be elucidated, several observations support the hypothesis that airway wall remodeling is the consequence of chronic Th2-mediated airway inflammation. *In vitro* studies suggest that inflammatory cells have the potential to induce features of remodeling through the release of inflammatory mediators, cytokines, and proteases. Histamine (324), the cysteinyl leukotrienes (325), IL-1b, TNF-a (167), and mast cell tryptase (326) all can induce ASM proliferation. IL-1b, TNF-a (167), and mast cell tryptase (327) are also mitogens for fibroblasts. In addition, IL-4 (167) and mast cell tryptase (328) act on fibroblasts and upregulate the expression of genes encoding extracellular matrix (ECM) proteins. IL-4 induces the expression of a-smooth muscle actin, thereby promoting the differentiation of fibroblasts into myofibroblasts (329). As a consequence of changes in the protein composition of the ECM, (myo)fibroblasts have the potential to modulate inflammatory and structural cell function through altered cell–matrix signaling (330). For example, fibronectin prolongs

eosinophil survival (331).

Proteases are also likely to play an important role in the remodeling process through their action on ECM proteins. Matrix volume and turnover are dependent on ECM protein deposition and degradation, the latter mediated primarily by matrix metalloproteinases (MMPs). Inflammatory cells are a major source of MMPs, and mast cell tryptase can cleave and activate MMP-3 (stromolysin), which can itself cleave and activate MMP-9 (gelatinase-B) (332). Tissue inhibitors of MMPs (TIMPs) also regulate MMP activity, however, and although levels of MMP-9 are increased in sputum samples from patients with asthma, the MMP-9/TIMP-1 ratio is reduced and correlates with airflow obstruction. This finding led to the suggestion that an imbalance between MMP-9 and TIMP-1 accounts, at least in part, for the increase in ECM volume in asthma (333).

Eosinophils are also a source of transforming growth factor-b (TGF-b), and one study reported a positive correlation between the degree of subepithelial fibrosis and numbers of activated (EG^+) eosinophils expressing TGF-b_1 mRNA in bronchial biopsies from asthmatic individuals (212). Like IL-4, TGF-b can induce (myo)fibroblast proliferation and collagen gene expression (167) and can promote the differentiation of fibroblasts into myofibroblasts (329). In common with a number of other growth factors, TGF-b in its latent form binds to ECM proteins and remains encrypted until its release and activation by proteases, including MMP-9, plasmin, and thrombospondin. Thus, airway inflammation may promote the remodeling process through increased protease activity.

Epithelial–Mesenchymal Trophic Unit

Evidence supports the hypothesis that airway wall remodeling is driven primarily by repeated epithelial injury and repair (209). A three-dimensional coculture system of bronchial epithelial cells and myofibroblasts demonstrated that myofibroblast proliferation and ECM protein deposition can occur in response to paracrine growth factor signals from the repair phenotype of the airway epithelium. The fibroproliferative and profibrogenic growth factors involved include TGF-b_2, basic fibroblast growth factor (bFGF, FGF-2), ET-1, insulin-like growth factor-1 (IGF-1), and platelet-derived growth factor (PDGF) (334). Other *in vitro* studies showed that activated myofibroblasts also release TGF-b and PDGF, in addition to proinflammatory cytokines, and that ASM proliferation can be induced by ET-1, FGF-2, IGF-1, and PDGF (335). This coculture system models the epithelial-mesenchymal trophic unit (EMTU), which consists of the airway epithelium and subepithelial attenuated (myo)fibroblast sheath, separated by the basement membrane zone, and so named because of its pivotal role in branching morphogenesis during fetal lung development (209). This anatomic and functional unit is also thought to play a fundamental role in orchestrating an integrated response toward environmental insults and airway wall injury, with the epithelium as key regulator and (myo)fibroblast as key effector, amplifying and propagating defensive and repair responses throughout the airway wall. In asthma, it is postulated that inappropriate and persistent reactivation of the EMTU drives both chronic airway inflammatory and airway wall remodeling (209).

The phenotype of the asthmatic epithelium appears to be altered, giving rise to unusual fragility and impaired repair responses. This fragility is evident by the tendency of columnar cells to shed more easily than normal (173), suggesting a disturbance of intercellular adhesion mechanisms. This may be the consequence of direct attack on junctional proteins by environmental and inflammatory agents, including Der p 1 (177), major basic protein, eosinophil cationic protein (172), mast cell tryptase, and MMPs (336). Alternatively, increased fragility may reflect the sensitivity of asthmatic epithelial cells to oxidant-induced apoptosis (337). Despite upregulated expression of the EGFR (206), the asthmatic epithelium fails to proliferate as part of the normal repair response in areas of structural damage (338), suggesting suppression of mitogenic signaling by the EGFR (209). These changes in epithelial behavior are thought to account for the extensive epithelial damage in asthma, which is not a feature in other chronic inflammatory disorders of the airway, such as chronic bronchitis or cystic fibrosis. It is therefore suggested that chronic airway inflammation and airway wall remodeling are both the consequence of the asthmatic epithelium being “locked” in a repair/stress phenotype, continually releasing cytokines and growth factors (209).

Because primary asthmatic epithelial cells appear to proliferate as well as normal controls under standard *in vitro* culture conditions, it is suggested that *in vivo* suppression of EGFR-mediated mitogenic signaling in asthma results from antagonistic signals from other factors in the microenvironment. In this respect, interest has focused on TGF-b, which is known to generate antiproliferative signals via the activation of SMAD transcription factors. This hypothesis is consistent with increased levels of TGF-b_1 observed in BAL fluid from patients with asthma, when compared with normal controls (339) and would reflect events that normally occur within the EMTU at branching points during embryonic lung development (209). In view of the apparent importance of TGF-b in models of asthma, promoter polymorphisms for this growth factor have been proposed as candidate susceptibility and disease-modifying genes (340). The role of growth factor signaling in airway wall remodeling remains controversial, however, largely because of inconsistencies in comparative levels between individuals with asthma and normal controls (167).

Summary

Evidence suggests that programming of Th2-like responses into long-term immunologic memory results from multiple gene–environment interactions early in life. Evidence also suggests that determinants within the lung drive chronic Th2-mediated airway inflammation and airway wall remodeling, both of which appear to be necessary for the development of chronic asthma. In recent years, models of the disease had to take into account the recognition that structural cells of the airway wall are potentially important sources of cytokines, chemokines, and growth factors. In particular, attention focused on the airway epithelium, the phenotype of which appears altered in asthma, with increased susceptibility to chronic injury and stress from environmental and inflammatory agents. Persistence of the epithelial stress/repair phenotype might therefore be a key determinant in asthma, driving both inflammatory and remodeling processes. The underlying disturbance of the asthmatic epithelium is also likely to result from multiple gene–environment interactions, probably occurring in parallel with those responsible for the development of Th2-like responses (Fig. 65.10).

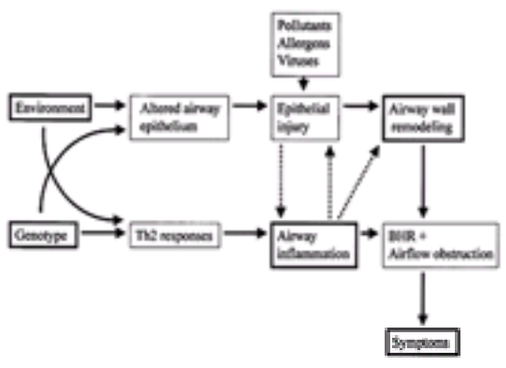

Figure 65.10. An integrated model of asthma. Multiple gene–environment interactions give rise to parallel and interacting processes of chronic T-helper cell type 2 (Th2)-mediated airway inflammation and airway wall remodeling, both of which contribute to BHR, airflow obstruction, and asthma symptoms.

ANIMAL MODELS

Asthma is a disease unique to humans, and animal models fail to simulate its complexity (341). Instead, animal models reproduce allergic airway inflammation, characterized by allergen-specific IgE production, IgE-mediated mast cell activation, eosinophil and T-cell recruitment to the airways, Th2 cytokine (IL-4 and IL-5) expression, airflow obstruction, and BHR. They lack a number of features characteristic of asthma, however, including the persistence of airway inflammation in the absence of allergen exposure and airway wall remodeling. Nevertheless, animal models have made an important contribution to our understanding of the cellular and molecular mechanisms underlying the allergic inflammatory response within the airway mucosa, and they have played an important role in the development of novel asthma therapies. The results of animal studies must be interpreted with caution, however, when attempting to apply them to the human disease. Of the animal models available, that of the mouse is most commonly used.

Although airway eosinophilia can be induced in the murine model after a single allergen provocation, induction of BHR requires repeated provocation (342). This finding suggests that factors other than airway eosinophilia alone are required for the expression of BHR. In the murine model, anti-IL-5 blocking antibodies can inhibit both eosinophilic inflammation and BHR (343), and this effect may last for up to 3 months after a single injection. In clinical trials, a single injection of a blocking anti-IL-5 humanized monoclonal antibody reduced eosinophil levels in blood and sputum for several weeks (344). Although this treatment prevented the recruitment of eosinophils into the airways in response to inhaled allergen challenge, it had no effect on the EAR, LAR, or BHR (344). Thus, the LAR and BHR may occur independently of recruited eosinophils, but eosinophils already resident in the airways at the time of allergen challenge may be involved.

Some murine models do behave in a manner similar to that of humans with asthma when treated with anti-IL-5 antibodies, with reduced eosinophil responses to allergen but no effect on BHR (345). In these mice, however, BHR can be reduced by anti-CD4 antibodies, which deplete $CD4^+$ T cells (345). This finding suggests that BHR is the consequence of mediator release, other than IL-5, from activated $CD4^+$ T cells. Indeed, the adoptive transfer of $CD4^+$ T cells from sensitized to naive mice

can induce BHR (346), supporting the concept of the T cell as key regulator of airway responses to allergen.

In the murine model, anti-IL-4R blocking antibodies inhibit allergen-induced eosinophil recruitment and BHR (347). Decoy soluble IL-4R provides an alternative means of competitively inhibiting IL-4 activity, and early clinical trials using once weekly nebulized soluble IL-4R in subjects with moderate atopic asthma appear promising, with significant improvements in symptom scores and lung function (348).

When administered to mice by nebulizer, IFN-g prevents allergen-induced eosinophil recruitment into the airways by inhibiting Th2 cells (349). Clinical trials that included patients with asthma have proved disappointing, however, with no significant reduction in eosinophilic airway inflammation demonstrated (350). Anti-IFN-g antibodies prevent allergen-induced BHR in the murine model, suggesting an important role played by IFN-g in this process (351). How this relates to clinical asthma is unclear, however.

When inoculated with BCG 14 days before allergen challenge sensitization, the murine model demonstrated reductions in allergen-specific IgE production and allergen-induced eosinophil recruitment and BHR, in association with increased levels of IFN-g (352). Similar results have been observed in mice treated with a single injection of heat-killed *Mycobacterium vaccae* (353). Thus, BCG and *M. vaccae* both appear to be capable of skewing T-cell responses toward the Th1 phenotype, consistent with the hygiene hypothesis. This raises the possibility of a vaccine that might be capable of promoting the maturation of Th1-like responses in early childhood, reducing the risk of atopy and allergic disease in later life. Although currently no published data are available that address the question of primary prevention in humans, there are promising signs that *M. vaccae* might be of use as tertiary prevention for patients with established asthma. When administered a single injection of heat-killed *M. vaccae*, allergen-challenged asthmatic patients demonstrated a significant reduction in the LAR, but not EAR (354). This reduction was associated with a fall in serum IgE level and decreased production of IL-5 by PBMCs in response to allergen, *in vitro* (354).

Other novel therapies have shown promise in the murine model but still must be assessed in humans with asthma. Anti-IL-9 (355) and anti-IL-13 (356) blocking antibodies both prevent allergen-induced eosinophilic inflammation and BHR. IL-10 therapy can dampen Th2 responses, inhibiting the release of IL-5, GM-CSF, TNF-a, and chemokines and reducing the eosinophil response to allergen challenge (357). By promoting Th1 responses, both IL-12 therapy (358) and the anti-CD86 blocking antibody (255) have been shown to prevent allergen-induced Th2 cytokine production, eosinophil recruitment, and BHR.

The likelihood of non-IgE-dependent mechanisms operating in parallel with IgE-dependent mechanisms to promote Th2-mediated airway inflammation already has been mentioned as an explanation for the partial response to anti-IgE monoclonal antibody treatment by patients with asthma. Of relevance is the observation in IgE-deficient mice that allergen provocation still can induce an eosinophil response and BHR (359). The mechanisms that are involved remain unclear, however.

FUTURE DIRECTIONS

Models of asthma have evolved over the past century, with focus shifting from the mast cell and the eosinophil to the T cell, and more recently to the structural cells of the airway wall. Although the past decade has seen advances in our knowledge of asthma pathogenesis, many fundamental questions remain to be answered. The challenge of the new century is to understand how environmental factors interact with the human genome to reveal the asthma phenotype. Elucidating the cellular and molecular pathways involved not only will aid the identification of novel therapeutic targets, but it also should lead to the development of preventive strategies so that the rising prevalence of the disease can be halted and reversed.

66 URTICARIA AND ANGIOEDEMA: PATHOGENESIS, ASSESSMENT, AND TREATMENT

Allen P. Kaplan, M.D.

Urticaria (hives) and angioedema (swelling) are common disorders that affect 20% of the population at some point during their lifetime. Urticarial lesions itch, have a central white wheal that is elevated, and typically are surrounded by an erythematous halo. The configuration of the lesions can vary; typically, they are rounded and circumscribed but also can be serpiginous or, rarely, more diffuse. Characteristically, hives blanch with pressure, and they generally resolve within 24 hours, leaving no residual change to the skin. Lesions that do not blanch, that cause pigmentation or scarring of the skin, or do not itch should be assessed for other dermatologic processes. The redness is due to dilated blood vessels in superficial layers of the skin, and the wheal is due to leakage of these vessels. Thus, fluid extravasates and compresses the vessels beneath it so that the central area appears clear.

Swelling of deeper layers of the skin, or *angioedema*, commonly accompanies urticaria. This swelling often results from the same inflammatory processes that cause hives. The redness that surrounds superficial lesions is not present, but the swelling can be readily appreciated. Angioedema generally occurs on the extremities and digits as well as on the head, neck, face, and, in men, genitalia. It is often described as painful or burning.

Urticaria alone or with angioedema is more common in women, whereas angioedema without urticaria is more common in men. Most urticarial outbreaks are acute and self-limiting. Fewer than 10% of urticarial eruptions become a chronic process. Acute urticaria is a common problem, and the cause is often elusive; however, its self-limited character limits morbidity. Chronic urticaria and angioedema tend to be recurring and recalcitrant problems, often causing significant disability and interfering with the patient's quality of life. Chronic urticaria is associated with angioedema in as many as 50% of cases. About 10% of cases have only angioedema in the absence of urticaria, and the remaining 40% have only urticaria.

CLASSIFICATION AND CAUSES OF URTICARIA

Although urticaria and angioedema can be classified by several characteristics, the most common classification is based on duration. Episodes that last for 6 weeks or less are considered *acute*, and those that persist beyond 6 weeks are designated *chronic*. This distinction is important because the causes and mechanisms of hive formation are different in each case, as are the prognoses and the approaches to treatment.

Acute Urticaria

Both children and adults commonly experience acute urticaria, which is often caused by an allergic [immunoglobulin E (IgE)-mediated] reaction. This type is a self-limited process that occurs when mast cells in the skin become activated, degranulate, and secrete histamine, leukotrienes, platelet-activating factor (PAF), enzymes such as tryptase and chymase, cytokines, and chemotactic cytokines (chemokines). When an allergen (for example, a food) to which the person is allergic is carried by the bloodstream to mast cells in the skin, it binds to the IgE; the mast cells become activated and degranulate. Allergens that can cause acute urticaria include foods; drugs, particularly antibiotics such as penicillin and sulfa; and venoms from bee, wasp, yellow jacket, hornet, and fire ants. Virtually any allergen that can be disseminated throughout the body, and to which there is an IgE response, has the potential to cause generalized urticaria. When a patient presents with an isolated event of urticaria, the physician must attempt to identify a specific cause or exposure. In a child, typical allergens that cause acute urticaria include medications such as antibiotics or food. The leading food allergens in children are derived from egg, milk, soy, peanut, and wheat. In adults, commonly encountered foods that result in allergic reactions include shellfish, peanut, and tree nuts (walnuts, hazelnuts, pecans). Historical evidence usually reveals that the initial outbreak of hives occurred shortly after ingestion of a particular food and repeated ingestion of that food results in repeated episodes of acute urticaria. One should be suspect of a patient's belief that he or she is allergic to a particular food if it has been ingested on other occasions without typical urticarial or allergic symptoms. When an allergen penetrates the skin locally, hives develop at the site of exposure. Contact urticaria, for example, might occur after exposure to latex from latex gloves if sufficient latex penetrates the skin (see Natural Rubber Latex Allergy, Chapter 73). In general, if an allergic reaction causes hives or swelling, it is usually ingested (food, oral drug) or injected (drugs, stings) and only rarely inhaled. Inhaled allergens typically cause allergic rhinitis and asthma and in children may contribute to atopic dermatitis.

Acute urticaria also can result from “nonspecific” stimulation of mast cells; in this case, IgE on the surface of mast cells usually is not directly involved. For example, mast cells can degranulate in such a fashion during exposure to certain radiocontrast media (RCM), which change the osmolality of the environment in which the mast cell resides. Complement also may be directly activated by these agents, and C5a can cause mast cell degranulation. Patients who develop acute urticarial eruptions can have other accompanying manifestations of allergy such as wheezing, laryngeal edema, cramps, diarrhea, and hypotension, that is, anaphylaxis. Newer low-ionic radiocontrast agents lessened the occurrence of this particular acute urticarial event. Acute viral illnesses in children can be associated with urticarial eruptions that last for a few weeks and then spontaneously subside. The children typically have symptoms of viral rhinitis, pharyngitis, or bronchitis. When such patients are also given an antibiotic, the cause of the hives becomes less clear because a drug reaction becomes an alternative possibility. If penicillin or related antibiotics have been given, it may be worthwhile to do skin testing for penicillin or cephalosporin allergy rather than simply assume that the child is “penicillin allergic.” Although viral infections can cause hives in children, they do not generally do so in adults; however, hives can be caused in any age group by early infection with hepatitis B (1) or infectious mononucleosis (Epstein–Barr virus) (2); and numerous helminthic parasites also are associated with hives. Codeine and other opiate-derived medications can cause mast cell degranulation by stimulation of opiate receptors rather than via IgE. This urticarial eruption is therefore not a specific allergic process, although it is indistinguishable from the urticarial eruption of allergy and is treated similarly. In certain persons, urticaria and angioedema can result from agents that alter the metabolism of arachidonic acid. Therapeutic agents in this category are aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs). These responses to NSAIDs have the potential to be fulminant and life-threatening because the associated angioedema can lead to prominent swelling of the tongue or throat or both. The widespread acceptance of NSAIDs for the treatment of musculoskeletal symptoms and their availability as over-the-counter medications have resulted in many episodes of urticaria and angioedema following their use. Furthermore, aspirin enjoys popularity because of its benefit in preventing heart disease and can cause repetitive urticarial eruptions that resemble chronic hives if taken daily. Over-the-counter preparations must be considered possible causes of urticaria in all patients. The use of angiotensin-converting enzyme (ACE) inhibitors, a class of drugs used to treat hypertension, can result in recurrent episodes of angioedema without urticaria. Examples include captopril, benazepril (Lotensin), enalapril (Vasotec), lisinopril (Zestril, Prinivil), and quinapril (Accupril). The swelling is thought to be due to elevated bradykinin levels because ACE inactivates bradykinin. Thus, the inhibition of ACE leads to the accumulation of bradykinin, which causes dilatation and leaking of vessels in deep layers of the skin.

Chronic Urticaria

Chronic urticaria and angioedema are diagnosed when hives and swelling are present for longer than 6 weeks and symptoms commonly exceed 12 weeks (Fig. 66.1). Moreover, it must be established that this protracted episode of urticaria is not caused by repeated exposure to an allergen or agent that results in recurrent acute urticaria. Although patients with chronic urticaria and angioedema often are assessed for IgE-mediated causes that result in recurring hives, IgE-mediated hypersensitivity is uncommonly found. Food-elimination diets and skin testing to foods, although generally negative, often help to convince the patient and the clinician alike that foods are not contributing to this process. A thorough review of the patient's medications will disclose whether any agents might be causing a chronic urticarial eruption, although this, too, is uncommon. Unnecessary medications should be eliminated, and alternative medications may be substituted for those that are necessary.

Figure 66.1. Typical lesions of chronic urticaria with serpiginous, elevated lesions borders variable degrees of central clearing. (See Color Figure 66.1.)

Once an evaluation has been completed and the chronic hives appear not to be associated with any other systemic disease process and are not due to one of the physically induced urtcarias (see later sections), the lesions are by exclusion deemed *idiopathic*, that is, of unknown origin. In the past, idiopathic urticaria accounted for more than 95% of all cases of chronic urticaria. New information has improved our understanding of chronic idiopathic urticaria, and the latest research suggests an autoimmune etiology in 35% to 45% of such patients (see later).

Other Modes of Classification

Urticaria also can be divided into two general types on the basis of the rate at which hive formation occurs and the length of time it is evident. One type of urticaria, with lesions that last 1 to 2 hours, typically is encountered with physically induced hives (see next section). The inciting stimulus is present only briefly, and there is prompt mast cell degranulation; biopsy of such lesions reveals little or no cellular infiltrate. The second type is accompanied by a prominent cellular infiltrate, and individual lesions can last from several hours up to 36 hours. This type is encountered with food or drug reactions, delayed pressure urticaria, chronic urticaria, and urticarial vasculitis.

An allergic mechanism, in the strictest sense, requires an interaction of IgE antibody with the allergen (e.g., food or drug) or other mechanisms for cross-linking either IgE or the IgE receptor (3), followed by degranulation of cutaneous mast cells. When an allergic person is skin-tested (e.g., intracutaneous administration of ragweed antigen to a person with ragweed-induced rhinitis), the immediate wheal-and-flare reaction lasts a few minutes and may be followed by swelling 4 to 6 hours later (the late-phase reaction) (4). The late-phase reaction is dependent on the preceding IgE reaction (5,6); it consists of a mixed cellular infiltrate containing mononuclear cells, neutrophils, eosinophils, and basophils (6,7) and is associated with a second wave of secretion of histamine (8) from infiltrating basophils. Cutaneous injection of 48/80, a polypeptide that causes mast cell degranulation, also can lead to late-phase reactions (9). It appears that the late-phase reaction in the skin requires something besides a single burst of mast cell degranulation, but no conclusive data are available. We can theorize that the persistence of mast cell degranulation over time or the persistence of antigenic stimulation over time is the critical difference. This situation would be absent in virtually all the physical urticarias except delayed-pressure urticaria. Perhaps the persistence of the hive in food or drug reactions is related to this phenomenon.

Serum sickness reactions (including the prodrome of hepatitis B infection) can be seen as a manifestation of drug reactions, and on biopsy there is evidence of a small-vessel cutaneous vasculitis (10). Urticaria in association with systemic lupus erythematosus (11,12) or other vasculitides appears similar. Atypical aspects of the gross appearance of the hives should heighten concern that the hives or swelling may be but one manifestation of such a more general disease process. Lesions that do not blanch or are associated with bleeding into the skin or black and blue marks suggest vasculitis (Fig. 66.2). In chronic urticaria, inflammation surrounds the blood vessels, but they are not damaged (Fig. 66.2A). Lesions that result in pigment changes, scarring, or blistering those that persist for longer than 36 hours require a more extensive evaluation, including a skin biopsy. The history, physical examination, and laboratory evaluation should seek evidence of organ involvement other than skin. With a true vasculitis, there is necrosis of the vessel wall (most prominent in small venules), infiltration with neutrophils, and deposition of immunoglobulins and complement. It is thought that these disorders are caused by the following sequential steps: (a) immune complex deposition in the dermal vasculature; (b) release of histamine (and other mediators) from perivenular mast cells as a result of local formation of the anaphylatoxins C3a, C5a, and C4a (13) (IgE antibody to the initiating antigen may also be contributory); (c) chemotactic attraction of cells, particularly neutrophils, to the vessel wall; (d) neutrophil activation and secretion of oxidants, serine proteases (elastase, cathepsins), and metalloproteinases (collagenases and proteoglycanases) to cause cell injury and digestion of connective tissue; and (e) local thrombus formation, activation of fibrinolysis, and formation of “fibrinoid” material by partial digestion of fibrin–fibronectin complex.

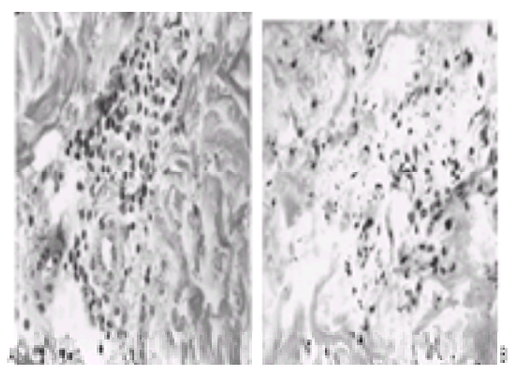

Figure 66.2. Comparison of biopsy specimens from a patient with chronic urticaria and a patient with cutaneous vasculitis. **A:** The vasculitis biopsy has a small venule just to the right of center that is destroyed. There is a predominantly neutrophilic infiltrate with fragmented cells (leucocytoclasis) throughout. **B:** In chronic urticaria, the integrity of the blood vessel wall is maintained, and a nonnecrotizing, predominantly mononuclear cell infiltrate is seen. (See Color Figure 66.2.)

PHYSICAL URTICARIAS

Physically induced hives and swelling share the property of being reproducibly induced by environmental factors such as a change in temperature or by direct stimulation of the skin by pressure, stroking, vibration, or light (14). These serve as investigative models (15) from which we have learned a great deal about the pathogenic mechanisms for hive formation and swelling. A classification of these disorders, which includes virtually all described types, is given in Table 66.1.

Cold-dependent disorders
idiopathic cold urticaria
Cold urticaria associated with abnormal serum proteins: cold agglutinins, cryoglobulin, cryofibrinogen, Donath-Landsteiner antibody
Systemic cold urticaria
Cold-induced cholinergic urticaria
Cold-dependent dermographism
Delayed cold urticaria
Localized cold urticaria
Localized cold reflex urticaria
Exercise-induced disorders
Exercise-induced anaphylaxis (idiopathic or food dependent)
Cholinergic urticaria (cold-dependent variant: cold-induced cholinergic urticaria)
Exercise-induced angioedema
Local heat urticaria
Familial variant
Dermographism
Urticaria pigmentosa–systemic mastocytosis
Cold-dependent variant (cold-dependent dermographism)
Delayed dermographism
Pressure-induced urticaria-angioedema (delayed)
Immediate pressure urticaria
Solar urticaria
Types I–VI
Aquagenic urticaria
Vibratory angioedema
Familial
Sporadic

TABLE 66.1. Classification of Physically Induced Urticaria and Angioedema

Cold-dependent Disorders

Idiopathic cold urticaria is characterized by the rapid onset of pruritus, erythema, and swelling after exposure to a cold stimulus. The location of the swelling is confined to those parts of the body that have been exposed; in this sense, it is a local, rather than a systemic, disorder. Total body exposure, such as that which occurs during swimming, can cause massive release of vasoactive mediators, resulting in hypotension; if the person “passes out,” death by drowning can result. The disease can begin at any age and has no apparent sex predilection. When the disease is suspected, an ice-cube test can be performed to confirm the diagnosis. The ice cube is placed on the patient's forearm for 4 to 5 minutes and then are removed. In a positive reaction, a hive the shape of the ice cube forms within 10 minutes after the cube is removed. The time course of this reaction (i.e., cold challenge followed by hive formation as the area returns to body temperature) demonstrates that a two-step reaction has occurred in which exposure to cold is a prerequisite, but hive formation actually occurs as the temperature increases.

The term *idiopathic* was used to indicate that the cause of cold urticaria is unknown and is unassociated with abnormal circulating plasma proteins such as cryoglobulins. There is evidence, however, that many of these cases are in fact caused by an immunologic reaction. Within this group, most have been shown by passive-transfer studies to be IgE dependent (16). The serum of the patient is injected intradermally into a normal recipient. After 48 hours, the injection site is challenged with an ice cube. Although the incidence of positive transfer has varied among studies, our experience suggests an incidence of about 10%. This figure is undoubtedly an underestimate because the passive transfer is far less sensitive than an ice-cube test in the propositus, and only those with sufficient pathogenic IgE in the circulation (rather than those with IgE bound to mast cells) are detected. In two cases, an IgM antibody was shown to mediate cold urticaria (17). In these cases, passive transfer was positive after a short interval of 3 to 6 hours but was negative at 48 hours, in contrast to an IgE-mediated reaction, which remains positive at 48 hours. We also reported a similar passive transfer (i.e., positive only after short-term sensitization) that seemed to be caused by an IgG antibody (18).

Studies of the pathogenesis of cold urticaria demonstrated release of mediators into the circulation on challenge by placing one hand of the patients in ice water for 5 minutes (Fig. 66.3) and obtaining serial blood samples for 20 minutes thereafter. As with the ice-cube test, swelling is usually not evident while the hand is being chilled; instead, swelling appears between 4 and 8 minutes thereafter and is associated with marked pruritus. In this case, chilling occurs in the deep dermis and subcutaneous tissue in addition to the more superficial skin layers; thus, the entire hand swells, and angioedema results. Studies documented the release of histamine (19), eosinophilotactic peptides (20), high-molecular-weight neutrophil chemotactic factor (NCF) (21), PAF (22), and prostaglandin D_2 (23,24) into the circulation with a time course that parallels the swelling. It is envisioned that chilling initiates a reaction mediated by IgE bound to mast cells and that, on warming, mediators are released into the circulation. When skin biopsy specimens were chilled and then warmed, histamine was released (25) (Fig. 66.4); however, chilling and warming the basophils of patients did not result in histamine release, even in those with documented IgE-mediated disease. Thus, it is unlikely that the disorder is caused by a circulating IgE cryoglobulin (unless the patient's basophils are desensitized). Rather, the presence of cutaneous mast cells seems essential.

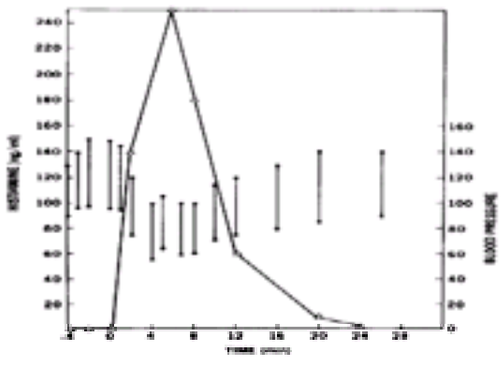

Figure 66.3. Time course of histamine release into the venous circulation of a patient with severe cold urticaria. The patient's hand was placed in ice water for 4 minutes, and arterial blood samples were obtained from the brachial vein draining that arm. Histamine was determined by radioeznyme assay. The vertical lines indicate systolic and diastolic blood pressure throughout the time course; a drop coincides with peak histamine levels.

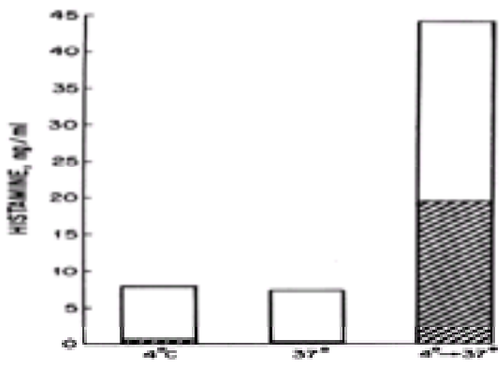

Figure 66.4. Histamine release from biopsy specimens taken from two patients with cold urticaria. Specimens were incubated at either 4°C for 30 minutes

One explanation for such a result is that patients have an IgE autoantibody to a cold-induced skin antigen. Thus, sensitization might occur in the cold, and mediators are released as the cells warm. Studies to test this hypothesis thus far have proved negative. We also found high levels of IgM and IgG antibodies directed against the Fc portion of IgE in patients with cold urticaria (18). Although the clinical significance of such autoantibodies is unclear (26), one such serum caused release of histamine when it was incubated with normal basophils. Because this reaction is demonstrable at 37°C and does not require chilling followed by warming, its relationship to the disease is not clear. Cyproheptadine (Periactin) in divided doses (4–8 mg four times daily) is the drug of choice for the treatment of cold urticaria. Histamine release is unaffected by doses that completely control symptoms (27); therefore, the drug to act as a classic antihistamine (i.e., by blockade of H_1 receptors). Other antihistamines of comparable potency are less effective; the reason is unclear. Although cyproheptadine has antiserotonin activity, serotonin does not appear to be released in cold urticaria. Some patients do not respond well to cyproheptadine, and symptoms do not always correlate well with histamine release (28). Thus, other vasoactive factors may make a significant contribution for some patients. Experimental cromolyn-like drugs, which inhibit mast cell degranulation, are effective in controlling symptoms and suppressing a positive response to the ice-cube test in patients who responded poorly to cyproheptadine (29). Ketotifen, in particular, inhibits histamine release and is effective for a variety of physically induced urticarias (30).

Localized cold urticaria, in which only certain areas of the body urticate with cold contact, has been reported after predisposing conditions such as cold injury as well as at sites of intracutaneous allergen injections, ragweed immunotherapy, and insect bites. We described a patient with cold urticaria confined to the head and face who had no identifiable antecedent or associated event (31). Such cases argue against the presence of a circulating factor and speak in favor of a local abnormality of mast cells.

Cold urticaria also has been described in association with cryoproteins such as cold agglutinins, cryoglobulins, cryofibrinogen, and the Donath–Landsteiner antibody of secondary syphilis (paroxysmal cold hemoglobinuria). The only reported studies that address mechanisms of hive formation are those performed in patients with associated cryoglobulins. The isolated proteins appear to transfer cold sensitivity and activate the complement cascade on incubation *in vitro* with normal plasma (32,33). It is possible that hive formation in these persons is due to cold-dependent anaphylatoxin release. Therapy is directed toward the underlying disease plus the administration of antihistamines. Cryoglobulinemia can be associated with cutaneous vasculitis as well as with cold urticaria, and other associations between these two entities have been reported. Eady and Greaves (34) reported that frequent and repeated cooling of the skin in patients with idiopathic cold urticaria can cause vasculitic lesions. In one patient, immune reactants (IgM and C3) were deposited in the vessels of such lesions (35). In two other patients, leukocytoclastic vasculitis occurred in association with cold urticaria, and circulating immune complexes were evident (36,37). It appeared that the mediator release caused by cold challenge could localize immune complexes to cutaneous sites where they caused vasculitis (36). Sites of typical urticarial vasculitis independent of temperature change were also evident (37).

Other cold-dependent syndromes have been reported, but their incidence is unknown. A delayed form of cold urticaria was described (38) in which swelling appeared 9 to 18 hours after cold exposure. Studies of mediator release were unrevealing, the cold sensitivity could not be passively transferred, and biopsy of a lesion revealed edema and a mononuclear cell infiltrate. Family studies suggested a dominant mode of inheritance. Four patients have been described in whom exercise in a cold

environment induced hives similar to those in cholinergic urticaria; however, hive formation did not occur if exercise was performed in a heated environment. In this disorder, the cold exposure is systemic rather than local, and the disorder should be suspected in any patient whose symptoms suggest either cold urticaria or cholinergic urticaria and in whom standard tests for each disorder are negative (39). Exercise in a cold room or running on a winter day will lead to generalized urticaria and confirm the diagnosis. Because of the visual resemblance of the lesions to those of typical cholinergic urticaria, the disorder has been called *cold-induced cholinergic urticaria*. In a study of 13 patients with symptoms suggestive of cold urticaria and cholinergic urticaria, two patients did not have both disorders but had the cold-induced cholinergic-type hives (40).

In another related disorder, called *systemic cold urticaria*, severe generalized hive formation occurs over covered or uncovered parts of the body after systemic cold challenge. Symptoms are unrelated to exercise or other activities (41), and the ice-cube test is negative. Histamine release on cold challenge (with or without exercise as appropriate) has been seen in cold-induced cholinergic urticaria as well as in systemic cold urticaria. Treatment regimens of hydroxyzine plus cyproheptadine in high doses (42) or of doxepin (43) have been used successfully.

Cold-dependent dermatographism is a disorder in which prominent hive formation occurs if the skin is scratched and then chilled (41). The ice-cube test and systemic cold challenge yield no hives. Scratching the skin yields a weakly positive dermatographic response that is dramatically accentuated when the scratched area is chilled. Treatment is the administration of high-dose antihistamines, for example, 200 mg of diphenhydramine per day or a combination of hydroxyzine (100–200 mg per day) and cyproheptadine (8–16 mg per day).

Finally, a disorder called *localized cold reflex urticaria* has been reported in which the ice-cube test is positive, but hives form in the vicinity of the contact site and not where the cube is applied (44,45). The hives resemble the punctate lesions of cholinergic urticaria, and there is no confluent hive where the ice cube is applied. A methacholine or acetylcholine skin test for cholinergic urticaria is negative, although the symptoms of one such patient resembled cold-induced cholinergic urticaria in that exercise-induced hives appeared in a cold environment (44).

Exercise-induced Disorders

Cholinergic or generalized heat urticaria is characterized by the onset of small punctate wheals surrounded by a prominent erythematous flare associated with exercise, hot showers, sweating, and anxiety (46). Typically, lesions first appear about the neck and upper thorax; when viewed from a distance, hives may not be perceived and the patient appears flushed. Pruritus is a prominent feature of the reaction; on close inspection, it is possible to discern small punctate wheals, sometimes no larger than 1 mm in diameter, which are surrounded by a prominent flare. Gradually, the lesions spread distally to involve the face, back, and extremities, and the wheals increase in size. In some patients, the hives become confluent and resemble angioedema (47). Symptoms of more generalized cholinergic stimulation, such as lacrimation, salivation, and diarrhea, occur occasionally. These stimuli have the common feature of being mediated by cholinergic nerve fibers, which innervate the musculature via parasympathetic neurons and innervate the sweat glands by cholinergic fibers that travel with the sympathetic nerves (48). The characteristic lesion of cholinergic urticaria can be reproduced by intradermal injection of 100 µg of methacholine (Mecholyl) in 0.1 mL of saline. When positive, the resultant localized hive surrounded by satellite lesions is indistinguishable from the patient's spontaneously induced lesions and confirms the diagnosis. We found that only about one third of patients give a clearly positive skin test, and these are generally the most severely affected. Challenge by exercise (e.g., running in a room warmed to 30°C (85°F) or using a bicycle ergometer for 10 to 15 minutes) is a far more sensitive test. Thus, the skin test can be used to confirm the diagnosis but cannot be used as a diagnostic test (19,49). Those patients who have a positive methacholine skin test demonstrate a “hypersensitivity ” to cholinergic mediators, but they have no evidence of an immunoglobulin-mediated allergy to acetylcholine. It is possible that the disorder is due to an intrinsic cellular abnormality that results in abnormal mediator release in the presence of cholinergic agents. One study addressing this issue demonstrated an increased number of muscarinic receptors in urticarial sites. These receptors were further augmented when exercise followed patch testing to copper-containing materials (50). The increased number of acetylcholine binding sites may be an important key to understanding the pathogenesis of cholinergic urticaria. The importance of copper is unclear, but it may affect ligand–receptor affinity.

There is evidence that a reflex consisting of afferent humoral and efferent neurogenic components is involved in this urticarial disorder. If a patient's hand is placed in warm water with a tourniquet tied proximal to that hand, there is no urticaria until the tourniquet is released. A generalized eruption then ensues. Thus, a central perception of a temperature change transmitted via the circulation appears to be followed by an efferent reflex leading to urticaria. Such a reflex could also account for the association of hives with anxiety (51), although the emotional reaction may be completely appropriate. Cholinergic urticaria is the only form of hives in which emotional stimuli can initiate an urticarial reaction in some patients.

Studies of mediator release during attacks of cholinergic urticaria demonstrated that in most cases elevated plasma histamine levels parallel the onset of pruritus and urticaria (19). Subsequent studies confirmed the presence of histaminemia in association with cholinergic urticaria (19,52), and the release of eosinophilotactic peptides and neutrophil chemotactic factor also has been observed (53). When patients were challenged while wearing a plastic occlusive suit to produce maximal changes in cutaneous and core body temperature, significant falls occurred in the 1-second forced-expiratory volumes, maximal midexpiratory flow rate, and specific conductance in association with a rise in residual volume. In four of seven patients, wheezing was detected by auscultation. Thus, under such conditions, an abnormality in pulmonary function can be detected, reflecting either primary pulmonary involvement or altered pulmonary mechanics secondary to circulating mediators. A clinically significant alteration in pulmonary function is unusual in cholinergic urticaria and has no known association with exercise-induced asthma. Kaplan et al. (54) also described two patients with typical cholinergic urticaria in whom lesions became confluent and were associated with prominent elevations of plasma histamine as well as with recurrent episodes of hypotension. Thus, some extreme cases of cholinergic urticaria can resemble the exercise-induced anaphylactic syndrome. An important distinguishing feature is that an increase in core body temperature of greater than 0.7°C with the use of hyperthermic blankets or submersion in warmed water causes hives, histamine release, and anaphylactic symptoms in patients with cholinergic urticaria and anaphylaxis-like symptoms but not in patients with the exercise-induced anaphylactic syndrome (55). Combinations of “physical urticarias” can occur in the same patient, for example, cold urticaria (52) or dermatographism (53) in association with cholinergic urticaria. Furthermore, combined cold and cholinergic urticaria, fulfilling separate criteria for each disorder (40,52), is distinguished from cold-induced cholinergic urticaria (39).

Generally, cholinergic urticaria is treated with hydroxyzine (100–200 mg daily) in divided doses (51). Many, but not all, patients respond to this regimen. Anticholinergic agents such as atropine or propantheline bromide (Pro-Banthine) have little effect, perhaps due to an inability to attain a sufficient systemic level; however, injected atropine can reverse the methacholine skin test (52).

Exercise-induced anaphylaxis was first described in a series of patients who experienced various combinations of pruritus, urticaria, angioedema, wheezing, and hypotension exercise. Symptoms did not occur with each exercise experience, and most of the patients were accomplished athletes (56). The disorder is distinguished from cholinergic urticaria by the following criteria. First, although exercise is the precipitating stimulus of each disorder, hot showers, sweating in the absence of exercise, and anxiety do not trigger attacks of exercise-induced anaphylaxis as they do with cholinergic urticaria (46). Second, the hives in exercise-induced anaphylaxis are large (10–15 mm), in contrast to the punctate lesions characteristic of cholinergic urticaria. Finally, when patients with exercise-induced anaphylaxis were challenged in an occlusive suit, pulmonary function was unchanged, although histamine release was documented (57). Optimal therapy for the exercise-induced anaphylactic syndrome is uncertain, and attempts at prophylaxis with H_1 and H_2 antagonists have not generally been effective (58). In contrast, classic cholinergic urticaria usually responds to prophylactic use of hydroxyzine.

Subtypes of food-related exercise-induced anaphylaxis also have been described. One patient experienced exercise-induced anaphylaxis if the exercise took place 5 to 24 hours after eating shellfish, whereas exercise alone or eating shellfish alone did not produce symptoms (59). In five other patients, two had symptoms if exercise followed the ingestion of any food within 2 hours (59,60); and three had symptoms if exercise followed the specific ingestion of celery within 2 hours (61). The latter patients also had positive skin tests to celery. Treatment of the various forms of food-dependent, exercise-induced anaphylaxis requires avoiding specific foodstuffs before exercising or avoiding exercise within certain time intervals after eating. Kivity et al. (62) performed skin tests to compound 48/80 (a cutaneous mast cell degranulating agent) and to histamine and demonstrated augmented wheal responses to 48/80, but not to histamine, in persons with food-induced (skin-test-positive), exercise-induced anaphylaxis. Food or exercise alone did not affect the response to 48/80, suggesting increased mast cell releasability was caused by the combination of food plus exercise.

Other Physically Induced Forms of Urticaria or Angioedema

The other forms of physically induced hives or swelling are, with the exception of dermographism, relatively rare disorders. They include local heat urticaria, pressure-induced urticaria/angioedema, solar urticaria, aquagenic urticaria, and hereditary vibratory angioedema.

Local Heat Urticaria

A local form of heat urticaria is a rare disorder in which urticaria develops within minutes after exposure to applied heat (63). Sixteen patients with local heat urticaria have been reported, most of whom are female. When suspected, the disorder can be tested for by the application of a test tube of warm water at 44°C to the arm for 4 to 5 minutes. A hive that appears a few minutes after the test tube is removed indicates a positive diagnosis. Mediator release in patients with local heat urticaria resembles that reported for cold urticaria; plasma histamine levels peak 5 to 10 minutes after heat exposure (64,65), although passive transfer studies have been negative. The release of neutrophil chemotactic factor was also identified in one study (64); thus, mast cell degranulation in response to heat challenge seems likely.

Complement abnormalities have been reported in the absence of histamine release (66). Association with other forms of physical allergy sometimes occurs, for example, combined cold urticaria and local heat urticaria (67). Therapy has been problematic, because antihistamines such as hydroxyzine or cyproheptadine as well as oral disodium cromoglycate have been ineffective. One patient was desensitized successfully by repeated daily immersion in hot baths, but caution is advised because systemic reactions are possible (66).

A familial variant of this disorder has been described in which urticaria occurred 1.5 to 2 hours after application of a warm stimulus (68) and persisted for 6 to 10 hours. Sunbathing with pronounced heating of the skin could produce wheals as a result of the temperature effect, whereas sunlight itself could be tolerated. An area could be desensitized with repeated challenge every few days. Skin biopsy specimens showed a pronounced inflammatory cell infiltrate in the upper dermis and around hair follicles. The pathogenesis of this form of local heat urticaria is unknown. Partial control can be achieved with oral antihistamines.

Dermographism

The ability to write on skin with a sharp object, termed *dermographism*, can occur as an isolated disorder that often presents as traumatically induced urticaria. It can be diagnosed by observing the skin after stroking it with a tongue depressor or fingernail. In patients who have this disorder, a white line secondary to reflex vasoconstriction appears, followed by pruritus, erythema, and a linear wheal, as seen in a classic wheal-and-flare reaction. Dermographism is said to be present in 2% to 5% of the population (15,69); however, only a small fraction of these individuals have cases of sufficient severity to warrant treatment. Biopsy of the skin reveals few changes, but most occur in the epidermis and consist of (a) vacuolation of keratinocytes and basal epidermal cell pseudopodia and (b) the appearance of typical mast cell granules (70). In about 50% of cases, passive transfer studies demonstrated an IgE-dependent mechanism (71,72). Thus, many patients have an abnormal circulating IgE that confers a particular form of pressure sensitivity to dermal mast cells. Such observations further suggest that histamine is one of the mediators of dermographism, although the demonstration of such release has been difficult because of the localized nature of the reaction. Early studies suggested the following: that (a) histamine is released into whole blood (73); (b) induced blisters over lesions contain elevated histamine levels (74); (c) 24-hour urine histamine levels are elevated (75); and (d) histamine is increased in the perfusate, as shown by *in vivo* subcutaneous perfusion studies (76). In a single patient with an unusually severe case of IgE-mediated dermographism, plasma histamine levels became elevated within 1 minute of stroking the skin, and the baseline histamine level was abnormal in multiple determinations, suggesting that “leakage” of histamine is continuous (77).

Although a formal study has not been performed, dermographism has been described anecdotally as a consequence of drug reactions (69); in one case, dermatographism could be observed only on challenge with the offending agent—in this instance, penicillin (78). Dermographism is treated with antihistamines (79,80); high doses may be needed for severe symptoms. The initial objective of therapy is to decrease pruritus so that scratching is diminished. Many patients complain of a sensation of itching or “skin crawling” that is readily relieved by antihistamines. At higher doses, the wheal-and-flare reaction to stroking is also markedly diminished.

Dermographism occurs in association with other disorders; for example, a mild form may be seen in some patients with chronic urticaria. Severe dermographism is associated with disorders in which the number of dermal mast cells is markedly increased (e.g., urticaria pigmentosa or systemic mastocytosis). Histamine is released in these disorders (75). It is also possible that other vasoactive agents released from cutaneous mast cells can be implicated in dermatographism and, in fact, in all forms of physically induced urticaria. An example is the increased level of prostaglandin D^2 (PGD^2) metabolites in the urine of patients with systemic mastocytosis, which may contribute to the hypotension associated with this disorder (81).

Pressure-induced Urticaria and Angioedema

Pressure-induced urticaria differs from most of the previously described types of hives or angioedema because symptoms typically occur 4 to 6 hours after pressure has been applied (82). The disorder is clinically heterogeneous. Some patients may complain of swelling secondary to pressure with normal-appearing skin (i.e., no erythema or superficial infiltrating hive); so the term *angioedema* is more appropriate; in others, the manifestation is predominantly urticarial and may or may not be associated with significant swelling. When urticaria is present, an infiltrative lesion characterized by a perivascular mononuclear cell infiltrate and dermal edema similar to those of chronic idiopathic urticaria is seen (83). Immediate dermographism is not present, but delayed dermographism is present and may represent the same disorder (42). Symptoms occur around tight clothing; the hands may swell with activity such as hammering; foot swelling is common after walking; and buttock swelling may be prominent after sitting for a few hours. A diagnostic test can be performed by placing a sling with a 5- to 15-pound weight attached over the forearm or shoulder for 10 to 20 minutes. Devices that apply gradual pressure in grams per square millimeter also can be used (83). Few studies are available regarding pathogenesis; mediators that cause pain rather than pruritus (e.g., kinins) have been considered because the lesions typically are described as burning or painful. Nevertheless, blisters induced over the lesions revealed histamine release following the time course of hive formation (74). Antihistamines, however, have little effect on the disorder, and patients with severe disease often have to be treated with glucocorticoids.

Although pressure urticaria and angioedema can occur as an isolated disorder, it occurs most often in association with chronic urticaria. Therapy usually is directed toward the chronic urticaria. Data suggest an increased incidence of food allergy in patients with chronic urticaria in whom pressure-induced symptoms are also prominent (84).

Immediate-pressure urticaria has been described in patients with the hypereosinophilia syndrome characterized by an acute wheal-and-flare reaction within 1 to 2 minutes of applied pressure (e.g., pressing on the back with one's thumb). Those patients also had dermographism, although those with dermatographism typically do not have immediate-pressure urticaria and require a stroking motion to produce a hive (85).

Solar Urticaria

Solar urticaria is a rare disorder in which brief exposure to light causes the development of urticaria within 1 to 3 minutes. Typically, pruritus occurs first, within about 30 seconds, followed by edema confined to the light-exposed area and surrounded by a prominent erythematous zone caused by an axon reflex. The lesions usually disappear within 1 to 3 hours. When large areas of the body are exposed, systemic symptoms may occur, including hypotension and asthma. Although most reported patients have been in their third and fourth decades of life, the disorder can occur in any age group and has no association with other allergic disorders.

Solar urticaria has been classified into six types, depending on the wavelength of light that induces lesions and the ability or inability to transfer the disorder passively with serum (86,87 and 88). Types I and IV can be passively transferred and may therefore be immunologically (IgE) mediated; they are associated with wavelengths of 280 to 320 nm and 400 to 500 nm, respectively. An antigen has not been identified. Histamine release, mast cell degranulation (89), and formation of chemotactic factors for eosinophils and neutrophil (90) occurred coincident with the induction of lesions when ultraviolet light (type I) was applied to skin. Type VI, indicated by a wavelength of 400 nm, is clearly an inherited metabolic disorder in which protoporphyrin IX acts as a photosensitizer; it is synonymous with erythropoietic protoporphyria. Type VI is caused by ferrochetalase deficiency (91,92). In contrast to other forms of porphyria, the urinary porphyrin excretion is normal; however, red-blood-cell protoporphyrin, fecal protoporphyrin, and coproporphyrin levels are elevated. The irradiation of serum samples from affected persons resulted in activation of the classical complement pathway and generation of C5a chemotactic activity (93); this activity was proportional to the serum level of protoporphyrin (94). Irradiation of the forearms of two such patients also resulted in *in vivo* complement activation as assessed by a diminution of titers of C3 and C5 and generation of C5a (95). Consistent with these observations is the deposition of C3 and the accumulation of neutrophils in the dermis (96,97) and the detection of complement fragments in the serum and suction blister fluid of irradiated skin (96). Type VI responds to oral b-carotene, which absorbs light at the same wavelengths as protoporphyrin IX (98). The mechanism by which urticaria is produced in types II, III, and V is unknown, but these types are induced by inciting wavelengths of 320 to 400, 400 to 500, and 280 to 500 nm, respectively. As a simple screen, fluorescent tubes that emit a broad, continuous spectrum can be used to test the patient, and filters then can be used to define the spectrum that causes urticaria. Therapy of this disease requires avoidance of sunlight, protective garments to cover the skin, and the use of topical preparations to absorb or reflect light. A 5% solution of paraaminobenzoic acid in ethanol, as in sunscreen lotions, can be helpful in the wavelength range of 280 to 320nm; however, it is more difficult to screen out the visible spectrum. The most effective agents for this purpose contain titanium oxide or zinc oxide. The efficacy of antihistamines, antimalarials, and glucocorticoids in these disorders is not clear and needs to be evaluated in each case.

Aquagenic Urticaria

Thirteen patients have been described who developed small wheals after contact with water, regardless of its temperature, and who could be distinguished from patients with cold urticaria or cholinergic urticaria. This disorder has been termed *aquagenic urticaria* (99), and its presence can be tested for by direct application of a compress of tap water or distilled water to the skin. The diagnosis should be reserved for those rare patients who test positively for water but test negatively for all other forms of physical urticaria. Combined cholinergic and aquagenic urticaria has been reported, and histamine release into the circulation has been documented on challenge with water (100).

Hereditary Vibratory Angioedema

Hereditary vibratory angioedema has been described in a single family in whom it was inherited in an autosomal dominant pattern. It is properly viewed as a physically induced angioedema because patients complain of intense pruritus and swelling within minutes after vibratory stimuli (101). The patients do not have dermographism or pressure-induced urticaria. Lesions can be reproduced by gently stimulating the patient's forearm with a laboratory vortex for 4 minutes. Rapid swelling of the entire forearm and a portion of the upper arm ensues, and histamine is released (102). With care, patients can avoid vibratory stimuli, and their symptoms can otherwise be

partially relieved with diphenhydramine (Benadryl). Nonfamilial, sporadic cases also have been described.

CHRONIC IDIOPATHIC URTICARIA AND IDIOPATHIC ANGIOEDEMA

This common disorder of unknown origin occurs in persons who do not have an increased incidence of atopic dermatitis, allergic rhinitis, or asthma compared with the incidence of these disorders in persons without chronic urticaria. Their IgE level, as a group, is within normal limits. Some patients have dermographism, although it is usually of milder degree than occurs with the IgE-dependent dermographism described earlier. The dermographism may wax and wane, just as the urticaria may vary from severe to mild or may intermittently subside. These patients have a normal white blood cell count and erythrocyte sedimentation rate (ESR) and have no evidence of systemic disease. Thus, they do not have evidence of any of the causes of urticaria or angioedema discussed earlier (i.e., foods, drugs, additives, infection, systemic disease, association with other allergic phenomena, or triggering by physical agents). Chronic urticaria does not appear to be an allergic reaction in the classic sense, because IgE antibody is not involved and no external allergen is needed to initiate or perpetuate the process. It differs from allergen-induced skin reactions or from physically induced urticaria (e.g., dermatographism or cold urticaria) in that histologic studies reveal a cellular infiltrate predominantly about small venules (1). External examination reveals infiltrative hives with palpably elevated borders, sometimes varying greatly in size and shape but generally rounded.

The typical lesion of chronic urticaria consists of a nonnecrotizing perivascular mononuclear cell infiltrate (Fig. 66.2A); however, many types of histopathologic processes can occur in the skin and manifest as hives. For example, patients with hypocomplementemia and cutaneous vasculitis can have urticaria (or angioedema); and biopsy specimens from patients with urticaria, arthralgias, myalgias, and an elevated ESR as manifestations of necrotizing venulitis reveal fibrinoid necrosis with a predominant neutrophilic infiltrate (103,104). The incidence of vasculitis in patients with urticaria varies widely (105,106,107 and 108). Mathison et al. (105) found that 10 of 78 patients had hypocomplementemia, and many showed evidence of activation of the classical complement pathway. Six of the ten had elevated levels of circulating immune complexes. If hypocomplementemia and vasculitis are equated, the incidence of presumed vasculitis was 14%. Monroe et al. (106) found neutrophilic leukocytoclastic angiitis in 20% of patients; the other 80% had a perivascular infiltrate of mononuclear cells that was classified as “dense” or “sparse.” The “vasculitis,” “dense,” and “sparse” groups had circulating immune complex levels of 33%, 29%, and 13%, respectively, as measured by multiple assays. Phanuphak et al. (108) used the criterion of significant cellular infiltrate within vessel walls to define vasculitis (rather than that of endothelial damage, nuclear dust, fibrin deposition, or red blood cell extravasation).They found a 52% incidence of vasculitis (various types of predominant cells) and a 48% incidence of a perivascular mononuclear-cell infiltrate. Deposits of immune complexes were found in the skin of 18% of the persons with vasculitis, almost exclusively in those with an abundance of neutrophils.

Our group studied the histopathology of chronic idiopathic urticaria in 43 consecutive patients (107). All but one patient had a nonnecrotizing perivascular infiltrate consisting primarily of lymphocytes. We found necrotizing vasculitis to be a rare cause of urticaria and believe that our group of patients is comparable to the group without vasculitis in the study of Mathison et al. (105), to the “sparse” or “dense” infiltrate groups of Monroe et al. (106), and to the “perivasculitis” group of Phanuphak et al. (108).

We noted a tenfold increase in the number of mast cells and a fourfold increase in the number of mononuclear cells in skin biopsy specimens from the patients with chronic urticaria compared with specimens from unaffected control subjects. The number of basophils was not increased; however, circulating basophils of patients with chronic urticaria are reported to be less responsive to anti-IgE than are circulating basophils of unaffected individuals, suggesting *in vivo* desensitization (109). Although eosinophils were not prominent in the skin biopsies of our series of patients when considered as a group, an occasional patient had a prominent eosinophil accumulation.

In another study, deposits of eosinophil major basic protein were identified in skin specimens of 50% of patients with chronic urticaria, although only a fraction of the specimens had obvious eosinophil infiltration (110). Thus, degranulated eosinophils may be present, perhaps more commonly than previously recognized. The increase in the number of mast cells may account for (a) the increased amount of histamine found in suction blister fluid obtained from patients with chronic urticaria compared with the amount from unaffected control subjects (74) and (b) the increased level of total skin histamine in such patients (111). Immunoperoxidase staining of cell-surface antigens with monoclonal antibodies specific for monocytes, T cells, B cells, and natural killer (NK) cells and histochemical staining of mast cells revealed the infiltrate in chronic urticaria to consist of 50% T-lymphocytes, 20% monocytes, 11% mast cells, and 19% unidentified cells (112). Perhaps a lymphokine or monokine is released that causes mast cell proliferation (or accumulation) and degranulation. A factor [called histamine-releasing factor (HRF)] that can cause basophil degranulation is released from lymphocytes (113,114), including T cells, B cells, monocytes (115), and alveolar macrophages (116) as well as from neutrophils (117) and platelets (118).

We concluded that most chronic urticaria is characterized by a nonnecrotizing perivascular mononuclear cell infiltrate with an accumulation of mast cells. Patients with vasculitis and urticaria are a separate subpopulation in whom the cause and pathogenesis of hive formation probably involves immune complexes, complement activation, anaphylatoxin formation, histamine release, and neutrophil accumulation, activation, and degranulation.

Association with Autoimmune Thyroid Disease

The first studies of autoimmunity in patients with chronic urticaria were by Leznoff et al. (119,120), who reported that patients with chronic urticaria have an increased frequency of Hashimoto thyroiditis. The association was with the presence of antibodies to thyroglobulin or a microsomal-derived antigen (peroxidase), even if the patients were euthyroid. In these initial reports, the incidence of thyroid autoantibodies in patients with chronic urticaria was about 12%. We now routinely check thyroid function and thyroid antibodies in patients with chronic urticaria. The incidence of abnormal thyroid function, either increased or decreased thyroxine (T_4) or increased or decreased thyroid-stimulating hormone (TSH) or both, is 19%. The incidence of finding an elevated level of antithyroglobulin antibody is 8%, an antimicrosomal antibody is 5%, and the coincidence of elevated titers of both antibodies is 14%, for a total incidence of 27%. There are no data to suggest that either of these antibodies is pathogenic in terms of hive formation, and we believe these are associated, parallel, autoimmune events. A report (121) suggested that there is a positive effect on the severity of the urticaria if the dose of thyroid hormone is raised somewhat (i.e., to high normal levels but not overtly hyperthyroid). We do not recommend thyroid supplementation beyond that required to achieve the euthyroid state. A significantly elevated T_4 or depressed TSH need not be indicative of the presence of Graves disease or hyperfunctioning nodules but rather may reflect the early stage of Hashimoto thyroiditis with liberation of thyroxine before thyroglobulin stores are depleted. Eventually, all such patients are at risk of becoming hypothyroid, with low T_4 and elevated TSH levels.

Antibodies to IgE or IgE Receptor

Gruber et al. (122) first reported an increased incidence of IgG antibodies to IgE in patients with chronic urticaria. The incidence was 10%, and about half of these were shown to be functional by basophil degranulation. We were able to stimulate basophil degranulation and histamine release by cross-linking cell-surface IgE with a patient's serum. Although an occasional patient with cold urticaria had demonstrable IgM or IgG anti-IgE antibody, those with other forms of urticaria did not. Such antibodies were not specific for chronic urticaria, however, and were detected in patients with atopic dermatitis. The next important observation was made by Grattan et al. (123), who found that a substantial number of patients with chronic urticaria have a positive autologous skin test (123); that is, if serum of the patient is used as a skin-testing reagent in that patient, a significant wheal and flare reaction occurs. Most members of subpopulation of positive patients studied in much greater detail were found to have an IgG antibody directed to the a subunit of the IgE receptor (124,125) (Fig. 66.5). By using rat basophil leukemia cells transfected with the human a subunit, the release of histamine or the enzyme b-hexosaminidase could be demonstrated (124,126). Thus, it appeared that the antibody could cross-link the IgE receptor (a subunit) and degranulate the cells. The incidence of such antibodies is about 35%, and an additional 5% to 10% of patients have anti-IgE antibodies rather than anti-IgE receptor antibody. Activation of basophils *in vivo* may relate to the basopenia reported in patients with chronic urticaria (127,128,129 and 130).

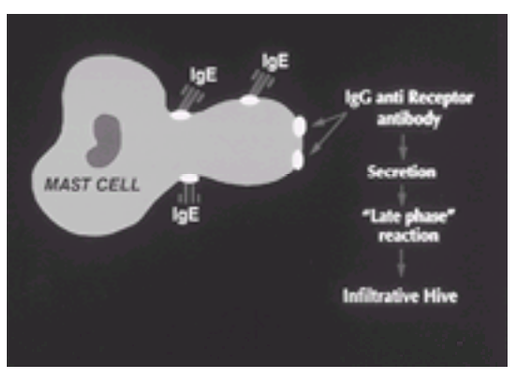

Figure 66.5. Diagrammatic representation of cutaneous mast cell activation by immunoglobulin G (IgG) antibody to the IgE receptor. (See Color Figure 66.5.)

Immunoblot Analysis

Fiebiger et al. (131) and Tong et al. (126) first used immunoblot analysis to demonstrate anti-IgE receptor antibodies, which were shown to bind to the 34-kd cloned a subunit. A Western blot depicting the presence of antibody in a serum at 1:500 and 1:1,000 dilutions is shown in Fig. 66.6. We found that normal sera tested at a 1:50 dilution or less are often positive; thus, it is common to have a low titer of this antibody present. Nevertheless, at a 1:500 dilution, normal sera are positive only rarely, whereas the sera of patients with chronic urticaria have an incidence of 45% positive (132). A second concern is the observation that positives can be obtained in patients with connective tissue disorders, particularly dermatomyositis, bullous pemphigus, systemic lupus erythematosus, and bullous pemphigoid (133); however, none of these sera released histamine from human basophils. This fact was attributed, in part, to a skewing of the antibody population to the IgG_1 and IgG_3 subclasses in chronic urticaria and to the IgG_2 and IgG_4 subclasses in the other disorders. These data also suggested that activation of basophils might require complement (133), C5a in particular, and that cross-linking of the IgE receptor may not explain cell activation.

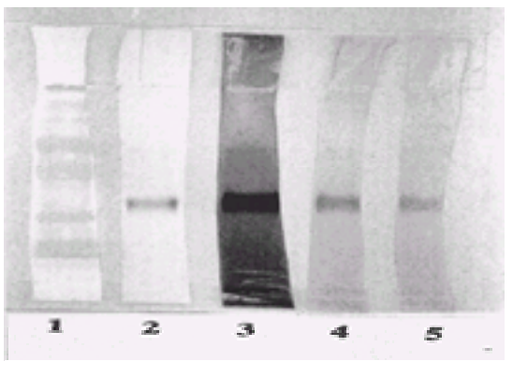

Figure 66.6. Immunoblot analysis to ascertain the presence of immunoglobulin G (IgG) antibody to the a subunit of the IgE receptor Fc_eRIa. Soluble recombinant Fc_eRIa was subjected to sodium dodecyl sulfate–polyacrylamide gel electrophoresis and blotted onto nitrocellulose. Membranes were inoculated with monoclonal antibody or whole sera from patients with chronic urticaria or unaffected control subjects. Antibody binding was detected with alkaline phosphatase-conjugated goat antimouse IgG antibody or goat antihuman IgG fragment-specific antibody, respectively. Lane 1, molecular marker; lane 2, mouse monoclonal antibody (positive control); lanes 3–5, serum at dilutions of 1:50 (lane 3), 1:500 (lane 4), and 1:1,000 (lane 5).

Another important variable in these assays is the donor basophils used for functional analysis. Basophils saturated with IgE (using an IgE myeloma protein) are best for the demonstration of activation by anti-IgE, whereas basophils stripped of IgE by treatment with lactate buffer are used to assay antireceptor antibodies. With unaltered basophils, the level of responsiveness to antireceptor antibodies may depend on the percentage of receptors occupied by IgE. Zweiman et al. (134) showed that the addition of exogenous IgE inhibits the detection of antireceptor antibodies, and we have abolished the responsiveness of blood basophils and cutaneous mast cells by saturating IgE receptors with an IgE myeloma protein (unpublished observations).

Activation of Mast Cells: A Role for Complement

Nimi et al. (135) were first to demonstrate that antibodies to the IgE receptor activate cutaneous mast cells. This finding is important because the mast cell is a critical effector cell in chronic urticaria, whereas the role of the infiltrating blood basophil, if any, is unclear. We observed that the portion of cutaneous mast cells activated by sera from patients with chronic urticaria approaches 50% and correlates strongly with the activation of basophils and the results of immunoblot analysis, although there are occasional sera for which the functional assay is positive and the immunoblot is negative or vice versa. When we compared whole sera with IgG isolated from those sera, the purified IgG was incapable of activating cutaneous mast cells. When IgG isolated from patient sera was added to pooled normal sera, however, the normal serum was capable of activating mast cells; the addition of the IgG to either C2-deficient plasma or C5-deficient plasma was ineffective (Fig. 66.7). These data indicate a role for the classical complement pathway in cutaneous mast cell activation, and C5a is the likely effector. Attempts to inhibit mast cell activation with commercially available peptides that compete with C5a for binding to the C5a receptor were equivocal, in part because the competitors had agonist activity. On a molar basis, C5a is superior to C3a as an activator of cutaneous mast cells, and C3a is rapidly degraded to an inactive peptide (C3a des-arg) by a plasma carboxypeptidase; the analogous peptide, C5a des-arg, retains activity that is augmented by vitamin D–binding protein (C5a cochemotaxin) (136,137). Although C5a is a potent chemotactic factor, cellular infiltration secondary to injected peptide is largely mast cell dependent (138).

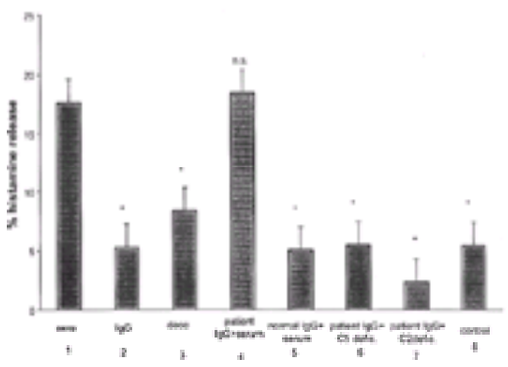

Figure 66.7. Complement dependence of histamine release; 75-µL samples of a cell suspension containing 2×10^5 mast cells were incubated for 20 minutes at 37°C with one of the following: 75 µL of patient serum (1), 1 to 10 mg/mL of protein G-eluted IgG (2), 75 µL of decomplemented patient serum (for 1 hour at 56°C) (3), 15 µL of purified patient IgG plus 60 µL of pooled normal serum (4), 15 µL of purified patient IgG plus 60 µL of pooled normal serum (5), 15 µL of purified patient IgG plus 60 µL of C5-deficient serum (6) or C2-deficient serum (7), or 75 µL of buffer (8). Results are expressed as a percentage of histamine release from two cell suspension replicates. Cells were boiled to determine total histamine content. Significant differences ($p < 0.05$, as determined by the Student *t*test) for paired samples, each of which was compared with the histamine release for patient sera (far left bar), are indicated by asterisks. Each bar represents an average of histamine release by using five different patient sera, each of which was assayed five times with duplicates ($n = 50$)

The cellular infiltration with T cells and monocytes described above appears to be critical because chronic urticaria responds rapidly to glucocorticoids and steroids have little effect on the degranulation of cutaneous mast cells. Thus, like late-phase allergic reactions, the perpetuation of the inflammatory response by cellular infiltration is critical to disease manifestations, and degranulation of mast cells alone, regardless of the mechanism, is insufficient to explain the clinical course. Thus, antihistamines, although of value in the treatment of chronic urticaria, are often not fully effective. About 40% to 50% of patients with chronic urticaria often have associated angioedema, commonly facial. Thus, when maximal $H_{1/>}$ or H_2 receptor blockade has been achieved, we advocate alternate day steroids as the most effective treatment (139). In general we administer 20 mg of prednisone in a single morning dose on alternate days and decrease it by 2.5 to 5.0 mg every 3 weeks, depending on the patient's response. The goal is a slow, gradual decline in dosage toward zero. Antileuleotriene agents may also be helpful. Experimental approaches that have a rationale, given the pathogenic mechanism described here, include intravenous gamma globulin, plasmapheresis, and immunosuppression with cyclosporine. Some preliminary reports using these approaches have appeared (140,141 and 142), but I believe these approaches should be used in research protocols or reserved for the small percentage of patients who do not respond to glucocorticoids or who require prohibitive dosages to achieve control. In general, NSAIDS, hydroxychloroquine sulfate (Plaquenil), sulfasalazine, colchicine, and dapsone have been ineffective. One exception is the hypocomplementemic urticarial vasculitis syndrome (143) associated with autoantibodies to C1q (144), which responds to Plaquenil (145).

67 Atopic Dermatitis

Donald Y.M. Leung, M.D., Ph.D., and Mark Boguniewicz, M.D.

Atopic dermatitis (AD) is a chronically relapsing inflammatory skin disease commonly associated with respiratory allergy (1,2). It is the most common chronic skin disease of young children, affecting 5% to 20% of children in most countries (3). Similar to the trends seen with asthma, the prevalence of AD has increased, especially in Western countries. Poorly controlled AD is often associated with sleep deprivation, school absenteeism, occupational disability, and emotional stress and has a significant impact on the quality of life of patients and their families. AD also may be associated with significant morbidity, especially when complicated by erythroderma or concomitant infection.

The term *atopic dermatitis* was first introduced in the 1930s to describe both the weeping eczema of infancy and childhood and the chronic xerosis and lichenified lesions more typical of older patients (4). This term also recognized the close relationship between AD, asthma, and allergic rhinitis. Acute AD, like asthma and allergic rhinitis, is associated with the local infiltration of T cells with a T helper 2 (Th2) cytokine profile (5). In addition, the eosinophil is a common effector cell in chronic AD and the allergic respiratory diseases. Furthermore, patients with AD can have nonspecific, as well as specific triggers, similar to patients with asthma and allergic rhinitis. A recent review suggested that the immune mechanisms underlying AD and asthma have more similarities than differences (6). In more than 50% of patients with AD, asthma and allergic rhinitis develop (7), and thus AD is an important early marker of the atopic diathesis.

EPIDEMIOLOGY

Genetics

Although genetic susceptibility to respiratory allergy has been suggested by localization of a locus for atopy on chromosome 11q13 (8), linkage to this gene had previously not been demonstrated in patients with AD (9). More recently, however, linkage of both AD and asthma to polymorphisms within the gene for the b subunit of the high-affinity immunoglobulin E (IgE) receptor on chromosome 11q12-13 has been reported but must be substantiated (10). By contrast, there has been particular interest in the role of chromosome 5q31-33 in AD, as it contains a clustered family of cytokine genes [interleukin (IL)-3, IL-4, IL-5, IL-13, and granulocyte/macrophage colony-stimulating factor (GM-CSF)] expressed by Th2 cells (11). Chan et al. (12) found that abnormal IL-4 gene expression in AD may be linked to alterations in nuclear protein interactions with IL-4 promoter elements. A study examining linkage between markers at and near the IL-4 gene and AD in 88 Japanese nuclear families found a genotypic association between the T allele of the –590 C/T polymorphism of the IL-4 gene and AD (13). Because the T allele was reported to be associated with increased IL-4 gene promoter activity compared with the C allele, the data suggest that genetic differences in transcriptional activity of the IL-4 gene may influence predisposition for AD, particularly in this population, because of the high frequency of the T allele. In addition, an association of atopy with a gain-of-function mutation in the a subunit of the IL-4 receptor has been reported in a small group of patients with AD (14). The authors speculated that the R576 allele may predispose persons to allergic diseases by altering the signaling function of the receptor. Finally, Mao et al. (15) demonstrated a significant association between a specific polymorphism in the mast cell chymase gene and AD, but no association with asthma or allergic rhinitis. This finding may reflect the population studied and requires confirmation; but it suggests that a genetic variant of mast cell chymase, which is a serine protease secreted by skin mast cells, may have an organ-specific effect and contribute to the genetic risk for AD.

Although the mode of transmission remains uncertain, limited studies support an autosomal dominant inheritance pattern. Uehara and Kimura (16) found that 60% of adults with AD had children with AD. The prevalence of AD in children was 81% when both parents had AD, 59% when one parent had AD and the other had respiratory allergy, and 56% when one parent had AD and the other had neither AD nor respiratory allergy. Diepgen and Fartasch (17) showed that 42% of first-degree relatives of patients with AD also had AD, whereas 28% had respiratory allergy. In contrast, only 12% of first-degree relatives of persons with respiratory allergy without skin disease had AD, whereas 43% had respiratory allergy. In a follow-up study of the familial aggregation of AD, allergic rhinitis, and allergic asthma in the relatives of 426 patients with AD and 628 persons with no history of AD, the odds ratio of familial aggregation for AD was 2.16 if no distinction was made between the degree of relationship, 3.86 among siblings, and 1.90 between parents and siblings (18). For AD, the odds ratio differed between mother/sibling pairs (2.66) and father/sibling pairs (1.29), suggesting environmental events affecting the fetus *in utero* or shared environmental exposures. The fact that all of the atopic diseases demonstrated a stronger correlation between siblings than between siblings and parents supports the hypothesis that exposure to environmental factors during childhood is responsible for the recently observed increased prevalence of atopic diseases.

Environmental Factors

Studies indicate an increasing prevalence of AD. Schultz Larsen (19) demonstrated a cumulative incidence rate up to 7 years of 12% for twins born between 1975 and 1979 compared with a rate of 3% for twins born between 1960 and 1964. A cross-sectional questionnaire study conducted in 1992 confirmed this increased prevalence (20). In this study of 3,000 7-year-olds from Denmark, Germany, and Sweden, the frequency of AD was 15.6%. Similarly, questionnaire studies of Swedish schoolchildren showed an increase in prevalence of AD from 7% in 1979 to 18% in 1991 (21), and the point prevalence of AD in schoolchildren living in northern Norway has been reported to be 23% (22).

In a study in Japan, the authors performed skin examinations rather than relying on questionnaires to ascertain the prevalence of childhood and adolescent AD (23). More than 7,000 patients were examined, with AD observed in 24% of the 5- to 6-year-old group, 19% of the 7- to 9-year-old group, 15% of the 10- to 12-year-old group, 14% of the 13- to 15-year-old group, and 11% of the 16- to 18-year-old group. The prevalence of AD in 9- to 12-year-old children was two times, and in 18-year-old adolescents, five times as high as that in similar age groups examined 20 years ago.

Increased exposure to pollutants and indoor allergens, especially house-dust mites, and a decline in breast-feeding, along with increased awareness of AD, have been suggested as reasons for the increased frequency of AD (24). In a prospective study, Zieger et al. (25) found that restricting the mother's diet during the third trimester of pregnancy and lactation as well as the child's diet during the first 2 years of life resulted in decreased prevalence in AD of the prophylactic group as compared with a control group that followed standard feeding practices at age 12 months, but not at 24 months. Follow-up through age 7 years showed no difference between the prophylactic and control groups for AD or respiratory allergy (26). A large study of an ethnically and socially diverse group of children in suburban Birmingham, England, also found that breast-feeding did not affect the lifetime prevalence of 20% (27). A study of prevalence of childhood eczema found a correlation with increased socioeconomic class that was not due to heightened parental awareness (28). Finally, the effects of genetic and environmental factors on allergic diseases were studied in two Japanese cities with differing climates (29). The prevalence of AD in the city with a temperate climate was significantly higher than in the one with a subtropical climate, even after controlling for genetic and environmental factors. In both cities, children from atopic families had a significantly higher risk of contracting respiratory allergies and AD.

Atopic Diathesis

AD, like asthma and allergic rhinitis, is classified as an atopic disease occurring in individuals with a genetic predisposition to develop an IgE response to common environmental allergens. Abnormal IgE responses are associated with cellular abnormalities, resulting in overproduction of Th2 cytokines, which also contribute to the eosinophilia in these diseases. Genetic linkage of the atopic diseases has been suggested, as discussed earlier.

Early onset of AD is associated with an increased risk for respiratory allergy. The highest incidence of asthma at a given age has been observed in children with onset of AD before age 3 months, in those with severe AD, and in those with a family history of asthma (30). A more recent study confirmed the association of increased risk for respiratory allergy (asthma and/or rhinoconjunctivitis) with early onset of AD (31). Respiratory allergy occurred in 50% of children with onset of AD in the first 3 months of life and with two or more atopic family members compared with 12% of those with onset of AD after age 3 months and with no atopic family members.

Like patients with asthma and allergic rhinitis, patients with AD can react to both allergic and nonspecific triggers. Skin reactivity to irritants such as sodium lauryl sulfate (SLS) has been shown in patients with both active and inactive AD, as well as in patients with allergic respiratory disease with no dermatitis, compared with nonatopic individuals (32). The authors hypothesized that an abnormal intrinsic hyperreactivity in inflammatory cells in atopic individuals predisposes to a lowered threshold of irritant responsiveness. A more recent study confirmed and extended these observations by showing that stratum corneum abnormalities in noninvolved AD skin were associated with increased diffusional water loss even 7 days after application of SLS (33). Furthermore, SLS induced a similar eosinophilic infiltrate in patients with allergic rhinitis. In patients with AD, no constitutionally impaired stratum corneum barrier has been definitively proven (34), whereas atopy has been transferred through bone marrow transplantation (35), suggesting that the cutaneous abnormality results from a complex interaction of resident and infiltrating cells. Finally, in a study of bronchial and cutaneous reactivity in asthmatic patients with or without AD (36), the authors found a latent predisposition for bronchial asthma in patients with AD and implicated activated eosinophils as the common effector cells.

A global survey of the prevalence of asthma, allergic rhinoconjunctivitis, and AD reported on 463,801 children aged 13 to 14 years in 155 collaborating centers in 56 countries (37). The highest prevalence rates for AD were reported from scattered centers, including Scandinavia and Africa, that were not among centers with the highest asthma prevalence rates; however, the lowest prevalence rates for AD were in centers located similarly to those with the lowest prevalence rates of asthma and allergic rhinoconjunctivitis. Thus the ultimate presentation of an atopic disease may depend on a complex interaction of environmental exposures with end-organ response in a genetically predisposed individual.

CLINICAL PRESENTATION

Natural History

AD typically is seen in early childhood with onset before age 5 years in approximately 90% of patients (1). Although a 20-year follow-up study found that approximately 84% of children outgrew their AD by adolescence, these results may be flawed, as patients with seborrheic dermatitis may have been included in the study population (38). Other studies show less optimistic outcomes. AD resolved in only 18% of children followed up from infancy until age 11 to 13 years, although it had become less severe in 65% (7). In another study, 72% of patients diagnosed in the first 2 years of life continued to have AD 20 years later (39). Finally, in a prospective study from Finland, between 77% and 91% of adolescent patients treated for moderate or severe AD had persistent or frequently relapsing dermatitis as adults, although only 6% had severe disease (40). More than half of those adolescents with mild disease experienced a relapse as adults.

Clinical Features

AD has no pathognomonic skin lesion(s) or unique laboratory parameters; thus diagnosis is based on the presence of major and associated clinical features (Table 67.1). The principal features include severe pruritus, a chronically relapsing course, typical morphology and distribution of the skin lesions, and a history of atopic disease (1). The presence of pruritus is critical to the diagnosis of AD, and patients with AD have been shown to have a reduced threshold for pruritus.

Major features
Pruritus
Chronicity of skin disease
Typical distribution of dermatitis
Facial and extensor involvement in children <2 yr old
Flexural involvement in children >2 yrs old or adults
Other features
Age of onset <5 yrs old
Course influenced by environmental/emotional factors
Itch when early sweating
Intolerance to wool and lipid solvents
Xerosis (dry skin)
White dermatographism
Recurrent conjunctivitis
Infraorbital darkening
Facial pallor or erythema
Hand/foot dermatitis
Hyperlinear palms
Frequent cutaneous infections, especially by *Staphylococcus aureus*

TABLE 67.1. Clinical Features of Atopic Dermatitis

Acute AD is characterized by intensely pruritic, erythematous papules associated with excoriations, vesiculations, and serous exudate. Subacute AD is characterized by erythematous, excoriated, scaling papules, whereas chronic AD is characterized by thickened skin with accentuated markings (lichenification) and fibrotic papules. Patients with chronic AD may have all three types of lesions present concurrently. In addition, patients usually have dry skin. Significant differences exist between the pH, capacitance, and transepidermal water loss of AD lesions and those measurements in uninvolved skin in the same patients and in the skin of normal control subjects (41).

During infancy, AD involves primarily the face, scalp, and extensor surfaces of the extremities; the diaper area is typically spared. When involved, it may be secondarily infected with *Candida*, in which case, the dermatitis does not spare the inguinal folds. In contrast, infragluteal involvement is a common distribution in children. In older patients with long-standing disease, the flexural folds of the extremities are the predominant location of lesions. Localization of AD to the eyelids may be an isolated manifestation but should be differentiated from an allergic contact dermatitis. Chronic traumatization of the skin due to pruritus can result in prurigo nodules.

Complicating Features

Patients with AD often have a nonspecific hand dermatitis. This condition is frequently irritant in nature and aggravated by repeated wetting, especially in the occupational setting. A recent study suggested that a history of AD at least doubles the effects of irritant exposure and, thus, doubles the risk in occupations in which hand eczema is a common problem (42).

Ocular complications associated with AD can lead to significant morbidity. Increased numbers of IgE-bearing Langerhans cells have been found in the conjunctival epithelium in patients with AD (43). These cells may capture aeroallergens and present them to infiltrating T cells, thus contributing to ocular inflammation. Atopic keratoconjunctivitis is always bilateral, and symptoms include itching, burning, tearing, and copious mucoid discharge. It is frequently associated with eyelid dermatitis and chronic blepharitis and may result in visual impairment from corneal scarring. Vernal conjunctivitis is a severe bilateral recurrent chronic inflammatory process of the upper eyelid conjunctiva, usually occurring in younger patients. It has a marked seasonal incidence, often in the spring. The associated intense pruritus is exacerbated by exposure to irritants, light, or sweating. Examination of the eye reveals a papillary hypertrophy or “cobblestoning” of the upper inner eyelid surface. Keratoconus is a conical deformity of the cornea believed to result from persistent rubbing of the eyes in patients with AD and allergic rhinitis. Anterior subcapsular cataracts may develop during adolescence or early adult life.

Patients with AD have an increased susceptibility to infection or colonization with a variety of organisms including *Herpes simplex* and *Molluscum contagiosum*. Raychaudhuri and Raychaudhuri (44) demonstrated a direct relationship between interferon g (IFN-g) concentrations and the cytopathic effect of *Herpes simplex* and an inverse relationship between IL-4 and the cytopathic effect of *Herpes simplex*. This finding suggests that the T cell–associated cytokine abnormalities in AD may enhance viral infections. Superimposed dermatophytosis including *Trichophyton rubrum* can also cause AD to flare (45). *Pityrosporum ovale* has been associated with a predominantly head and neck distribution of AD (46).

A number of studies have elucidated the importance of *Staphylococcus aureus* in AD. *S. aureus* can be cultured from the skin of more than 90% of patients with AD

compared with only 5% of unaffected individuals (47). A recent study confirmed the higher rate of *S. aureus* colonization in AD lesions compared with that in lesions from other skin disorders and showed that this finding may be associated with colonization of the nares (48). In addition, this study pointed to the importance of *S. aureus* carriage on the hands, suggesting that this may be the vector for transmitting these bacteria from the nasal reservoir to lesional skin and to close contacts of these patients. In another study looking at reservoirs, the prevalence of *S. aureus* in the anterior nares of patients with AD was more than 5 times higher than that in the anterior nares of patients with other skin diseases or in healthy adult control subjects, and the prevalence of *S. aureus* in the subungual spaces was 10 times higher in the patients with AD compared with that in the other groups studied (49). The phage type of *S. aureus* strains isolated from the anterior nares was similar to that of the strains isolated from the subungual spaces. Although recurrent staphylococcal pustulosis can be a significant problem in AD, invasive *S. aureus* infections occur rarely and should raise the possibility of an immunodeficiency such as hyper-IgE syndrome.

Patients with AD have high levels of anxiety and lower life quality compared with unaffected individuals (50). Patients often respond to stress or frustration with itching and scratching. Stimulation of the central nervous system may intensify cutaneous vasomotor and sweat responses and contribute to the itch/scratch cycle. In some instances, scratching is associated with significant secondary gain or with a strong component of habit. Severe disease may lead to problems with social interactions and self-esteem.

Differential Diagnosis

A contactant should be considered in those patients whose AD does not respond to appropriate therapy. Typical distribution for a suspected contactant may be suggestive, although allergic contact dermatitis complicating AD may appear as an acute flare of the underlying disease. Proper diagnosis depends on confirmation of a suspected allergen with patch testing. Scabies is an intensely pruritic skin disease. However, distribution in the genital and axillary areas, presence of linear lesions, and skin scrapings should distinguish scabies from AD. In young infants, immunodeficiencies or metabolic disorders can present as an eczematoid eruption recalcitrant to treatment. In adults with an eczematous dermatitis and no history of childhood eczema or other atopic features, cutaneous T-cell lymphoma must be ruled out. Eczematous rash suggestive of AD can be seen in human immunodeficiency virus (HIV) disease.

THERAPEUTIC MANAGEMENT

Conventional Therapy

Conventional therapy includes skin hydration, antiinflammatory therapy, and elimination of exacerbating factors and clinically relevant allergens (Table 67.2). In children who have undergone blinded, controlled challenges, milk, egg, peanut, soy, wheat, and fish account for approximately 90% of the food allergens found to exacerbate AD (51). Avoidance of foods implicated in controlled challenges results in clinical improvement (51,52). More recently, the *in vitro* CAP test has been shown to measure specific IgE to egg, milk, peanut, and fish allergens with clinically relevant predictive values (53). In dust-mite–allergic individuals, environmental control measures aimed at reducing dust-mite load result in clinical improvement of AD in patients with specific IgE to dust-mite allergen (54). Counseling, relaxation, behavioral modification, or biofeedback may be of benefit, especially in those patients with habitual scratching. Patients and their families should be counseled about the natural history and prognosis of the disease, with appropriate vocational counseling.

Recover skin barrier function with skin hydration/emollients
Reduce chronic inflammatory response
Remove allergens and microbes which aggravate skin disease and can alter response to steroids
Importance of patient education
New role for topical macrolide immunomodulators

TABLE 67.2. Principles for Management of Atopic Dermatitis

Atopic skin shows enhanced transepidermal water loss and reduced water-binding capacity. Use of an effective emollient, usually in ointment or cream form, in combination with hydration therapy, helps to restore and preserve the stratum corneum barrier and can result in a decreased need for topical glucocorticoids.

Glucocorticoids reduce inflammation and pruritus in AD. In addition, topical glucocorticoids can decrease *S. aureus* colonization. In a double-blind, randomized, 1-week trial of a low-potency topical glucocorticoid compared with vehicle in children with AD, clinical scores improved and *S. aureus* density significantly decreased in the glucocorticoid-treated group, but not in the vehicle-treated patients (55). Although topical corticosteroids have been used to treat visibly abnormal skin, studies have shown that the uninvolved skin of patients with AD has an inflammatory cell infiltrate and manifests cutaneous hyperreactivity (32,56). To define a potential role for intermittent treatment with topical glucocorticoids as part of maintenance therapy in adult patients with recurring AD, Van Der Meer et al. (57) treated patients with moderate to severe AD for 2 weeks with topical fluticasone propionate. Patients whose AD had completely healed were entered into a second phase with topical fluticasone propionate or placebo ointment applied to healed skin lesions twice per week for 16 weeks. Patients treated with intermittent fluticasone propionate were more successful in maintaining the skin improvements achieved after the initial treatment phase with significantly reduced risk of relapse. Side effects include thinning of the skin with telangiectasias, bruising, hypopigmentation, acne, striae, and secondary infections, which may occur especially with more potent glucocorticoid preparations. Contact allergy to topical glucocorticoids can complicate treatment of inflammatory skin diseases, often in an insidious manner, and may be difficult to identify through patch testing (58). Systemic corticosteroids should be avoided in the management of chronic AD, as improvement may be followed by dramatic flaring of AD after discontinuation.

Systemic antibiotic therapy may be necessary to treat AD secondarily infected with *S. aureus*. Maintenance antibiotic therapy is rarely indicated and may result in colonization by methicillin-resistant organisms. Patients with disseminated eczema herpeticum usually require treatment with systemic acyclovir. Recurrent cutaneous herpetic infections can be controlled with daily prophylactic oral acyclovir. Superficial dermatophytosis and *P. ovale* can be treated with topical or, rarely, systemic antifungal drugs.

Systemic antihistamines and anxiolytics may be most useful through their tranquilizing and sedative effects and can be used primarily in the evening to avoid daytime drowsiness. Nonsedating antihistamines are less effective in treating the pruritus associated with AD. However, a beneficial effect has been reported in a double-blind study in children with AD treated with cetirizine, 5 to 10 mg daily for 8 weeks (59). Cetirizine, 10 mg twice daily, also has been shown to reduce both eosinophils and neutrophils in early- and late-phase reactions in a placebo-controlled, double-blind study in allergen-specific challenge, suggesting antiinflammatory along with antihistamine effects (60).

Ultraviolet (UV) light therapy can decrease the expression of activation markers such as human leukocyte antigen (HLA)-DR, IL-2 receptor, and CD30 on cutaneous lymphocyte antigen (CLA)-positive T cells (61). UVB has been shown to be effective in the treatment of AD, although narrow-band UVB may be a safer alternative (62). Alternatively, high-dose UVA1 is a fast-acting and effective phototherapeutic approach in patients with acute exacerbations of AD. Unlike traditional UVA/UVB phototherapy, which appears less effective for acute exacerbations and acts primarily in the epidermis, high-dose UVA1 therapy significantly decreases dermal IgE-binding cells, including mast cells and dendritic cells (63). UVA1 may exert antiinflammatory effects indirectly by downregulating proinflammatory cytokines or directly by inducing apoptosis in skin-infiltrating $CD4^+$ T cells (64).

Photochemotherapy with oral methoxypsoralen therapy followed by UVA (PUVA) may be indicated in patients with severe AD, especially with failure of topical therapy in patients with significant glucocorticoid side effects. Short-term adverse effects may include erythema, pruritus, and pigmentation, whereas long-term adverse effects include premature skin aging and cutaneous malignancies (65). Topical psoralens combined with UVA may be equally effective. Topical PUVA has no risk of systemic side effects and may be especially useful for patients with chronic hand eczema who are resistant to other topical medications (66). PUVA therapy in children with severe AD and growth suppression has resulted in significant clinical improvement, with a significant number of patients experiencing sustained remission as well as accelerated growth (67). However, long-term risk of cutaneous malignancies has precluded general use of this treatment modality in children.

Patients with AD who are erythrodermic or who appear toxic may need to be hospitalized. Hospitalization also may be appropriate for patients with severe disseminated disease resistant to first-line therapy. Removing the patient from environmental allergens or stressors, together with intensive education and assurance of compliance with therapy, usually results in marked clinical improvement. In this setting, the patient also can undergo appropriately controlled provocative challenges to

help identify potential triggering factors.

Immunomodulatory Therapy

INTERFERON-g

IFN-g suppresses IgE synthesis (68) and inhibits Th2-cell function (69). Treatment with subcutaneous recombinant human (rh)IFN-g reduces the clinical severity and the total circulating eosinophil counts in patients with AD (70,71). In addition, treatment with rhIFN-g significantly decreases the number of circulating activated lymphocytes (72). Clinical improvement also correlates with reduction in white blood cell (WBC), eosinophil, and lymphocyte counts and normalization of the CD4/CD8 ratio among large lymphocytes (73). Some patients may show persistent improvement several months after discontinuing therapy. Thus, the *in vivo* effects of rhIFN-g therapy are likely to be complex, with modulation of Th2 cell–directed allergic inflammation the primary action. Recently, two open long-term studies have shown clinical efficacy in patients with AD treated for a minimum of 22 months with 50 μg/m^2 rhIFN-g given daily or every other day (74,75). These studies demonstrate that patients with AD can be treated on a long-term basis with rhIFN-g without deterioration of their disease or significant adverse effects. This is noteworthy because IFN-g has been shown to have proinflammatory effects in some clinical settings. Importantly, effective dosing with rhIFN-g is associated with a decrease in eosinophil counts, suggesting that rhIFN-g acts primarily on the allergic inflammatory response, as opposed to IgE synthesis. Thus it is possible that a subset of patients treated with rhIFN-g would respond to individualized titration of their treatment dose (76).

CALCINEURIN INHIBITORS

Cyclosporin A (CsA) is an immunosuppressive agent that acts primarily on T cells, interfering with cytokine transcription (77). The drug binds to an intracellular protein, cyclophilin, and this complex in turn inhibits calcineurin, a Ca^{++} calmodulin-dependent protein phosphatase involved in signal transduction (78). Activation of calcineurin is necessary for cytokine gene transcription to be initiated. Maintenance of chronic inflammation in AD appears to be associated with increased IL-5 gene expression and eosinophil infiltration (5), and preliminary *in vitro* data with mononuclear cells from atopic patients demonstrate suppression of IL-5 production by CsA (79). A significant decrease in the number of circulating eosinophils and in soluble CD30 and soluble E-selectin levels also has been observed with CsA therapy (80,81). A number of studies of oral CsA in severe AD have documented both clinical benefits (82,83) and improvement in quality of life (84). These data have been substantiated in long-term trials, although patients can relapse even after 48 months of therapy (85). Open studies have demonstrated that children with AD treated with CsA tolerated the treatment and showed significant improvement in both clinical signs and quality of life (86,87). Discontinuation of treatment resulted in relapse, although the rate of relapse was variable. Short-term oral CsA therapy can result in increased serum urea, creatinine, and bilirubin concentrations, but these normalize after treatment is discontinued (83). Because of the concern for progressive or irreversible nephrotoxicity with extended treatment, few patients have been evaluated on maintenance therapy. Patients with severe AD treated with oral CsA, 5 mg/kg per day for 6 weeks, were followed up until relapse, and then those who relapsed were treated with a second 6-week course (88). After both treatment periods, approximately half the patients relapsed after 2 weeks, and after 6 weeks, the relapse rate was 71% and 90%, respectively. However, a few patients did not relapse after the first or second treatment courses. All of these patients were still in remission after 1 year, suggesting that although this treatment regimen did not result in lasting remission for the majority of patients, a subset of patients may have derived extended clinical benefit. Because of concerns for systemic toxicity, topical administration of CsA has been tried. However, in a 3-week double-blind vehicle-controlled study with 10% CsA gel and 10% CsA ointment, patients failed to show significant improvement (89).

Tacrolimus (FK506), a macrolide isolated from *Streptomyces tsukabaensis*, is an immunosuppressive agent with a spectrum of activity similar to that of CsA, although it is structurally unrelated to CsA (90). Tacrolimus also acts by binding to a cytoplasmic protein, FK506-binding protein, and this complex in turn inhibits calcineurin, interfering with gene transcription (78). Of note, other cells important in allergic skin inflammation including mast cells, basophils, eosinophils, keratinocytes, and Langerhans cells have tacrolimus (FK506)-binding proteins and downregulate their mediator or cytokine expression after treatment with tacrolimus (91,92). Preliminary data with tacrolimus in ointment form suggested clinical benefit in AD with markedly diminished pruritus within 3 days of initiating therapy, and biopsies done on days 3 and 7 of treatment showed diminished T-cell and eosinophilic infiltrates (93). Randomized, double-blind vehicle-controlled studies in adults and children with moderate to severe AD showed that three concentrations of tacrolimus ointment were significantly better than vehicle alone (94,95). In these 3-week trials, burning at the application site was the only significant adverse event seen with the active drug, and mean blood tacrolimus levels were not elevated during these studies. Because skin inflammation in AD is associated with increased permeability, an aspect of therapy with tacrolimus ointment that possibly contributes to its safety profile is its self-regulatory activity (i.e., as it heals inflamed skin, tacrolimus absorption is decreased) (96). In addition, unlike topical glucocorticoids, tacrolimus ointment does not cause cutaneous atrophy (97). Multicentered, blinded, vehicle-controlled phase 3 trials with tacrolimus 0.03% and 0.1% ointment have been completed in both adults and children with moderate to severe AD; because AD is a chronic disease, long-term studies with tacrolimus ointment applied on up to 100% body surface area are in progress. The optimal treatment regimen with this agent remains to be defined. However, because recent studies suggest that the T-cell activation in AD is biphasic, with predominance of the Th2 cytokines, IL-4, IL-5, and IL-13, during the acute phase and increased expression of the Th1 cytokines, IFN-g and IL-12, in chronic lesions (5,98,99 and 100), the capacity of tacrolimus to inhibit the activation of multiple cell types and cytokines may account for its efficacy in AD.

Topical 1% SDZ ASM 981 has been studied in a randomized, double-blind, vehicle-controlled, right-and-left comparison trial in adult patients with moderate AD (101). Twice-daily application of 1% SDZ ASM 981 cream was significantly more effective than use of the corresponding vehicle and more effective than once-daily treatment over a 21-day period. No clinically relevant drug-related adverse effects were noted. Phase 3 trials in children are in progress.

MYCOPHENOLATE MOFETIL

Mycophenolate mofetil, a purine biosynthesis inhibitor, has been used as an immunosuppressant in organ transplantation and more recently for inflammatory skin disorders (102). Oral mycophenolate mofetil, 2 g daily as monotherapy, resulted in clearing of skin lesions in two adults with AD resistant to other treatment including topical and oral glucocorticoids and PUVA (103). Improvement was evident 2 to 4 weeks after initiation of therapy. Both patients continued on mycophenolate mofetil for an additional 4 weeks, and no side effects were noted. Neither patient experienced relapse of their AD during a 12-week follow-up period. Because the side-effect profile is favorable compared with that of other systemic therapies for AD, further studies with this agent may be warranted.

INTRAVENOUS IMMUNOGLOBULIN

Because chronic inflammation and T-cell activation appear to play a critical role in the pathogenesis of AD, intravenous immunoglobulin (IVIG) could have immunomodulatory effects in this disease. IVIG also could interact directly with antigens, such as infectious agents or toxins involved in the pathogenesis of AD. IVIG contains high concentrations of staphylococcal toxin-specific antibodies that inhibit the *in vitro* activation of T cells by staphylococcal toxins (104). In this study, two different pooled IVIG preparations both contained high titers of antibodies to eight staphylococcal toxins, and binding by the pooled IVGG was toxin specific. The mechanism of inhibition by IVIG was shown to be direct blocking of toxin binding to, or presentation by, antigen-presenting cells. Further rationale for use of IVIG in AD includes the recent observation that IVIG reduces IL-4 protein expression in AD (105). Treatment of severe refractory AD with IVIG has yielded conflicting results. Studies have not been controlled and have involved small numbers of patients. Kimata (106) reported dramatic improvement of AD with this treatment modality. However, in another open label study, nine patients with severe AD were treated with high-dose (2 g/kg) IVIG (Venoglobulin I; Alpha Therapeutic Corporation, Los Angeles, CA) monthly for seven infusions (107). Skin disease lessened slightly in six patients, whereas their average daily prednisone dosage did not change significantly. Mean serum IgE levels did not decrease significantly during IVIG therapy, and *in vitro* IgE production by peripheral blood mononuclear cells (PBMCs) IL-4 and anti-CD40 stimulation was not significantly reduced. The authors concluded that IVIG was of no clear clinical benefit in this small group of patients. However, controlled studies are needed to answer the question of efficacy in a more definitive manner.

PHOSPHODIESTERASE INHIBITORS

Leukocytes from patients with AD have increased cyclic adenosine monophosphate (AMP)-phosphodiesterase (PDE) enzyme activity, with monocytes having a unique, highly active PDE isoenzyme. Monocytes from patients with AD produce elevated levels of prostaglandin (PG) E_2 and IL-10, both of which inhibit IFN-g production. PDE inhibitors such as Ro 20-1724 decrease IgE synthesis (108) and basophil histamine release *in vitro* (109). Culture of AD monocytes with Ro 20-1724 also resulted in significant reduction of abnormal levels of IL-4, IL-10, and PGE_2 (110). Patients with AD treated with CP80,633, a potent inhibitor of PDE type IV, applied topically in a blinded, placebo-controlled paired-lesion study, showed significant clinical improvement with the active drug (110). In a recent study, the selective PDE type IV inhibitor rolipram inhibited *S. aureus* enterotoxin B–mediated generation of cutaneous lymphocyte-associated antigen positive $CD3^+$ cells from PBMCs by reducing IL-12 production in a concentration-dependent manner (111).

Experimental and Unproven Therapies

ALLERGEN DESENSITIZATION

Although uncontrolled trials have suggested that desensitization to specific allergens may ameliorate AD, such results have not been verified in controlled trials (112).

Controlled trials of sufficient duration with standardized extracts of allergens relevant to AD are needed before this form of therapy can be recommended.

TRADITIONAL CHINESE HERBAL THERAPY

Traditional Chinese herbal therapy comprising herbs with antimicrobial, sedative, antiinflammatory, and glucocorticoid-like activities has been shown to inhibit the low-affinity receptor for IgE on peripheral blood monocytes in a dose-dependent manner not due to a toxic effect (113). It has been used in the form of decoctions to treat AD in both children (114) and adults (115). A controlled trial of this therapy failed to show any benefit in the treatment of recalcitrant AD (116). In addition, the possibility of toxicity associated with long-term use, contamination with glucocorticoids, or idiosyncratic reactions remains a concern (117,118).

ESSENTIAL FATTY ACIDS

A number of disturbances in the metabolism of essential fatty acid have been reported in patients with AD (119). A double-blind, placebo-controlled, parallel-group randomized study that avoided the methodologic and analytic problems of a number of previous studies found no clinical benefit of either evening primrose oil or fish oil in AD (120).

LEUKOTRIENE MODIFIERS

The role of cysteinyl leukotrienes has not been well defined in AD, although a recent study with skin chambers demonstrated antigen-specific release of LTB_4 *in vivo* in nonlesional skin from patients with AD (121). Case reports with the LTD_4 receptor antagonist zafirlukast suggest benefit in some patients with AD (122), although controlled studies are needed to evaluate the role of leukotriene modifiers in the treatment of AD.

IMMUNOPATHOLOGY

Immune Responses in AD

The finding of elevated serum IgE levels and the occurrence of eczematous lesions indistinguishable from AD in patients with primary T-cell immunodeficiency disorders suggest an immunologic basis for AD (123). In Wiskott-Aldrich syndrome, bone marrow transplantation results in correction of the immunologic defect and resolution of the dermatitis. In addition, nonatopic recipients of bone marrow transplants from atopic donors have been shown to develop atopic symptoms and positive skin tests after successful engraftment (35). These data suggest that AD results from a bone marrow–derived cell dysfunction rather than from a constitutive skin defect.

Immunoregulatory Dysfunction

A number of immunoregulatory abnormalities have been described in AD (Table 67.3). B cells from patients with AD synthesize high levels of IgE (124). Lymphocytes from these patients produce increased amounts of IL-4 and express abnormally high levels of IL-4 receptor (124,125). In addition, the spontaneous production of IgE can be inhibited *in vitro* by addition of anti–IL-4 (126). PBMCs isolated from patients with AD have a decreased capacity to make IFN-g, and this characteristic is inversely correlated with serum IgE levels (127).

Increased serum IgE
Eosinophilia
Increased basophil spontaneous histamine release
Increased expression of CD23 on mononuclear cells
Chronic macrophage activation with increased secretion of GM-CSF, PGE_2 and IL-10
Expansion of IL-4- and IL-5-secreting Th2-type cells
Decreased numbers of IFN-γ-secreting Th1-type cells
Increased serum soluble IL-2 receptor levels
Increased serum levels of eosinophil cationic protein, eosinophil-derived neurotoxin, and eosinophil major basic protein

GM-CSF, granulocyte–macrophage colony-stimulating factor; $IFN_γ$, interferon-γ; IgE, immunoglobulin E; IL, interleukin; PGE_2, prostaglandin E; Th1, T-helper cell type 1; Th2, T-helper cell type 2.

TABLE 67.3. Peripheral Blood Immunologic Findings in Atopic Dermatitis

Studies also have shown an increased frequency of both circulating and cutaneous allergen-specific IL-4 and IL-5 secreting Th cells in patients with AD (98,128). Recently, Nakazawa et al. (129) used flow cytometry to demonstrate at the single-cell level that the frequency of Th2 cytokine–secreting cells was significantly higher in patients with AD compared with that in normal controls (129). In addition, CD30, an activation marker of T-cell clones with a Th2 cytokine profile, is significantly elevated in soluble form in children with AD (130).

In addition to acting as an IgE isotype-specific switch, IL-4 also inhibits production of IFN-g and downregulates the differentiation of Th1 cells (131). IFN-g production also is inhibited by PGE_2 and IL-10, both of which are secreted in increased amounts by monocytes from patients with AD (132,133). A recent study did not find any defect in the capacity of cells from AD patients to produce IL-12, an important inducer of IFN-g (134). However, neutralization of IL-10 and IL-4 was able to correct production IFN-g. Thus the activation of Th2 cells and monocytes may be central to the immune dysregulation in AD.

A role for the costimulatory molecules CD80/CD86 has been investigated in AD. With immunohistochemical analysis, Ohki et al. (135) showed predominantly CD86 on Langerhans cells in both the epidermis and the dermis in AD. They also demonstrated almost complete inhibition of antigen-specific T-cell proliferation with an anti-CD86 monoclonal antibody. Studies also have suggested that these accessory molecules differ in their capacity to generate Th1 versus Th2 T-cell responses. A recent study found that the expression of CD86 on B cells of AD patients was significantly higher than that on B cells from normal patients and psoriasis patients, whereas there was no significant difference in CD80 expression among the three subject groups (136). Interestingly, total serum IgE from AD patients and normal subjects correlated significantly with CD86 expression on B cells, suggesting a role for $CD86^+$ B cells in IgE synthesis. Purified $CD86^+$ B cells produced significantly more IgE than did $CD86^-$ B cells *in vitro*, and anti-CD86, but not CD80, monoclonal antibody (mAb) significantly decreased IgE production by PBMCs stimulated with IL-4 and anti-CD40 mAb. Furthermore, $CD86^+$ B cells had a significantly higher level of IL-4R and CD23 expression than did $CD80^+$ B cells. These data demonstrate the predominant expression of CD86 in AD and suggest a role in IgE synthesis.

Immunohistology

Clinically *normal*-appearing skin of patients with AD contains a sparse perivascular T-cell infiltrate (56). Acute papular skin lesions are characterized by marked intercellular edema (spongiosis) of the epidermis. Dendritic antigen-presenting cells, including Langerhans cells and macrophages in lesional and, to a lesser extent, in nonlesional skin of AD, exhibit surface-bound IgE molecules (137). A sparse epidermal infiltrate consisting primarily of T lymphocytes also is frequently observed. In the dermis of the acute lesion, there is a marked perivenular T-cell infiltrate with occasional monocyte/macrophages. The lymphocytic infiltrate consists predominantly of activated memory T cells bearing CD3, CD4, and CD45 RO, suggesting previous encounter with antigen. Eosinophils, basophils, and neutrophils are rarely present in acute AD, whereas mast cells are present in various stages of degranulation.

Chronic lichenified lesions are characterized by a hyperplastic epidermis with elongation of the rete ridges, prominent hyperkeratosis, and minimal spongiosis. There are increased numbers of IgE-bearing Langerhans cells in the epidermis, and macrophages dominate the dermal mononuclear cell infiltrate. The number of mast cells and eosinophils is increased, and eosinophils undergo cytolysis with release of granule protein contents into the upper dermis of lesional skin (138). Eosinophil-derived extracellular major basic protein can be detected in a fibrillar pattern associated with the distribution of elastic fibers throughout the upper dermis. Eosinophils are thought to contribute to allergic inflammation by the secretion of cytokines and mediators that augment allergic inflammation and induce tissue injury in AD through the production of reactive oxygen intermediates and release of toxic granule proteins (139). Eosinophil major basic protein, eosinophil cationic protein, and eosinophil-derived neurotoxin are elevated in AD sera and correlate with disease severity (140).

Cytokine Expression in Skin Lesions

Both Th2 and Th1 cytokines contribute to the pathogenesis of skin inflammation in AD, with the relative contribution of each cytokine dependent on the acute nature of the skin lesion (Fig. 67.1). As compared with the skin of normal control subjects, uninvolved skin of patients with AD has an increased number of cells expressing IL-4 and IL-13 messenger RNA (mRNA), but not IL-5, IL-12, or IFN-g mRNA (5,100). Acute and chronic skin lesions, when compared with normal skin or with uninvolved skin of patients with AD, have significantly greater numbers of cells that are positive for IL-4, IL-5, and IL-13 mRNA. However, acute AD skin lesions do not contain significant numbers of IFN-g or IL-12 mRNA-expressing cells.

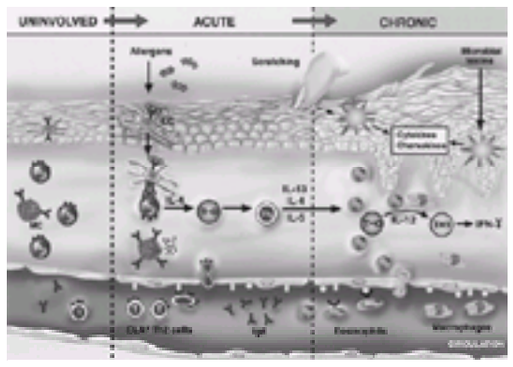

Figure 67.1. Cellular interactions in atopic dermatitis. The acute skin lesion is associated with overexpression of Th2 cytokines, whereas the chronic skin lesions show a shift to Th1 cytokine expression. Two potential reasons for the shift to Th1 cytokine expression include interleukin (IL)-4–induced eosinophil secretion of IL-12 or superantigen-induced stimulation of macrophage, or dendritic cell secretion of IL-12. *MC*, mast cell. (See Color Figure 67.1.)

Chronic AD skin lesions have significantly fewer IL-4 and IL-13 mRNA-expressing cells, but increased numbers of IL-5, GM-CSF, IL-12, and IFN-g mRNA-expressing cells than do acute lesions. Thus acute T-cell infiltration in AD is associated with a predominance of IL-4 and IL-13 expression, whereas maintenance of chronic inflammation is associated with increased IL-5, GM-CSF, IL-12, and IFN-g expression accompanied by the infiltration of eosinophils and macrophages. The increased expression of IL-12 in chronic AD skin lesions is noteworthy because IL-12 plays a key role in Th1 cell development, and its expression in eosinophils and/or macrophages is thought to initiate the switch to Th1 cell development in chronic AD (141).

The importance of Th1 and Th2 cytokines in the development of allergic skin inflammation was demonstrated by a study with a murine model of AD in mice with targeted deletions of the IL-4, IL-5, and IFN-g cytokine genes to assess the role of these cytokines. The data suggested that both the Th2 cytokines IL-4 and IL-5 as well as the Th1 cytokine IFN-g play important roles in the skin inflammatory response of AD. Allergen-sensitized skin from IFN-g knockout mice had reduced dermal thickening; IL-5 knockout mice had no detectable eosinophils and exhibited decreased epidermal and dermal thickening; and IL-4 knockout mice displayed normal thickening of the skin layers but had a drastic reduction in eosinophils (142).

The biphasic pattern of T-cell activation in AD also has been demonstrated in studies with the atopy patch test (reviewed in ref. 141). Twenty-four hours after allergen application to the skin, the expression of IL-4 mRNA and protein is increased, after which IL-4 expression declines to baseline levels. In contrast, IFN-g mRNA expression is not detected in 24-hour patch-test lesions, but is strongly overexpressed at the 48- to 72-hour times. This finding is consistent with studies demonstrating that T-cell clones obtained from early times of evolving allergen patch-test sites secrete Th2-type cytokines, whereas most of the allergen-specific T-cell clones derived from later patch-test sites (>48 hours) exhibit a Th1- or Th0-type cytokine profile. The increased expression of IFN-g mRNA in atopic patch test lesions is preceded by a peak of IL-12 expression coinciding with the infiltration of macrophages and eosinophils.

Identification of mechanisms controlling infiltration of inflammatory cells into AD skin is an area of active investigation (143). Studies have demonstrated that IL-16, a chemoattractant for $CD4^+$ T cells, is more highly expressed in acute than in chronic AD skin lesions (144). Levels of C-C chemokines, RANTES (regulated on activation normal T cell expressed and secreted), monocyte chemotactic protein (MCP)-4, and eotaxin also are increased in AD skin lesions and likely contribute to the chemotaxis of eosinophils and Th2 lymphocytes into the skin (145, 146). A role has been suggested for cutaneous T cell–attracting chemokine (CTACK/CCL27) in the preferential attraction of CLA^+ T cells into the skin (147). The chemokine receptor CCR3, which is found on eosinophils and Th2 lymphocytes and can mediate the action of eotaxin, RANTES, and MCP-4, has been reported to be increased in nonlesional and lesional skin of patients with AD (146). LTB^4 also is released on exposure of AD skin to allergens and may act as a chemoattractant for the initial influx of inflammatory cells (121).

Persistence of Cutaneous Inflammation

Chronic AD is linked to the prolonged survival of eosinophils and monocyte/macrophages in atopic skin. The increase in IL-5 expression during the transition from acute to chronic AD likely plays a role in the prolongation of eosinophil survival and function. In chronic AD, there also is a marked increase in GM-CSF expression (148). GM-CSF plays an important role in maintaining the survival and function of monocytes, Langerhans cells, and eosinophils. Enhanced production of GM-CSF by epidermal keratinocytes and infiltrating macrophages has been shown in AD lesions (148,149). Supernatants from cultured keratinocytes of patients with AD induced a significantly higher proliferative response in PBMCs than did supernatants from control keratinocytes of nonatopic individuals, and this proliferative response could be totally abrogated by an anti–GM-CSF monoclonal antibody. Supernatants from PMA-stimulated keratinocytes of patients with AD, together with exogenous IL-4, also supported the maturation of monocytes into dendritic cells. Epidermal keratinocytes stimulated simultaneously with IFN-g and tumor necrosis factor (TNF)-a produced increased levels of RANTES, which enhanced the chemotaxis of eosinophils (150,151). This may serve as one mechanism by which the increase in IFN-g during chronic AD enhances the chronicity and severity of eczema. Mechanical trauma also can induce the release of TNF-a and many other proinflammatory cytokines from epidermal keratinocytes (152). Thus prolonged scratching plays a role in the perpetuation and elicitation of skin inflammation in AD.

The environmental triggers that contribute to the chronicity of AD are unknown. However, chronic AD is frequently associated with colonization by superantigen-producing *S. aureus* (153). To examine a potential role for microbial superantigens in the prolongation of monocyte/macrophage survival, Bratton et al. (154) incubated PBMs from patients with AD with various concentrations of toxic shock syndrome toxin-1, a prototypic superantigen, and examined the incidence of apoptosis. This superantigen, in a concentration-dependent manner, significantly inhibited monocyte apoptosis and stimulated production of the prosurvival cytokines GM-CSF, IL-1b, and TNF-a. Their data also showed that GM-CSF production was the primary cytokine responsible for inhibition of apoptosis. More recently, staphylococcal enterotoxin B (SEB)-stimulated CLA^+ $CD4^+$ and $CD8^+$ T cells were shown to increase the life span of eosinophils, with the $CD8^+$ subset significantly more effective than the $CD4^+$ subset (155).

Finally, recent studies on mononuclear cells from patients with atopic asthma indicated that allergen-induced immune activation can alter T-cell response to glucocorticoids by inducing cytokine-dependent abnormalities in glucocorticoid receptor binding affinity (156). PBMCs from patients with chronic AD also have reduced glucocorticoid receptor binding affinity, which can be sustained with the combination of IL-2 and IL-4 (157). Endogenous cortisol levels control the magnitude of cutaneous allergic inflammatory responses, suggesting that impaired response to steroids could contribute to chronic AD (158).

Immunologic Triggers

FOOD ALLERGENS

Based on double-blinded, placebo-controlled food challenges, approximately 40% of infants and young children with moderate to severe AD have food allergy (159). Guillet and Guillet (160) evaluated 250 children with AD and found the increased severity of AD and younger age of patients was directly correlated with the presence of food allergy. Removal of the food allergen from the patient's diet can lead to significant clinical improvement but requires a great deal of education, because most of the common causal allergens (e.g., egg, milk, wheat, soy, and peanut) contaminate many foods and are therefore difficult to avoid.

Laboratory studies also support a role for food allergy in AD. Infants and young children with moderate to severe AD frequently have positive immediate skin tests or serum IgE directed to various foods. Positive food challenges are accompanied by significant increases in plasma histamine concentrations and eosinophil activation (159,161). Furthermore, children with AD who are ingesting foods to which they are allergic have increased spontaneous basophil histamine release compared with children without food allergy. Immediate skin tests to specific allergens, however, do not always indicate clinical sensitivity, and patients who outgrow AD frequently

continue to have positive skin tests. Thus the relationship between IgE and clinical AD is not exclusively dependent on IgE-mediated mast cell degranulation.

IgE molecules also can participate in T cell–mediated reactions by binding to Langerhans cells through their high-affinity IgE receptors. Food allergen–specific T cells have been cloned from lesional skin and normal skin of patients with AD (162,163). In support of a role for food allergen–specific T cells in AD, patients with food-induced AD have been studied to analyze the relationship between eczematoid reactions to food allergens and the expression of skin-homing receptors on T cells activated *in vitro* by the relevant allergen. In these studies, T cells from children with casein-induced AD were assessed for their CLA expression after stimulation *in vitro* with casein and compared with T cells collected from patients with milk-induced gastroenteropathy or healthy controls (164). Casein-reactive T cells from patients with milk-induced eczema had significantly higher levels of CLA than did *Candida albicans*–reactive T cells from the same patients, and either casein- or *C. albicans*–reactive T cells from nonatopic controls. These studies provide strong scientific evidence that foods can play a role in the pathogenesis of AD.

AEROALLERGENS

As atopic children grow older, inhalant allergens play a more important role in the pathogenesis of their AD (reviewed in ref. 165). Walker (166) first reported, in 1918, that several of his patients had exacerbation of their AD after exposure to horse dander, timothy grass, or ragweed pollen. In the 1950s, Tuft and Heck (167) found that patients with AD developed pruritus and eczematoid skin lesions after intranasal inhalation challenge with either *Alternaria* or ragweed pollen, but not with placebo. More recently, Tupker et al. (168) reported a double-blind, placebo-controlled challenge study that demonstrated inhalation of house-dust mites by bronchial challenge resulted in both new AD lesions and exacerbation of existing skin lesions.

Most reports, however, have focused on the development of eczematoid eruptions after epicutaneous application of aeroallergens. In these studies, patch testing of uninvolved atopic skin with aeroallergens gave rise to eczematoid reactions in 30% to 50% of patients with AD (169,170). In contrast, patients with respiratory allergy and healthy volunteers rarely have positive allergen patch tests. Because there is considerable variation in the performance and interpretation of patch tests, however, their clinical usefulness is still questionable. Nonetheless, patch testing continues to be used as a research tool.

Several studies have examined whether avoidance of aeroallergens results in reduced skin symptoms due to AD. Most of these reports have involved uncontrolled trials in which patients were placed in mite-free environments, and their AD improved. One double-blind placebo-controlled study with a combination of effective mite-reduction measures in the home has been reported (171). Although both active and control groups decreased *Dermatophagoides pteronyssinus* (Der p 1) concentrations in carpeting, the reduction in the amount of dust was greater on the mattresses in the active group, and their AD symptoms decreased significantly more.

These clinical studies suggest that inhalation or contact with aeroallergen may exacerbate AD. Laboratory data supporting a role for inhalants include the finding of IgE antibody to specific inhalant allergens in most patients with AD. One study found that sera from 95% of patients with AD had IgE to house-dust mites compared with sera from 42% of individuals with asthma (172). The degree of sensitization to aeroallergens was directly associated with the skin severity of AD. The isolation from AD skin lesions and allergen patch test sites of T cells that recognize Der p 1 and other aeroallergens provides further evidence that the inflammatory response in AD can be elicited by aeroallergens (173).

MICROBES

Patients with AD have an increased tendency to develop bacterial and fungal skin infections. *S. aureus* colonizes more than 90% of AD skin lesions. In contrast, only 5% of normal subjects harbor this organism. The importance of *S. aureus* is supported by the observation that even AD patients without superinfection show a reduction in severity of skin disease when treated with a combination of antistaphylococcal antibiotics and topical glucocorticoids (174,175). The fact that a combination of antibiotics and topical glucocorticoids is much more effective than topical glucocorticoids alone in reducing the severity of AD suggested that *S. aureus* may secrete a toxin that alters the response to glucocorticoids.

Studies suggest that one strategy by which *S. aureus* exacerbates or maintains skin inflammation in AD is through the secretion of superantigens that stimulate marked activation of T cells and macrophages. Several lines of investigation support a role for superantigenic toxins in AD. First, more than half of patients with AD have *S. aureus* cultured from their skin that secretes superantigens such as enterotoxins A and B and toxic shock syndrome toxin-1 (TSST-1) (153,176,177). An analysis of the skin-homing CLA^+ T cells from these patients as well as their skin lesions reveals that they have undergone a T-cell receptor V-b expansion consistent with superantigenic stimulation (178,179). Second, most patients with AD make specific IgE antibodies directed against the staphylococcal toxins found on their skin (175,176 and 177). Basophils from patients with anti-toxin IgE release histamine on exposure to the relevant toxin but not in response to toxins to which they had no specific IgE. Third, a correlation has been found between the presence of IgE antisuperantigens, the density of superantigen-producing *S. aureus*, and the severity of AD. In a humanized murine model of skin inflammation, *S. aureus* superantigen plus allergen had an additive effect in inducing cutaneous inflammation (178). Superantigens also augment IgE synthesis by PBMCs to specific allergens and induce glucocorticoid resistance, suggesting that several mechanisms exist by which superantigens could aggravate the skin severity of AD (179,180). Fourth, the superantigen SEB, applied to the skin, can induce skin changes of erythema and induration, and the infiltrating T cells are selectively expanded in response to SEB (181,182). Furthermore, in a prospective study of patients recovering from toxic shock syndrome, it was found that in 14 of 68 patients, chronic eczematoid dermatitis developed, whereas in no patients recovering from gram-negative sepsis did eczema develop (183). Thus superantigens can induce an eczematoid process in the skin. Superantigens have been demonstrated to induce T-cell expression of the skin-homing receptor through stimulation of IL-12 production (184). In the case of AD, staphylococcal superantigens secreted at the skin surface may penetrate inflamed skin and stimulate epidermal macrophages or Langerhans cells to produce IL-1, TNF, and IL-12. Local production of IL-1 and TNF induces the expression of E-selectin on vascular endothelium, allowing an initial influx of CLA^+ memory/effector cells. Local secretion of IL-12 could increase CLA expression on those T cells activated by allergen or superantigen and thereby increase their efficiency of T-cell recirculation to the skin, perhaps including areas with only low levels of vascular E-selectin and minimal inflammatory activity. IL-12 secreted by toxin-stimulated Langerhans cells that migrate to skin-associated lymph nodes (and serve as antigen-presenting cells there) could upregulate the expression of CLA and influence the functional profile of virgin T cells activated by the toxins, thereby creating additional skin-homing memory-effector T cells. Together, these mechanisms would amplify the initial cutaneous inflammation in AD.

There also has been considerable interest in fungus, particularly *Malassezia furfur* (*P. ovale* or *P. orbiculare*), as a pathogen in AD. *M. furfur* is a lipophilic yeast commonly present in the seborrheic areas of the skin. IgE antibodies against *M. furfur* are frequently found in AD patients, most often in those with head and neck dermatitis (185). In contrast, IgE sensitization to *M. furfur* is rare in normal controls or in patients with asthma. The potential importance of *M. furfur* as well as other dermatophyte infections is further supported by the reduction of AD severity in the skin of such patients after treatment with antifungal agents (186,187).

AUTOALLERGENS

Valenta et al. (reviewed in ref. 188) has reported that the sera from most patients with severe AD contain IgE antibodies directed against human proteins. Such antibodies were not detected in patients with chronic urticaria, systemic lupus erythematosus, graft-versus-host disease, or healthy controls. Several of the autoallergens have been cloned and found to be mainly intracellular proteins. Nevertheless, they have been detected in IgE immune complexes of AD sera, suggesting that release of these autoallergens from damaged tissues could trigger IgE- or T cell–mediated responses. These data suggest that although IgE immune responses are initiated by environmental allergens, allergic inflammation can be maintained by human endogenous antigens particularly in severe AD.

FUTURE DIRECTIONS

The pathogenesis of AD is complex and incompletely understood. Most patients have a systemic Th2 response with high serum IgE levels, eosinophilia, and an expansion of T cells expressing IL-4, IL-5, and IL-13, a finding also in patients with AD with an increased tendency to develop respiratory allergy. Once the process of skin inflammation is elicited, there is an evolution from uninvolved skin, which has a sparse infiltrate of Th2 cells, to acute papular skin lesions with epidermal spongiotic changes and a marked influx of Th2 cells. The activation of Th2 cells by epicutaneous application of allergens is thought to involve antigen capture and presentation by IgE-bearing Langerhans cells. However, ingestion of foods or inhalation of aeroallergens also may involve mucosal antigen-presenting cells, which become armed with allergens and activate T cells that then home to the skin. Th2-type cytokines released from T cells and mast cells also enhance development of Th2 cells and induce the release of chemokines, such as eotaxin, from various cell types including keratinocytes, fibroblasts, and endothelial cells. Prolonged skin inflammation results in chronic AD associated with epidermal hyperplasia and lichenification. Unlike acute AD, the chronic inflammatory response is dominated by a Th1-type response driven by the subsequent infiltration of IL-12–expressing eosinophils, dendritic cells, and macrophages, which follows the initial Th2 response (Fig. 67.1). The mechanism for increased IL-12 expression during chronic AD is not known but may be related to the ability of IL-4 to induce IL-12 expression by eosinophils (189). In the case of dendritic cells and macrophages, microbial superantigens are known to be a potent inducer of IL-12 production (190). IFN-g, but not IL-4, has been correlated with the clinical severity of AD. This may be related to the capacity of IFN-g to enhance eosinophil viability and augment eosinophil activation and cytotoxic activity as well as activation of vascular endothelial molecules, which increase the infiltration of eosinophils and thereby contribute to chronic AD.

Atopic skin inflammation involves both allergen-specific and nonantigen responses that amplify inflammatory responses. This process is reflected in studies demonstrating AD is associated with a lower itch threshold, cutaneous hyperreactivity, and an overly active inflammatory response. Scratching plays a key role in the elicitation of eczematoid skin lesions. Once the itch/scratch cycle is triggered, mechanical trauma to the keratinocytes results in the release of a proinflammatory

cytokine cascade that contributes to the infiltration of cells into the skin.

Finally, studies indicate that AD is associated with defective skin-barrier function. Although these changes may be related to the constant scratching and immune activation that is ongoing, these patients also have decreased ceramide levels in their skin, which may lead to reduced water-binding capacity, higher transepidermal water loss, and decreased water content (191). These changes also contribute to increased antigen absorption by the skin and therefore create a vicious cycle leading to further immune activation and perpetuation of skin inflammation.

Targeting specific cytokines or their receptors represents a potentially unique and specific treatment modality for AD. Anti–IL-5 antibody completely blocks eosinophil infiltration in sensitized animals, whether administered before or after allergen challenge (192). Pilot studies are under way with a humanized monoclonal antibody against IL-5 in patients with asthma, and such an approach could also be considered in AD. Soluble IL-4 receptor molecules can effectively bind IL-4 and suppress IL-4–mediated T- and B-cell functions (193). Preliminary clinical trials with soluble IL-4 receptor in patients with moderate asthma have found it to be safe and effective (194). In patients with AD, soluble IL-4 receptor downregulates allergen-specific lymphocyte function *in vitro* and may prove to be an effective therapeutic agent (195). Development of specific chemokine antagonists may also lead to use in AD. Finally, novel therapies based on an improved understanding of the immunopathogenesis of AD would be expected to result in improved outcomes, especially in recalcitrant disease, and lead to specific, rather than symptomatic therapy. However, much remains to be learned about the complex interrelationship of genetic, environmental, immunologic, and pharmacologic factors in AD before the ultimate goal of prevention can become a reality.

68 ALLERGIC REACTIONS TO FOODS

Dean D. Metcalfe, M.D.

Allergic reactions to foods result from heightened immunologic responses to glycoprotein components in these substances. Children and adults in whom such reactions develop are said to have a *food allergy*, a term synonymous with *food hypersensitivity* (1). *Food intolerance* is defined as an exaggerated or abnormal reaction to a food that has a pharmacologic, toxic, or metabolic basis. Conceptually, food allergy is divided into two subgroups: those reactions that depend on food antigen-specific immunoglobulin E (IgE), and those problems that result from non–IgE-dependent immunologic mechanisms. Most food allergies in adults depend on IgE-mediated mechanisms, whereas in infants and children, there is evidence that a substantial minority have food allergies because of non–IgE-dependent events.

The prevalence of adverse reactions to foods in children younger than 6 years has been stated to be approximately eight in 100 (2). One fourth to one half of these reactions seem to depend on immunologic mechanisms. A prospective study of Danish infants during the first 3 years of life found the prevalence of cow's milk allergy to be 2.4% (3). The prevalence of food allergy in adults may be somewhat less. In a study in the Netherlands based on questionnaires, clinical follow-up, and double-blind, placebo-controlled food challenge, the prevalence of food allergy and intolerance together was 2.4% (4). The prevalence of peanut and tree nut allergy in the United States as determined with a random-digit-dial telephone survey was found to be 1.1% of the general population (5).

It also is clear from general population surveys that a large number of individuals believe they have had allergic reactions to foods. For example, in a study in Great Britain commissioned by the Ministry of Agriculture, Fisheries, and Food, and with the electoral register used as a sampling frame, 15.6% of 18,582 respondents stated that they had allergies to foods, and 7.4% stated that they had allergies to food additives (6). Although the responses to the question about food allergy were not evaluated, the responses to the question about additive reactions were. Patients who believed themselves sensitive to additives were interviewed; and if the reaction was thought possibly to be due to food additives, they underwent placebo-controlled, double-blind challenges with the additives. After this evaluation, which excluded possible reactions to monosodium glutamate or sulfites, the investigators estimated a 0.01% to 0.23% prevalence of food additive intolerance.

FOOD ALLERGENS

The gastrointestinal barrier is exposed to a heterogeneous group of proteins that varies, in part, according to age. For example, infants ingest proteins from fewer sources than do older individuals; their food sources consist of mother's milk or commercial formulas, including those based on bovine milk or soybean proteins. The dietary proteins ingested by older children and adults are derived from meat, poultry, and fish (42.3%); dairy products (21.2%); flour and cereal products (18.6%); dry beans, peas, nuts, and soya products (5.4%); vegetables (6.2%); eggs (4.9%); and fruits and miscellaneous sources (1.4%) (7). Commercially processed proteins used as food ingredients include casein and whey from bovine milk; gelatin and collagen from animal tendons and hides; soy protein isolates from soybeans; and gluten from the flours of wheat, corn, and oats (8).

The sources of dietary proteins are changing in response to the nutritional requirements of progressively larger populations. Newer sources of proteins now include genetically modified foods. Changes in the processing of foods also are having their impact. Chemical modification of foods by ultrafiltration, high-temperature processing, or preservation by irradiation have the potential to create new antigenic sites or to decrease digestibility.

Despite the wide variety of foods ingested, only a relatively few cause allergic reactions. For example, in children, most allergic reactions are due to milk, peanuts, egg, and soybean. In adults, the most common food allergens are peanuts, tree nuts, crustaceans, fish, and eggs. Other foods not infrequently implicated include cereal grains and seeds.

Much has been done to isolate and characterize components of food that are responsible for immunologic reactions. Attempts to isolate relevant antigens have often focused on their ability to bind to an antigen-specific IgE. In early studies, water-soluble food components were evaluated for antigenicity by their ability to induce immediately positive skin tests in individuals with immediate reactions to foods. Later studies have characterized antigens with *in vitro* assay techniques that examine the ability of water-soluble food proteins to bind IgE in serum from these patients, followed by the isolation and determination of the antigenic molecular structure.

Food antigens are almost always proteins or glycoproteins. Molecular masses of these antigens tend to be between 10 and 40 kd. These antigens are often, but not always, resistant to denaturation by heat and to degradation by proteases.

Allergen M (Gad c 1) from codfish has been well studied. Codfish hypersensitivity is common in countries where consumption of this fish is high. Allergen M is a parvalbumin, a calcium-binding protein found in the muscle of fish and amphibians. It has a molecular mass of approximately 12 kd, is heat stable, is partially resistant to proteases, and exists as a single polypeptide chain (9,10). Allergen M consists of 113 amino acids and one glucose molecule. Linear peptides corresponding to regions 13 to 32, 49 to 64, and 88 to 103 have been synthesized and bind IgE from cod-allergic individuals.

A number of other food antigens have been purified (Table 68.1). The major allergen in shrimp is tropomyosin (Pen a 1, Pen i 1, Met e 1) with a molecular mass of 34 to 36 kd. Linear fragments bind tropomyosin-specific IgE (11,12). Tropomyosin is a common allergen also found in lobster, crab, and crawfish.

Allergen	Source	Mol Wt (Da)	Characteristics
Gad c 1	Codfish	12,328	A parvalbumin, chelates calcium
Pen a 1, Pen i 1, Met e 1	Shrimp	34,000–36,000	A tropomyosin
Ara h 1	Peanut	63,500	
Ara h 2	Peanut	17,000	
Ara h 3	Peanut	14,000	
Ory s 1	Rice	14,764	α-amylase inhibito
Gal d 1	Egg	28,000	Ovomucoid
Gal d 2	Egg	45,000	Ovalbumin
Gal d 3	Egg	77,700	Ovotransferrin
Gal d 4	Egg	14,300	Lysozyme

TABLE 68.1. Examples of Water-Soluble Food Antigens

Peanuts are highly allergenic. Three main peanut allergens (Ara h 1, Ara h 2, Ara h 3) account for much of this legume's allergenicity (13,14). Peanut products such as flours retain their allergenicity, although highly refined peanut oil appears generally safe (15). Soybeans are similarly a major crop of the legume family. At least in one instance, an allergic reaction to soybeans was traced to a reaction to Kunitz soybean trypsin inhibitor (16). Similarly, the rice major allergenic protein has been isolated from a complementary DNA (cDNA) library of maturing rice seeds (17). The cDNA had an open reading frame of 486 nucleotides that coded a 162-amino acid residue

polypeptide. The deduced amino acid sequence of the rice major allergenic protein was similar to those of barley trypsin inhibitor and wheat a-amylase inhibitor.

In addition to identifying and isolating specific proteins with allergenic activity, many studies have examined major proteins or protein fractions for their allergenic activity when available. Such is the case for milk. For milk, casein, a-lactalbumin, b-lactoglobulin, and bovine serum albumin produce the highest rates of skin-test reactivity in children with milk allergy (18). In oral challenge studies of 45 children, 62% reacted to b-lactoglobulin, 60% to casein, 53% to a-lactalbumin, and 52% to bovine serum albumin (19). Studies indicate that children who are allergic to cow's milk are also frequently allergic to goat's milk (20).

Chicken egg is a common food allergen, particularly in children. The yolk is often less allergenic than the white. Ovomucoid (Gal d 1) constitutes 10% of the egg-white protein and is the dominant allergen. Other major allergens are ovalbumin (Gal d 2; 50% of egg white), ovotransferrin (Gal d 3), and lysozyme (Gal d 4) (21,22,23,24 and 25).

IgE-MEDIATED REACTIONS

A number of reactions involving multiple target organs are caused by IgE-mediated immediate adverse reactions to food antigens. These reactions include hives, atopic dermatitis, angioedema, gastrointestinal reactions, asthma, the oral allergy syndrome (26) (see later) anaphylaxis, and allergic eosinophilic gastroenteritis. These patterns of food allergies share a common pathogenesis, are evaluated with similar testing procedures, and in general are managed with related treatment approaches.

Pathogenesis

Clinical and experimental observations support a role for mast cells, basophils, and IgE in immediate reactions to foods. The presence on mast cell surfaces of IgE that reacts with food antigens has been demonstrated by immediate wheal-and-erythema reactions in the skin after local injection of minute amounts of food antigen (27). Such reactions have been passively transferred by intracutaneous injection of serum from an allergic donor into the skin of a normal recipient, followed 24 hours later by local injection into the recipient of the food antigen to which the donor was sensitive (Prausnitz-Küstner test). This test, useful for demonstrating the passive transfer of a sensitizing agent in the serum, was discovered when the serum of Küstner, who was allergic to fish, was injected into Prausnitz, and a positive response was elicited on local challenge with fish antigen (28). Similar local reactions have been reported when the food antigen was administered orally to the normal recipient 24 hours after injection of allergic donor serum into the skin (29).

Food antigen–specific IgE has been demonstrated indirectly to lead to degranulation of mast cells in the gastrointestinal tract. Local mucosal reactions reminiscent of those that follow mast cell degranulation in human skin have been reported *in vitro* after passive sensitization of human ileum and colonic mucosa (30). Local reaction after passive sensitization could be induced by ingestion or by direct application of the antigen. Human mucosal mast cells have been reported to degranulate *in vitro* in IgE-dependent reactions (31).

Mast cells exert their effects on surrounding tissues during allergic reactions by the generation, synthesis, and release of potent chemical mediators (32). Mediator release, or degranulation, is triggered by a variety of stimuli. These diverse stimuli may be endogenous substances, such as neuropeptides; or they may be exogenous substances to which mast cells become exposed *in vivo*, such as antigens. Although food antigen–specific IgE appears to be responsible for the induction of immediate food reactions, other stimuli including anaphylatoxins may play a role in delayed reactions.

Mast cells in the mucosa of the gastrointestinal tract are uniquely positioned to affect reactions to substances presented orally. Small quantities of luminal proteins may gain access to the mucosa. If IgE antibody specific to such substances is on the surface of mucosal mast cells, mast cell activation and mediator production result. This local intestinal anaphylaxis increases mucosal permeability and the entry of a food antigen into the body, where it may be distributed to other target organs and initiate degranulation of mast cells at those sites. The gastrointestinal tract, by virtue of food processing, also is in a position to alter the timing of such reactions. Thus antigenic sites on food antigens may be unmasked or degraded as food is digested.

The ability of some individuals but not others to limit or prevent the synthesis of food-specific IgE appears to be largely genetically determined. There is some ingress of intact antigen in the normal state. Consequently, there is no requirement for an alteration in mucosal permeability as the underlying defect in the genesis of IgE-mediated food allergy. This conclusion is consistent with clinical data that have failed to demonstrate defects in IgA synthesis, to find gastrointestinal disease including achlorhydria, or to generate evidence of immune complex diseases in patients with immediate reactions to foods. The most reliable clinical correlates of immediate reactions to foods are a family and personal history of atopy and the presence of positive skin tests to foods and inhalants, strongly suggesting that the basis of the production of IgE in response to foods is related to inherited patterns of IgE synthesis and regulation. Food allergy is not necessarily associated with the overproduction of IgE. Patients with food allergy mediated by IgE may not give a family history of adverse reactions to specific foods, suggesting that multiple factors contribute to the development of IgE directed to food antigens.

Clinical Patterns of Target-Organ Responses

Foods are generally implicated as the etiologic agents of immediate reactions to foods because of a clear temporal relation between eating and induction of symptoms. However, in any discussion of food antigen–induced reactions, a number of alternative conditions and diseases must be considered (Table 68.2). These alternative diagnoses represent diseases exacerbated by the process of ingestion; those caused by intrinsic pharmacologic agents, additives, and contaminants in foods; and those due to infectious organisms and their products.

TABLE 68.2. Differential Diagnosis of Immunologically Mediated Reactions to Foods

The clinical expression of immediate reactions logically follows the sequence in which target tissues are exposed to the food antigen that is the etiologic agent. Oropharyngeal reactions are often observed first and are characterized by pruritus and urticaria in and around the mouth. Uvular edema also may be present. Rarely does the initial exposure to antigen result in obstructed airflow. Such reactions are transient and are not necessarily followed by other allergic manifestations.

This development of oropharyngeal symptoms with food ingestion is sometimes referred to as the oral allergy syndrome, especially when it occurs in the absence of systemic reactions. In such cases, it is most commonly due to fruits or vegetables. Symptoms include pruritus, tingling, and angioedema of the lips. Throat tightness, facial flushing, oral mucosal blebs, and hoarseness have been reported. As with other immediate reactions, symptoms occur within minutes after exposure to the provoking foods. The entry of the offending food into the stomach and subsequently into the intestine may result in nausea, cramping pain, abdominal distention, vomiting, flatulence, and diarrhea. In children, gastrointestinal manifestations of immediate food reactions are common and may be the only problem noted. In adults, isolated gastrointestinal complaints caused by immediate adverse reactions to foods are less common. In one study of 27 patients with irritable bowel syndrome who suspected foods as being the cause of their symptoms, only three patients had their complaints reproduced by food challenge (33).

Food allergy also may be expressed in one or more extraintestinal target tissues. The basis of the preferential reactivity of one system over another is unknown. The skin is a common target organ in food allergy. Skin reactions are evidenced by acute urticaria or angioedema and much less frequently by chronic urticaria. In one report of 554 patients with urticaria, food allergy was demonstrated in only 1.4% (34). When the acute urticaria is due to foods, in most situations, it is not a diagnostic problem, as the symptoms usually occur shortly after eating the food, and the patient is aware of which food caused the symptoms.

Food reactions that include asthma have been verified by oral challenge with suspected foods. The frequency of reactions that include asthma is unknown but seems to be low (35). Although hay fever and asthma are frequently suspected to be caused by foods, they appear less frequently than do gastrointestinal symptoms and

rarely occur without other organ involvement (36,37).

Systemic anaphylaxis as a result of allergy to ingested foods generally occurs within minutes, but occasionally has been reported to occur hours after ingestion of the offending food (38). The first anaphylactic episode may be unexpected or may have been preceded by minor symptoms such as abdominal discomfort or urticaria on previous exposure to the food. Systemic anaphylaxis involves multiple target organs, as evidenced by abdominal pain, nausea, emesis, diarrhea, dyspnea, cyanosis, chest pain, urticaria, angioedema, arrhythmias, hypotension, and shock. These severe, life-threatening reactions are most often associated with the ingestion of peanuts, tree nuts, fish, and shellfish. Fatal reactions may develop quickly or begin with mild symptoms and progress over a 1- to 3-hour period to cardiorespiratory arrest and shock. Factors that predispose to anaphylaxis include a personal history of atopy, a family history of atopy, and dietary exposure. Atopic patients have an increased risk of developing food allergies if they have asthma and allergic rhinitis (39). Food allergy is the single most common cause of anaphylaxis seen in hospital emergency departments (40).

In addition to foods, other factors such as exercise may be necessary to provoke the reaction. Anaphylaxis has been reported in persons exercising within 3 to 4 hours after the ingestion of certain foods such as shrimp, wheat, milk, fish, and celery (41,42 and 43). Attacks are precipitated by various types of strenuous exercise, including running, fast walking, tennis, and dancing (44). In some patients, attacks are associated with meals, but no foods specifically can be implicated. The general assumption is that anaphylaxis that occurs during exercise and after meals is associated with increased antigen absorption.

Atopic Dermatitis

Atopic dermatitis is an inflammatory condition or state of the skin, seen as a small, round patch as in nummular eczema or as a widespread eruption involving large areas of the body. Atopic dermatitis can be acute (with erythema, edema, and weeping) or chronic (with scaling, thickening, and hyperpigmentation). The chronicity of atopic dermatitis distinguishes it from immediate and self-limited immediate reactions as described earlier. Atopic dermatitis is frequently associated with hay fever and asthma. In fact, bronchial hyperreactivity with or without asthma is more frequent in patients with atopic dermatitis (45). The prevalence of atopic dermatitis is estimated to be 10% to 12% of the pediatric population (46). A complete review of atopic dermatitis appears in Chapter 67.

A number of studies have examined the role of foods in the pathogenesis of atopic dermatitis and have concluded that food hypersensitivity contributes to skin symptoms in children in at least one third of the cases (47); and that the more severe the dermatitis, the greater the possibility that food allergy is playing a role (48). In one classic study of 26 children, 16 had positive blind challenges (49). Positive responses included pruritus, erythematous macular or maculopapular rashes, nausea, abdominal pain, vomiting, diarrhea, nasal congestion, rhinorrhea, sneezing, and mild wheezing. All symptoms developed 10 minutes to 2 hours after challenge. Foods producing positive challenges were egg, milk, peanut, wheat, soy, chicken, fish, chocolate, potato, and rye. Complete removal of the incriminated foods resulted in significant improvement of the dermatitis.

Atopic dermatitis is associated with elevated serum IgE levels. In some instances in which challenge with food allergen provokes the disease, a concomitant increase in plasma histamine levels has been documented (50). These observations and positive skin tests to provocative foods strongly implicate IgE-mediated mast cell activation in the skin. The reaction is not self-limited, as in food-induced urticaria, but results in chronic dermatologic changes. The frequent findings of peripheral blood eosinophilia, elevated serum eosinophil cationic protein levels after food challenge (51), and the dermal deposition of eosinophil granule major basic protein (MBP) suggest that the recruitment of eosinophils to the skin may contribute to the pathologic changes (52). The involvement of eosinophils indicates that the pathogenic mechanism in the dermis in atopic eczema is similar to that for IgE-mediated late phase reactions. Surface-bound IgE also is found on Langerhans cells in biopsy specimens (53). In addition to IgE-dependent dermal mast cell activation, patients with atopic dermatitis exhibit a high “spontaneous basophil histamine release,” possibly due to release of a “histamine-releasing factor” from immune peripheral monocytes (54).

Eczematous lesions in patients with atopic dermatitis also are infiltrated with T cells, most of which synthesize interleukin (IL)-4 and IL-5. These infiltrating T cells are enriched for cutaneous lymphocyte antigen (CLA)-positive cells. In contrast, T cells from the lungs of patients with asthma are CLA negative (55).

An intestinal mucosal defect independent of food reactions is suggested by studies with polyethylene glycol. High-molecular-mass polyethylene glycol (4 kd) was absorbed in patients with eczema to a greater extent than in normal individuals. Low-molecular-mass polyethylene glycol (0.6 kd) was absorbed equally (56).

Allergic Eosinophilic Gastroenterocolitis

Eosinophilic gastroenterocolitis (57) is an uncommon chronic digestive disease characterized by peripheral eosinophilia and by edema and eosinophilic infiltration of the stomach or, to a lesser extent, the small and large intestines (58). It is seen most frequently during the third decade of life (59), although this disease develops also in children (60). Clinical symptoms are related to the extent of eosinophilic infiltration in the bowel wall. When the eosinophilic infiltration is in the mucosa, symptoms correspond to those of malabsorption. If the infiltration is predominantly in the muscular layer, the clinical picture is that of obstruction. Significant eosinophilic infiltration of the serosa is characterized by a clinical picture of ascites. These pathologic findings may occur singly or in combination. Thus when the eosinophilic infiltration is limited to the esophagus and disease manifestations reflect this pathology, the disease is referred to as allergic eosinophilic esophagitis. Similarly, when the disease is limited to the stomach, it may be referred to as allergic eosinophilic gastritis (57).

Many patients with the mucosal pattern of this disease complain of abdominal symptoms that are brought on or are aggravated by the ingestion of specific foods. These patients often are atopic, have an elevated serum IgE level, and have specific IgE antibodies to multiple food antigens (58,61). Taken together, these clinical and laboratory findings support the thesis that allergic mucosal diseases are due to severe food allergies, leading to repeated immediate and late phase immediate hypersensitivity reactions in the mucosa. This construct is supported by the finding that patients with this disease have T cells that produce abnormally high amounts of IL-4 and IL-5 after mitogenic stimulation (62). In fact, lymphocytes in some patients produced IL-5 in the absence of mitogen. In contrast, interferon-g (IFN-g) messenger RNA (mRNA) could not be detected by the reverse transcription (RT) polymerase chain reaction (PCR) in biopsy specimens from patients with allergic eosinophilic gastroenteritis but was present in those from normal individuals.

Diagnostic Tests

The diagnosis of an immediate IgE-mediated reaction to a food depends on the history, an appropriate exclusion diet, selective skin tests or antigen-specific IgE *in vitro* tests, and blinded provocation. There is no convincing evidence that measurement of food-specific IgG or IgG4 antibody levels or of food antigen/antibody complexes has diagnostic value in the evaluation of immediate reactions to foods.

IN VITRO *TESTS*

Laboratory procedures supporting the clinical diagnosis of an IgE-mediated food hypersensitivity depend on the identification of antigen-specific IgE in serum to water-soluble food allergen extracts. Examples of such tests are *in vitro* measurements of antigen-specific IgE, as in the radioallergosorbent test (RAST) or enzyme-linked immunosorbent assay (ELISA), and basophil histamine release. Laboratory tests such as total IgE determinations and eosinophil counts do not correlate with immediate hypersensitivity reactions to foods.

The RAST, an *in vitro* test, is generally considered somewhat less sensitive than skin testing (63). Although there have been modifications of the RAST, all involve antigens coupled to a solid phase (e.g., paper disk). Patient sera are incubated with the solid phase. After washing, the amount of bound IgE antibody is calculated by adding labeled antihuman IgE antibodies. The ELISA is a variation on this method. Depending on the available antibody sites, such tests may be more subject to inhibition by antigen-specific IgG.

Basophil degranulation tests also may be used to evaluate allergic reactions to foods. For this test, heparinized venous blood or separated blood leukocytes are incubated with extracts of suspected foods. Histamine is released into the supernatant fluid and is measured as an index of reactivity and the amount of antigen-specific IgE on the basophil surface that interacts with allergens within the food extract. The outcome of the basophil degranulation test is generally comparable to that of the RAST.

IN VIVO *TESTS*

Skin testing with food extracts consists of the application of extracts to the dermis. It is the most reliable method to demonstrate food allergen–specific IgE antibodies. The usual method is the puncture or prick skin test, in which a drop of food extract is placed on the skin. The skin is then punctured through the drop with a sterile needle. Extracts of testing are usually supplied as 1:20 (wt/vol) extract in 50% glycerine. Skin testing with 1:1,000 (wt/vol) extracts may be performed by the intradermal technique. Intradermal tests, however, are more likely to produce clinically irrelevant positive results (64) and are associated with a higher frequency of systemic reactions that, in rare instances, have been fatal. Allergic reactions to foods are unusual in the face of negative skin tests (false negatives). Food extracts, including peanuts, tree nuts, egg, milk, soy, and fish, induce reactions that correlate reliably with allergic manifestations.

Patients should never be advised that they are allergic to certain foods solely on the basis of positive skin tests, because skin tests may be positive to foods in the absence of symptomatic food allergy (false-positive tests). In cases of the oral allergy syndrome, the use of extracts of fresh fruits and vegetables is often necessary to exclude IgE-mediated food hypersensitivity. Patients with allergic eosinophilic gastroenterocolitis have as many as 15 to 25 positive skin tests to various foods. Skin testing is not feasible or recommended in some clinical situations. Thus, in patients with extensive skin disease or significant and prolonged dermographism, or in patients in whom exposure to minute quantities of a specific food resulted in a life-threatening reaction, *in vitro* diagnostics are used to demonstrate food allergen–specific IgE.

ORAL CHALLENGE

Double-blind, placebo-controlled food challenge is the diagnostic procedure by which other diagnostic approaches are measured (65). Such testing is used in difficult cases in children and adults (66). Before these challenges, suspected foods should be eliminated for 10 to 14 days. Antihistamines are discontinued long enough to establish a normal histamine skin test. Other medications are minimized to levels sufficient to prevent breakthrough of acute symptoms. The food challenge is administered in a fasting state, starting with a dose unlikely to provoke symptoms. The dose is then doubled every 30 to 60 minutes or more, depending on the type of reaction suspected and the length of time required to produce symptoms. If the patient has tolerated 10 g lyophilized food blinded in capsules or liquid, clinical reactivity is generally ruled out. If the blinded challenge is negative, the food must be given openly in usual quantities under observation to rule out the rare false-negative challenge. To control for a variety of confounding factors, an equal number of placebo and food-antigen challenges are necessary, and the order of administration should be randomized. Double-blind, placebo-controlled food challenges should be conducted in a clinic or hospital setting, especially if an IgE-mediated reaction is suspected; furthermore, they should be done only if trained personnel and equipment for treating systemic anaphylaxis are present, and only with informed consent.

Treatment

Strict elimination of offending foods is the one proven therapy for immediate reactions to foods. However, severe elimination diets may lead to malnutrition or eating disorders (or both) and must be instituted with nutritional guidance. Patients must be instructed on how to read and understand food labels to detect hidden food allergens. Clinical reactivity to food allergens is generally specific. Patients may react to more than one member of a botanic family or animal species. No appropriately designed trial has demonstrated clear efficacy for the use of prophylactic medications or injection immunotherapy for preventing allergic reactions to foods.

Patients sometimes inadvertently consume food to which they are sensitive. Treatment for a specific symptom that results from inadvertent exposure is the same as that used when other factors provoke symptoms. Laryngeal or pulmonary symptoms after an inadvertent food exposure should be treated immediately with epinephrine, bronchodilator therapy, or both. The treatment of food-induced anaphylaxis is essentially the same as that for anaphylaxis due to a medication or insect sting (67). A patient with potential anaphylactic reactivity must be taught how to self-administer epinephrine and must have an epinephrine-containing syringe and an antihistamine available at all times. For children, day-care centers and schools should have a plan of action including a list of emergency numbers with backups to be called. Patients may exhibit only mild symptoms during the first few minutes after ingesting a food to which they are allergic, but this reaction may be followed 10 to 60 minutes later by hypotension and other severe problems. After self-medication for systemic reactions, the patient should immediately seek medical attention. All patients with IgE-mediated food allergy should be warned about the possibility of developing a severe anaphylactic reaction and should be educated in the treatment measures to be instituted in case of an accidental ingestion.

For those with atopic dermatitis, when exacerbation has been documented to food allergens, those foods should be eliminated from the diet. Symptomatic control of pruritus may be attempted with antihistamines. In severe cases, a brief application of topical glucocorticoid to control a flare of the disease may be warranted. When an infection is suspected, an antistaphylococcal antibiotic may be prescribed. Other general measures include avoidance of irritants such as soaps, wools, and trauma (e.g., that due to scratching). Maintenance of skin hydration is an important component of therapy.

Treatment of allergic eosinophilic gastroenterocolitis is often unsatisfactory. History and skin testing or *in vitro* measurements of food antigen-specific IgE may identify food allergens for a trial of elimination. A trial diet that eliminates multiple food antigens from the diet may be performed when no clear evidence of IgE-mediated hypersensitivity is found. In patients with eosinophilic gastroenteritis and food sensitivity, the number of foods involved may preclude the long-term use of an elimination diet for symptom control. Patients who respond poorly to dietary restrictions and those without evidence of food hypersensitivity may require oral glucocorticoid therapy with prednisone. Although this measure usually results in clinical improvement, the need for long-term glucocorticoid therapy is variable. As evidenced by improvement of clinical symptoms and resolution of the histologic abnormalities, prednisone may be tapered to an every-other-day regimen (58).

NON–IgE-MEDIATED REACTIONS

Dietary Protein Enterocolitis

Dietary protein enterocolitis is a disease of infants and children (57). It is diagnosed by documenting changes in the structure of the intestinal mucosa that occur in response to the ingestion of particular foods. These changes are transient and resolve with time, presumably because of maturation of the gastrointestinal and immune systems. Transient enteropathies have been associated with cow's milk, soy protein, fish, rice, chicken, and egg, as summarized elsewhere (68,69).

The pathogenesis of food protein–induced enteropathy is unknown. Because it is a disease of infants and resolves with age, it is assumed to be due in part to the immaturity of the gastrointestinal and immune systems. In some instances, food protein–induced enteropathy follows episodes of acute gastroenteritis, a condition that facilitates uptake of intact antigen. It is possible that the increased uptake of food protein due to the immaturity of the mucosal barrier and exacerbated by infections is the initial pathogenic feature. Multiple immune responses are then provoked, including recruitment of T cells secreting tumor necrosis factor-a (TNF-a) (70), and damage to the intestinal mucosa results.

A role for antibodies in the pathogenesis of mild protein-induced enteropathy has not been clearly demonstrated. During the neonatal period, circulating antibodies to cow's milk protein are virtually absent. However, by age 2 years, 95% of formula-fed infants have specific antibodies, primarily IgA and IgG. The presence of such antibodies provides evidence only of milk consumption and is not diagnostic of milk allergy. The serum IgE level is often normal in patients with cow's milk gastroenteropathy (71).

The most common cause of food protein–induced enteropathy is cow's milk. Clinically, in patients with cow's milk–induced enteropathy, chronic diarrhea and malabsorption may develop, typically associated with mucosal changes. At least 30% of the affected infants have a family history of some form of allergy. The mean onset of the milk-induced malabsorption syndrome is approximately 1 month after the introduction of cow's milk into the diet (68). Symptoms, typically vomiting and diarrhea, occur with either acute or gradual onset. It may be difficult to distinguish this illness from acute gastroenteritis in cases of acute onset. The presence of blood in the stool is indicative of milk protein colitis (72).

The intestinal villous structure is virtually normal if gastrointestinal symptoms are mild. Patients who are diagnosed and treated early typically show normal jejunal histology of partial villous atrophy. With active disease, marked changes consisting of increased numbers of lymphocytes, plasma cells, eosinophils, and neutrophils are seen in the mucosa and between the epithelial cells. The distribution and severity of associated lesions can vary substantially. Some infants have severe damage to the jejunum without involving the colon; in other cases, damage occurs predominantly in the colon (72). When cow's milk in eliminated from the diet, the prognosis is good for patients with gastrointestinal symptoms. Most patients become milk tolerant by age 2 years (73).

The treatment of food-induced enteropathy depends on the removal of milk or other sensitizing protein from the infant's or child's diet. An elemental formula or formulation or even a period of total parenteral nutrition may be required to allow repair and return of normal gastrointestinal function. Because this disease often resolves with time, reintroduction of the offending protein may eventually be attempted.

Other Food-induced Reactions

Vasoactive substances in food (e.g., caffeine, histamine, ethanol, nitrites) have been implicated in the onset of migraine headaches. Most studies have failed to associate migraine headaches with immunologically mediated adverse reactions to foods. This area remains controversial. One double-blind, placebo-controlled study implicated specific food-induced symptoms in 15% of 104 adults with migraine headaches (74).

Allergic reactions to foods have been implicated in some cases of sudden infant death syndrome (SIDS). Elevated serum tryptase levels were found in 40% of 50 infants who had died of SIDS. Fifteen of 38 had b-lactoglobulin–specific IgE compared with one of nine normal subjects (75). Similarly, another study found elevated serum mast cell tryptase levels in infants dying of SIDS compared with others dying unexpectedly of causes later explained; this finding suggests anaphylaxis around the time of death (76).

NATURAL HISTORY OF FOOD ALLERGIES

Food allergies in general cannot be prevented. However, food hypersensitivity reactions in infants may be delayed and in some cases avoided by breast-feeding. Many infants eventually become tolerant to the foods provoking reactions. In prospective studies of adverse food reactions in infants, 80% to 87% of confirmed symptoms were no longer present by age 3 years (2). In addition to infants, older children (77,78) and even some adults (79) lose their sensitivity if the responsible food allergen is identified and completely eliminated from the diet; after 1 to 2 years of allergen avoidance, as many as one third of children and adults lose their clinical sensitivity (78,79 and 80). Loss of sensitivity correlates with allergen avoidance, but skin-prick test and RAST may remain positive and do not allow prediction of which individuals will lose clinical reactivity to specific foods. Patients with an allergy to peanut, tree nut, fish, or shellfish rarely lose their clinical reactivity (78,80,81).

GENETIC MODIFICATION OF FOODS

The identification of Brazil-nut allergen in transgenic soybean (82) and the subsequent decision not to market this product have paralleled efforts to develop rational approaches to prevent or limit the spread of food allergens. This effort is occurring when it has become technically possible to alter the genetic composition of foods derived from both plant and animal sources to increase yield, to provide pesticide or drought resistance, or to alter the composition of the food to decrease allergenicity or to improve its nutritional value.

At least four technical approaches may be used to determine if a modified food may be or is enhanced in its allergenic potential (82,83,84,85 and 86). First, the amino acid sequence coded for by a transferred gene may be determined. A search is then performed to identify similarity to known allergens from both plant- and animal-derived foods; inhalant allergens such as pollens and fungal spores; insect venoms; and allergens that provoke immediate contact reactions. Because the optimal peptide length for binding appears to be between eight and 12 amino acids for T-cell epitopes and even longer for B-cell epitopes, some have suggested that the sequence identity requires a match of at least eight contiguous identical amino acids. There are significant limitations to this molecular approach. For example, not all food allergens have been sequenced, and this strategy does not identify conformational or noncontiguous epitopes. As a second approach, when a gene is transferred from a known allergenic food or an allergenic food of concern, a determination may be made about whether serum from individuals sensitive to the food of origin contains allergen-specific IgE that will bind with the gene product. These assays are usually performed as solid-phase immunoassays, such as the RAST or RAST inhibition assays or the ELISA. If the gene transferred is derived from a source in which there is no general history of its use in the population and thus its allergenic potential cannot be assessed, a third approach, stability to digestion, may be used. As a general principle, food allergens appear to be relatively resistant to acids and proteases. It has thus been argued that stability of food allergens to digestion may be used to help identify the products of transferred genes as to their possible allergenicity (87). However, insufficient information is available on possible differences in susceptibility to acid denaturation and susceptibility to proteases among various allergenic food proteins and with proteins that possess weak or no allergenic potential to use this test in any way other than as a relative indication of allergenic potential (88). Finally, the use of animal models in the determination of food-protein allergenicity also may be considered. Such an approach would help identify whether a gene product is allergenic in the absence of a history of exposure to that protein in the general population. A screening test to determine the allergenic potential of a modified food with an animal model also would help to address the question as to whether the genetic manipulation led to the expression or upregulation of an allergen in the recipient organism. It is possible to make animals of various species allergic to specific proteins, usually by injecting them intraperitoneally with the protein in an adjuvant. The most commonly applied mouse model of asthma uses ovalbumin as its antigen, which is administered intraperitoneally in alum. The difficulty arises in using sensitization by this means as a test for allergenicity, because both allergenic and nonallergenic proteins applied in this manner may provoke antigen-specific IgE. Indeed, it may be too much to expect any one animal model to predict allergenicity in humans to a specific food. However, it may be reasonable to expect (with careful selection of the study animal, the route, and the frequency of administration of the antigen) that an animal model might be developed that provides some ranking of allergenicity.

SUMMARY AND CONCLUSIONS

Adverse reactions to foods can be either immediate or delayed. Immediate reactions to foods seem to be due to the production of food-specific IgE in some predisposed individuals. Interactions between food antigen and specific IgE leads to a pathologic process mediated by mast cells and basophils. The food antigens involved are those more likely to survive the process of digestion by virtue of their intrinsic properties. Delayed reactions to food are more diverse in their expression and in the biologic mechanisms involved.

It is perhaps surprising that adverse reactions to foods are not more frequent. Survival depends on food ingestion, which is a continual process. Mechanisms to regulate digestion and immune responses are complex and interrelated. For these reasons, the belief that many more diseases might be related to, or influenced by, adverse responses to foods has long been attractive. The search for such associations should continue, with sufficient scientific skepticism to ensure that valid observations result.

In all probability, the number of adverse reactions to foods will increase with time. Much of the increase will be directly related to two factors: the need to feed a growing population with protein from increasingly diverse sources, and the development of new biologic techniques to process, preserve, and alter foodstuffs. In the first case, potential reactors are simply exposed to more antigens to which they may respond. In the second instance, new antigens are created that are capable of eliciting adverse reactions. The potential for a real increase in the number of adverse reactions to foods is accompanied by an increasing public awareness of the reality that reactions to foods do occur. These factors will undoubtedly combine to heighten scientific interest in reactions to foods.

69 INSECT VENOM ALLERGY

Martin D. Valentine, M.D.

Warm breeze aloft,
Bees in nectar buzz. Does this
foretell my next sting?
A Poet
Hot day.
Step on a bee, you may get stung.
You expected maybe honey?
A Cynic

A small proportion of individuals who are stung by members of the order Hymenoptera have not only local irritation but also varying degrees of the signs and symptoms of acute, generalized anaphylaxis. This chapter is devoted primarily to a review of the evolution of our understanding of the anaphylactic response to insect stings: its diagnosis, treatment, and prevention. Inhalant allergy to the detritus of other insects and insectlike arthropods (cockroach, midge, and house-dust mite) is covered in Chapter 61.

TAXONOMY

The phylum Arthropoda includes creatures with segmented bodies and jointed appendages. It is divided into a number of classes, among which is the class Insecta, which includes bugs, beetles, butterflies, and the order Hymenoptera. The only insects that have a true stinger are the Hymenoptera; and because the stinger is a modified ovipositor, only the female can sting.

The family Vespidae of the order Hymenoptera includes a variety of socially organized insects that make paper nests constructed from wood fiber, chewed until pulpy; they are referred to as hornets or wasps. There are three important genera of vespid insects. The genus *Vespula* includes the ground-nesting yellow jackets and the aerial New World hornets, which construct large globular nests found suspended from the branches of shrubs or trees. Wasps of the genus *Polistes* also construct suspended paper nests; but because they do not enclose the nest in a paper sheath, the hexagonal cells where eggs are laid and the young develop are in plain sight. The genus *Vespa* comprises the Old World hornets, which are common in North America.

The family Apidae includes the honeybee *Apis mellifera*, which was introduced from Europe and is represented by several races of a single species. The African “killer” bee represents an aggressive race introduced to Latin America in an attempt to breed bees with superior honey-producing qualities. Bumblebees (genus *Bombus*) are closely related to honeybees and have been reported to cause allergic sting reactions, as have their more distant relatives, the sweat bees (family Halictidae).

In North America, allergic reactions to Hymenoptera stings are usually due to the honeybee (family Apidae), yellow jacket, yellow hornet, bald-faced hornet (genus *Vespula*), and paper wasp (genus *Polistes*). In the South, such reactions are also caused by the imported fire ants (genus *Solenopsis*), which have true stingers in addition to the mandibles used to grasp and pivot on the victim.

Honeybees, if held individually, expel a droplet of venom when the abdomen is placed in apposition to a suitable surface. The solids that remain after evaporation of the volatile portion of the venom weigh, on average, 50 µg per droplet and appear to represent the entire contents of the venom apparatus of the honeybee, which, under more natural circumstances, stings only once in its life. The honeybee's barbed stinger resists easy removal and usually remains behind as the bee flies away, resulting in fatal exenteration for the bee. Vespids do not generally leave their stingers behind and may sting several times in rapid succession. It has been estimated that a vespid sting delivers 2 to 20 µg of venom protein (1).

VENOM CONSTITUENTS

The term *venom* implies the presence of constituents with toxic properties. Hymenoptera venoms are inherently toxic to other members of the same species and to other small creatures, and they serve as a defense against individual or territorial depredation. The omnivorous Vespidae also use the venom in their stings to immobilize and capture live prey, on which they may feed. Honeybees subsist on pollen and nectar and thus sting only in defense, which perhaps accounts for the apparent qualitative differences between honeybee venom and other venoms. Pollen proteins are not present in honeybee venom, although they do appear in honey. Of the Hymenoptera venoms, that of the honeybee has been studied most extensively. Habermann (2) reviewed this subject and enumerated various constituents. Low-molecular-weight vasoactive substances in honeybee venoms include a significant amount of histamine, which also is present in vespid venoms. Honeybee venom contains three major allergenic enzymes, which functionally are phospholipase A_2, a hyaluronidase, and an acid phosphatase (3,4 and 5). Melittin, another polypeptide in honeybee venom, possesses detergent activity; a small polypeptide called apamin has neurotoxic properties. Honeybee phospholipase A_2 is immunologically distinct from enzymes with phospholipase A activity from other sources.

The major vespid venom allergens include a nonenzymatic protein designated antigen 5, as well as proteins with phospholipase A and hyaluronidase functional activity; these constituents have physical and immunologic properties that are different from those of the honeybee venom allergens (4,6,7). It has been shown, however, that there is a low-grade cross-reactivity between yellow jacket and honeybee venoms in a few unusual patients (8,9). The various vespid venoms, in contrast, have a high degree of cross-reactivity and contain essentially the same allergens (3,6,7,10,11). The yellow jacket and hornet venoms are so closely related that 95% of vespid-allergic patients have positive skin tests to all three of the common skin-test preparations: yellow jacket, yellow hornet, and white-faced hornet venoms. *Polistes* wasps are more distantly related to the other vespids, and only 50% of yellow jacket–allergic patients have positive skin tests to wasp venom (12,13).

Although it is now widely accepted that Hymenoptera venoms are the materials to be used for the diagnosis and therapy of insect sting allergy, this has been the case only since 1979. From the early part of the twentieth century, the allergic sensitivity to stings was thought to be directed against an “intrinsic bee protein” present in the insects' bodies and venoms. Benson and Semenov (14) studied a beekeeper who manifested allergy both to stings and to inhalation of material in the air around bee colonies. This patient had become sensitized to venom and developed anaphylaxis when he was stung. He also displayed symptoms of asthma on inhaling the bee body dust, which was stirred up when he worked around beehives. Skin testing this patient gave positive results with both venom and whole-body extracts (WBEs). Some years later, studies with antisera raised in animals showed one or more antigens common to venom and body extracts and antigens common to several Hymenoptera (15,16). These studies notwithstanding, only venoms, not WBEs, can distinguish patients with anaphylactic sting reactions from normal individuals by skin tests (17,18) or *in vitro* tests for specific immunoglobulin E (IgE) antibodies such as the radioallergosorbent test (RAST) (19,20) and leukocyte histamine release (12,21,21a). Some investigators have proposed a live sting challenge before prescribing immunotherapy to assess risk of future reactions (22). WBE preparations retain negligible quantities of biologically active venom antigens (23,24). Most important, WBE is ineffective for preventing allergic sting reactions, and many treatment failures, even deaths, have been reported (23,25). However, WBE of imported fire ants is still used for diagnosis and treatment of this common sensitivity, as it contains most of the relevant allergens (26,27 and 28).

MANIFESTATIONS OF SYSTEMIC REACTIONS

The terminology describing systemic allergic reactions to insect stings may vary, but the events themselves seem fairly straightforward. Although it is simpler to regard reactions as either systemic or local, there is a continuum ranging from the least local response to the ultimate systemic response, death. All the responses that occur fairly promptly after a sting can be explained in terms of our current knowledge of the nature of IgE-mediated reactions: They seem to result from increased vascular permeability, smooth muscle contraction, a vasodepressor effect, or a combination of these manifestations (29). These effects result from the release or production of chemical mediators of anaphylaxis by the mechanisms outlined in Chapter 24. When death occurs, it may be the result of irreversible hypotension, asphyxiation secondary to laryngeal edema, or severe bronchospasm.

The variability of the allergic response to insect stings is not well understood. Many patients give a history of predictable large local reactions to stings. Others have had systemic symptoms on some occasions and local reactions on others. Furthermore, it has been observed that 35% to 60% of sting-allergic patients fail to react when deliberately challenged, even though they may react to subsequent stings (22,30,31,32,33 and 34). This observation is reminiscent of the situations in penicillin allergy and food allergy, in which only half of skin test–positive patients react to a provocative challenge (34,35). Although it is widely believed that allergic reactions become progressively worse with each subsequent sting, systemic reactions to stings tend to recur in a stereotyped fashion; a patient rarely experiences reactions of increasing severity. When successive reactions to stings occur in unimmunized adult patients, the clinical pattern is most often the same as it had been on the occasion of a previous sting (31). In unimmunized children with histories of systemic reactions limited to the skin (e.g., urticaria), the risk of subsequent sting reactions is not the 50% to 60% seen in adults but, rather, 10% to 20% (36). Moreover, the risk of progression to more severe reactions in such children is small.

Systemic allergic sting reactions present the classic manifestations of anaphylaxis. Cutaneous, vascular, or respiratory symptoms may occur singly or in any combination. Cutaneous symptoms are most common (affecting 80%); they are the sole manifestation in 15% of sensitive adults and more than 60% of affected children (37,38 and 39). Almost 50% of children and adults have respiratory complaints. Although uncommon in children, hypotension occurs in more than 60% of adults, and half of these patients experience loss of consciousness. Fatal reactions are rare, although the risk of a fatal outcome increases with age, as might be expected. Fatal anaphylaxis may occur without a history of sting allergy (40).

Large local reactions are perhaps misnamed, as it is the late and prolonged time course that is characteristic. Exaggerated local inflammation, progressive over 24 hours and lasting 2 to 7 days, may cause significant morbidity. These reactions resemble the late cutaneous allergic response described by Umemoto et al. (41) and the late-phase reaction studied by Solley et al. (42), both of which are IgE dependent. From 50% to 80% of patients with large local reactions have detectable venom-specific IgE (43,44 and 45).

Insect stings may result in a variety of unusual reactions involving the neurologic and vascular systems (for example, serum sickness, vasculitis, nephropathies, encephalitis, and other neurologic manifestations including Guillain-Barré syndrome, and peripheral and central neuropathies) (46,47). Large numbers of stings have resulted in rhabdomyolysis and renal failure (48). Immune mechanisms may mediate some of these reactions, but the relation to immediate hypersensitivity is obscure.

INCIDENCE OF SYSTEMIC REACTIONS

Although only 40 deaths per year resulting from insect stings have been reported in the United States (49), there may be many more that are not recognized because the immediate cause of death (e.g., myocardial infarction or stroke) is really a vascular complication of anaphylaxis. Postmortem blood samples have been analyzed to determine if some cases of unexplained death were due to insect-sting anaphylaxis (50,51). Formerly, the only published studies of the epidemiology of insect sting anaphylaxis were surveys of the medical records of Boy Scouts during summer camp. Two such studies found the frequency of systemic sting reactions in children to range from 0.4% to 0.8% (52,53).

There have been reports of the frequency of insect sting allergy in adults (54). In the largest study, a stratified random sample of a population of “normal” factory workers was found to have a 4% cumulative prevalence of systemic allergic sting reactions, and more than 20% had either RAST or skin-test evidence for sensitization to Hymenoptera venom (55). Others have confirmed these findings (56). It seems probable that a significant number of adults develop transient venom sensitivity from stings and fail to have reactions when next stung because the level of their IgE antibody to venom has spontaneously declined. The actual risk for a systemic sting reaction in a person with a positive skin test but no prior sting reaction is unknown. Patients with both positive tests for venom-specific IgE antibody (skin or *in vitro*) and a previous systemic reaction are at high risk, but clearly at less than 100%. Their risk of reaction ranges from 25% to 60% for any given sting (30,31 and 32). In contrast, patients with positive tests for venom IgE and previous large local sting reactions (but no systemic reactions) have a risk of approximately 5% to 10% for future systemic sting reactions (43,57). Because asymptomatic sensitization (positive venom tests with a negative history) may be present in 10% to 15% of the general population (55), routine use of venom skin testing as a screening procedure is of no benefit. The frequency of sting reactions is similar in atopic, nonatopic, and unselected populations (58), but venom sensitivity on skin test seems to occur more frequently in persons with skin test sensitivity to inhalant allergens (55).

Because an obvious prerequisite for sting-induced anaphylaxis is exposure, it is expected that individuals with increased exposure would experience an increased rate of systemic reactivity. In fact, areas supporting agricultural crops that require pollination by honeybees and that also require a relatively large work force for harvesting report that most sting-related reactions are due to honeybees. In other areas, vespids seem to account for more reactions. Beekeepers and their families form a group with a greatly increased risk of sting sensitivity (59). It is significant that professional beekeepers, who are stung regularly (as often as 50 to 100 times a week) seem to experience fewer systemic reactions than do less frequently stung amateurs, or their family members. Furthermore, when beekeepers do experience anaphylaxis, it is usually when they receive their first or second sting of the spring, having not been stung since the previous autumn. One may therefore conclude that frequent, regular stings are associated with the development of immunity but that infrequent stings at irregular intervals may predispose to an increased risk of anaphylaxis.

DIAGNOSIS OF STINGING-INSECT ALLERGY

The diagnosis of insect-sting allergy rests on a convincing history and positive venom skin or serologic tests for IgE antibodies. The clinical history is perhaps the most critical aspect of diagnosis because in the absence of an appropriate history, all other techniques are merely suggestive. The risk of future reactions has not been ascertained in relation to skin tests or *in vitro* tests alone. No diagnostic test can absolutely rule out venom sensitivity or risk in the presence of a convincing history. Because successive stings may evoke differing responses because of induced alterations in the patient's immune status, even an uneventful deliberate sting challenge cannot entirely ensure future immunity.

The method of choice for detecting IgE antibody to venoms is intradermal skin testing with Hymenoptera venoms and venom sac extracts. Five such extracts are available for clinical use: honeybee (HB), yellow jacket (YJ), yellow hornet (YH), white-faced hornet (WFH), and *Polistes* wasp (Pol). Venoms are provided as lyophilized powders, to be reconstituted with special diluent containing human serum albumin as a stabilizing agent. Dilutions of venom more concentrated than 3.0 µg/mL are irritating to a significant number of nonallergic individuals, and 1.0 µg/mL is usually the highest concentration used for skin testing. Approximately 90% of individuals with histories of systemic or large local sting reactions have positive skin tests to one or more venoms at a concentration of 1.0 µg/mL or less. The testing procedure is generally started intradermally at a concentration of 0.01 µg/mL; this dose is preceded by a scratch or prick test if there is concern about provoking a systemic reaction with this small amount of venom. Because sting reactions may have occurred to only one insect type despite sensitization to others, skin testing should always be performed with a complete set of Hymenoptera venoms and a negative diluent control. If all tests are negative, a positive histamine control can demonstrate the ability of the skin to react.

Our experience with more than 1,000 patients has confirmed the findings of Hunt et al. (17) that the diagnosis of nearly 25% of patients with systemic sting reactions would have been missed if the patients had not been tested at concentrations up to 1.0 µg/mL. Furthermore, the degree of skin-test sensitivity has not been consistently correlated with the severity of the sting reaction, as there are many individual patients with positive skin tests only at concentrations of 1.0 µg/mL who have had severe life-threatening sting reactions. Occasionally a patient is seen in whom there is a convincing history of systemic anaphylaxis, yet whose skin tests with the highest venom concentrations yield negative or equivocal results. This condition might be the result of spontaneous loss of the insect-allergic state, attributable to a gradual diminution of IgE antibody production, as occurs in some patients who successfully avoid stings for a long time (37). In patients with a recent episode of sting anaphylaxis, negative skin tests are of unclear significance. Some believe that a period of “anergy” follows a sting reaction. In any case, it would be prudent when in doubt to repeat the skin tests several months later, as some persons may become more clearly positive. There have been reports of reactions to stings in patients with negative skin tests (60); whether the reactions are IgE mediated or anaphylactoid is uncertain. In some individuals with urticaria pigmentosa, after stings, systemic reactions develop, caused by a nonimmunologic release of mediators from the abnormally large numbers of mast cells present (61).

There are many patterns of skin test sensitivity to the Hymenoptera venoms. Honeybee sting allergy is independent of allergy to other insects because honeybee venom is antigenically distinct from all other venoms. Fifteen percent of our adult patients evaluated for sting reactions have honeybee venom sensitivity, and many of these individuals are beekeepers or their families. Honeybee venom allergy is more common in children and in the southwestern United States. More than half of these honeybee-sensitive patients also are sensitive to vespid venoms (17,18). The vespid venoms are highly cross-reactive, so that more than 90% of vespid-sensitive patients have positive skin tests to yellow jacket, yellow hornet, and white-faced hornet, even though most have been stung only by a yellow jacket (13). Half of these patients are also sensitive to *Polistes* venom, and the converse is true of patients with primary wasp-sting allergy (12). Few patients have positive skin tests to only one or two insect types, presumably denoting a uniquely selective response to nonshared antigenic epitopes. Sensitivity to all five Hymenoptera venoms is not uncommon but appears most frequently in careless children and in patients who have had previous WBE therapy (39).

An alternative method for detecting venom-specific IgE antibodies is the RAST, which measures the quantity of such antibodies in the patient's serum. The sensitivity and specificity of the venom RAST are less than those of the skin tests, and certain vagaries may make the RAST test less reliable than the skin test (62). The test depends on the ability of antigen-specific antibody to bind to antigen that is coupled to an insoluble and inert support: paper disks, modified cellulose particles, or other, similar material. Unless care is taken to use a pure, “clean” antigen preparation, nonspecific binding can take place, resulting in false-positive tests. In serum samples in which antibodies are present that belong to both the IgE and the IgG classes, as would be expected to occur in the patient who has been receiving immunotherapy with venom and in a patient who has had a fairly recent sting, the smaller (nanogram) quantities of IgE antibody may have difficulty binding to the allergen disk because of the presence of microgram quantities of IgG antibody. The practical consequence of this type of error is gross underestimation of the amount of IgE antibody present. Technical means are available to compensate for the disparity in concentrations of the two classes of antibody, although they are not usually used routinely with the RAST technique. Thus although the RAST is a good test, we have found it more expensive and less sensitive than the skin test (15% of patients with positive histories and positive skin tests have a negative RAST), and in our clinic, the test is used primarily as an adjunct for evaluating patients with insect-sting allergy.

During studies of the natural history of insect-venom sensitivity, the clinical significance of a positive venom RAST has been reevaluated (63,64). It is possible that individuals with a positive venom RAST and a negative skin test would have had positive skin tests at an earlier time, and that the RAST-positive, skin test–negative state represents one stage in the gradual, spontaneous loss of venom sensitivity. A positive RAST in the presence of a negative skin test is often seen after a patient has undergone several years of venom immunotherapy (M.D. Valentine, unpublished observation). After 2 years of observation, the previously positive RAST became negative in 6% of skin test–positive patients and in 52% of skin test–negative patients. Transient serologic evidence of sensitization after a sting is common, even when the skin tests remain negative. In the studies cited, individuals without prior sting-reaction histories were not at risk for subsequent reactions unless both RAST and skin tests became positive. In view of these discrepancies, we believe that the skin test remains the diagnostic test of choice.

TREATMENT OF ACUTE REACTIONS

Acute reactions to stings are treated symptomatically (65). Most large local reactions can be managed with ice packs, rest, and antihistamines. Extremely large local reactions (e.g., reactions large enough to interfere with normal activities, or if in the head or neck, reactions that hinder breathing or swallowing because of localized edema) may be attenuated by a brief, tapering course of steroids.

Hypotension and hypoxia are two of the manifestations of insect-sting anaphylaxis that require urgent and vigorous treatment. The two drugs of choice are epinephrine and oxygen. Both the a- and b-adrenergic stimulating effects of epinephrine appear to be useful in treating anaphylaxis, causing vasoconstriction, bronchial relaxation, and reversal of the enhanced vascular permeability that results from the release of mediators such as histamine. Vasoconstriction without replenishment of the depleted intravascular volume may further aggravate impaired perfusion of vital organs, and volume replacement with saline or plasma may be necessary to restore normal blood pressure (29). Epinephrine may be ineffective or paradoxically harmful if given to patients who are taking a b-blocking drug. b-Blockers are relatively contraindicated in patients at risk of insect-sting anaphylaxis or in those receiving immunotherapy for whom anaphylaxis, though unlikely, remains a risk.

Antihistamines taken orally may inhibit urticaria and pruritus but are unlikely to reverse shock, laryngeal edema, or bronchospasm; overgenerous parenteral doses of antihistamines may worsen or cause hypotension. The role of glucocorticoids in anaphylaxis remains unsettled, although such drugs clearly cannot by themselves effect rapid reversal of the more serious manifestations. When honeybee stings result in a retained stinger and attached venom sac, the stinger should be flicked away, not pulled. Whether the sac still retains some venom is not known, but it is generally considered advisable to avoid squeezing it as the stinger is removed.

The National Institutes of Health Consensus Development Conference recommended that (a) epinephrine kits be available to all individuals at risk of systemic sting reactions; (b) patients be carefully instructed in the use of such kits; and (c) the lay and professional public be better educated on the dangers of insect stings and the means of treating them (65). A recent survey of allergists and other physicians found that most of those surveyed were unable to provide correct instructions in the use of an epinephrine autoinjector (66).

PREVENTION OF STINGS

Some stings are unavoidable. Certain precautions make others less likely. It is prudent for allergic persons to avoid going barefoot, to eschew perfumed cosmetics and toiletries, to avoid eating and drinking in areas accessible to stinging insects, and to dress in neutral colors, avoiding floral prints. Such bucolic pleasures as grass cutting and hedge trimming should be relegated to nonallergic relatives, willing neighbors, or professionals. Fallen fruit and laden trash cans invariably attract the Hymenoptera and should be avoided. Some allergists have recommended oral thiamine in doses sufficient to render the subject an object of olfactory repugnance. Whether the Hymenoptera shun this odor is not proven, although it is clear that certain aromatic esters attract specific insects (*n*-pentyl valerate has been used as an olfactory bait in commercial yellow-jacket traps).

IMMUNITY FROM VENOM-INDUCED ANAPHYLAXIS

IgG Antibodies

The mechanism of action of allergen immunotherapy is not completely understood. Of the many immunologic responses evoked by immunotherapy, increased production of specific IgG antibodies has been most consistently and directly correlated with clinically successful treatment (67,68,69,70 and 71). Functional “blocking” activity was first found in the sera of pollen-immunized hay-fever patients when it was demonstrated that these sera contained an antigen-specific substance capable of blocking the Prausnitz-Küstner reaction in the skin of nonallergic recipients (72). Later it was shown that “blocking” could be demonstrated by inhibition of antigen-induced histamine release *in vitro*, and that this blocking capacity was entirely contained within the IgG fraction of serum (71). Serum containing high titers of such blocking antibodies with specificity for honeybee venom has successfully conferred passive immunity on individuals allergic to honeybee sting (33,73). It thus seems that IgG-blocking antibodies are at least partially responsible for the protection induced by venom immunotherapy. Venom-specific IgG antibodies can now be accurately measured in the serum with sensitive and specific assays similar to the RAST (74). When determined by this method, the level of venom-specific IgG has been correlated with the degree of protection from systemic reactions to challenge stings and has become a useful test for monitoring the efficacy of treatment (44,75). Observations of more than 200 sting challenges showed that systemic reactions, albeit mild, occurred in only 1.6% of patients with an IgG level greater than 3 µg/mL, whereas those with lower IgG levels had a 16% frequency of reactions (44). Of interest was the fact that there was no such increase in reaction rate in patients who had undergone venom immunotherapy for more than 4 years. Perhaps prolonged venom immunotherapy provides clinical protection by another mechanism that is of late onset but still unknown (76).

History

Initial attempts to use Hymenoptera venoms for immunization were on an entirely empiric basis (77). Investigations of venom therapy were started in patients who were clearly not protected by WBE treatment. The first such patient was gradually immunized with increasing doses of venom until he could tolerate an injection containing venom equivalent to approximately two stings. At that point, his serum was found to contain a high titer of IgG-blocking antibodies that could inhibit venom-induced histamine release from sensitive leukocytes. When he was challenged in the hospital with a live bee sting, he had no systemic reaction (71). This initial success led to the treatment of a small series of patients who also were successfully challenged with live insect stings.

The definitive study of venom therapy was conducted as a double-blind comparison of therapy with Hymenoptera venom, placebo, or WBE (68). Live challenge stings resulted in systemic reactions in 60% of both the placebo-treated and WBE-treated patients but in only 5% of the venom-treated patients. When the placebo- and WBE-treated patients were subsequently treated with venom, they too had a 5% systemic reaction rate. Additional trials of venom therapy in several hundred adults and children confirmed the safety and efficacy of the treatment and helped to establish the optimal regimens for initial and maintenance therapy (44,78).

Indications

Patients are selected for venom immunotherapy on the basis of their history and the results of venom skin or serologic tests (17,64,68). The only clear indication at present is to prevent future anaphylactic sting reactions in patients with a history of such reactions who have positive tests for venom-specific IgE antibodies (79). Patients with negative tests are not candidates for venom immunotherapy; such patients may have had a sting from an insect whose venom is not available for testing or treatment [e.g., bumblebee or sweat bee (80)] or may have spontaneously lost their sensitivity (31). Although some do not advise treatment of adults with mild (cutaneous only) reactions, no prospective data are available that define the risk of withholding treatment in this group. Children with reactions confined to the skin (urticaria, angioedema, or generalized flushing and pruritus) have been found in a prospective study to be at low risk of future reactions of similar severity and at negligible risk of reactions of greater severity (36,38). Although such children can be safely managed conservatively (counseling in sting avoidance, use of epinephrine self-treatment kits), venom therapy should be offered to those children who have had severe reactions.

From 50% to 90% of child and adult patients who have had only large local sting reactions without systemic symptoms have been found to have positive venom tests for IgE antibody (43,81,82) but are not usually immunized, as their risk of a future systemic reaction is estimated at only 5% to 10% (43,81). There is still no test *in vitro*

or *in vivo*, except the sting challenge, that can predict who of this relatively large group will react systemically when stung. In fact, large local reactions occur so commonly that it is of doubtful use to perform venom skin or blood tests on such patients, although a negative test should rule out the possibility of a future systemic reaction. However, children treated for prevention of systemic allergic reactions have been found to experience fewer large local reactions than did a group of comparable, unimmunized children (45).

Initial Therapy

To initiate venom immunotherapy, the physician must decide which venoms to use, the maximal dose to achieve, and the schedule to follow. The choice of venoms is based primarily on venom-test results. Although we currently recommend that immunotherapy include all venoms giving an unequivocally positive test, aiming to provide maximal security to the patient, others suggest that the clinical history can be used to limit the number of venoms used (83). Despite the marked cross-reactivity of the various vespid venoms, we believe the most practical approach to the patient with positive reactions to hornet and yellow jacket venoms is to treat with mixed vespid venoms. It has been shown that treatment of yellow jacket–sensitive patients with mixed vespid venoms provides a better clinical and IgG antibody response than does treatment with yellow jacket venom alone (13). However, when sophisticated laboratory facilities are available, it can often be established with the technique of RAST inhibition that multiple positive serologic tests for venom IgE antibodies are due to cross-reactivity. The most common example of this type of cross-reactivity in Baltimore, Maryland, for example, is a positive test for the *Polistes* wasp resulting from yellow jacket sensitization.

One problem with single-venom therapy is that the IgG response is not so great as with mixed vespid venoms. Complete clinical protection was less frequently observed with yellow jacket venom alone (80% to 85%) than with mixed vespid venoms (98%) (13). In such cases, increased venom doses (up to 200 µg) may be required. There also is evidence that, aside from the obvious antigenic differences, the results of yellow jacket venom therapy are different from the results of therapy with honeybee venom (84). The usual recommended dose to be achieved with the initial treatment schedule is 100 µg of each relevant venom because this regimen provides virtually complete protection to 98% of patients treated. Half-dose (50 µg) treatment may be adequate for some patients but has proved to be inadequate in as many as 20% of patients(67).

The recommended treatment schedule for the venom-sensitive patient is more intensive than traditional regimens for other allergen immunotherapy, achieving the maximal recommended dose with a series of six to eight weekly injections (85). This course, although seemingly accelerated, has been associated with fewer adverse reactions per treatment course and a greater, more rapid increase in venom-specific IgG antibodies than the slower, more traditional regimen. Both regimens, however, are clinically effective (85).

Adverse reactions to venom immunotherapy are much less common than had been feared, occurring no more frequently than with effective immunizing doses of any other allergen. When systemic reactions occur, they often resemble the patient's original sting reaction, usually in the same individual pattern, and may vary in severity from such a subtle subjective sensation as a lump in the throat or lightheadedness to more severe reactions. Systemic reactions to venom injections occur in 5% to 15% of patients during the induction phase of therapy, regardless of the regimen used (85). Although mild systemic symptoms are not infrequently reported, objective reactions requiring treatment occur less often and are only rarely a serious impediment to the therapeutic regimen. Although adverse reactions appear to be less common in children (37), our experience with adults parallels that of Levine (86), who observed systemic reactions to all types of immunotherapy in 15% of his patients, one third of whom required treatment with epinephrine.

Systemic reactions usually occur early in treatment, especially at doses less than 2.5 µg or in the range of 20 to 30 µg. After the IgG response becomes measurable (at doses >25 µg), these reactions are rare. Recurrent problems occasionally require prolonged treatment with submaximal doses until the patient's tolerance improves. However, it may be counterproductive to reduce the dose repeatedly after recurrent systemic reactions, because low-dose therapy can stimulate IgE but not IgG production. In such a case, it is preferable to discontinue therapy for 6 to 12 months and then try again. Alternatively, patients may be pretreated with mediator antagonists with a regimen similar to the one recommended for preventing reactions to iodinated contrast media (87).

Large local reactions to venom injections occur in 50% of patients and only rarely interfere with the progress of therapy. These reactions are seen most frequently (20 reactions per 100 injections) at doses between 15 and 50 µg, when the immune response is not yet optimal. At lower and higher doses, large local reactions are uncommon (five reactions per 100 injections) (88). Slow regimens are associated with the same frequency of reactions as rush regimens, and large local reactions often continue to occur until immunologically effective doses are administered. Furthermore, in contrast to popular belief, large local reactions do not indicate an increased risk of systemic reactions at larger doses. Patients may tolerate these local reactions (unless they are extreme or involve a joint) if they understand that the best way to overcome them is to proceed with the prescribed regimen. Long-term toxicity or side effects have not been observed to date. After 20 years of venom immunotherapy, we have observed no physical or laboratory abnormalities attributable to venom immunotherapy. Routine hematologic, biochemical, and urine tests have remained unchanged. Although it is not known if administration of venom solutions over a much longer term has toxic effects, it is reassuring to note that beekeepers and their families, who experience hundreds or thousands of stings over the course of a year or two, have had no adverse clinical or laboratory results.

Maintenance Therapy

During the first several years of treatment, boosters help to maintain the protective IgG response, which declines gradually if treatment is discontinued. Seasonal therapy is not recommended because it involves as many visits and injections, and as much expense, as would year-round therapy. Once the full dose of 100 µg (of each venom) is attained, the dose is repeated monthly. Although the rate of treatment failure is low, we advocate measuring the serum IgG antibody level against the immunizing venom(s) to confirm that the response has been adequate (44,75). Poor immune responses are seen in fewer than 5% of patients treated with mixed or multiple vespid venoms and up to 10% of patients treated with any single venom. Such patients may require treatment with doses of venom increased 50% or 100% to achieve “adequate” IgG levels.

After six monthly maintenance doses, the interval between doses can be safely lengthened to 6 weeks if the serum venom-specific IgG is 3.5 µg/mL (88). Six months later we recheck the IgG and do so again at 12 to 18 months. Others omit these measurements (89).

The question of when venom immunotherapy may be safely stopped must have a different answer for each patient (90). Many of the immunologic consequences of the treatment have been documented. There is a brisk increase in IgG antibody soon after treatment is started; and this response is maintained in most patients during many years of booster injections. The venom-specific IgE antibody level also increases when immunotherapy is initiated and decreases toward pretreatment levels after the first year of therapy. There is a steady subsequent decline as treatment is continued. Venom skin-test sensitivity also declines in at least half of treated patients but remains unchanged in the others. After 5 years of observation, 5% to 10% of treated and untreated patients lose all evidence of venom-specific IgE antibodies (negative skin tests and RASTs) (45,57). After 8 to 10 years, venom skin tests and RASTs become negative in 25% of untreated patients and in 50% of treated patients (19,91).

It seems reasonable to discontinue treatment if both skin test and serologic evidence of IgE antibodies has disappeared. However, the risk of sting reactions in patients with persistent IgE venom antibodies who stop venom immunotherapy after 1 to 3 years of treatment increases to an unacceptable figure soon after cessation of therapy (31). Within 6 months after venom therapy is stopped in such patients, the serum levels of venom-specific IgG antibodies decline to levels typical of those of untreated patients (57,92).

Although venom therapy is usually associated with an increase in IgG antibodies as IgE antibodies decrease, the relation is not strictly reciprocal. Although it has been recommended that therapy be continued indefinitely or until skin and RAST (IgE) tests are negative, studies suggest that prolonged (4 to 5 years) venom immunotherapy results in a state of resistance to sting reactions that is independent of elevated IgG or suppressed IgE antibodies (91). This finding is in sharp contradistinction to the definite dependent relation sting immunity bears to elevated IgG antibodies earlier in the course of treatment. In patients who have undergone 5 uninterrupted years of venom immunotherapy, sting challenges as many as 5 years after stopping treatment have been well tolerated, with only 5% to 10% of such patients demonstrating a return of clinical sensitivity on challenge. Risk factors for recurrent sensitivity to stings include repeated reactions to immunotherapy and severe initial reactions.

In 1991, Khan et al. noted that successful venom immunotherapy is correlated with the presence of antiidiotypic antibodies. Whether this is an epiphenomenon or bears significantly on the immune state is unclear.

Finally, it seems prudent to reevaluate a patient who, having successfully stopped therapy, is hapless enough to incur repeated stings, as there are as yet no long-term data regarding the risk of resensitization in such patients.

70 IMMUNOLOGIC LUNG DISEASE

Michael B. Levy, M.D., and Jordan N. Fink, M.D.

Interstitial lung disease encompasses a group of pulmonary disorders that may have features ranging from alveolitis to fibrosis. Pulmonary infiltration with immune effector cells, secretion of effector molecules, and a wide variety of immune responses are characteristic of these disorders. Such responses include the lymphocytic and granulomatous alveolitis of hypersensitivity pneumonitis, the cellular infiltration of eosinophilic pneumonias, and end-stage fibrosis. Both cellular (Th1) and humoral (Th2) immune mechanisms have been implicated in the pathogenesis of these diseases, and defined antigens have been implicated in some syndromes. A review of the clinical and immune aberrations and potential pathogenesis of these major disease entities follows (Table 70.1).

Disease	Agent
Hypersensitivity pneumonitis	Organic dusts, chemicals microorganisms
Eosinophilic pneumonias	
Allergic bronchopulmonary aspergillosis	*Aspergillus fumigatus*
Acute eosinophilic pneumonia	Parasites, idiopathic
Drug-induced eosinophilic pneumonia	Multiple drugs
Chronic eosinophilic pneumonia	Unknown
Vasculitis	Unknown antigen, viral?
Allergic granulomatosis	Unknown
Idiopathic pulmonary fibrosis	Unknown
Fibrotic lung diseases due to inorganic dusts	Silica, asbestos, beryllium

TABLE 70.1. Interstitial Lung Diseases with Suspected Immunologic Origin

HYPERSENSITIVITY PNEUMONITIS

Hypersensitivity pneumonitis or extrinsic alveolitis comprises lymphocytic and granulomatous alveolar and interstitial pulmonary inflammation due to an ever-expanding variety of environmental antigens in organic dusts, chemicals, and drugs (Table 70.2). The immune inflammatory responses may be reversed by avoidance of antigen, or may lead to end-stage pulmonary fibrosis with repeated or continuous exposure to the antigen. Initially described by Ramazzini in 1713 (1), the most common disorder was presented as “farmer's lung” by Campbell in 1932 (2). Clinical features include systemic as well as respiratory symptoms temporally associated with inhalation of the offending agent; however, in only between 7% and 15% of individuals so exposed does the disease pattern develop (3,4). Whereas most patients initially have acute repetitive “flu-type” symptoms, a number of patients also may have “chronic bronchitis” or progressive pulmonary impairment (3,4).

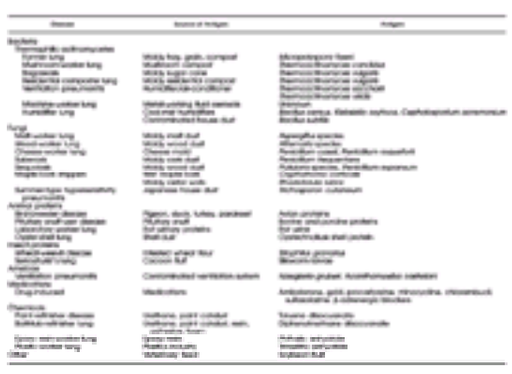

TABLE 70.2. Etiologic Agents in Hypersensitivity Pneumonitis

Clinical Characteristics

The disorder occurs in three forms: acute, subacute, and chronic. The acute form occurs in the majority of patients and is seen as the sudden onset of cough, dyspnea, malaise, myalgia, fever, and chills 4 to 6 hours after exposure to antigen. The episode subsides over the next 8 to 12 hours, only to be repeated with subsequent exposures. With frequent episodes, anorexia and weight loss may develop. Physical examination is characteristic with bilateral end-inspiratory crepitant rales. Cyanosis may be detected, but clubbing is rare. Laboratory examination reveals leukocytosis with a leftward shift, variable eosinophilia, and broad increases in immunoglobulin (Ig) levels except for IgE. Chest radiographs show nodular changes predominantly in the lower lobes (Fig. 70.1). Pulmonary-function changes are characteristic of interstitial disease, with restriction manifested by decreases in forced expiratory volume in 1 second, forced vital capacity, total lung capacity, and diffusion capacity, as well as arterial oxygenation. With resolution of the acute episode, the clinical features resolve, although crepitant rales may persist, and decreases in arterial oxygenation may be detected on exercise for several weeks. Repeated acute attacks are common, but progression of the pulmonary abnormalities is not, except in patients with farmer's lung (5,6).

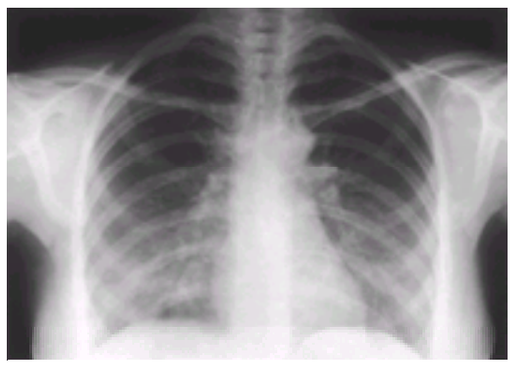

Figure 70.1. Chest radiograph of a 34-year-old patient with recurrent respiratory and systemic symptoms as a result of hypersensitivity pneumonitis due to repeated inhalation and sensitization to thermophilic actinomycetes contaminating the forced-air heating system.

The subacute form of hypersensitivity pneumonitis, which occurs in about 15% of patients, initially shows an almost continuous productive cough with or without purulent sputum, dyspnea, fatigue, anorexia, and weight loss. Acute episodes may occur after exposure to large amounts of antigen. The physical findings are those of interstitial lung disease with diffuse crackling rales, and pulmonary-function abnormalities are mainly of the restrictive type, with decreased diffusion capacity. Laboratory evaluation usually reveals polyclonal elevations of immunoglobulins, low-grade white blood cell count elevations, and normal erythrocyte sedimentation rates. Chest radiograph features include diffuse increases in interstitial markings or nodular formations. Histopathologic studies of the lung (Fig. 70.2) demonstrate lymphocytic interstitial inflammation and bronchiolitis, with maturity of the granulomas increased over the acute form with birefringent materials in some giant cells (7,8). Prolonged avoidance of exposure accompanied by glucocorticoid therapy usually results in resolution of the clinical abnormalities. The need for more aggressive therapy in the subacute form of hypersensitivity pneumonitis suggests that it is a more advanced form of the disease.

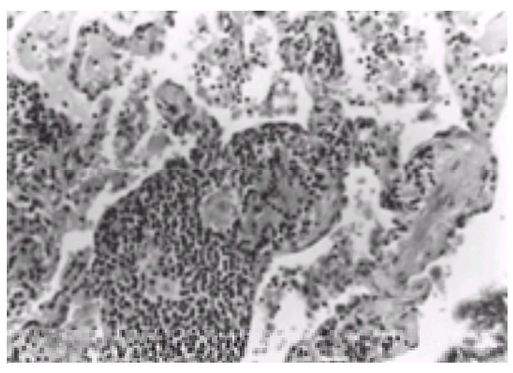

Figure 70.2. Lung biopsy specimen from a pigeon breeder with “bronchitic” symptoms and restrictive defect on pulmonary function. The specimen demonstrates lymphocytic interstitial pneumonitis and granuloma formation.

Long-term exposure to antigen is associated with a chronic and progressive form of the disease. Such individuals initially have progressive dyspnea and cough without systemic features. The disease may progress to respiratory failure with cor pulmonale and may be fatal (9). Physical examination reveals findings of tachypnea, cyanosis, and at times, clubbing of the nails. Cardiac findings of cor pulmonale also may be present. Pulmonary-function studies demonstrate either severe restriction with diminished diffusion capacity or high-grade irreversible obstruction, and these findings are associated with either diffuse fibrosis or features of hyperinflation and honeycombing seen on chest radiographs (Fig. 70.3). Chronic hypersensitivity pneumonitis may be confused clinically with idiopathic pulmonary fibrosis. Pulmonary tissue biopsy may be necessary to differentiate these two entities. Clinical guidelines for the evaluation of hypersensitivity pneumonitis have been published (10).

Figure 70.3. Chest radiograph of a farmer with recurrent episodes of respiratory symptoms related to his barn. The radiograph demonstrates the fibrotic picture of chronic hypersensitivity pneumonitis.

Factors Favoring Development of Disease

ANTIGENS

Numerous organic antigens are associated with hypersensitivity pneumonitis, and sensitization develops after repeated inhalation (Table 70.2). At present, there is little information regarding the levels of exposure necessary to cause the disease in susceptible individuals. Thermophilic actinomycetes are the major antigens inducing such diseases as farmer's lung, bagassosis, ventilation pneumonitis, and mushroom worker's lung. These organisms are complex antigens. Immunologic studies have demonstrated that they contain enzymes, glycoproteins, and numerous proteins, all of which may be antigenic, but none of which can be identified as disease specific (11,12,13 and 14). In avian dust–induced hypersensitivity pneumonitis, responsible antigens have been more thoroughly characterized, especially those found in pigeon serum and excreta. Pigeon droppings contain proteases resistant to inhibition by human serum; hydrolases that degrade lung surfactant phospholipid, esters, and elastins; and other enzyme activities that promote inflammation (12,13,15). Recent work has identified a 21-kd protein in pigeon-dropping extract as the responsible agent for the Th1 response in pigeon breeder's disease (16).

Further inflammation-enhancing characteristics of these antigens include their prolonged presence in alveolar macrophages related to their inherent resistance to lysosomal degradation. This allows long-term host immune or foreign-body responses to occur. Some thermophilic organisms can activate complement by either the classic or the alternative pathway, thus inducing inflammatory processes, and such organisms also act as adjuvants in enhancing cellular immune responses (17). Some of the antigens contain endotoxins that also can incite and accelerate inflammation (14). Thus the basic nature of the inhaled dust may be important in subsequent inflammatory processes.

HOST CHARACTERISTICS

The prevalence of hypersensitivity pneumonitis in various exposed populations studied ranges from 3% to 15%, suggesting that host factors must be considered in its development (3,18). The prevalence of farmer's lung, for instance, may vary between countries and even within a country. In the United States, most cases of farmer's lung have been reported in Wisconsin, where there was heavy occupational exposure, with a prevalence in an agricultural population a number of years ago of 3.9%. Since then, changes in farming methods have greatly reduced the frequency of the disease. If there is heavy exposure to contaminated air-conditioning systems, the

risk of disease increases to between 15% and 60% (19). In between 6% and 21% of pigeon breeders, the disease develops (20). Paradoxically, hypersensitivity pneumonitis occurs less frequently in cigarette smokers than in nonsmokers (21), suggesting a role for the damaged alveolar macrophage in protection. Genetic factors have been suggested as important in the pathogenesis of farmer's lung and pigeon breeder's disease, by assessment of major histocompatibility haplotypes in groups of patients (22,23,24 and 25). However, in studies of larger populations when asymptomatic and similarly exposed individuals were evaluated, no significant correlations with disease could be identified (26). Similarly, in studies of other genetic markers such as P blood groups, human leukocyte antigen (HLA)-A, -B, -C, and -DR antigens, and Gm allotypes, there were no correlations with disease (27). In animal studies, however, chronic pulmonary granulomatous inflammation after bacille Calmette-Guérin (BCG) administration was shown to be controlled by thymus-derived $CD8^+$ cells that are cyclophosphamide sensitive (28). Furthermore, the extent of the inflammation was shown by mouse inbreeding studies to be associated with the immunoglobulin heavy-chain locus and with decreased cell-mediated responses to other antigens (29). In addition, some strains of BCG-inflamed mice produce macrophage-derived factors that suppress the inflammation, whereas other strains cannot develop such suppression, and intense and prolonged pulmonary inflammation results (30). This and later work provide evidence that the expansion of Th1 cells, with their subsequent cytokine and chemokine secretion, are involved in granulomatous formation. Mutations described in the interferon-g (IFN-g)-receptor gene with subsequent increased susceptibility to mycobacterial infection have provided additional information toward our understanding of this cytokine/chemokine interaction (31,32).

IMMUNE RESPONSES

As the demonstration of immune responses is the hallmark of disease, immune parameters are most important. Precipitating antibodies that react with the offending antigen are uniformly demonstrated in the serum of ill patients (3,33). However, up to 50% of exposed but asymptomatic individuals also may have such circulating precipitins (3). By macrophage migration inhibition, an *in vitro* technique to detect cell-mediated immunity, the peripheral blood lymphocytes of ill pigeon breeders, but not those of healthy exposed pigeon breeders, were shown to be sensitized to pigeon antigens (34,35 and 36). This technique, therefore, more clearly defined the sick and well pigeon breeder population than did humoral antibody tests and pointed to cell-mediated immune mechanisms in the pathogenesis of the disease, considered as the Th1 type of immunologic response. The development of newer animal models and the further study of bronchoalveolar lavage (BAL) fluids have reinforced this concept.

Immunopathogenesis

Evidence from both human and animal studies indicates that hypersensitivity pneumonitis most likely results from the interaction of the humoral and cell-mediated immune mechanisms. Studies of BAL fluid have consistently demonstrated a predominance of T cells, and particularly increased numbers of T cells (37,38) expressing CD8 and the natural killer (NK) markers CD56 and CD57. Such T-cell populations have been documented in both symptomatic and asymptomatic but exposed groups, with levels higher in the ill individuals. The T cells are activated and respond to stimulation with mitogens and produce cytokines. If antigen exposure persists, the increased $CD8^+$ T-cell population continues, and the number and activity of NK cells increase. With avoidance of exposure, the alveolar lymphocyte population reverts toward normal (38).

Although both symptomatic and asymptomatic but exposed populations have lymphocytic alveolitis, studies of lung suppressor cell function have shown differences. $CD8^+$ T cells obtained from ill pigeon breeders have reduced function in interaction with mitogens or pigeon antigens; cells from exposed but healthy breeders do not (39). These results suggest a failure of immunoregulation in patients with disease.

The number of mast cells is increased in lavage fluids from patients with hypersensitivity pneumonitis (40). Such cells may influence both $CD4^+$ and $CD8^+$ T-cell responses by release of modulating cytokines and may influence pulmonary vascular responses through release of histamine, prostaglandins, or leukotrienes. Because arachidonic acid metabolites can regulate immune cell function and inflammatory responses, they may be important in the development of the interstitial lesions. Evidence suggests that mast cells may be the key in the development of fibrosis (41), and these cells also may be important in the pathogenesis of hypersensitivity pneumonitis.

The presence of serum and alveolar antibodies of IgG, IgA, and IgM isotypes specific for the offending antigen points toward humoral mechanisms in hypersensitivity pneumonitis, especially those leading to a vasculitis. Although vasculitis is not common in alveolitis, immune complexes could initiate inflammation by complement fixation, by releasing inflammatory cytokines such as interleukin (IL)-1 and tumor necrosis factor (TNF) from alveolar cells, by activating pulmonary macrophages and inducing granulomas in pulmonary parenchyma, as well as by participating in the maintenance of chronic inflammation.

Animal model experiments have confirmed the complex nature of hypersensitivity pneumonitis. In early studies with rabbit models of the disease induced by ovalbumin, the development of lesions correlated better with the induction of cell-mediated hypersensitivity than with antibody (18). However, in the guinea-pig model, immune complex–induced pneumonitis that developed after a single antigen challenge could be converted into a granulomatous pneumonitis by repeated challenge (42). Recent work in mouse experimental hypersensitivity pneumonitis has identified that the Th1 cells capable of adoptive transfer are activated/memory T cells, and that Th2 cells do not have this ability (43).

Other experiments have detected high levels of IL-1 in sensitized mice with pulmonary granulomas, which may act by signaling elaboration of other cytokines such as IL-2. The regulation of IL-2 production appears to be under the control of $CD8^+$ cells or macrophages in such animals (44). Recent work in mouse models has shown that the lack of IL-10, which counteracts many of the effects of IFN-g, or the blocking of IL-13 activity, results in a more severe granulomatous inflammatory response (45,46). These studies suggest that activated macrophages and $CD8^+$ cells incapable of suppressing them contribute to the inflammatory environment in the disease.

Other animal studies have shown a role for macrophage-derived arachidonic acid (eicosanoid) metabolites in pulmonary granuloma formation (47). The development of such granulomas has been associated with the generation of leukotrienes C_4 and D_4 and 5- and 12-hydroxyeicosatetraenoic acid (HETE) from macrophages. In addition, the lesions could be suppressed by treatment with antilipoxygenase compounds (48). Such compounds inhibit Ia antigen expression in pulmonary macrophages and inhibition of antigen presentation to T cells, which in turn could reduce the cellular immune responses.

Thus the development of hypersensitivity pneumonitis in animal models and possibly in sensitized individuals may be a complex interaction of cytokines, chemokines, eicosanoid metabolites, immune complexes, and pulmonary macrophages with $CD4^+$ and $CD8^+$ T cells, resulting in the development of granulomas, perhaps related to genetically controlled responses.

Diagnostic Considerations

The diagnosis of hypersensitivity pneumonitis should be considered in patients with histories of systemic and/or respiratory symptoms resembling influenza or bronchitis but temporally associated with a particular environment. Physical examination may suggest interstitial lung disease, and pulmonary-function testing may indicate restriction or obstruction with diffusion defects. In some cases, cautious inhalation challenge with a suspected antigen or purposeful exposure to the suspected environment may be useful in establishing a relationship between an environment and the disease. BAL studies with enumeration of the cellular population or lung biopsy to show a lymphocytic interstitial pneumonitis with granulomas in obtained specimens may be useful.

Several syndromes should be considered when evaluating patients for hypersensitivity pneumonitis. These include the organic dust toxic syndrome (ODTS), which occurs in workers after exposure to dusts contaminated with multiple bacterial and fungal species, humidifier fever, mucosal irritation or “sick building syndrome,” and disorders that cause interstitial lung disease with progressive pulmonary and systemic symptoms. The latter include sarcoidosis, primary pulmonary histiocytosis, and idiopathic pulmonary fibrosis. A careful history, review of pulmonary functions, radiographic studies, and immunologic findings should classify the diagnosis.

Treatment

The treatment of hypersensitivity pneumonitis is avoidance of the offending antigen or environment once it is identified. This may entail the use of protective respiratory devices; alteration of forced-air heating, cooling, or humidification systems; substitution of workplace chemicals; or avoidance of the workplace. Glucocorticoids markedly reduce the pulmonary inflammatory process if parenchymal destruction has not already occurred and return the patient to normal, as long as avoidance measures are instituted. Long-term sequelae are generally minimal once such avoidance is instituted.

EOSINOPHILIC PNEUMONIAS

The eosinophilic pneumonias are characterized by pulmonary infiltration with eosinophils and the clinical effects of those inflammatory cells. Such infiltrations may be due to a variety of known and unknown causes with overlapping clinical features and responses to therapy. The disorder may or may not be associated with bronchospasm (Table 70.3). Whereas pulmonary infiltrates may occur without peripheral eosinophilia, most affected patients usually have a peripheral eosinophil count greater than 500 cells/µL.

Asthmatic	Nonasthmatic
Allergic bronchopulmonary aspergillosis	Loeffler pneumonia
Tropical eosinophilia	Chronic eosinophilic pneumonia
Vasculitis	
Polyarteritis	Drug-induced
Allergic granulomatous angiitis	Eosinophilic granuloma

TABLE 70.3. Patient Characteristics in Eosinophilic Pneumonias

Allergic Bronchopulmonary Aspergillosis

Allergic bronchopulmonary aspergillosis (ABPA) occurs as a result of hypersensitivity reactions after the colonization of the respiratory tract with *Aspergillus*, most commonly *Aspergillus fumigatus*. The syndrome occurs largely in atopic patients with underlying asthma, which may be mild or glucocorticoid dependent. It was first described in 1952 (49) and has been characterized by episodic wheezing, fleeting pulmonary infiltrations, sputum and blood eosinophilia, immediate wheal-and-flare skin reactivity, and specific serum IgG and IgE antibodies to *A. fumigatus*, markedly elevated levels of total serum IgE, and central bronchiectasis (Fig. 70.4 and Fig. 70.5) (50).

Figure 70.4. Chest radiograph of a patient with asthma, recurrent infiltrates, and elevated serum immunoglobulin E level. The radiograph demonstrates the nodular infiltrates of allergic bronchopulmonary aspergillosis.

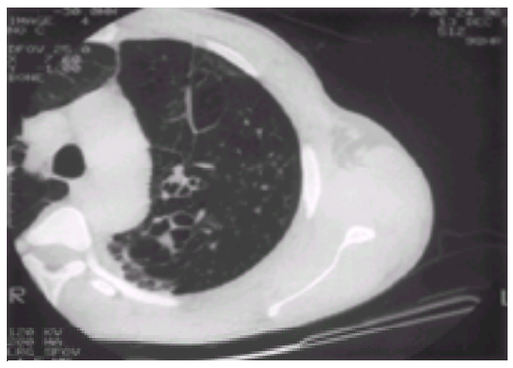

Figure 70.5. High-resolution computed tomography scan of the chest of a patient with allergic bronchopulmonary aspergillosis, demonstrating areas of saccular bronchiectasis.

Although ABPA may be asymptomatic, the disorder should be considered when asthmatic episodes become more severe and are associated with constitutional symptoms. *Aspergillus* organisms are ubiquitous, are widely dispersed in the environment, and thus are not avoidable, nor can a source usually be pinpointed. The spores are abundant in disturbed soil, decaying organic matter, hay or grain piles, and vegetable compost. It is not understood why *A. fumigatus* spores are able to colonize the mucus of patients with ABPA but not that of the many other patients with asthma.

ABPA should be considered in patients with asthma who have immediate wheal-and-flare skin reactions to *Aspergillus* antigens. An elevation of total serum IgE and specific IgE and IgG antibodies is reasonable evidence for the disease. Thin-section computed tomography of the chest should then be carried out to evaluate bronchiectasis (51).

A number of different histopathologic changes may be seen in ABPA, including mucoid impaction syndrome, eosinophilic pneumonia, bronchiolitis obliterans, granulomatous bronchiolitis, and fibrosis, in addition to the expected changes of asthma (52). Thick tenacious mucus includes fibrin, eosinophils, and Charcot-Leyden crystals. *Aspergillus* hyphae may be identified; however, invasion of the bronchial wall is not characteristic. Microscopically there is bronchial wall inflammation with the presence of mononuclear cells and/or eosinophils.

Treatment of the disorder consists of control of the underlying asthma with immunologic or pharmacologic means and resolution of the inflammatory process with glucocorticoids. If such antiinflammatory treatment is not carried out, then progression of the disease, with increasing sputum plugs, further bronchiectasis, and pulmonary fibrosis, is likely. With glucocorticoid therapy, serum IgE levels regress, pulmonary infiltrates disappear, and bronchiectatic areas stabilize (50). Itraconazole may provide effective adjunctive therapy for patients with glucocorticoid-dependent ABPA (53).

IMMUNOPATHOGENESIS

Characteristically, total serum IgE levels are elevated in ABPA. However, the elevation is largely nonspecific, as most of the IgE is not directed toward *Aspergillus* (54). Specific IgG also is necessary to induce pulmonary lesions after *A. fumigatus* inhalation, as shown in passive-transfer animal experiments. No changes of ABPA were induced when animals were given IgG or IgE antibody alone before challenge (55). Circulating immune complexes and activation of complement have been demonstrated (56).

A. fumigatus (Af), as an antigen, has multiple immunoreactive components. Crossed immunoelectrophoresis of culture filtrates of *Aspergillus* with sera from patients with ABPA identifies about 35 precipitin arcs, of which eight to ten show IgE reactivity (57,58).

Characterization of the epitopes has aided our understanding of the immunopathogenesis of the disease. The pathogenesis of ABPA probably depends on specific cytokines and immunoglobulins secreted by lymphocytes on stimulation with different epitopes of those allergens. Asp f 1 has been identified as an 18-kd protein member of the mitogillin family of ribotoxins. With Asp f 1, specific IL-4–producing $CD4^+$ Th2 clones with HLA restriction reacting to two epitopes were demonstrated in patients with ABPA (59). Further evidence for activation of $CD4^+$ T cells was provided when it was shown that soluble IL-2 receptors were increased in the sera of patients with ABPA (60). *Aspergillus* appears to function as an eosinophil growth factor by potentiating IL-5–induced growth and differentiation (61). Asp f 2, a 37-kd

protein, exhibits IgE binding in patients with ABPA (62). In a mouse model, of five peptides from the sequence of Asp f 1, one showed a clear Th1, whereas another showed a Th2 response, suggesting that a number of epitopes of diverse activities are present and may be involved in the pathogenesis through differential cytokine secretions (63).

Acute Eosinophilic Pneumonia

PARASITE INDUCED

In 1932 Loeffler (64) described four patients with peripheral blood eosinophilia and transient pulmonary infiltrates accompanied by minimal clinical findings. It was later recognized that infestation with *Ascaris lumbricoides* and other parasites such as *Toxicara, Strongyloides, Schistosoma, Trichina,* and *Necator* can cause the syndrome (65). The exudative eosinophilic reaction is a response to larval parasitic migration through pulmonary parenchyma. Because emigration from the lung to the gastrointestinal tract is a part of the life cycle of the parasite, the pulmonary lesions are transient.

TROPICAL EOSINOPHILIA

Tropical eosinophilia occurs as a hypersensitivity reaction to filarial infestations with *Wuchereria bancrofti* or *Brugia malayi.* Although infestation with these organisms is usually associated with lymphangitis, fibrosis, and subsequent lymphatic obstruction, in some patients, paroxysmal cough, wheezing, eosinophilia, and patchy pulmonary parenchymal infiltrates develop (66). Donohugh (67) characterized patients with the disease as having a history of a dry irritating nocturnal cough, episodic wheezing, dyspnea, pulmonary infiltrates, and eosinophilia greater than 2,000 cells/µL, serologic evidence of filarial infestations, and a response to diethylcarbamazine. Recently the essential role for IL-5 and eosinophils in *B. malayi*–induced airway hyperreactivity was demonstrated in a mouse model (68).

DIAGNOSIS

The clinical findings of eosinophilic pneumonia due to parasitic infestation include mild cough, low-grade fever, malaise, and anorexia, and are accompanied by chest radiographic features of unilateral or bilateral homogeneous infiltrates in an alveolar/interstitial pattern, often in the periphery. The reaction may be more intense if the burden of parasites is heavy. Serologic evaluations for parasite infestation and examination of stool specimens for ova may be rewarding. Larval stages may, on occasion, be detected in sputum or alveolar lavage fluid.

Because of the transient pulmonary localization of the parasite, the pulmonary lesions also are transient. However, if parasitic elements can be detected, treatment with antihelmintics is warranted. Glucocorticoids may be useful in effecting rapid resolution of the pulmonary infiltrates.

OTHER ACUTE EOSINOPHILIC PNEUMONIAS

When no agent or inciting event can be associated with the onset of eosinophilic pneumonia, the term *pulmonary infiltration with eosinophilia* (PIE) syndrome is often used. The disorder may occur rapidly, demonstrate pulmonary and systemic symptoms, and persist for a variable period. Control is achieved with glucocorticoids, and long-term disability is uncommon.

A more acute eosinophilic pneumonia was reported by Allen et al. (69). No etiologic agent was uncovered in these cases, and the patients had symptoms of an acute febrile illness and clinical hypoxemia, diffuse infiltrations as seen on chest radiograph films, and eosinophilia noted in the BAL fluid. Respiratory failure occurred in two of the patients, and treatment with glucocorticoids resulted in rapid resolution.

Recent studies of the level of IL-5 in peripheral blood and in BAL fluids have found high levels of the cytokine in acute eosinophilic pneumonia, but not in the chronic variety (70).

Drug-induced Eosinophilic Pneumonia

A wide variety of drugs have been described to cause pulmonary infiltration with eosinophils or interstitial pneumonitis (Table 70.4) (71). The clinical features of the reaction vary and generally occur as dyspnea with or without wheezing, fever, or various degrees of cough. There is often a latent period between the use of the drug and the onset of symptoms. Peripheral blood eosinophilia is often present, and eosinophils may be detected in increased numbers in sputum or BAL fluid. The chest radiograph is not specific and demonstrates unilateral or bilateral infiltrates. Examination of a lung biopsy specimen reveals eosinophilic and mononuclear infiltration of the pulmonary parenchyma and alveolar spaces. Glucocorticoids may resolve all of the clinical abnormalities, but cessation of the causative drug remains primary therapy.

Acetylsalicylic acid[b]	Melphelan
Asenicals[a]	Mechanesin[a]
Amiodarone[b]	Methotrexate[a,b]
Azathioprine[b]	Mitomycin[b]
Beclomethasone[c]	Nadolol[b]
Bleomycin[a,b]	Naproxen[a]
Busulfan[b]	Nitrofurantoin[a]
Carbamazepine[a]	Nitrosourea[b]

TABLE 70.4. Some Drugs Associated with Interstitial Pulmonary Disease

Reactions to nitrofurantoin may be present in an acute or chronic fashion. The acute reaction begins shortly after institution of the drug, as previously described. The chest radiograph may demonstrate pleural effusion along with infiltrative disease, and a lung biopsy specimen shows parenchymal eosinophilic and mononuclear infiltration and, in some cases, vascular involvement. Peripheral eosinophilia and elevation of the sedimentation rate are usual. In the chronic nitrofurantoin reaction, the onset may occur up to 5 years after beginning therapy with the drug. The clinical features of this form include chronic progressive cough and dyspnea, and interstitial fibrosis on chest radiographs may be prominent. Cessation of drug therapy remains the mainstay of treatment, but glucocorticoids may be necessary to reduce progression of the disease process.

Pulmonary eosinophilia can occur after the use of a number of sulfonamides and appears clinically as pneumonitis.

Phenytoin derivatives used to treat seizure disorders and on occasion arrhythmias also can induce a pulmonary disorder. Acute eosinophilic pneumonia associated with fever, cough, and dyspnea may occur days to months after institution of the drug. The symptoms also may be associated with features of a nonspecific dermatitis, hepatitis, and generalized lymphadenopathy, including hilar nodes. Resolution occurs with cessation of the drug.

Chronic Eosinophilic Pneumonia

In 1969, Carrington et al. (72) described a chronic pulmonary eosinophilic syndrome in which no etiologic agent could be detected. The patients initially had fever, sweats, progressive dyspnea, and weight loss. Asthma occurred in 50%. The chest radiographs were characterized as the “photographic negative” of pulmonary edema with peripheral pulmonary infiltrates, but patchy migrating infiltrates, pleural effusion, and cavitation also were seen. Respiratory failure in patients with severe disease has been reported (73). Blood eosinophilia is characteristic, and the sedimentation rate and platelet count may be elevated (74), as may the total serum IgE level (75). Lung biopsy specimens demonstrate interstitial and alveolar infiltrations with eosinophils and multinucleated giant cells with minimal fibrosis. Institution of glucocorticoids is usually associated with resolution or at least a shortening of the course of the disease (72).

The clinical features of bronchospasm, eosinophilia, elevated serum IgE levels, and response to glucocorticoids suggest the involvement of an IgE/mast cell–dependent mechanism of immediate wheal-and-flare reactions, and the mononuclear cell infiltration suggests involvement of the late-onset reaction; however, the

inflammatory action of eosinophils is most likely the key to the tissue damage. BAL fluid analysis has revealed increased levels of eosinophil cationic protein and expression of class II major histocompatibility complex (MHC) molecules, reflecting eosinophil degranulation and activation (76,77). After treatment with glucocorticoids, IL-2 receptor positive and HLA-DR positive T cells decrease in the analyzed lavage fluid (78).

Further work on the biology of the eosinophil and the mechanisms that control its activation, recruitment, and degranulation will help us to understand its role better in these inflammatory disorders.

IDIOPATHIC PULMONARY FIBROSIS

Idiopathic pulmonary fibrosis (IPF) is an interstitial pulmonary disorder of unknown etiology that has been referred to as the *Hamman-Rich syndrome, cryptogenic fibrosing alveolitis,* or *desquamative, usual,* or *lymphocytic pneumonitis.* The patients originally described by Hamman and Rich (79) had a progressive pulmonary disease with associated connective tissue disorders such as rheumatoid arthritis.

IPF is a disease of unknown etiology but has fairly well characterized clinical, laboratory, and histopathologic features. The prevalence is about three to five cases per 100,000 (80), and it occurs more often in patients between ages 40 and 70 years, with a slight predilection for men. The clinical course of the disease varies, but the mean survival time after diagnosis ranges between 3 and 5 years with or without treatment.

Clinical Features

The characteristic clinical features of IPF include the gradual onset of progressive shortness of breath. It occurs at first on exertion, but eventually at rest, and is often accompanied by a dry, nonproductive, persistent cough. Some patients may have a preceding influenza-like illness, and in others, anorexia and weight loss develop. Characteristic physical findings include dry bibasilar inspiratory “Velcro” rales, with clubbing and cyanosis occurring late. Pulmonary-function tests reveal a restrictive pattern with decreased lung volumes and reduced diffusing capacity. As the disease progresses, the restrictive and gas-exchange abnormalities increase. The chest radiograph typically demonstrates diffuse infiltrates, which are most prominent in the lower lobes, where a reticulonodular pattern is characteristic and may be visualized on thin-section computed tomography (81). However, the chest radiograph may appear normal in up to 15% of patients with IPF (82,83). High-resolution computerized tomography (HRCT) is now widely used in the investigation of patients with suspected or known diffuse lung disease (84).

The histopathologic features of the disease are heterogeneous, with a spectrum ranging from an alveolitis to end-stage fibrosis or diffuse honeycombing. Early in the disease, the pulmonary parenchyma may appear normal, and the disease process is spotty. Thus lung biopsy is often necessary for confirmation of the diagnosis. Evaluation of series of lung biopsy specimens has led to classification of the histopathologic features into three broad groups (85,86 and 87). *Desquamative interstital pneumonia* (DIP) occurs as a cellular pattern with an increased number of macrophages and lymphocytes filling the intraalveolar spaces. Interstitial edema also may be prominent (85,87). Fibrosis is not present, and lymphocytes and eosinophils may be found in the alveolar septa. *Usual interstitial pneumonia* (UIP) occurs as a mixed cellular and fibrotic picture and may represent progression of the disease. There is more intense inflammation with derangement of the alveolar walls by edema and injury of endothelial and epithelial cells (85). Fibroblasts proliferate, and there is infiltration of alveolar walls and septa with lymphocytes, eosinophils, and mesenchymal cells. Organized inflammation and fibrosis are present, and with further parenchymal derangements, proteinaceous debris may be found in the intraalveolar spaces. The *end stage* or honeycombing is characterized by replacement of pulmonary parenchyma by cystic spaces lined with cuboidal epithelium and encircled by connective tissue with little inflammation (88). Smooth-muscle hyperplasia, small-airway narrowing, and changes in the pulmonary arterioles suggestive of pulmonary hypertension are features of this phase of IPF.

The recognition of these putative stages of IPF may be helpful in evaluating the prognosis in a given patient. Carrington et al. (72,85) determined that patients with less aggressive disease (DIP) had a lower mortality rate of 27.5%, compared with patients with the more aggressive form (UIP), in which the mortality during follow-up was 66%. Other studies showed that patients with a more cellular pattern on biopsy specimens respond better to glucocorticoid therapy than do those in the fibrotic phase (86).

Thus open lung biopsy is useful in confirming the diagnosis, evaluating the response to therapy, and determining the prognosis of the patient.

BRONCHOALVEOLAR LAVAGE

BAL studies have shown that cell counts from the fluid correlate with the histopathologic features of IPF and also may be useful in predicting the response to therapy (89,90). Patients with progressing IPF and sarcoidosis have increased expression of proinflammatory chemokines such as IL-8 and TNF-a in BAL fluid (91). IL-8 is increased in the BAL fluid and serum of patients with IPF and may reflect the degree of neutrophilic alveolitis (92). Other recent observations indicate that TNF-a may be involved in the recruitment of eosinophils, which are believed to be important in the development of fibrosis (93). The detection of lymphocytosis in BAL fluid correlates with alveolitis without honeycombing, but the detection of neutrophilia and eosinophilia does not correlate with biopsy findings (35). Furthermore, the relative increase in lymphocytes but not other cellular elements in BAL fluid correlates well with glucocorticoid responsiveness. The response of the BAL fluid cellular elements to treatment is variable in spite of clinical improvement (94,95).

Other described abnormalities in BAL fluid include changes in the phospholipid components of pulmonary surfactant with decreased phospholipids, a decreased phosphatidylglycerol-to-phosphatidy1choline ratio, and a relative decrease in the dipalmitoyl form of phosphatidy1choline, as well as the demonstration of lipoprotein macroaggregates (96). These lipid aberrations may correlate with the clinical response of patients with IPF or with the cellularity of the biopsy tissue (96,97).

THERAPY

Since the study of Carrington et al. (85) in 1978, glucocorticoids have been the mainstay of treatment. Between 40% and 70% of patients with IPF so treated reported subjective improvement, but only 10% to 30% had correlative objective improvement (85,98). In general, those patients with the more cellular phase of IPF respond favorably to the drug, probably related to the suppression of the inflammatory process. Because the cellular phase of IPF may represent an earlier and more responsive phase, patients with suspected disease need early diagnosis, preferably detected by open lung biopsy, followed by suppressive doses of glucocorticoid. Regulation of the drug dose should be carried out with periodic chest radiograph studies, pulmonary-function evaluations, and in some cases, BAL studies. The duration of glucocorticoid therapy varies from 3 months to 1 year to lifetime. If the condition of the patient deteriorates during such therapy, glucocorticoid should be reduced or discontinued and alternative immunosuppressive/antiinflammatory therapy should be started.

Cyclophosphamide may be beneficial in reducing the pulmonary neutrophilic inflammation (99,100), thus reducing the gas-transfer disruption across the alveolar membrane. Azathioprine, chlorambucil, colchicine, and vincristine have also been used alone or in combination, with varied results (98,101). Finally, transplantation of a lung or of a heart and lung has been successful in some patients who have uncomplicated disease (102,103). To date, this therapy offers the best prognosis for long-term survival.

PATHOGENESIS

IPF is a chronic inflammatory process of the lung in which inflammation is unregulated by the normal repair processes. As a result, mesenchymal cells proliferate and extracellular connective tissue is deposited, leading to disturbances in gas transfer (80,104). Although the inciting injury is unknown, viral, immune, inflammatory, and genetic processes may be important in the initiation and maintenance of the disease process. Cytokines, which may be divided into proinflammatory, antiinflammatory, and growth-stimulatory groups, play important roles as soluble signaling molecules that dictate and coordinate these inflammatory and immune responses.

A genetic component of IPF has been postulated because of an association of the disease with specific HLA haplotypes. Whereas some studies detected no correlations (105,106), others showed an increased frequency of HLA-B12 (23), HLA-B15, HLA-Dw6 (107), HLA-DR2 (33), and HLA-B8 (108). Additional studies correlated IPF with specific a_1-antitrypsin phenotypes (109), with other genetic disorders such as Gaucher disease (110), neurofibromatosis (111), Neimann-Pick disease (112), and tuberous sclerosis (113), and with familial occurrences in which there is variable penetrance of an autosomal dominant pattern. These findings suggest genetic influences in the disease such as linking of IPF with other inheritable disorders (114,115).

Viral infections may be important. Many patients have a history of a flulike illness before the development of IPF, and some have intracellular inclusion bodies in the alveolar epithelial cells (81,116). Additional studies suggested a relationship between Epstein-Barr viral (EBV) infection and IPF, with increased titers in the serum and BAL fluid of specific IgG against the viral antigens (117,118). However, such studies are not conclusive, as infection with EBV is common in the population.

Immune mechanisms have been implicated in the pathogenesis of IPF because up to 20% of these patients have other connective tissue disorders such as rheumatoid arthritis, systemic sclerosis, myositis, and systemic lupus erythematosus (119,120 and 121). The immune abnormalities in the connective tissue disorders such as hyperimmunoglobulinemia, cryoglobulinemia, elevated antinuclear antibody and rheumatoid factor titers, and decreased complement components have been detected

in IPF (122). Furthermore, circulating immune complexes have been detected in the disease, and levels of the complexes may correlate with the level of pulmonary infiltration (123,124). The latter correlates with immunofluorescent staining of lung tissue, which has demonstrated deposits of immunoglobulins and complement in alveolar walls and capillaries (125). However, the specificity of the antigen(s) coupled to the immunoglobulins has not been identified. These data may represent pathogenetic mechanisms or may merely be epiphenomena.

Other studies suggested that cytokine-mediated activation of immune effector cells may play a role in inflammation and the sustenance of the alveolitis (126). Activated macrophages that can release multiple modulators of inflammation such as leukotriene B, platelet-derived growth factor (PDGF), fibronectin, growth factors, proteases, and reactive oxygen species accumulate in the lung, where inflammatory processes are amplified (127,128,129,130,131,132,133,134 and 135). The macrophages in the lung of a patient with IPF have been shown to be young and recently differentiated, and replicate at a level above those from normal lungs (136). Thus mechanisms that control macrophage proliferation are likely disturbed in IPF.

Other inflammatory cells found in excess in the lungs of patients with IPF include neutrophils and lymphocytes. Neutrophils are attracted and activated by macrophage-derived cytokines and may thus contribute to the inflammatory process. The accumulation of these inflammatory effector cells disturbs the pulmonary parenchymal structure through release or secretion of proteases and reactive oxygen species, and the cells enhance further inflammation by release of cytokines with growth and proliferation capabilities. The production of Th2 cytokines by $CD8^+$ T cells in the BAL fluid of patients with systemic sclerosis is associated with greater decline in pulmonary function (137).

FIBROTIC LUNG DISEASES DUE TO INORGANIC DUSTS

The various mineral-induced pneumoconioses, especially silicosis, berylliosis, and asbestosis, have been of major immunologic interest for years, and immune mechanisms have been considered contributory to the pathogenesis of these diseases. Patients with silicosis inhale dust containing silicon dioxide (SiO_2) for prolonged periods and develop progressive pulmonary fibrosis with clinical pulmonary impairment. At-risk occupations include hard-rock mining, stone crushing, foundry work, sand blasting, and granite work; development of such occupation-associated disease can be markedly reduced by control of the levels of inhalable silica.

The clinical features of silicosis include progressive dyspnea, cough, and sputum. Physical findings may be normal or may demonstrate obstructive or restrictive defects. Chest radiograph features include diffuse rounded opacities predominating in the upper lung fields, eggshell calcification of the hilar nodes, and coalescence of the nodule to form “progressive massive fibrosis” (138). Histopathologic study demonstrates nodules comprised of fibroblasts, macrophages, and lymphocytes surrounding a central core of whorled collagen and reticulin (138). The nodules may coalesce to form the masses of fibrosis. Silica particles may be detected in a central location by electron microscopy, and these particles may play a key role in the activation of alveolar macrophages and induction of the inflammatory process (138,139).

Immunologic evaluation of patients with silicosis has revealed abnormalities in both cellular and humoral responses. Polyclonal elevations of immunoglobulins and the detection of antinuclear antibody, rheumatoid factors, and circulating immune complexes have been described (140). Alterations in $CD4^+$ and $CD8^+$ T-cell numbers and variances in lymphocyte responses to mitogens can be demonstrated in patients with silicosis (141). These abnormalities do not correlate with the clinical status of the patient and may represent secondary effects or the result of immune cascades stemming from alveolar macrophage activation by silica. Such macrophage activation has been demonstrated in animal models of the disease and results in release of proinflammatory cytokines and active oxygen radicals, ultimately enhancing the fibrotic process (142).

In the past, asbestos was widely used in the construction, automotive, insulation, and cement industries. Governmental controls, however, have reduced the use of the material considerably. Asbestosis occurs after the inhalation of fibers that can be deposited in the terminal airways. The clinical features of asbestosis are similar to those of IPF but are usually not apparent until about 20 years after exposure. Progressive dyspnea and cough leading to respiratory insufficiency are frequent findings. Features of interstitial lung disease with end-inspiratory rales, clubbing, and ultimately cor pulmonale are found. Pulmonary-function abnormalities include restrictive and diffusion defects. Chest radiograph abnormalities depend on the degree of involvement and may range from small irregular lower lung-field shadows to more extensive infiltrates that may mimic features of IPF. Areas of pleural thickening, often with calcification, are characteristic, and the occurrence of mesothelioma is most often associated with asbestos exposure. Bronchiogenic carcinoma is increased in tobacco users also exposed to asbestos, suggesting that the mineral may act as a “promoter” (143).

Patients with asbestosis do not have a consistent pattern of immune abnormalities. Some studies indicated reduced circulating lymphocyte numbers, decreased helper-induced lymphocytes, and decreased mitogen responses (144). Other studies showed decreased levels of $CD8^+$ T cells and normal levels of helper and NK cells (141,145). Studies of BAL fluids from patients with asbestosis detected increases in neutrophils, eosinophils, lymphocytes, and macrophages (146,147 and 148). Evaluations of T-cell subsets in the lung fluid detected significant increases in $CD4^+$ T cells (146). In addition, lung-fluid analysis demonstrated both asbestos fibers and fibers coated with various degrees of proteins or iron (ferruginous bodies), the numbers of which correlate with the degree of asbestos exposure (149). Such bodies may activate complement pathways and interact with pulmonary lymphocytes and macrophages to release proinflammatory cytokines. They also may induce release of cellular-activating and fibrosis-promoting factors to enhance further the lesions of asbestosis.

Pulmonary disease due to beryllium may appear as an acute toxic pneumonitis (150) or as a chronic pulmonary granulomatous disorder. Initially described in the fluorescent lamp industry (151), most cases now occur in individuals in mining, milling, or melting occupations or in the formulation of beryllium alloys. An HLA class II marker (HLA-DPB1 Glu69) is strongly associated with the disease. The gene confers increased susceptibility to beryllium in exposed workers (152,153). Symptoms of chronic beryllium disease develop insidiously months to years after exposure. Dyspnea is most common and may be associated with nonproductive cough, with fever, sweats, general malaise, anorexia, and weight loss, as the disease progresses. Physical examination may reveal features of interstitial pulmonary disease, with cyanosis, clubbing, and cor pulmonale occurring in advanced disease. Pulmonary function abnormalities include restrictive and diffusion defects, and chest radiograph features include widespread small reticular opacities, conglomerate nodules, and hilar adenopathy (154,155). The characteristic lesion is that of a diffuse interstitial infiltration of the pulmonary parenchyma along with noncaseating granulomas that may contain calcifications (155). Clinical laboratory features may resemble those of sarcoidosis, with elevated angiotensin-converting enzyme levels, increased gallium uptake on scans, increased levels of calcium in blood and urine, and nonspecific immunoglobulin elevations (156,157). Beryllium is antigenic in humans, inducing cell-mediated responses that can be demonstrated in workers with disease. Results of patch tests with beryllium salts have largely been positive in such workers (158), and blast transformation and production of macrophage migration inhibition with peripheral blood lymphocytes have been demonstrated in exposed but not necessarily ill workers (159). Studies of BAL fluids from ill workers showed increased numbers of T lymphocytes with a predominance of $CD4^+$ cells, which preferentially could be stimulated by beryllium salts (159). Activation of pulmonary $CD4^+$ cells with subsequent release of proinflammatory cytokines and interaction with macrophages might then lead to interstitial infiltrative and granulomatous pneumonitis characteristic of the disease.

71 ALLERGIC CONTACT DERMATITIS

Stephen I. Katz, M.D., Ph.D.

Allergic contact dermatitis is a very common inflammatory skin disease that represents a form of delayed-type hypersensitivity. Contact dermatitis and primary irritant dermatitis, which results from exposure to irritants, make up almost 40% of all occupationally acquired illnesses (1). Despite the clinical importance of contact dermatitis, knowledge about why a given individual becomes sensitized to a particular chemical is limited. In recent years the role of the skin in the generation of contact dermatitis has become better understood.

ETIOLOGY

Chemical Causes

Allergic contact dermatitis is due to a delayed-type hypersensitivity to simple compounds, usually of low molecular weight, applied to the skin. Approximately 3,000 different compounds have been implicated as causes of allergic contact dermatitis. Haptens vary in their ability to sensitize. Haptens such as 2,4-dinitro-l-chlorobenzene (DNCB), squaric acid dibutyl ester, and diphenylcyclopropenone are strong sensitizers and induce allergic contact dermatitis with a single exposure to no more than 0.1 mL of a 0.5% to 1.0% solution placed on a 2-cm circular diameter of forearm skin. The majority of common environmental or commercial sensitizers require repeated exposures to induce sensitization. For humans, the time from hapten recognition to the development of allergic contact dermatitis is typically 14 days (range, 7 to 20 days). When sensitization has been accomplished from a single exposure to a hapten, the induction site typically flares without the application of a second or eliciting dose 7 to 20 days later. The reason is that very small amounts of the original dose remain in the skin and act as the second (eliciting) stimulus once sensitization has developed. In most clinical cases of allergic contact dermatitis, the original sensitization occurs some time during multiple induction exposures. When the unknowingly sensitized individual is reexposed to the material, contact dermatitis is expressed 1 or 2 days later (the time can be as short as 6 hours or can take up to 3 or 4 days). The important point is that it takes 7 to 20 days for the initial sensitization to take place; but once that has occurred, subsequent reactions typically occur within 8 to 96 hours, depending on the hapten concentration, the manner of exposure, and the individual's degree of sensitization. Most contact dermatitis is therefore an expression of an exposure 1 or 2 days previously. Occasionally, the only exposure that can be documented for a patient with contact dermatitis occurred several weeks before the development of the dermatitis. This finding represents the development of sensitization during the 2-week period, with flaring from the residual of the first exposure. Clinically, this situation is uncommon but important to recognize as a form of contact dermatitis. It has been observed in patients who had contact dermatitis induced by a large exposure to poison ivy or hair dye.

Most patients find it difficult to believe that they have become allergic to commercial products used for years as cosmetics or medications. Modest or weak haptens induce sensitization when repeatedly used under certain conditions (see Factors Influencing Sensitization, below). The product's major ingredient, the components of the delivery vehicle, the preservative system, and fragrances are likely causes of the dermatitis. To complicate matters, allergic contact dermatitis is frequently a superimposed condition on a nonallergic dermatitis. Thus an individual may use over-the-counter topical medicaments for a preexisting condition, and contact dermatitis may develop to an ingredient in the topical medication.

Probably the most common causes of allergic contact dermatitis are plants such as poison ivy, poison oak, and poison sumac. Other common sensitizers include *para*-phenylenediamine, nickel compounds, rubber additives, and numerous biocides used for the preservation of products that contain water. Health-care workers, now required to wear latex rubber gloves, can develop both a delayed and an immediate (urticarial) hypersensitivity to the gloves (see Chapter 73). The rubber additives and antioxidants are typically responsible for the delayed hypersensitivity, although the latex itself can be the cause of contact urticaria or anaphylaxis (2,3 and 4). It is now well understood that certain proteins from the latex itself are mainly responsible for the immediate contact urticaria. The investigation of a latex glove reaction requires clinical skills in both patch testing and immediate skin testing for urticaria. Topical glucocorticoids, often used to treat various forms of dermatitis, have been identified as themselves causing contact dermatitis (5).

Photoallergic contact dermatitis is manifested as an exaggerated response to sunlight and requires exposure to light after the topical application of certain chemicals. Agents that may be responsible for photoallergic contact dermatitis include sunscreens, after-shave lotions, topically applied sulfonamides, antihistamines, certain plants, and antibacterial agents in soaps (although many of these agents have been removed from soaps). This form of photosensitivity must be differentiated from photosensitivity reactions to systemically administered drugs.

Factors Influencing Sensitization

Three important variables influence the development of allergic contact dermatitis on an experimental or clinical level: (a) increasing the concentration of the allergen increases its rate of sensitization (6), (b) increasing the number of exposures leads to higher sensitization rates, and (c) allergen exposure through preexisting inflammation also increases the rate of sensitization. For example, exposure to a potential allergen on an area of irritated skin such as an area of stasis dermatitis will increase its chance of inducing allergic contact dermatitis (7). Strong sensitizers are typically irritating to the skin (creating their own nonspecific inflammation), but not all strong irritants are sensitizers.

CLINICAL PRESENTATION

Clinical Findings

The clinical findings of allergic contact dermatitis depend on the severity of the eruption. Factors that dictate the severity and persistence of lesions include the sensitivity of the individual, the dose of antigenic exposure, and the potency of the antigenic stimulus.

The clinical lesions vary from transient redness to edematous red papules that become vesicular and, at times, even bullous (Fig. 71.1). Itching is one of the hallmarks of the disease and varies in intensity. Any part of the skin that comes into contact with the sensitizing substance may be involved. Characteristically, the dermatitis is, at first, limited to the skin sites exposed to the antigen, although later it may spread to other areas.

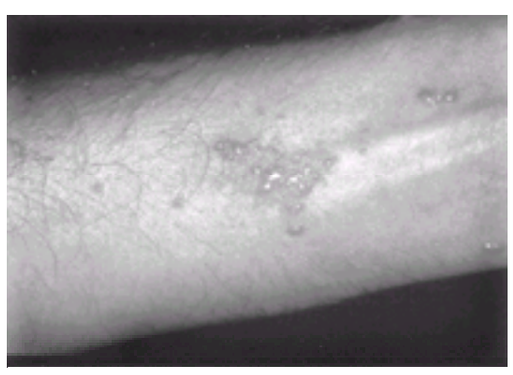

Figure 71.1. Acute allergic contact dermatitis on the arm, showing various-sized blisters.

The course is variable. If the cause is removed, simple redness may fade within several days. However, when vesicles occur, they often rupture, resulting in oozing and crust formation (Fig. 71.2A and Fig. 71.2B). As the inflammation subsides, scaling and some temporary thickening of the skin develop. Continuing exposure to the antigen or complications such as excoriations, infections, or irritation, or allergy to the medicaments applied for the treatment of the primary eruption may perpetuate the dermatitis. Chronic lesions are almost always pruritic and are characterized by lichenification (thickening of the skin with accentuation of skin markings) and scaling without any apparent vesicle formation.

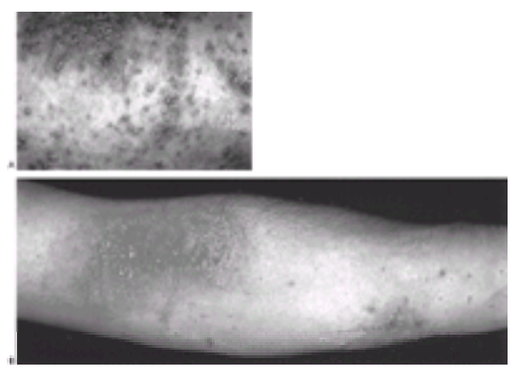

Figure 71.2. A, B: Subacute allergic contact dermatitis on the arm, showing erythema, oozing, and crust formation.

Histologic Features

The histopathologic features of allergic contact dermatitis vary according to the severity of the eruption. Although the findings may be strongly suggestive of contact dermatitis, no pathognomonic features distinguish allergic contact dermatitis from many other forms of dermatitis. Perivascular infiltrates of lymphocytes and monocytes are seen in the upper dermis within 6 hours of exposure to antigen. The infiltration may be accompanied by considerable edema of the superficial dermis. Subsequently, intracellular and intercellular edema develops in the epidermis to form what is known as spongiosis (Fig. 71.3) (8). During these later stages (48 to 72 hours after onset), basophils may constitute about 5% to 15% of infiltrating cells (9). Eosinophils may also be present, albeit to a lesser extent. Fibrin deposition, as well as superficial dermal blood vessel changes, may be seen. More chronic lesions of allergic contact dermatitis are characterized by hyperkeratosis, acanthosis (thickening of the epidermis), and a variably dense mononuclear cell infiltrate in the superficial dermis.

Figure 71.3. Allergic contact dermatitis, acute stage. There is a superficial perivascular infiltrate composed predominantly of lymphocytes and monocytes, edema of the papillary dermis, and epidermal spongiosis with lymphocytes within the epidermis.

Differential Diagnosis

Because allergic contact dermatitis may resemble so many other types of dermatitis (e.g., primary irritant dermatitis, nummular dermatitis, atopic dermatitis, dermatitis herpetiformis, herpesvirus infections), an allergen should be suspected as the cause or as an aggravating factor in dermatitic eruptions. Skin biopsy may be useful in differentiating certain of these diagnoses but, as noted earlier, there is no definitive histologic pattern in allergic contact dermatitis. Characteristic skin changes and a history of exposure often suggest the correct diagnosis. Identifying the site of the initial lesion is helpful in identifying the cause. Identifying the responsible agent, however, may require exhaustive questioning of the patient regarding medical history, occupation, hobbies, household duties, wearing apparel, topical medications and cosmetics, vacation history, and spouse's activities.

Patch Testing

Patch testing with a suspected allergen or with a standard group of common contact allergens may be indispensable if questioning is fruit less. The clinical patch test was initially introduced by Jadassohn (10) in 1896 to demonstrate that allergic contact dermatitis was a clinical entity and could be simulated in individuals who had become sensitized. If a chemical is suspected as the cause of the dermatitis, the material (in the appropriate concentration) is applied to normal-appearing skin (usually the back) under a nonabsorbent adhesive patch and left for 48 hours. In recent years, patch-test kits with materials in their appropriate concentrations have become available (11). A positive patch-test reaction consists of redness with some papules and, at times, tiny blisters. Patch tests should not be performed when patients are experiencing an acute dermatitis because the allergen may worsen the eruption in a very sensitive individual or there may be nonspecific false-positive reactions. A positive result on the patch test, although indicating allergy, does not necessarily identify the agent causing the contact dermatitis. There should be a history of exposure to the test agent in the areas where the dermatitis originally appeared. The North American Contact Dermatitis group has identified the 20 most common allergens by patch testing (Table 71.1) (12). The 20 screening allergens commercially available for patch testing in the United States accounted for only 54% of the patients with positive allergic reactions (12).

Nickel sulfate	Carba mix
Fragrance mix	Diazolidinyl urea
Neomycin sulfate	Lanolin
Balsam of Peru	Imidazolidinyl urea
Thimerosal	Methylchloroisothiazolinone/ methylisothiazolinone
Formaldehyde	Ethylenediamine dihydrochloride
Quaternium-15	*p*-Tert-butylphenol formaldehyde resin
Bacitracin	Rosin (colophony)
Cobalt	Benzocaine
para-Phenylenediamine	
Thiuram mix

TREATMENT

The most important approach to treatment of allergic contact dermatitis is the identification and removal of the offending agent. Identification is best accomplished by taking a complete history and/or by patch testing. Patients with photoallergic contact dermatitis should avoid exposure to both sunlight and the antigen. In the acute phase of contact dermatitis, such as that caused by poison ivy, gauze or thin cloths dipped in lukewarm water and applied to the lesions are soothing and help stop the oozing; these open wet dressings should be applied for 20 to 30 minutes, 4 to 6 times daily. Blisters may be drained with a sterile needle, but the tops should not be removed. In severe or extensive cases or even in more localized eruptions in which there is facial involvement, early treatment with prednisone administered in an initial dose of 60 to 80 mg daily for 12 to 16 days is recommended. The prednisone dose should be decreased by 10 to 20 mg every 3 to 4 days. Topical glucocorticoids are not helpful in the blistering phase, but when the dermatitis becomes less acute, topical glucocorticoid creams or ointments should be rubbed into the lesions 4 to 5 times a day. Oral antihistamines are used for their sedative effect. Desensitization is generally ineffective in contact dermatitis. Although topical cyclosporine may be effective in preventing allergic contact sensitivity in animals, it is not available for use in humans (13). Various skin-surface protectants are available for use in humans to prevent allergic contact dermatitis to specific allergens, such as poison ivy (14,15).

PATHOBIOLOGY

Allergic contact dermatitis has been studied extensively because it represents a highly specific and reproducible form of delayed-type hypersensitivity. The importance of cellular mechanisms was demonstrated by Landsteiner and Chase (16), who showed that contact sensitivity from a sensitized guinea pig could be transferred to a nonsensitized guinea pig by peritoneal exudate cells rather than by serum. Subsequently, Chase (17) and others (18,19) used a variety of cell sources to conclude that lymphoid cells played the central role in this adoptive transfer. Other studies suggest that serum factors also may be important in the transfer of contact sensitivity (20,21).

Numerous studies have demonstrated the importance of skin in the generation of allergic contact dermatitis and other forms of delayed-type hypersensitivity. Macher and Chase (22) demonstrated that the induction of allergic contact dermatitis requires the interaction of hapten with peripheral tissues (skin). They showed that when hapten was injected into guinea pigs' ears and the ears were excised before a critical 24-hour period, sensitization did not occur. Furthermore, if the ears were excised between 12 and 24 hours after injection of the hapten, specific immunologic unresponsiveness occurred, presumably because of the tolerogenic effect of the rapidly escaping blood-borne hapten. These studies were very much in keeping with those of Sulzberger (23), who demonstrated that skin is a unique site for sensitization, in that when haptens were injected into organs other than skin, specific unresponsiveness ensued. Thus the immunologic outcome, that is, the degree of sensitization or tolerance, is governed by the influences that the routes and the manner (dose, schedule) of exposure exert on helper and suppressor subsets of T cells. When sensitization does occur, usually a downregulating component is generated as well.

Godfrey (24) expanded on prior work on antigenicity by demonstrating that not only was the ability of the hapten to bind covalently with a carrier protein important for allergenicity, but also the chemical's solubility and its local effects influenced the degree of sensitization. Many haptens responsible for allergic contact dermatitis have low molecular weights (<500) and are lipid soluble. The early concepts that induction and elicitation responses are directed toward hapten/carrier complexes remain valid today. The molecular complex recognized by T cells is now known. Studies suggest that haptens bind to endogenous peptides that are associated with class II or class I major histocompatibility complex (MHC) (25,26 and 27). These complexes are well represented on epidermal Langerhans cells (28). An alternative, and not mutually exclusive possibility, is that the hapten binds directly to the class II MHC molecules that are represented on the surface of Langerhans cells (29).

The induction of contact sensitivity involves interaction between T lymphocytes and class II–bearing Langerhans cells (Fig. 71.4 and Fig. 71.5). These latter cells are bone marrow derived but reside within the epidermis and can, in *in vitro* and *in vivo* animal models, replace macrophages and dendritic cells in the induction of various delayed-type hypersensitivity reactions (28). After allergen (hapten) application to skin, there is enhanced class II MHC antigen expression as well as enhanced T-cell stimulatory function by Langerhans cells (30). Indeed, certain haptens are capable of causing a selective and profound enhancement of various messenger RNAs for cytokines produced by the epidermis. Thus interleukin (IL)-lb, derived from Langerhans cells, and IL-10 and tumor necrosis factor (TNF)-a, both derived from keratinocytes, are upregulated in response to hapten application to nonsensitized skin (31). IL-1b and TNF-a are probably both required for the activation and migration of Langerhans cells from the epidermis to the regional lymph nodes (32,33,34,35 and 36). IL-10 downregulates immune responses by directly affecting the antigen-presenting capacity of Langerhans cells (37,38).

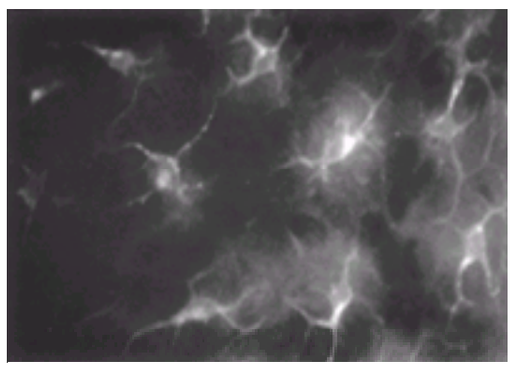

Figure 71.4. Immunofluorescent staining of normal epidermis with major histocompatibility complex (MHC) class II antigen antibody showing dendritic Langerhans cells. The epidermis was separated from the dermis and is viewed *en face*. There is no MHC class II antigen staining of keratinocytes.

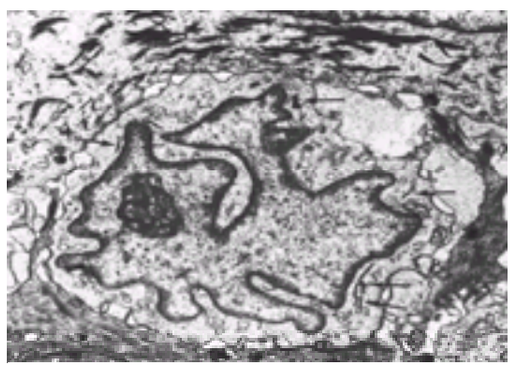

Figure 71.5. Electron photomicrograph of an epidermal Langerhans cell in a milieu of keratinocytes. The cell exhibits a lobulated nucleus, lacks tonofilaments (seen in adjacent keratinocytes), and contains typical cytoplasmic organelles (*arrows*) called Birbeck or Langerhans cell granules.

Macatonia et al. (39) demonstrated that increased numbers of dendritic cells appear in regional lymph nodes 24 hours after hapten application, implying that Langerhans cells migrate from skin into the regional lymph nodes and present antigen therein. Indeed, after intradermal challenge of sensitized animals with electron-dense allergens, Langerhans cells have been observed in dermal vessels resembling lymphatics and in draining lymph nodes (40).

After hapten painting, distinct T-cell subsets (CD8 as well as CD4 T cells) are generated, and both probably contribute to the generation of allergic contact dermatitis. However, it has been known for some time that CD4 T cells are capable of passively transferring contact sensitivity from a sensitized animal to one that has never been exposed to the hapten (41). Moreover, a distinctive subset of CD4 T cells, the Th1 subset that produces IL-2 and interferon-g, is capable of passively transferring contact sensitivity to nonsensitized mice (42,43). Indeed, these effector T cells can be generated by culturing hapten-modified Langerhans cells with virginal T cells (44). More recent studies have implicated CD8 T cells in the generation of contact sensitivity (45).

In addition to effector T cells mediating inflammation, specific CD8 T cells are also generated after sensitization with haptens (46). Thus the degree of immunity

achieved represents a balance between sensitization and tolerance, mediated by a complex suppressor circuit acting on both the afferent and efferent pathways of the delayed hypersensitivity reaction (47). Whether sensitization results in net effector or net CD8 activity depends on the dose and property of the allergens and on the integrity of the epidermal Langerhans cells. Many studies demonstrated, for example, that ultraviolet light irradiation and other physicochemical agents can alter the density or the cell-surface markers of Langerhans cells (48,49 and 50). These alterations may result functionally in the generation of specific immunologic tolerance rather than in sensitization. This tolerance is at least in part due to the generation of hapten-specific suppressor T cells (51). Exploration of various sensitization schedules and methods to alter Langerhans cell functions continues to use these types of information for modulating cutaneous immune responses in humans.

Several studies demonstrated that the dermal infiltrate in the elicitation phase of allergic contact dermatitis in humans consists of an admixture of CD4 and CD8 T cells, with CD4 T cells predominating (52,53). Similar results have, however, been reported for primary irritant dermatitis, suggesting the nonspecificity of these findings (54). This is not too surprising because only a small percentage of T cells infiltrating a cutaneous delayed-type hypersensitivity reaction has specificity for the antigen; the majority of infiltrating cells are therefore nonspecifically recruited (55,56 and 57). Keratinocytes also may participate in the inflammation in contact dermatitis by producing TNF-a and IL-8, by induction of intracellular adhesion molecule-1 (ICAM-1), and perhaps also by inducing the underlying endothelial cells to express various adhesion molecules (58).

FUTURE DIRECTIONS

Allergic contact dermatitis is a significant clinical problem that affects many people. It has also become an important paradigm used to study cell-mediated immune mechanisms both *in vitro* and *in vivo. In vitro* correlates of contact sensitivity have been very informative about the critical role that epidermal Langerhans cells play in the generation and perpetuation of contact sensitivity. *In vivo* models, particularly in mice, have provided important information regarding the dynamics of the cellular responses and have provided numerous opportunities to test various methods for the modulation of immune responses. These methods will continue to be needed to better understand the mechanisms involved in cell-mediated immune reactions in skin, as well as to generate more effective and more specific treatment methods.

72 ALLERGIC REACTIONS TO DRUGS

Rebecca S. Gruchalla, M.D., Ph.D.

Adverse drug-induced reactions (ADRs) have been defined by the World Health Organization as any noxious, unintended, and undesired effect of a drug that occurs at doses used in humans for prevention, diagnosis, or treatment (1). Because of inadequate reporting methods, it has been and continues to be difficult to determine the actual incidence of ADRs. Several groups who evaluated the extent of underreporting found that in hospitals, including university hospitals, only 6% to 12% of ADRs are reported (2,3).

Despite extensive underreporting, estimates of ADRs have been made. In a recent metanalysis of 39 prospective studies in the United States from 1966 to 1996, the overall incidence of serious ADRs in hospitalized patients was 6.7%; when both serious and nonserious reactions were considered together, this proportion rose to 15.1% (4). These reactions are associated not only with significant morbidity and mortality but also with substantial costs. Bates et al. (5) recently estimated that a 700-bed teaching hospital spends 5.6 million dollars because of ADRs in a single year.

Most ADRs involve the skin. Although most of these reactions are not associated with serious morbidity, they are important because they are the most frequently encountered ADR and are the major reason that drug therapy is discontinued. The Boston Collaborative Drug Surveillance Program, one of the most extensive studies of ADRs, evaluated data from more than 37,000 patients to determine the frequency of cutaneous reactions to drugs commonly used in the hospital (6,7). The data were evaluated in two series, and the overall reaction rate was approximately 2% for both series. Reaction rates were highest for amoxicillin (51 per 1,000 exposed patients) and for trimethoprim-sulfamethoxazole (TMP-SMX) (34 per 1,000 exposed patients); the most frequently encountered reactions were pruritus, morbilliform rashes, and urticaria.

The ADRs that are thought to be immunologically mediated have been designated *hypersensitivity* or *allergic* drug-induced reactions. Although they constitute only 6% to 10% of the ADRs in hospitalized patients (8), they often are serious and potentially life-threatening problems (9). In their metanalysis, Lazarou et al. (4) estimated that allergic reactions accounted for 23.8% of the ADRs identified, and many of these were serious.

Adverse drug-induced reactions are heterogeneous in nature and can be separated into two categories: those that are common and predictable (*type A reactions*) and those that are uncommon and not predictable (*type B reactions*) (10). About 80% of ADRs fall into the first group. In addition to being common and predictable, these reactions usually are dose dependent, are related to the pharmacologic actions of the drug, and occur in otherwise normal persons. Reactions in this category include toxicity, side effects, secondary effects, and drug interactions (reviewed in 11,12).

Less frequently, ADRs fall into the unpredictable drug reaction category. These reactions, in addition to being unpredictable, are uncommon, are typically not related to a drug's pharmacologic properties, and occur in susceptible persons. Reactions in this category include drug intolerance, idiosyncratic reactions, and allergic or hypersensitivity reactions. For details about drug intolerance and drug idiosyncrasy, the reader is referred to the previously mentioned reviews (11,12). This chapter focuses on allergic drug reactions only.

FEATURES OF ALLERGIC DRUG REACTIONS

Although evaluating whether or not a drug reaction involves an immune mechanism is not always easy, several features of allergic drug reactions are common to immunologic reactions in general. Typically, the initial course of therapy is uneventful because there must be a period of sensitization. Thus, if a first-dose reaction does occur, either the reaction is not allergic in nature or there was previous exposure to the drug or to a cross-reacting agent. Reactions are restricted to a limited number of syndromes that are known or are thought to have an immunopathologic basis. Typical drug-induced hypersensitivity reactions include urticaria, angioedema, anaphylaxis, hemolytic anemia, and allergic contact dermatitis, among others. Although many reactions are thought to have an immunologic cause, the actual mechanism involved has yet to be identified. Drug hypersensitivity reactions occur in a small proportion of the population because multiple factors must interact with each other before an allergic reaction is elicited. These factors include the molecular characteristics of the drug, its route of administration, the genetic and metabolic predisposition of the individuals, and environmental factors, such as concomitant infection. Before these important risk factors for the development of drug hypersensitivity reactions are discussed, the current classification system and its limitations are presented.

CURRENT CLASSIFICATION SYSTEMS

In 1963, Coombs and Gell (13) developed a classification system for hypersensitivity reactions that is still used today. Hypersensitivity reactions are classified into one of four categories based on the immune mechanism known or thought to be involved. *Immediate-type hypersensitivity reactions* are mediated by drug-specific immunoglobulin E (IgE) antibodies and include urticaria, angioedema, and anaphylaxis. *Drug-induced cytotoxicity reactions* are mediated by drug-specific IgG or IgM antibodies and include drug-induced hemolytic anemia, drug-induced thrombocytopenia, and drug-induced leukopenia. *Drug-induced immune complex reactions* are mediated by drug-specific IgG antibodies and include drug-induced vasculitis and glomerulonephritis. *Drug-induced T-cell-mediated reactions* are mediated by drug-specific T-lymphocytes and include allergic contact dermatitis and, possibly, drug-induced maculopapular eruptions, bullous eruptions, fixed drug eruptions, and Stevens–Johnson syndrome (SJS). Details of this classification system are provided by DeSwarte in a review (11) of drug allergy.

Unfortunately, most drug-induced allergic reactions cannot be classified easily into one of the Coombs and Gell categories because the responsible mechanisms are not known. Whereas many drug-induced cutaneous and other organ-specific reactions have features consistent with a hypersensitivity mechanism, the actual mechanism has not been identified. Thus, we need to begin thinking “out of the box.” Not only do many drug-induced hypersensitivity reactions not fit nicely into the Coombs and Gell classification scheme, but some reactions most likely involve both immune and nonimmune mechanisms, thus adding to the complexity. Once the underlying mechanisms are better elucidated, a more comprehensive and accurate classification scheme can be developed for allergic drug reactions. In addition, this knowledge will allow us to design more efficient methods to predict and prevent these reactions as well as to manage them if they occur. The elucidation of these mechanisms will not be easy because drug-induced hypersensitivity reactions are uncommon, unpredictable, and not reproducible in animal models.

MOLECULAR CHARACTERISTICS OF ALLERGENIC AGENTS, DRUG METABOLISM, AND ANTIGEN PROCESSING

Because of their macromolecular structure, some drugs are immunogenic in their native form. Drugs in this category include proteins and peptide hormones. Most drugs, however, are of low molecular weight (<1000 Da) and are incapable of inducing an immune response unless they are modified in some way. Because these drugs can and do elicit immune responses, their ability to do so is related to their propensity to combine covalently with large-molecular-weight compounds (14) coupled with successful processing and presentation of the formed immunogenic drug complex by antigen-presenting cells (15).

Our understanding of how drug hypersensitivity reactions occur is based largely on the hapten hypothesis (16,17): Because most drugs are not chemically reactive,

they must be metabolized or “bioactivated” to chemically reactive products. In most instances, drug metabolism is a “good thing,” a type of detoxification process by which drugs are converted from lipid-soluble, nonpolar compounds to more polar, hydrophilic compounds that are cleared by renal or biliary excretion (18). Typically, two sequential biochemical reactions, termed *phase I* and *phase II* reactions, are involved. Phase I reactions involve intramolecular rearrangements and often are mediated by hepatic enzymes of the cytochrome P450 monooxygenase system through oxidation, reduction, or hydrolysis. The products formed may be biologically reactive and more toxic than the parent drug. Typically, however, once these reactive intermediates are formed, they are promptly detoxified in phase II reactions through conjugation with glucuronyl, sulfate, or acetyl groups. Thus, to protect the organism, bioactivation is followed by bioinactivation (19) (Fig. 72.1). In some persons, genetic or environmental factors may perturb the normal balance between these two processes, leading to increased formation of, or decreased elimination of, reactive drug metabolites. If not eliminated, these metabolites may do one of several things. In some cases, they bind to macromolecules, such as lipids, proteins, or nucleic acids, and cause direct cellular damage. A well-known example of this type of direct cellular toxicity is acetaminophen-induced hepatotoxicity (20). Acetaminophen is metabolized to nontoxic metabolites by sulfation or glucuronidation, but a small amount (5%–10%) is oxidized by a number of cytochrome P450 enzymes to *N*-acetylbenzoquinoneimine. Although this reactive metabolite typically is detoxified by conjugation with glutathione, in an overdose situation, the conjugation pathways are saturated, inadequate detoxification results, and hepatic necrosis ensues (19,21).

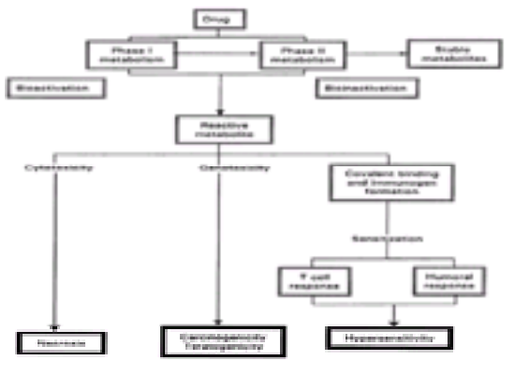

Figure 72.1. Role of drug-metabolizing enzymes in the bioactivation and bioinactivation of drugs. The formation of a chemically reactive metabolite, if inadequately detoxified, may lead to covalent binding to cellular macromolecules, resulting in various forms of toxicity including necrosis, teratogenicity, and hypersensitivity (Adapted from Pirmohamed M, Madden S, Park K. Idiosyncratic drug reactions: metabolic bioactivation as a pathogenic mechanism. *Clin Pharmacokinet* 1996;32:215–230, with permission.)

In addition to being directly cytotoxic, some reactive drug metabolites may covalently bind to, or haptenate, macromolecules, leading to the formation of immunogenic complexes that may then initiate a hypersensitivity reaction. The type of immune response that is elicited toward the hapten depends on the pathway by which the hapten is processed and presented to T cells, and it appears that the particular pathway involved is dictated by the chemical properties of the hapten. Small lipid-soluble molecules (e.g., urushiol) can enter the cytoplasm and can be presented on major histocompatibility complex (MHC) class I molecules for recognition by $CD8^+$ cells via the “endogenous” pathway. In contrast, polar haptens, such as nickel or cobalt, are more likely to be presented on MHC class II molecules for recognition by $CD4^+$ cells (“exogenous pathway”). Some haptens, such as dinitrofluorobenzene, may be processed by both pathways for presentation to both $CD8^+$ and $CD4^+$ T cells (15).

Until recently, little has been known about the antigen-processing pathways involved in drug-induced hypersensitivity reactions. Our increased understanding of drug metabolism and drug-induced diseases, however, is permitting definition of the possible immunologic mechanisms involved in these reactions. Not only are we beginning to be able to identify specific reactive drug metabolites that are formed, but also, through the histologic examination of the particular drug-induced disease, we are able to determine the processing pathways by which these drug-antigens are presented to the immune system.

Persons with morbilliform eruptions to sulfonamides have sulfonamide-reactive T cells in their peripheral blood (22). Moreover, sulfonamide-reactive $CD8^+$ T-lymphocytes have been isolated from sulfonamide-induced bullous eruptions (23). These data lend support to the hypothesis that, at least for some drugs, antigen presentation occurs through MHC class I presentation to $CD8^+$ T-lymphocytes. It is not surprising that this mechanism of antigen presentation may be operative in certain types of drug-induced hypersensitivity because many haptenic drugs undergo intracellular metabolic activation. If not detoxified, these reactive drug metabolites theoretically could conjugate with cytoplasmic proteins. Subsequently, these endogenous proteins would be degraded into drug–peptide complexes, transported into the endoplasmic reticulum, associated with MHC class I molecules, and delivered to the cell surface, where they would be presented to $CD8^+$ T cells. Although this proposed mechanism explains how drug metabolites may be presented to the immune system and how T cells may be involved in drug-induced hypersensitivity reactions, the critical question is whether or not this mechanism plays an important role in drug-induced allergic diseases. Later in this chapter, emerging new data are presented to show that T cells may be central to the pathogenesis of many drug-induced hypersensitivity responses.

PREDISPOSING FACTORS FOR THE DEVELOPMENT OF IDIOSYNCRATIC DRUG REACTIONS

Pharmacologists classify type B ADRs somewhat differently than do allergists, and their scheme actually may be more appropriate for evaluating risk factors for the development of drug-induced reactions. Whereas both groups agree on the definition of type A reactions, pharmacologists use the terms *type B reactions* and *idiosyncratic reactions* interchangeably; that is, they consider all type B reactions to be idiosyncratic because they are unpredictable, occur in a small number of patients, and are not related to the pharmacologic actions of the drug. Although many idiosyncratic reactions have clinical characteristics suggestive of drug allergy, there is no direct evidence that an immune mechanism is operative in all of them. Thus, the term *idiosyncratic drug reaction* is an operational term and does not imply a specific mechanism (24). Since idiosyncratic reactions often times are serious, it is important to elicidate if possible, the chemical, biochemical and immunologic mechanisms responsible for their elicitation.

As pointed out by Park et al. (24), perhaps the most important goal should be to characterize the individual factor(s) responsible for the idiosyncratic nature of the reaction. This information could be used prospectively to avoid drug toxicities by (a) identifying patients who have a genetically determined susceptibility to certain chemical classes of drugs; (b) analyzing cells from identified patients in preclinical experiments with new drugs that are chemically similar to drugs known to cause idiosyncratic reactions; and (c) designing drug analogs that retain the efficacy of the parent drug but that do not elicit idiosyncratic toxicity.

Both drug-related and host-related factors contribute to the development of drug-induced adverse reactions. An important drug-related factor is the presence of certain functional groups in the drug or its metabolite. Hypersensitivity reactions to the penicillins and cephalosporins occur not through the formation of reactive drug metabolites but through a directly reactive b-lactam ring. Because of its strained state, the b-lactam ring readily reacts with nucleophilic groups on proteins (25). This drug-carrier complex is formed in all individuals, but only some mount an immune response.

Other potentially important functional groups are aromatic amino groups. If possible, these groups are avoided during drug design because the metabolism of agents containing them leads to the production of hydroxylamines and nitroso compounds, oxidative metabolites that are unstable and extremely toxic. It is not always possible, however, to “design” a drug that is both clinically effective and chemically inert. Numerous drugs in use today possess an aromatic amino group; these agents include the sulfonamides, procainamide, and the aromatic anticonvulsants. Each of these important therapeutic agents has been associated with idiosyncratic reactions thought to result from the formation of oxidative metabolites (19,21,26,27).

Other drug-related risk factors include the route, frequency, and duration of drug administration. The topical route appears to be the most sensitizing route, and frequent short courses of therapy are more likely to result in the development of an immunologically mediated drug-induced reaction than are longer courses of therapy separated by several years. For an in-depth discussion of drug-induced risk factors, the reader is referred to two reviews (12,28).

Probably the two most important host-related risk factors for the development of drug-induced idiosyncratic reactions are the genetically determined events that dictate how a drug is metabolized and, once metabolized, how or if it is “recognized” in an immune sense. Genetic polymorphisms exist in numerous types of drug-metabolizing enzymes, including those that are responsible for drug oxidation, hydrolysis, acetylation, and conjugation (24). Probably the clearest association between a genetic polymorphism and idiosyncratic drug reactions has been found for *N*-acetyltransferase-2 (NAT-2). Because of this polymorphism, individuals differ in their NAT-2 activity, resulting in the slow- and fast-acetylator phenotypes. Slow acetylation leads to decreased formation of *N*-acetylated nontoxic products and increased formation of metabolically active, toxic products. Thus, persons with this phenotype may be predisposed to developing drug-induced reactions to particular compounds.

Because the liver is a major site of drug oxidation, it would seem to be most vulnerable to drug-induced injury. Balanced against this potentially damaging process is the simultaneous presence of numerous detoxifying processes along with a large glutathione reserve. Despite these “fail-safe” mechanisms, the liver often is involved

in drug-induced reactions. Toxic metabolites are formed that escape bioinactivation. Acyl halides derived from halothane metabolism (29), epoxide metabolites derived from the metabolism of tricyclic antidepressants (30,31 and 32), and hydroxylamines derived from sulfonamide metabolism (33,34) all may induce idiosyncratic hepatotoxicity via an immune mechanism when detoxifying systems are altered. Using an *in vitro* lymphocyte cytotoxicity assay, several groups have shown that persons who have experienced idiosyncratic drug reactions to drugs known to undergo metabolism have a decreased ability to detoxify reactive species formed from the parent compound (34,35). Although these results suggest that these persons have a detoxification defect, the actual genetic defect remains to be identified.

In addition to variations among individuals in drug metabolism, there also could exist variation in both the formation of immunogenic drug complexes and the response to these immunogens once they are formed. Although cell-surface antigens are thought to be more potent immunogens than circulating drug-protein complexes (16), studies in humans have been restricted to the analysis of drug antigens associated with plasma proteins. Lafaye and Lapresie (36) analyzed the amount of penicillin that is covalently bound to albumin in patients taking high doses of penicillin. They found little individual variation in the amount of penicilloyl groups formed. In contrast, Gruchalla et al. (37) found that patients with AIDS who were taking sulfonamide therapy for *Pneumocystis carinii* pneumonia (PCP) prophylaxis differed in their ability to produce sulfonamide-conjugated serum proteins. Moreover, only some of those who possessed these drug-protein serum complexes developed sulfonamide-induced hypersensitivity reactions, a finding that suggests that formation of immunogenic drug complexes is necessary but not sufficient for the development of a hypersensitivity response.

Many idiosyncratic drug reactions have immunologic features and thus, at least in part, are immunologically mediated. They occur only after several days of treatment and recur immediately on drug readministration. An immune mechanism offers a plausible explanation for the seriousness of these idiosyncratic reactions because both cytolytic and inflammatory components can be activated in response to a small amount of antigen or drug hapten located in a target tissue (16). Both the magnitude and the type of the immune response generated demonstrate variations among individuals. For both penicillins and cephalosporins, it appears that drug-induced IgE responses are under genetic control. Adkinson and Wheeler (38) demonstrated in the early 1980s that the immune response to the penicilloyl hapten is genetically restricted. They found that whereas some patients produced penicillin-specific antibodies when high-dose intravenous penicillin was administered for 10 days, most had no serologic response. It was postulated that these “nonresponders” were at decreased risk of developing drug-induced anaphylaxis as well as other types of drug-induced hypersensitivity reactions.

The fact that only a select group of persons is affected is related to their unique ability to mount an immune response, which is dictated by their specific MHC genotype. The MHC genes are the most polymorphic genes in higher vertebrates. This high degree of polymorphism causes some individuals to be more efficient at recognizing certain drug-carrier complexes than others, and thus they are “selected” to mount a vigorous drug-induced response. Associations have been made with specific genes encoded by both the class I [human leukocyte antigen (HLA)-A, -B, and -C)] and the class II regions (HLA-DP, -DQ, and -DR) of the MHC. Examples of such associations include hydralazine-induced systemic lupus erythematosus, which is associated with HLA-DR4 (39); oxicam-induced toxic epidermal necrolysis, which is associated with HLA-A2 and -B12 (40); and sulfonamide-induced toxic epidermal necrolysis, which is associated with HLA-A29, -B12, and DR-7 (40). The finding that immune responses to drugs may be governed by genes residing in both the class I and the class II MHC regions adds further support to the fact that both the endogenous (MHC class I) and the exogenous (MHC class II) pathways of antigen processing are important in the elicitation of drug hypersensitivity responses.

Although the positive HLA associations that have been identified may be used to estimate the relative risk of developing a drug-induced reaction, they do not predict absolutely that a reaction will occur in an individual patient. In the study of Batchelor et al. (39), most patients with hydralazine-induced lupus were HLA-DR4 positive, but 25% of the control subjects were HLA-DR4 positive as well. Thus, although specific genetic associations have been identified, it remains to be seen how these associations will help in predicting the development of drug-induced immune responses.

Finally, because an immune response is initiated, it is not certain that tissue damage will result. The production of antibodies alone is not a pathologic process (24). In some instances, patients may remain asymptomatic despite the fact that they develop drug-specific IgG antibodies during therapy. Thus, other factors that have not yet been elucidated are important in the translation of an immune response into clinical disease.

PATHOPHYSIOLOGY OF ALLERGIC DRUG REACTIONS: EMERGING CONCEPTS

Sites of Drug Metabolism

The liver is the main drug-metabolizing organ. Despite the fact that highly reactive drug metabolites constantly are being generated in this organ, adverse drug-induced hepatic reactions are relatively rare due to the liver's incredible detoxifying capacity. Nevertheless, reactions do occur. Long-term treatment with the diuretic drug tienilic acid may lead to autoimmune hepatitis in some patients; this reaction is associated with the production of autoantibodies directed against the cytochrome P-450 2C9 isoenzyme, which is the enzyme responsible for the metabolism of the drug to its reactive form (41,42). Thus, probably because of their highly reactive nature, the metabolites, immediately after they are generated, covalently bind to the enzyme responsible for their formation. A similar mechanism is operative for both halothane-induced hepatitis (43,44 and 45) and dihydralazine-induced hepatitis (46). Autoantibodies again are directed toward the neoantigen formed by the drug metabolite in conjunction with the cytochrome isoenzyme responsible for its formation.

Since most drug-induced reactions involve the skin, the question arises as to whether extrahepatic drug metabolism is occurring. It is possible that, after being formed in the liver, drug metabolites travel to distant sites where the reaction is manifested; but it is more likely that they are being formed at the reaction site itself. The skin, which is the largest organ in the body, is metabolically active and contains cells that have both phase I and phase II drug-metabolizing enzymes (47,48). Neutrophils, monocytes, macrophages, keratinocytes, and Langerhans cells all have drug-metabolizing enzymes that potentially could lead to the generation of reactive products (49). The skin also is an active immunologic organ, containing numerous cell types that play a strategic role in antigen presentation; this function, along with its metabolic properties, makes it a likely target for drug-induced diseases (50).

T-Cell Immune Responses to Haptens

T cells recognize peptides in the context of MHC class I or class II antigens. Initially, it was thought that T cells recognize only peptides and not haptens and that in the hapten-carrier model T cells recognize the peptide carrier whereas antibodies are specific for the hapten (51). Studies of T-cell responses to trinitrophenyl (TNP) protein derivatives revealed that T cells themselves do recognize and react to haptenated peptides (52,53,54,55 and 56). Whereas the early hapten recognition studies were performed in animal models, more recent studies evaluated T-cell responses to haptenic drugs, such as penicillin and sulfamethoxazole in humans.

In 1992, Martin et al. (57) generated class I-restricted, TNP-specific T-cell clones and then assessed their ability to recognize a variety of haptenated peptides. The hapten-specific, MHC-restricted T cells could recognize TNP-conjugated proteins irrespective of the exact amino acid sequence of the presenting peptide. Instead of recognizing a portion of the carrier protein, these T cells recognized only the TNP hapten. Another interesting finding was that most of the clones reacted to a major type of class I-associated octapeptide that carried TNP lysine in the central position 4. These results suggest that in hapten recognition by T cells, the peptide serves only to anchor the hapten to a defined position on the MHC surface and that it contributes little, if any, to the specificity of the antigenic epitope (Fig. 72.2A) (58,59).

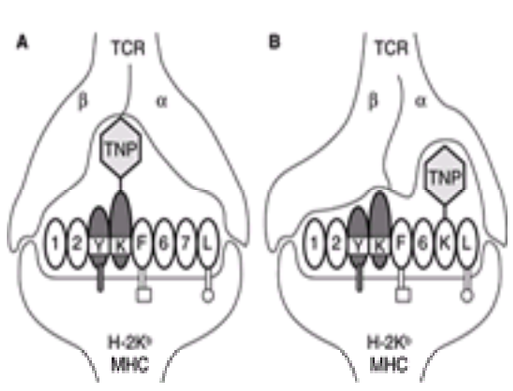

Figure 72.2. Two types of H-2K^b-restricted trinitrophenyl (TNP) determinants. **A:** The immunodominant TNP determinant on H-2K^b contains the hapten bound to lysine in the central position 4 of K^b-associated octapeptides. Many receptors recognizing this determinant predominantly contact the hapten itself in addition to haplotype-specific major histocompatibility complex (MHC) structures but barely interact with side chains of the carrier peptide. **B:** In contrast, T cells specific for peripherally (position 7) modified TNP peptides contact the hapten-peptide via two independent subepitopes: one represented by TNP, the other by amino acids in carrier positions 3 and 4 T-cell receptors (TCRs) a,b. (From Weltzien H, Moulon C, Martin S, et al. T cell immune responses to haptens: structural models for allergic and autoimmune reactions. *Toxicology* 1996;107:141–151, with permission).

In subsequent experiments with synthetic TNP-peptides, T cells specific for hapten peptides that carried TNP–lysine in the peripheral position 7 of the octapeptide were obtained. Although these cytotoxic T-lymphocytes (CTLs) also demonstrated class I-restricted reactivity to TNP, unlike the ones previously characterized, they recognized portions of the carrier peptide. In fact, this peptide reactivity was so strong that target cells that had been pulsed with homologous peptides that were not TNP-modified were lysed. Two subepitopes for these CTLs were identified, one the TNP hapten itself, the other a determinant formed by the side chains of amino acids 3 and 4 in the carrier peptide (Fig. 72.2B) (53,58,59). Thus, by positioning the TNP more peripherally on the octapeptide, a dual TNP and carrier peptide response was generated. In light of these data, it was hypothesized that hapten modification of self-proteins may lead to the triggering of T cells that, once activated, also may react with unmodified self-structures, inducing an autoimmune response.

Other studies demonstrated that TNP peptides also can be presented by class II molecules and that the $CD4^+$ T cells generated recognize TNP in the form of MHC-associated, haptenated peptides with the immunodominant TNP epitopes predominantly independent of the amino acid sequence of the carrier peptide (54). Thus, hapten-induced T-cell responses can be elicited via class I or class II antigen presentation. The type of T-cell response generated would depend on the type of antigen processing that occurs. In the case of skin-sensitizing haptens, one of four mechanisms potentially could be involved: (a) the reactive hapten may modify soluble proteins that then are endocytosed by Langerhans cells, processed, and presented by MHC class II antigens; (b) the reactive hapten may modify soluble proteins that then are endocytosed by Langerhans cells, processed, and presented by MHC-like molecules; (c) the reactive metabolite may bind directly to peptides already associated with MHC class I or class II antigens (no processing involved); or (d) the reactive hapten may penetrate the plasma membrane and modify cytoplasmic proteins that then would be processed and presented by MHC class I molecules (59).

The involvement of T cells in allergic reactions to haptenic drugs in humans could be inferred by the fact that T-cell derived cytokines are necessary for the generation, differentiation, and maturation of B cells that secrete drug-specific antibodies. Moreover, T cells themselves are directly involved in some drug-induced diseases (contact dermatitis), and drug-specific T cells have been isolated from drug-induced skin lesions (60,61 and 62). In addition, *in vitro* T-cell reactivity toward several drugs known to cause hypersensitivity reactions has been demonstrated in patients in whom reactions have occurred. Specifically, reactive human T cells have been found in patients who have developed reactions to penicillin, sulfonamides, nonsteroidal antiinflammatory drugs (NSAIDs), and aromatic anticonvulsants (63,64,65 and 66).

Human T-Cell Responses to Penicillin and Penicillin-induced Allergic Reactions

deWeck et al. (67) demonstrated in the early 1970s that penicillin can cause drug-specific T-cell activation. They found that peripheral blood lymphocytes from patients with clinical penicillin-induced reactions incorporated increased amounts of [^{3}H] thymidine in the lymphocyte transformation test compared with cells from nonallergic persons. When cloning technology became available, antigen-specific T-cell clones derived from the peripheral blood of b-lactam-allergic patients with maculopapular exanthems were shown to be $CD3^+$, $CD4^-$, $CD8^+$, HLA-DR^+ and to produce interleukin (IL-2) and interferon-g (IFN-g) on stimulation (60). Proliferation depended on the presence of both antigen and autologous antigen-presenting cells, and the fact that the clones were $CD8^+$ suggested that antigen recognition occurred in association with class I MHC molecules. This study was one of the first to demonstrate that the penicillin molecule itself acts as a true haptenic determinant in humans and that it appears to form a critical part of the epitope recognized by the T-cell receptor.

Subsequently, Hertl et al. (61) evaluated the actual skin-infiltrating lymphocytes in b-lactam antibiotic-induced vesiculobullous exanthems. Immunohistochemical studies revealed that $CD8^+$ T-lymphocytes were the predominant T-cell subset in these lesions. $CD8^+$ epidermal T-cell clones derived from the cutaneous lesions proliferated in response to penicillin-pulsed autologous antigen-presenting cells but not allogeneic antigen-presenting cells, indicating that the clones were not only antigen-specific but also MHC restricted. In addition, these clones were cytotoxic for epidermal cells, a finding that indicated that T cells might play a role in the keratinocyte necrosis associated with drug-induced blister formation.

While experiments in humans strongly suggests that pencillins, like TNP, form part of the epitopes that contact the antigen-specific receptors of b-lactam-specific T cells in allergic individuals, it has not been clearly shown exactly how penicillin recognition by T cells occurs. To define further the molecular constraints involved in the T-cell response toward penicillin, Padovan et al. (66) constructed “designer” peptides that contained both defined anchor residues for given HLA class II alleles and a lysine-bound penicilloyl group in specific T-cell-receptor contact sites. These allele-specific peptides were used to stimulate a panel of penicillin G-reactive T cells clones from two allergic patients who expressed the required DR allele. In addition to possessing particular amino acids at strategic sites in the peptide that served as HLA-anchoring residues, each peptide contained a lysine residue in a position that corresponded to one of the proposed T-cell-receptor contact sites (68). The lysine residue was derivatized with penicillin G after peptide synthesis, and, depending on the location of this amino acid residue, the penicilloyl hapten was positioned in either a central or a peripheral position of the formed peptide. A detailed analysis of two clones that were generated revealed that, for each, a precise positioning of the hapten on the peptide backbone was required for optimal T-cell stimulation. Because it is unlikely that the penicilloyl-associated peptide sequences that induce penicillin-specific T cells *in vivo* resemble the nonphysiologic sequences of the artificially constructed designer carrier peptides, these data suggest that hapten-specific human T cells, like those of the mouse (57,58 and 59), are characterized by position-specific but carrier-independent hapten recognition.

To determine whether penicillin-specific T cells from allergic patients could recognize other antibiotic agents, Mauri-Hellweg and Padovan and colleagues (65,69) evaluated the cross-reactivity of T-cell lines and clones against b-lactam antibiotics. They found two types of b-lactam-specific T-cell reactivity. One group of patients had a rather restricted recognition profile in that the penicillin-elicited T-cell lines generated from these patients proliferated only to the stimulating penicillin, but not to other b-lactam antibiotics, including cephalosporins, even if the side chain was identical. Thus, for these persons, the structure recognized by T cells appeared to be composed of both the penicilloyl determinant and a portion of the side chain. Cells from the second group of patients were stimulated not only by penicillin G but also by related penicillins. They were not, however, stimulated by cephalosporins. For this group, the penicilloyl moiety, common to all penicillins, appeared to be important for T-cell recognition.

Brander and Padovan and colleagues too found that the immune response to penicillin G was heterogeneous (63,70). On generating T-cell clones specific for penicillin-G or benzyl penicilloyl–human serum albumin (BPO-HSA) from peripheral blood mononuclear cells of penicillin-allergic patients, Brander et al. (63) found that many different penicillin G and BPO-HSA reactive clones were identified, even in a single individual. The clones that were stimulated *in vitro* by penicillin G were either $CD4^+$ or $CD8^+$, class II or class I restricted, and they did not require antigen processing because fixed antigen-presenting cells were capable of efficient antigen presentation. In contrast, T-cell clones that were stimulated by BPO-HSA were $CD4^+$ predominantly, and antigen processing was required for T-cell activation. Both penicillin-G- and BPO-HSA-specific T-cell clones produced a heterogeneous cytokine pattern; most produced high levels of IL-2 and IFN-g and variable levels of IL-4 and IL-5. In the case of penicillin-G, because no antigen processing was required, it was suggested that this hapten may cause T-cell stimulation by directly binding to MHC molecules or to their embedded peptides; this novel finding was subsequently confirmed by others (71). Alternatively, the drug may bind to serum proteins like HSA, which then must be processed and presented by antigen-presenting cells. The fact that the penicillin hapten undergoes multiple modes of antigen presentation to activate different T-cell subsets may be the reason for the extensive clinical heterogeneity of penicillin-induced human immune responses.

Although T-cell cloning studies have provided great insight for our understanding of how human T cells recognize the penicillin hapten, their clinical implications are not clear. Some penicillin-allergic patients produce broadly cross-reactive antibodies that are directed to the common penicilloyl moiety, whereas others produce antibodies that are more selective and that are directed toward the b-lactam side chain (72,73,74,75 and 76). Currently, we try to avoid administering penicillins to patients who have had b-lactam-induced drug hypersensitivity reactions. This therapeutic principle is based on the belief that penicillin-specific antibodies from penicillin-allergic patients may be extensively cross-reactive because they are directed toward the penicilloyl group common to all penicillins. In light of the fact that cephalosporins also contain this common group, they are avoided in penicillin-allergic patients as well. Because the extent to which the penicillins clinically cross-react either with each other or with cephalosporins is unknown, it is difficult to answer the age-old question of whether penicillin-allergic patients can safely receive cephalosporins. It appears that for those reactions mediated by penicillin-specific IgE antibodies, the antibodies are exquisitely specific in most cases because the incidence of cephalosporin reactions in penicillin-allergic patients appears to be low (77,78). Because these reactions do occur, however, and some are severe, it cannot be assumed that cephalosporins will be well-tolerated by all penicillin-allergic patients (79).

Although we can demonstrate the presence of penicillin-specific antibodies or T cells in patients who have had hypersensitivity reactions, we have been unable, for many of these reactions, to determine how, or even if, these immune products are responsible for the clinical manifestations. For penicillin-induced anaphylaxis and urticaria/angioedema, it is clear that penicillin-specific IgE antibodies are responsible. The same is true for penicillin-induced hemolysis: Penicillin-specific IgG/IgM antibodies are responsible; however, the mechanism for many other penicillin-induced reactions is unclear. Specific antibodies of the IgG or IgM class produced during a course of therapy may be clinically irrelevant. In addition, although drug-induced cytotoxic T cells may be responsible for the keratinocyte necrosis in penicillin-induced bullous eruptions, we generally do not understand the role played by T cells in drug-induced hypersensitivity reactions.

Human Immune Responses to Sulfonamides and Sulfonamide-induced Allergic Reactions

Sulfonamides cause a variety of unpredictable reactions, including anaphylaxis, urticaria, angioedema, maculopapular rashes, Stevens-Johnson Syndrome (SJS), hepatitis, nephritis, and blood dyscrasias (80). An immune component is thought to be involved in at least some of these reactions. Sulfonamide-specific T cells (64) and antibodies (81,82 and 83) have been demonstrated in hypersensitive patients, and sulfonamide-haptenated proteins have been found in the sera of treated patients (37,84).

Studies have begun to elucidate the way in which sulfonamides may elicit hypersensitivity responses. Shear and others (33,85) initially showed that, in addition to the usual acetylation reaction that yields nontoxic, easily excretable products, sulfonamides also may be oxidized by a cytochrome P450-dependent pathway to reactive hydroxylamine or nitroso intermediates that *in vitro* are cytotoxic for lymphocytes. In addition, lymphocyte cytotoxicity was more pronounced in persons who had a history of sulfonamide-induced hypersensitivity reactions than in those who had tolerated the drug (33,34,86). Carr and Rieder and colleagues (87,88) corroborated these findings in sulfonamide-allergic patients infected with human immunodeficiency virus (HIV) and also demonstrated that cytotoxicity was significantly reduced in the presence of glutathione. Two hypotheses regarding the increased frequency of sulfonamide-induced reactions in AIDS patients were put forth. Low glutathione levels (89), along with a decreased acetylation ability (90), may predispose these persons to develop increased levels of reactive sulfonamide metabolites that may be directly cytotoxic or that may elicit an immune response through covalent haptenation with serum or cell-surface proteins (Fig. 72.3) (37,91,92).

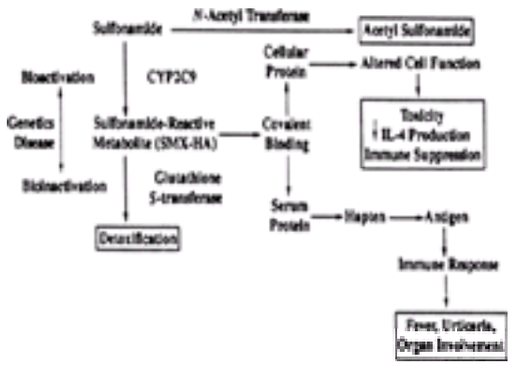

Figure 72.3. Sulfonamide metabolism. The role of sulfamethoxazole hydroxylamine (SMX-HA) in adverse reactions to sulfonamide (From Hess D, Rieder M. The role of reactive drug metabolites in immune-mediated adverse drug reactions. *Ann Pharmacother* 1997;31:1378–1387, with permission).

To dissect the role of T-cell-mediated immune mechanisms in sulfonamide-induced reactions, Kalish and colleagues (22) evaluated antigen-specific T-cell reactivity in patients who had experienced sulfonamide-induced skin eruptions. Using limiting dilution analysis, sulfamethoxazole-specific lymphocytes were detected in the peripheral blood of a patient who had experienced a sulfamethoxazole-induced morbilliform eruption at a frequency of 1 per 170,000 peripheral blood mononuclear cells. This frequency is similar to that observed for urushiol-reactive peripheral blood mononuclear cells in patients with poison ivy eruptions (93). Subsequently, cell lines were generated from sulfamethoxazole-allergic individuals who demonstrated a proliferative response to sulfamethoxazole but not to furosemide, a somewhat structurally similar drug. This study was one of the first to support a role for T cells in sulfonamide-induced reactions, and it corroborated earlier work done by others with penicillin (60,61,67).

Mauri-Hellweg and colleagues (64) extended the preceding studies by analyzing *in vitro* sulfamethoxazole-induced activation of $CD4^+$ and $CD8^+$ T-cell subsets, cytokine secretion, and T-cell proliferation in persons who developed generalized eruptions during sulfamethoxazole therapy. They found that sulfamethoxazole-induced proliferation of peripheral blood mononuclear cells was antigen specific and dose dependent and that IL-5 was the major cytokine secreted. Both $CD4^+$ and $CD8^+$ T cells were activated, and the sulfamethoxazole-specific T-cell clones generated from one patient were of several phenotypes: some were $CD4^+$ only, some were $CD8^+$ only, and some were $CD4^+$ and $CD8^+$. These results both supported and extended the findings of Kalish et al. (22) by showing that not only are sulfamethoxazole-specific T cells involved in sulfamethoxazole-induced reactions but also that MHC class I and class II antigen presentation occurs, a finding reminiscent of the data emerging from the penicillin studies (63,70). It remains to be seen exactly how T cells recognize the sulfamethoxazole hapten because recent data indicate that sulfamethoxazole may be presented to T cells by unconventional pathways (94,95).

Hertl and colleagues (62) demonstrated that sulfamethoxazole-induced T-cell responses were MHC restricted and cytochrome P-450 dependent. Previous studies demonstrated that sulfamethoxazole-induced lymphocyte cytotoxicity was enhanced in the presence of mouse liver microsomes, which are rich in cytochrome P-450-dependent enzymes (86,96). For that reason, dermal T-lymphocytes from a patient with a sulfamethoxazole-induced bullous exanthem were isolated, cloned, and stimulated with sulfamethoxazole in the presence or absence of mouse microsomes. Addition of the microsomes to the culture system caused markedly increased drug-specific T-cell proliferation, a finding that further supports the role of cytochrome P-450-dependent enzymes in the generation of allergenic sulfonamide metabolites. It was demonstrated previously that some patients with sulfonamide-induced cutaneous hypersensitivity reactions have a reduced *N*-acetylating capacity (97). Thus, these results together suggest that polymorphism of drug-metabolizing enzymes is at least one factor that may determine whether a patient is at risk of developing sulfonamide-induced hypersensitivity responses. In addition, because many of these drug-induced reactions are cutaneous in nature, the most relevant drug metabolism may be that which is occurring *in situ*, that is, in the skin (49).

Although Naisbitt and colleagues (98) found that both the *N*-hydroxy and nitroso metabolites of sulfamethoxazole can haptenate cell surface proteins at therapeutic drug concentrations, they hypothesized that under normal physiologic conditions, extensive haptenation probably is prevented due to the presence of plasma thiols. If, however, a balance between drug bioactivation and metabolite bioinactivation, both hepatic and peripheral, is disturbed, such as may occur in patients with systemic disease processes [such as acquired immunodeficiency syndrome (AIDS)], cell surface haptenation may be extensive and may lead to a hypersensitivity response. Sulfamethoxazole metabolites also induce apoptosis in T cells (99) and suppress sulfamethoxazole-specific T-cell proliferation and mitogen-induced antibody responses (100,101). Thus, although these metabolites appear to play multiple roles in sulfonamide hypersensitivity, the mechanisms by which they elicit hypersensitivity responses have not yet been clarified.

Sulfonamide-induced hypersensitivity responses are clinically heterogeneous, a characteristic that should not be surprising in light of the fact that numerous mechanisms appear to be responsible for these reactions. T cells seem to be involved in many of these reactions, but their function is unclear. The same is true for reactive sulfonamide metabolites. Data should evolve that will allow better characterization and thus better diagnosis and treatment of these reactions.

Hypersensitivity Syndrome

ROLES OF DRUG METABOLISM AND MOLECULAR MIMICRY

Drug-induced hypersensitivity syndrome (HSS) is a multiorgan, potentially fatal disorder caused by a select group of drugs that include dapsone and other sulfonamides (102), phenytoin and other anticonvulsants (103,104), allopurinol, (105), and minocycline (106). Symptoms consist of fever, rash, and lymphadenopathy, which typically occur several weeks into therapy. The rash, which often is initially a benign morbilliform eruption, may develop into frank exfoliative dermatitis. Some patients also develop hepatitis, nephritis, eosinophilia and other hematologic abnormalities, and myalgias and arthralgias (104).

The requirement for an induction period after the initial drug exposure only, but not after subsequent exposures, is consistent with an underlying immune-mediated process. In addition, the manifestations are not associated with any pharmacologic properties of the implicated agents. Although an immune process has been implicated, the specific mechanism has not been identified.

The aromatic anticonvulsant agents are metabolized, in part, by cytochrome P-450 to reactive arene oxides, and it has been hypothesized that these substances may be involved in the pathogenesis of drug-induced HSS. Shear and Spielberg (35) and others (107), evaluated lymphocytes from patients with known hypersensitivity to anticonvulsant therapy in an *in vitro* lymphocytotoxicity assay using mouse microsomes as a source of P-450 enzymes for the production of reactive drug metabolites. In contrast to lymphocytes from control subjects, lymphocytes from affected patients demonstrated marked cytotoxicity, and the fact that hepatic microsomes were necessary for the toxicity to occur suggests that reactive metabolites, rather than the parent drug, were responsible. Cells from patients' parents exhibited cytotoxicity levels intermediate between the values for cells from control subjects and patients.

Arene oxides normally are detoxified by epoxide hydrolase (16), and in light of the cytotoxicity studies, it has been hypothesized that this enzyme may be lacking or mutated in persons who develop drug-induced HSS (35,108,109). Characterization of the epoxide hydrolase gene failed to reveal any differences between patients with drug-induced HSS and controls (110), but it remains to be seen whether a defect in the regulatory region of the gene causes altered protein expression. The production of excess reactive metabolites through defective detoxification could contribute to the clinical disease process either by a direct cytotoxic mechanism or by the generation of an immune response after haptenation of protein carriers. Covalent protein haptenation by arene oxide metabolites produced from anticonvulsants or hydroxylamines or by nitroso metabolites from sulfonamides could lead to the elicitation of either a humoral or a cellular immune response.

Infections caused by certain pathogenic agents may stimulate T cells that then initiate a reaction toward cells expressing an epitope that mimics a viral or a bacterial protein (17,111). Epitope mapping studies are in progress to determine whether a similar type of molecular mimicry is involved in the generation of the autoantibodies

present in certain types of drug-induced hypersensitivity reactions (17). Gut et al. (112) provided evidence that molecular mimicry may be playing a role in halothane hepatitis. Antibodies in sera from patients with halothane hepatitis recognize liver trifluoroacetyl (TFA)-protein adducts, which arise on oxidative biotransformation of halothane. These antibodies also recognize the E2 subunit of the mitochondrial pyruvate dehydrogenase complex, and for this reason it has been proposed that molecular mimicry may be occurring between this "self" determinant and the TFA protein adducts. In 1992, Leeder and colleagues (113) identified antibodies to several cytochrome P-450 isozymes that are constitutively expressed as well as inducible in rat liver microsomes in the sera of patients with anticonvulsant-induced HSS. These antibodies were not found in sera from healthy control patients receiving chronic phenytoin therapy without toxicity or patients with hepatic failure not receiving anticonvulsants. Neither the impetus that caused their formation nor their role in disease pathogenesis was elucidated. The conjugation of arene oxide metabolites to self-proteins, in this case, cytochrome P-450 isozymes, may lead to the formation of altered self-proteins that trigger an autoimmune response.

Findings suggest that there may be an association between human herpes virus 6 (HHV-6) infection and drug-induced HSS (114,115). Suzuki and colleagues (114) found HHV-6-specific IgG antibodies, which increased with disease progression, in a patient who had allopurinol-induced HSS. Tohyama et al. (115) described two cases of sulfasalazine-induced HSS that were associated with reactivation of HHV-6. It had been shown that HHV-6 could induce severe infectious mononucleosis (116), graft-versus-host disease (117), and interstitial pneumonitis (118); but this demonstration was the first of a possible association between drug-induced HSS and reactivation of HHV-6. The mechanism by which the virus helps to elicit a drug-induced response is not known. Possibly, HHV-6 reactivation is facilitated by the immunologic events associated with hypersensitivity reactions. Alternatively, drug metabolism may be altered by HHV-6 reactivation and excessive reactive drug metabolites are formed. In light of the facts that T-cell activation is required for reactivation of HHV-6 (119) and that patients with drug-induced HSS have activated peripheral blood mononuclear cells (64), Tohyama et al. (115) hypothesized that drug-induced HSS may result from a two-step process. First, T-cell activation occurs in response to haptenation of tissue proteins by drug metabolites; second, HHV-6 is reactivated by activated T cells and causes symptoms characteristic of infectious mononucleosis and HSS.

Stevens–Johnson Syndrome/Toxic Epidermal Necrolysis

Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are serious drug-induced reactions thought by some to be similar disorders of different severity within the spectrum of erythema multiforme. Based on this concept, Bastuji-Garin and colleagues (120) developed a classification scheme of these disorders that is commonly used in the clinical setting. Both diseases have bullous lesions, mucosal involvement, and skin detachment; but they differ from each other by the amount of skin detachment, which is less than 10% in SJS and more than 30% in TEN. About 50% of cases of SJS are drug induced, and 50% are related to an infectious process. About 80% of cases of TEN are drug related. More than 100 drugs have been implicated in these diseases; the most common ones are sulfonamides, aromatic anticonvulsants, b-lactam antibiotics, allopurinol, and NSAIDs (121,122).

Although the mechanisms responsible for SJS and TEN are not known, it is thought that affected persons have an alteration in the ability to detoxify reactive drug metabolites (26,121,123). These may be directly cytotoxic, as previously discussed. Because SJS and TEN have features consistent with immunologically mediated hypersensitivity reactions (timing, linkage to certain HLA genotypes) (40,124,125), metabolites also are thought to elicit an immune response after covalent protein binding.

Because SJS and TEN may be immunologically mediated reactions, efforts were initiated to detect circulating cytotoxic antibodies, circulating immune complexes, or complement deposition. These efforts have been unsuccessful (126). In contrast to these disappointing endeavors, data have been generated that suggest a critical role of T cells in disease pathogenesis (62,127,128,129,130 and 131). Merot et al. in 1986 initially described the presence of T cells in skin biopsy specimens from an individual who had died from drug-induced TEN (127). Miyauchi and colleagues (128) confirmed these findings and also demonstrated that the predominant T-cell type in the dermis was $CD4^+$ and in the epidermis was $CD8^+$. Villada et al. (129) found that the dermal infiltrate in a patient with TEN was composed of activated T-lymphocytes. In addition, an aberrant expression of HLA-DR by keratinocytes was found that, before this study, had been demonstrated in inflammatory skin disorders (132,133). Subsequently, skin-blister fluid from patients with TEN was found to have high in lymphocyte cellularity (130). These cells were $CD8^+$, $CD29^+$ antigen-primed memory T cells ($CD45RA^-$). The fact that these cells expressed CD29, the common b-chain of the very low activation (VLA) adhesion molecule, suggests that these T-cell-associated adhesion molecules may be responsible for mediating T-cell interactions with skin endothelium (134) and with extracellular matrix proteins (135).

Correia et al. (130) demonstrated that blister-fluid cells were memory and not naive T cells, but they did not actually demonstrate that these cells were drug-specific. Evidence to support a role for drug-specific T-lymphocytes was provided by Hertl and colleagues, who generated penicillin-specific $CD8^+$ T-cell clones from cutaneous lesions of two patients with penicillin-induced SJS (61) and very late activation $CD8^+$ T-cell clones from the lesional skin of a patient with trimethoprim/sulfamethoxazole-induced TEN (62). Thus, one hypothesis that may explain the cell necrosis in SJS and TEN is that T-cell recognition of MHC-associated drug antigens leads to cytotoxic T-cell-mediated keratinocyte death (26). The situation is probably not so simple, however. Because the extent of cell death is marked relative to the number of T cells present, other factors such as cytokines, tumor necrosis factor (TNF) in particular (136), and other cell types (131,136,137) most likely contribute to the pathogenic process.

Recently, the final pathway responsible for epidermal cell death in SJS/TEN has become an intensive area of research (138,139 and 140). Since reactive drug metabolites have been implicated in these diseases, death may occur via direct cellular necrosis. However, in light of the data that suggest that an immune mechanism may be involved, and the fact that cytotoxic T lymphocytes and tumor necrosis factor are known to induce an apoptotic signal in target cells (141), apoptosis may be the more likely mechanism responsible. A characteristic pattern of DNA cleavage is the biochemical hallmark of apoptosis. Therefore, to determine if an apoptotic mechanism was involved, two groups evaluated the extent of keratinocyte DNA fragmentation in patients with TEN (138,139). Both found extensive keratinocyte DNA fragmentation indicating that, indeed, cell death was occurring via an apoptotic mechanism. Moreover, Inachi et al. (139) found that apoptosis was mediated by perforin, a cytoplasmic peptide that is believed to be a major "cytotoxic weapon" of cytotoxic T cells. Thus, these results together suggest that epidermal cell death occurs by cytotoxic T-cell-mediated apoptosis.

More recently, Viard and colleagues (140) found that keratinocytes from patients with TEN, in addition to expressing Fas, which is not atypical, also expressed lytically active Fas ligand. In addition, they found that keratinocytes from patients with TEN induced Fas-mediated cell death in Fas-sensitive target cells. They then showed that intravenous immunoglobulin (IVIG) inhibited Fas-mediated cell death by blocking the Fas receptor and that IVIG treatment led to marked clinical improvement in patients with TEN. Thus, as these investigators suggested, it appears that upregulation of keratinocyte Fas-ligand expression is the critical trigger for keratinocyte destruction in TEN. If IVIG proves to be an effective therapeutic modality for this disorder, it may also be effective in other disorders that involve Fas-mediated tissue destruction.

MANIFESTATIONS, DIAGNOSIS, AND MANAGEMENT OF ALLERGIC DRUG REACTIONS

Drug-induced Anaphylaxis

Anaphylaxis is an acute, life-threatening allergic reaction that is characterized by hypotension, urticaria, angioedema, bronchospasm, abdominal cramping, and cardiac arrhythmias, alone or in combination. The mechanism may be IgE mediated or immune-complex mediated, or it may involve non-IgE-mediated direct histamine release from mast cells and basophils. Although the term *anaphylactoid* sometimes is reserved for reactions that are thought not to be immunologically mediated, the clinical symptoms are the same regardless of the mechanism. The drugs most frequently implicated in drug-induced anaphylaxis are b-lactam antibiotics, NSAIDs, sulfonamides, high-molecular-weight agents (e.g., proteins), muscle relaxants, induction agents, and radiocontrast media (142). Some of these agents are thought to cause anaphylaxis via an IgE-mediated mechanism, and drug-specific antibodies have been identified for several of them (81,82,143,144,145 and 146). Other agents, like the muscle relaxants, may cause anaphylaxis both by immune and nonimmune mechanisms (147), whereas radiocontrast media reactions are thought to be caused by nonimmune mechanisms only (148,149). The mechanism responsible for systemic reactions induced by acetylsalicylic acid (ASA) or NSAIDs are generally due to inhibition of prostaglandin endoperoxide synthase 1 (PGHS-1), with consequent overproduction of cysteinyl leukotrienes. These reactions are class related (see Chapter 27). Occasionally, reactions to these agents have features that resemble IgE-mediated reactions (reaction is drug-specific and occurs after two or more exposures to the same drug), but drug-specific IgE antibodies have not been consistently identified (150).

Anaphylactic reactions usually are not difficult to recognize clinically, and, in many instances, the culprit drug is easily identified. During anesthesia, however, when many drugs are given in rapid succession, it is sometimes difficult to determine the cause of the anaphylactic event when one occurs. In addition, many of the administered drugs are known to cause anaphylactic or anaphylactoid reactions. Hypnotic agents and muscle relaxants are the most frequently implicated, along with opioids, benzodiazepines, neuroleptic agents, and nonanesthetic agents, such as antibiotics and latex (151).

Diagnostic tools include *in vivo* skin testing and *in vitro* radioallergosorbent tests for the relevant allergens. For therapeutic agents that are immunogenic in their native form (foreign antisera, hormones, enzymes, toxoids), specific IgE antibodies can be demonstrated by skin prick testing. Because most drugs are of low molecular weight and not immunogenic in their native state, skin testing is generally not useful. Skin tests with agents used in general anesthesia often are difficult to interpret because many of these drugs cause nonimmunologic histamine release. Skin testing is of value in the evaluation of allergy to muscle relaxants (152,153), barbiturates (152,154), chymopapain (155), streptokinase (156), insulin (157), latex (158), and miscellaneous other agents.

Currently, the immunochemistry of only one antibiotic, penicillin, is clearly known. Using both the major antigenic determinant and several minor determinants in testing,

numerous studies documented the presence of penicillin-specific IgE antibodies in persons who previously experienced penicillin-induced anaphylaxis or urticaria and angioedema (143,145,159,160,161,162,163,164,165,166,167,168,169,170,171,172,173 and 174). In contrast to penicillin, valid skin test reagents for detecting IgE antibodies to other antibiotics have not been developed.

In vitro measurements of allergen-specific IgE antibodies most often are performed with the radioallergosorbent (RAST) assay, which measures circulating IgE antibodies by a solid-phase radioimmunoassay. As with skin testing, application of this assay to drug allergy evaluations is limited due to insufficient knowledge of relevant drug metabolites. RAST assays have been developed to measure IgE antibodies to penicillin (major determinant) (175), insulin (157), chymopapain (155), muscle relaxants (146,176,177), thiopental (178), protamine (179), and latex (180). Both false-positive and false-negative test results do occur. False-positive tests may occur because of high nonspecific binding or high total serum IgE antibody levels. False-negative tests may occur because of interference by high concentrations of IgG "blocking antibodies," low assay sensitivity, obtaining blood samples too soon after a reaction, or the presentation of wrong immunogen on the solid-phase matrix. Only a limited number of reliable drug RASTs are available commercially.

An important test that has become available within the last few years is the tryptase determination. Tryptases are neutral proteases stored in mast cell granules, and their detection in serum indicates the likely occurrence of an anaphylactic–anaphylactoid event. Tryptase has a half-life in plasma of approximately 2 hours, and it is not prone to rapid degradation. For these reasons, tryptase determinations are favored over histamine determinations. Matsson and colleagues (181) reported two cases of intraoperative anaphylaxis to anesthetic drugs in which tryptase levels were elevated, and others too (182) reported elevated tryptase levels after drug-induced anaphylaxis. Schwartz and colleagues (183) recommend that tryptase levels be measured 1 to 2 hours after the onset of the anaphylactic episode. Normal levels are less than 2.5 ng per milliliter; levels higher than 10 ng per milliliter are associated with anaphylaxis, and levels may reach as high as 1,000 ng per milliliter (183). Unless the patient has systemic mastocytosis, an elevated tryptase level supports the occurrence of an anaphylactic event (see Chapter 36). Further skin testing or RAST testing may be performed to elucidate the actual agent responsible.

Management of acute anaphylaxis is not discussed in this chapter. For a discussion of this topic, the reader is referred to the *Anaphylaxis Practice Parameter* (184).

Patients who have experienced drug-induced anaphylaxis should not receive the implicated drug again unless it can be ascertained that drug-specific IgE antibodies are no longer present. If, however, future treatment is required with that drug, desensitization may be considered for those patients in whom drug-specific IgE antibodies are known or are presumed to exist. Whereas most drug desensitization protocols have been developed for b-lactam antibiotics (169,185,186 and 187), the principle of desensitization also has been applied successfully to other antibiotics, insulin, chemotherapeutic agents, vaccines, heterologous sera, and other proteins (28,79,188,189 and 190).

Drug-induced Immune-mediated Cutaneous Reactions

Because it is beyond the scope of this chapter to discuss all the various drug-induced cutaneous reactions, only a few that are known or are thought to have an allergic component are presented.

MACULOPAPULAR/MORBILLIFORM ERUPTIONS

The skin is the most frequently involved organ in drug-induced adverse reactions, and, of the skin reactions that are typically manifested, maculopapular or morbilliform eruptions are the most common. Although any drug can elicit a maculopapular eruption, the drugs most frequently implicated are b-lactams, sulfonamides, anticonvulsants, allopurinol, and NSAIDs (12). The eruptions often are generalized and symmetric, and they typically involve the trunk and extremities while sparing the face, palms, and soles. Associated symptoms may include fever, pruritus, malaise, and joint aches. Usually, the lesions arise within a week or two of therapy, but they have been known to appear a few days after therapy has been terminated. Typically, the lesions fade and ultimately resolve when the incriminating drug is stopped. If the drug is continued, in rare circumstances, the eruption may progress to generalized erythroderma or exfoliative dermatitis.

The mechanism underlying drug-induced maculopapular eruptions is not known, and thus few diagnostic tools exist. Most likely, more than one mechanism is operative in light of the variety of drugs that can elicit skin reactions of this type. To date, no role for drug-specific IgE or IgG antibodies has been found (123,191). Because most of these reactions occur several days into therapy and thus are delayed in nature, it has been thought that another immune mechanism, possibly a cell-mediated process, may be participating. Indeed, results from lymphocyte transformation studies support a role for T cells (192,193), and in some persons, patch-test positivity can be demonstrated (194,195 and 196). In addition, several groups have isolated penicillin- and sulfonamide-specific T-cell clones from the peripheral blood mononuclear cells of patients with maculopapular or morbilliform eruptions elicited by these agents (22,65,69,71,94,197). These results suggest that at least some drug-induced maculopapular eruptions may be T-cell mediated.

The treatment of maculopapular or morbilliform eruptions consists of discontinuation of the culprit drug and provision of symptomatic relief. Antihistamines usually are not of benefit because there is no evidence of mast cell involvement in reactions of this type. Because the mechanism is not thought to be IgE mediated, a graded challenge may be considered if the drug is required in the future (79). Readministration is absolutely contraindicated if the previous reaction had features that were consistent with SJS or TEN, however.

URTICARIA

Urticaria is another common drug-induced skin eruption that can be elicited by virtually any drug. The lesions typically are generalized and are characterized by pruritic, erythematous wheals that are evanescent. Drug-specific IgE antibodies may or may not be involved, and, for this reason, skin testing may or may not be helpful (see limitations of skin testing to drugs in preceding "anaphylaxis" section). Although antibiotic-induced urticaria is most likely caused by an IgE-mediated mechanism, some antibiotics, such as vancomycin and ciprofloxacin, may cause urticaria through direct histamine release (198,199 and 200). Therefore, reactions to these agents may occur with the first dose. Other drugs also may cause urticaria through direct histamine release or complement activation.

Treatment of drug-induced urticaria is straightforward. The culprit drug is identified and discontinued. While the lesions are resolving, patients should avoid known mast cell releasing drugs and NSAIDs. If possible, other drugs should be withheld because of the confusion that arises if the urticaria worsens after another drug is added. H_1-receptor antagonists are the mainstay of therapy and may be combined with H_2-receptor antagonists, especially if the urticaria is accompanied by systemic symptoms (201). If the reaction occurs during a course of therapy, the urticaria may be suppressed by antihistamine therapy if there is no alternative agent available. The patient must be monitored carefully, however, and the drug must be stopped if the rash progresses. Anaphylaxis has not been reported during uninterrupted therapy, but it may occur if the drug is discontinued and then readministered 24 to 48 hours later (75).

Drug-induced Allergic Hepatitis

Many drugs can cause liver damage. The most frequent drug-induced manifestation is hepatocyte necrosis; however, some drugs target the bile ducts or canaliculi, causing cholestasis only, whereas others affect sinusoidal or endothelial cells, resulting in venoocclusive disease or fibrosis (202). Still others affect multiple cell types, leading to a particular pattern of liver injury. Although drug-induced liver injury may be classified as hepatocellular, cholestatic or mixed, Lee (202) recommended that these reactions be categorized according to the type of reaction observed because this classification scheme takes into account the histologic changes, the involved cell type, and the clinical manifestations. Because the general topic of drug-induced hepatic reactions is too broad to discuss here, this section focuses on only one immunologically mediated drug-induced liver disease: allergic hepatitis.

Drug-induced hepatitis may be due to direct toxic effects of a drug or its metabolites, or it may result from an immune-triggered event. Severe halothane-induced hepatitis occurs only on secondary exposure and is characterized by fever and eosinophilia along with elevated transaminases. For these reasons, it is thought to be at least partially immunologically mediated (112,203). Drug-specific antibodies and autoantibodies have been detected in affected patients but not in control subjects (204,205). It is thought that halothane-protein adducts formed on the cell surface provide the antigen for immune recognition and that cell lysis is the ultimate event (112). Certain hydrochlorofluorocarbons, agents that are used in industry as substitutes for ozone-depleting chlorofluorohydrocarbons, are structurally related to halothane, and these drugs also may induce an allergic hepatitis similar to that induced by halothane (206). Drug-induced allergic hepatitis also occurs with sulfonamides, anticonvulsants, and other drugs (202).

The diagnosis of drug-induced hepatitis is relatively straightforward if a patient is taking few medications and only one of them is known to cause hepatitis. The situation is usually more complex, however, especially for hospitalized patients who are taking multiple drugs, several of which may be hepatotoxic. Lee (202) recommended that, in these circumstances, the best way to determine the culprit drug is to make a careful timeline of all drugs ingested and to be especially suspicious of those potentially hepatotoxic agents that were begun within 3 months of the onset of the hepatitis.

Treatment of drug-induced hepatitis is drug withdrawal and close observation to ensure that the reaction does not progress. Some agents, such as amoxicillin-clavulanic acid and phenytoin, have been associated with a syndrome in which the reaction worsens after the drug is stopped and several months are required for resolution (207). If the patient worsens clinically or there is laboratory evidence of hepatic failure, the patient must be hospitalized (208). Glucocorticoids may be used to treat those reactions presumed to be allergic in nature; however, their efficacy has not yet been proven (202). Drug rechallenge is not recommended

unless the drug is the only agent that is efficacious in treating a potentially life-threatening disorder.

Drug-induced Immune-mediated Hematologic Reactions

Drug-induced cytopenias include agranulocytosis, hemolytic anemia, and thrombocytopenia; and certain drugs are notorious for causing one or more of these reactions. Some, but not all, of these reactions are immune mediated. High-dose penicillin therapy is associated with hemolytic anemia in some patients because of the recognition of haptenated red blood cells by penicillin-specific IgG or IgM antibodies and subsequent complement activation (209,210). Cephalosporins have been implicated in drug-induced hemolysis, as have nomefensine, methyldopa, and other agents (211,212,213,214 and 215). Depending on the drug involved, the immune response may be directed toward the native drug, drug metabolites, or intrinsic red cell antigens (autoimmune hemolytic reactions) (27). In addition, hemolysis may occur via an “innocent bystander” mechanism in which drug-conjugated plasma proteins elicit antibody formation and the formed immune complexes adsorb to red cell surfaces, leading to complement activation and subsequent hemolysis (216).

Some types of drug-induced agranulocytosis and thrombocytopenia also may be immune mediated (217). The idiosyncratic nature of the reactions, along with their rapid recurrence with drug reintroduction, suggests immune involvement, although direct evidence for this involvement often is limited. Drugs that most commonly cause immune-mediated thrombocytopenia are quinine, quinidine, sulfonamides (antibacterials, sulfonylureas, thiazide diuretics), gold salts, and heparin. Immune-mediated agranulocytosis most commonly has been associated with pyrazolone derivatives, phenothiazines, thiouracils, sulfonamides, and anticonvulsants. Treatment is drug withdrawal.

Drug-induced Immune-mediated Pulmonary Reactions

Drugs can cause an array of adverse reactions in the lung, including alveolar hypoventilation, diffuse alveolar damage, usual interstitial pneumonia, hypersensitivity pneumonitis, pulmonary infiltrates with eosinophilia, noncardiogenic pulmonary edema, pulmonary hypertension, talc granulomatosis, pleuropulmonary disease from drug-induced lupus erythematosus, and bronchospasm (218). Although the mechanisms responsible for these reactions are not clearly known, several have been proposed: direct cytotoxic injury to alveolar capillary endothelial cells; oxidative injury; immunologically mediated injury via drug-induced systemic lupus erythematosus or hypersensitivity reactions; alterations in the lung matrix repair system that results in disturbed repair processes; and alterations in pulmonary capillary permeability caused by drug-related effects on neural control (219,220).

Clinical features that suggest that the participation of an immune mechanism include an acute or subacute onset, rapid resolution when the drug is withdrawn or glucocorticoid therapy is implemented, and the ability to reproduce the symptoms with reintroduction of the suspected agent. Histopathologic features typically are nonspecific. Laboratory findings that suggest the involvement of an immune mechanism include peripheral eosinophilia, elevated IgE levels, and enhanced lymphocyte blastogenesis as reflected by a positive lymphocyte transformation test (218).

An acute pneumonitis that is thought to be immune mediated can appear during treatment with nitrofurantoin, NSAIDs, and sulfasalazine. Clinical features include fever, cough, dyspnea, eosinophilia, and rash in some cases. Nitrofurantoin and sulfasalazine commonly cause interstitial pneumonitis with or without fibrosis, whereas the lesions caused by NSAIDs are more often alveolar. In many cases, lung function is restored after drug withdrawal. Significant pulmonary dysfunction can occur, however, especially if the drug is not discontinued promptly.

Drugs such as gold, procarbazine, and amiodarone induce pulmonary diseases that resemble hypersensitivity pneumonitis (221). Symptoms are both respiratory and systemic and include cough, dyspnea, fever, myalgias, and malaise. Examination of the patient reveals an ill, dyspneic person. Bibasilar rales are heard, and a leukocytosis is usually present. Pulmonary function testing typically shows reduced lung volumes and diffusing capacity. Infiltrates on chest radiogrphy may be interstitial, alveolar, or mixed. Treatment consists of drug avoidance and glucocorticoid therapy (218,221).

Some drugs have been associated with the development of a lupus-like syndrome. The most common agents in this category include hydralazine, isoniazid, procainamide, and the sulfonamides. The most frequent pulmonary manifestations are pleural effusion and pleuritic chest pain, and most patients have a positive antinuclear antibody titer (222). Drug discontinuation is the treatment of choice. Glucocorticoids may decrease the recovery time.

Finally, certain drugs may induce bronchospasm. The most common agents to elicit reactions of this type are the NSAIDs (223) (see Chapter 27).

Drug-induced Immune-mediated Renal Reactions

The two most common drug-induced hypersensitivity renal reactions are interstitial nephritis and nephrotic syndrome. Glomerular abnormalities also may occur in the presence of drug-induced immune complex disease.

Interstitial nephritis has been associated most commonly with methicillin; but other drugs, including other penicillins, cephalosporins, sulfonamides, captopril, furosemide, and thiazide diuretics, also have been associated with this disorder (224). Clinical features include fever, rash, blood eosinophilia, and urine eosinophilia. The patient typically has hematuria, proteinuria, pyuria, and sometimes azotemia. Both cellular and antibody-mediated mechanisms may be involved. Complete recovery typically occurs after drug withdrawal.

The nephrotic syndrome can be induced by gold salts, captopril, NSAIDs, and penicillamine (225). The syndrome is characterized by hematuria, hypoalbuminemia, hyperlipidemia, and edema. The prognosis is generally excellent when the implicated drug is discontinued. Treatment consists of supportive care, including bed rest, and dietary restriction of cholesterol, salt, saturated fat, and protein.

FUTURE DIRECTIONS

The understanding of drug-induced hypersensitivity responses in humans is limited. Not only can many of these reactions not be classified, but also the pathophysiologic processes responsible for them are unclear. Progress in this area has been hampered for several reasons. First, because of species specificity and intraspecies variability in the immune responses elicited to drug haptens, animal studies have not proved to be useful. Second, there is little knowledge of the immunochemistry of most drugs in relation to their metabolites, which represent reactive forms and clinically relevant immunogens. Once the relevant drug immunogens are identified, we should be able to better predict the type of immune response they may elicit and thus be able to understand better the underlying immunopathology of the reactions. Third, there is little understanding of predisposing genetic factors and other factors that allow for the prospective identification of individuals at risk. With improved understanding of the mechanisms responsible for drug-induced reactions, along with a better understanding of relevant risk factors, it should be possible to devise better classification schemes. Many drug-induced reactions, most likely, will involve multiple immune mechanisms or both immune and nonimmune components.

There is a need for enhanced postmarketing surveillance, perhaps a worldwide tracking system, to assess more fully the actual incidence and prevalence of drug-induced hypersensitivity diseases.

73 NATURAL RUBBER LATEX ALLERGY

James A. MacLean, M.D.

In the past two decades, natural rubber latex allergy has emerged as an important occupational and medical illness. The spectrum of hypersensitivity reactions to rubber products includes both delayed and immediate reactions. Delayed-type hypersensitivity reactions to rubber (1) have been recognized for many decades. Immediate-type hypersensitivity reactions initially were reported in Europe in 1979 (2), and several reports followed in the 1980s (3,4,5 and 6). The first report of latex allergy in the United States appeared in 1989 (7), and by 1992 the U.S. Food and Drug Administration (FDA) had received more than 1,000 reports of serious immediate-type allergic reactions to rubber products, including 15 deaths (8). In the last decade, numerous reports of natural rubber latex allergy have been published. Epidemiologic studies have elucidated the major risk factors for the development of adverse reactions to latex. The clinical syndromes that constitute latex allergy have been well characterized, and considerable progress has been made in determining the proteins and chemicals that cause latex hypersensitivity reactions. This progress led to improved diagnosis of latex allergy and also established methods for determining the levels of contaminants in manufactured rubber products. The management of persons with latex allergy has been refined and has focused on the elimination of exposure in both home and the workplace environments. The pathobiologic mechanisms involved in latex allergy and potential immunomodulatory therapeutic options for affected persons are the subjects of ongoing investigations.

The term *latex* refers to the milky white sap produced by the cells of various seed plants. Latex is a complex colloidal suspension that consists of multiple organic compounds, including proteins, alkaloids, starches, oils, tannins, resins, and gums. The latex from certain plants contains “natural rubber” as a major constituent. Natural rubber is an organic polymer whose chemical structure is cis-1,4-polyisoprene. Most of the world supply of natural rubber comes from the latex of rubber trees (*Hevea brasiliensis*) that are grown on commercial plantations in Southeast Asia and Africa. Natural rubber constitutes about 30% to 50% (wt/wt) of rubber tree latex and is the raw material from which rubber products are manufactured. The term *latex* may also be defined as “a water emulsion of synthetic material.” When used in this way (e.g., “latex” paint), the term does not imply the presence of natural rubber tree latex in the product.

The manufacturing of natural rubber products from raw rubber tree latex is a complex multistep process (reviewed in 9). Proteins in the latex may contaminate the raw natural rubber material and persist in the final manufactured product. Protein contamination occurs to a greater degree in dipped products (e.g., gloves, balloons, condoms) than in molded products (e.g., tires, rubber stoppers) (9). Various compounding agents (e.g., accelerants, antioxidants, and cross-linking agents) are added to the raw material during manufacturing (9). The compounded raw material is heated in the presence of sulfur (*vulcanization*) to catalyze the cross-linking of the polyisoprene chains. Compounding and vulcanization improve the elasticity, durability, and tensile characteristics of the final manufactured products. As with the rubber tree proteins, the chemical compounding agents may contaminate the manufactured end products. Synthetic alternatives to natural rubber exist (e.g., neoprene). Unlike natural rubber, synthetic polymers are not contaminated by protein, but they may contain chemical contaminants (10).

Persons who are exposed to rubber products may become sensitized either to the protein or to chemical contaminants in rubber products. Those with sensitivity to latex proteins can manifest immunoglobulin E (IgE)-mediated immediate-type hypersensitivity reactions while those with a sensitivity to chemical contaminants manifest cell-mediated delayed-type hypersensitivity reactions.

EPIDEMIOLOGY

High-risk Groups

Epidemiologic studies have identified several groups that are at high risk for developing IgE-mediated reactions to natural rubber latex. The occupational use of rubber gloves is the most often cited risk factor for IgE-mediated latex allergy, and health care workers represent the largest group of affected individuals (8,11). The prevalence of latex allergy among health care workers in Europe and North America is reported to be between 2.4% and 12% (3,12,13,14 and 15). The variability in prevalence rates between studies may be accounted for by differences in methods used to define and detect latex allergy. Sensitization of health care workers is believed to occur through exposure to rubber gloves and latex-containing medical devices. Other factors associated with an increased prevalence rate of sensitization among health care workers include a history of atopy or preexisting hand eczema (16). The prevalence of latex allergy in non–health care workers who are regularly exposed to rubber gloves is less well studied but may approach the rates reported for health care workers (17,18 and 19).

Individuals with spina bifida represent the second major risk group for IgE-mediated reactions to natural rubber latex (20,21,22,23,24 and 25). Affected persons are believed to become sensitized by repeated exposures to latex gloves and medical products during surgical procedures and through the use of indwelling latex catheters. Persons with spina bifida have the highest rates of sensitization among high-risk groups; prevalence rates vary between 18% and 50% (20,21,22,23,24 and 25). Undergoing multiple surgical procedures in childhood appears to be an independent risk factor for the development of latex sensitization for persons with spina bifida (25,26).

Rubber factory workers represent another defined risk group with an increased prevalence rate of immediate hypersensitivity to latex proteins. Workers in rubber glove manufacturing plants have been reported to have a prevalence of IgE-mediated latex reactions of 11% (27) and workers in rubber doll manufacturing plants a prevalence rate of 10% (28).

General Population

The frequency of immediate-type hypersensitivity to latex proteins in the general population is unknown. The earliest European studies reported a prevalence of IgE-mediated latex allergy in the general population to be less than 1% (3). More recent studies reported that the prevalence of latex sensitization in occupationally unexposed groups is between 0.12% and 1% (29,30). The prevalence of latex allergy in adults and children who visit allergy clinics is also about 1% (31,32 and 33). The prevalence of latex-specific IgE detected by serologic testing in the general population may be considerably higher. Assays of residual blood samples from donors in the United States and Europe revealed a prevalence of latex-specific IgE of about 6% (34,35). The presence of latex-specific IgE, however, does not indicate the presence of clinically expressed disease (14,36). The significance of a positive serologic test for latex-specific IgE in the absence of symptoms and the long-term prognosis for asymptomatic, sensitized persons are not known.

CLINICAL PRESENTATION

Spectrum of Reactions

The spectrum of hypersensitivity reactions to natural rubber latex is outlined in Table 73.1. Reactions are distinguished by the pathologic mechanism and the causative agent. The most common reaction to rubber products is irritant contact dermatitis (11), which is a nonimmunologically mediated irritation of the skin that is seen most commonly with the use of rubber gloves and is caused by having the hands under occlusion. Glove-donning powder may act as an abrasive to compound the irritation. Irritant contact dermatitis may be further aggravated by defatting of the skin through the use of detergents and alcohol or by exposure to irritating chemicals in the workplace (e.g., antiseptics). Irritant contact dermatitis may range from mild erythema and pruritus to chronic fissuring and hyperkeratosis.

Clinical Entity	Immunologically Mediated	Mechanism	Causative Agent
Irritant contact dermatitis	No	Irritant	Irritants
Aggravation of atopic dermatitis	No	Irritant or preexisting eczema	Irritants
Allergic contact dermatitis	Yes	Cell-mediated	Chemical additives
Contact urticaria/angioedema	Yes	IgE-mediated	Rubber proteins
Immediate disease	Yes	IgE-mediated	Rubber proteins
Rhinitis			
Conjunctivitis			
Bronchospasm			
Anaphylaxis	Yes	IgE-mediated	Rubber proteins
Food-related oral symptoms and anaphylaxis	Yes	IgE-mediated	Plant proteins with homology to rubber proteins

IgE, immunoglobulin E.

TABLE 73.1. Spectrum of Reactions to Natural Rubber

Allergic contact dermatitis is an immunologically mediated cutaneous eruption that is a manifestation of a cell-mediated immune response (1). When seen in association with rubber products, the immune response is directed against one of the chemical additives that exist as contaminants in the end products. Allergic contact dermatitis may be difficult to distinguish from irritant contact dermatitis. Irritant reactions predominantly affect the dorsum of the hand and spare the palmar surface. Weeping, vesiculation, and lichenification of the skin occur more commonly with allergic contact reactions. Both allergic and irritant reactions localize to the area of contact and often have well-defined borders that suggest a contactant as the cause. Persons who have preexisting hand eczema secondary to atopic dermatitis may have aggravation of their dermatitis when their hands are placed under occlusion or are exposed to irritants. Distinguishing active atopic hand eczema from allergic contact dermatitis can be difficult by clinical examination alone and may require diagnostic patch testing to rule out a sensitization to a rubber chemical.

Contact urticaria is an immunologically mediated cutaneous eruption that is a manifestation of an IgE-mediated immune response (11). Affected persons make IgE antibodies to protein contaminants in manufactured latex products. Contact urticaria is a frequent manifestation of IgE-mediated latex allergy (5,16,37,38). In contrast to irritant and allergic contact reactions, which have a delayed onset (usually days), contact urticaria usually manifests within minutes of exposure. The symptoms consist of erythema, pruritus, and the development wheals on areas of contact. Angioedema may be the presenting complaint with contact on mucosal surfaces. Contact urticarial lesions tend to resolve quickly (i.e., minutes to hours) after removal of the inciting agent, in contrast to allergic contact dermatitis, which may persist for days to weeks. Distinguishing between irritant contact, allergic contact, and contact urticaria reactions in persons with glove-related illness is important because the diagnostic testing and treatment options differ for these conditions.

The IgE-mediated reactions to natural rubber latex proteins also may manifest as inhalant disease (38,39 and 40). Inhalation of airborne latex proteins may lead to symptoms of rhinitis or bronchospasm, and deposition of latex proteins on the ocular surface may lead to conjunctivitis, chemosis, and periorbital angioedema. If there is significant systemic exposure or absorption of latex protein through a mucosal surface, anaphylaxis can occur (38). Latex-induced anaphylaxis and death have been reported in association with barium enema examinations; anaphylaxis occurred after the inflation of the latex retention balloon against the rectal surface (41). Systemic anaphylaxis has also been the presenting manifestation of latex allergy in patients undergoing surgical or obstetric procedures; therefore, latex allergy should be considered in the differential diagnosis of anaphylaxis during operative procedures (26,42,43 and 44).

Persons with IgE-mediated sensitivity to natural rubber latex proteins have an increased prevalence of food-related reactions. The prevalence of food-related syndromes in individuals with latex allergy has been estimated to be between 20% and 40% (45,46 and 47). Most studies examining the relation between latex and food allergy have relied on historical information and positive skin tests. Because the existence of the food allergy has not been confirmed by placebo-controlled food challenges, the prevalence rates for food reactions may be overestimated. The spectrum of food-related reactions ranges from localized oropharyngeal reactions (oral allergy syndrome) to systemic anaphylaxis (45,46 and 47). The foods most commonly associated with this condition are chestnuts, bananas, avocados, and kiwi fruit (45). The food-related reactions occur as a result of cross-reacting IgE antibodies that recognize proteins in foods that share homology with natural rubber latex proteins (45).

Laboratory Testing

Laboratory tests available for use in the diagnosis of IgE-mediated latex allergy include skin testing, serologic testing, and provocative testing. Cell-mediated immune reactions to rubber chemicals are confirmed by patch testing.

SKIN TESTING

Skin testing is the preferred diagnostic procedure for persons with suspected IgE-mediated latex allergy. Accurate and reproducible skin testing relies on the availability of a reliable skin testing extract. Latex extracts are currently available in Canada and some European countries. An extract is under development in the United States but is not currently available (Greer Laboratories, Lenoir, NC, U.S.A.). The safety and efficacy of this extract were documented in a study of 324 subjects (304 adults, 20 children) (48). The sensitivity of the extract at a concentration of 1 mg per milliliter was 99% with a specificity of 96% (48). Comparison studies suggested that skin testing is more sensitive and specific than serologic testing (49). In the absence of a commercial extract in the United States, some centers prepare their own extracts from raw latex sap (ammoniated or nonammoniated) or by extraction of manufactured latex products (e.g., latex glove extracts) (50,51 and 52). These extracts must be used with caution because anaphylaxis has occurred during skin testing (51). Furthermore, the protein content of these extracts may vary considerably, depending on the source material used (e.g., raw latex vs. manufactured product) (52,53). Extracts made from gloves that do not contain all the relevant antigens may elicit negative skin test results in sensitized individuals (54). Precautions to minimize risk during skin testing include the initial use of dilute solutions of extract and the use of prick rather than intradermal testing methods. Skin testing should be performed by personnel experienced in skin testing and in the management of anaphylaxis.

SEROLOGIC TESTING

Latex-specific IgE may be measured by enzyme-linked immunosorbent assay (ELISA) or radioallergosorbent test (RAST). In the United States, three FDA-licensed tests are available commercially: the CAP system (Pharmacia-Upjohn, Uppsala, Sweden), the AlaSTAT assay (Diagnostic Products Corp., Los Angeles, CA, U.S.A.), and the HY-TEC assay (Hycor Biomedical Inc., Irvine, CA, U.S.A.). In study of the diagnostic performance of these three assays, the sensitivities and specificities were 75% and 91% for CAP, 79% and 95% for AlaSTAT, and 89% and 67.5% for HY-TEC, respectively (49). The sensitivity of the two most commonly used tests (CAP and AlaSTAT) is less than 80%, indicating that about 20% of persons with clinical latex allergy may not be identified by serologic testing alone.

PROVOCATIVE TESTS

Use testing has been reported as an alternate diagnostic test for persons with suspected immediate hypersensitivity to latex (39,50,55,56). The glove-use test procedure involves placing glove material over a dampened finger or hand for 15 to 30 minutes. The test is usually graded on a semiquantitative scale on the basis of the presence of erythema or wheals. The hand gloved with latex is compared with the one gloved with nonlatex material. Glove-use testing by this method has correlated well with the results of skin-prick testing in diagnosing persons with immediate-type hypersensitivity to latex (50,54).

Provocative testing for latex allergy has been refined and validated (57,58). A two-stage latex glove provocation procedure was used in a recent study of the efficacy of a latex skin test reagent (48). The two-stage protocol involved the use of both a contact (glove-use test) and an inhalant (glove-powder inhalation test) component. Provocative tests were used selectively and were not used in persons with positive skin tests to avoid serious reactions.

The major limitation of inhalation tests is the inability to quantitate the amount of latex protein the test subjects receive. Two exposure chamber devices have been developed to improve latex exposure quantification during inhalation challenges (58,59). These techniques are largely reserved for research purposes because of their technical complexity.

PATCH TESTING

Persons with suspected latex-associated allergic contact dermatitis should be referred for patch testing. The Standard Allergen Series for patch testing, approved by the U.S. FDA, includes the chemicals most commonly associated with allergic contact dermatitis (60). Table 73.2 lists the rubber-associated chemicals included in the Standard Allergen Series. Accelerators account for most contact allergic reactions associated with rubber products (60). Occupationally related allergic contact dermatitis may be due to chemicals other than those found in rubber. Testing with additional chemicals may be required, depending on the exposure history (60). Standard concentrations of chemicals should be used for testing to avoid nonspecific irritant reactions. Patch testing should be performed by experienced personnel to

ensure proper application and interpretation.

Test Material	Composition	Function
Thiuram mix	Tetramethylthiuram disulfide Dipentamethylenethiuram Tetramethylthiuram monosulfide Tetraethylthiuram disulfide	Accelerator
Mercaptobenzothiazole		Accelerator
Mercapto mix	N-cyclohexyl-2-benzothiazole-sulfenamide 2,2-benzothiazyl disulfide 4-morpholinyl-2-benzothiazyl disulfide	Accelerator
Carbamate mix	1,3-diphenylguanidine Zn diethyldithiocarbamate Zn dibutyldithiocarbamate	Accelerator
Black rubber mix	*N*-phenyl-*N*-cyclohexyl-*p*-phenylenediamine *N*-isopropyl-*N*-phenyl-*p*-phenylenediamine *N,N*-diphenyl-*p*-phenylenediamine	Antioxidants

Management

CONTACT DERMATITIS

Therapy for hand dermatitis depends on the severity of the illness. Persons who develop irritant cutaneous reactions should be treated with topical emollients and a reduction in exposure to strong detergents, irritating chemicals, and abrasives. Allergic contact dermatitis can be managed by identifying the causative chemical and eliminating exposure. Therapy directed at the ongoing dermatitis may include drying compresses, oral antihistamines, topical glucocorticoids, and, occasionally, oral steroids. Emollients are used for desiccated and lichenified skin. Significant eczematous dermatitis (cracking and weeping of the skin) may require a temporary work restriction. Persons who react to the chemicals in latex gloves may use non–chemical-containing latex gloves as substitutes. Other alternatives include polyvinyl chloride or nonlatex synthetic gloves. It should be noted that some nonlatex synthetic gloves still contain chemicals that can cause allergic contact dermatitis reactions (10).

IGE-MEDIATED REACTIONS

The treatment of an ongoing immediate allergic reaction to latex depends on the manifestations and severity but conforms to the standard treatment of IgE-mediated reactions. Anyone who has latex allergy should obtain a Medic-Alert bracelet and self-injectable adrenaline (61). The mainstay of the long-term treatment of immediate reactions to latex products is avoidance. Affected persons should be educated about avoidance both at home and in the workplace. Lists of latex-containing devices have been compiled, along with suitable non–latex-containing alternatives (Spina Bifida Association of America, Washington, D.C.). Careful preparation is needed for latex-sensitive persons who require hospitalization or dental or surgical procedures. All procedures on latex-sensitive persons should be performed in a “latex-safe” environment, which is defined as one in which no natural rubber latex product is brought in direct contact with the affected person (61). Management protocols for the perioperative and routine in-hospital care of individuals with latex allergy have been established to safeguard against inadvertent latex exposures (62). Because the prevalence of latex protein sensitization in individuals with spina bifida is high, it is recommended that all medical procedures on these patients, regardless of history, be performed in an environment free of latex (61). Furthermore, to reduce sensitization rates in this group, latex exposure should be minimized.

The prophylactic use of glucocorticoids and antihistamines before surgical procedures remains controversial. Holzman (63) reported on the successful use of latex avoidance without prophylaxis in a large series of children with latex allergy. Others reported the occurrence of anaphylaxis despite premedication, suggesting that prophylaxis may not be effective in preventing reactions if significant exposure still occurs (44,64). Current data suggest that there is no substitute for the strict avoidance of latex (65).

Guidelines for the prevention of reactions to natural rubber products in the workplace have been established (66). These guidelines stress the importance of appropriate barrier protection for workers exposed to infectious or other hazardous material. The use of reduced-chemical and reduced-protein gloves that are powder free is recommended. Institutions that have adopted these recommendations have noted a reduction in airborne latex aeroallergens in the work environment (67,68).

PATHOBIOLOGY

Latex Allergens

The characterization of the proteins present in *H. brasiliensis* latex led to the identification of a number of latex allergens. More than 200 proteins have been identified by two-dimensional electrophoresis of the aqueous phase of rubber tree latex (69). Additional proteins can be identified bound to latex particles present in the sap. Proteins range in size from 5 to 200 kd. Not all latex proteins are allergens; about 50 latex proteins are allergenic (70). Immunoprobing of latex proteins separated by electrophoresis led to the identification of a number of latex allergens (reviewed in 71). The latex allergens that have been given designated names in accordance with the nomenclature system for allergens are listed in Table 73.3. Several other *H. brasiliensis* proteins have been isolated and characterized but have not been yet been classified as major latex allergens (71).

Allergen (Reference)	Alternate Name	MW (kd)	Function
Hev b 1 (57,58)	Rubber elongation factor	14.6	Involved in rubber biosynthesis
Hev b 2 (59–61)	α-1,3-glucanase	34–43	Glucanase
Hev b 3 (58,62,63)	Small rubber particle protein	24–27	Involved in rubber biosynthesis
Hev b 4 (,[3])		100–115	Microhelix component
Hev b 5 (,[3,64,65])		16–17.5	Homology to proteins in kiwi and potato
Hev b 6			
Hev b 6.01 (PR,1,[3])	Profilin	15	Chitin-binding proteins
Hev b 6.02 (,[3])			
	Hevein	5 (N-domain) 14 (C-domain)	
Hev b 7 (,[3],66,67)		45	Homology to patatins; storage proteins in plants
Other allergens			
Hevamine (68)		39.5	Lysozyme/chitinase activity

MW, molecular weight

TABLE 73.3. Designated Allergens from Hevea brasiliensis

Routes of Exposure

Susceptible persons become sensitized to natural rubber latex proteins after repeated exposures. The multiple potential routes of exposure to latex proteins include the following: cutaneous (e.g., gloves), mucosal (e.g., dental procedure or indwelling urinary catheter), percutaneous (e.g., surgical procedure), and inhalant (e.g., inhalation of latex protein on an airborne carrier). The major route of sensitization currently remains unknown. The route of sensitization may differ for different high-risk groups. For example, persons with spina bifida are exposed to latex by repeated orthopedic and urogenital surgical procedures (latex-containing medical devices) and through the use of latex urinary catheters. Persons who use latex gloves occupationally are exposed by direct cutaneous contact and also may be exposed by the inhalation of glove powder that is contaminated with latex protein. The pattern of IgE reactivity to latex differs among different populations with latex allergy (72,73).

The importance of glove powder in the pathobiology of latex allergy must be emphasized. Cornstarch powder can bind latex proteins and act as a carrier for both airborne and contact dispersal of latex allergens (74,75). Studies in hospital centers have identified high levels of latex aeroallergens in areas with extensive use of powdered gloves, whereas areas with minimal use of powdered gloves have substantially lower concentrations of latex aeroallergens (76). These data suggest that glove powder can be a major contributor to airborne latex proteins in hospital environments. Further studies have documented a substantial reduction in latex

aeroallergens in the hospital setting after the removal of high-protein, powdered gloves (68).

Immunologic Response

Serologic testing of persons with latex allergy reveals that most make IgE antibodies to multiple allergens (77). The spectrum of reactivity may differ from one high-risk group to another, depending on the route of exposure (72,73). Serologic testing revealed the presence of IgE antibodies to various food allergens in some persons with latex allergy (45). These antibodies are believed to result from cross-sensitization to food proteins that share homology with latex proteins. Lymphocytes from persons with latex allergic proliferate *in vitro* on exposure to latex proteins, suggesting a role for T-cell-mediated immune regulation in the development of latex allergy (78,79,80 and 81). Allergic contact eczematous dermatitis results from a cell-mediated delayed-type hypersensitivity response to latex-compounding chemical additives.

ANIMAL MODELS

Experimental animals have been used in many roles in the study of natural rubber latex allergy. Immunization of rabbits with crude latex preparations led to the development of polyclonal antibodies that have aided the identification and characterization of latex proteins and allergens (82,83). These reagents also have been used to detect the presence of latex allergens in manufactured latex products (84,85). More specific reagents, such as monoclonal antibodies, have been used for the affinity purification of specific antigens (86,87). Antibodies from animal and human sources also have been used to identify specific epitopes on latex allergens to define allergenic and antigenic determinants of these molecules (88).

Models of allergic pulmonary inflammation induced by latex allergens have been described in mice, guinea pigs, and rabbits (89,90,91 and 92). These studies support a role for IgE and eosinophils in the immunopathogenesis of immediate-type hypersensitivity responses to latex proteins. Other studies examined the use of DNA vaccines with latex allergen transcripts as immunomodulatory therapeutic interventions for latex allergy (93). Animal models also have been used to elucidate the possible role of immune adjuvants (e.g., endotoxin) in sensitization to latex proteins (94). Finally, murine systems have been used to elucidate the role of different routes of exposure on the development of immunologic responses to latex proteins (95).

FUTURE DIRECTIONS

Latex allergy presents unique challenges for rubber manufacturers, federal regulators, and medical investigators. The challenge for rubber manufacturers will be to reduce rates of sensitization by reducing both protein and chemical contaminants in rubber products. Cost-effective alternatives to natural rubber gloves, which maintain an effective barrier protection, are being investigated. Federal regulations mandating the labeling of medical products containing natural rubber were instituted in 1998 (96). Further steps to reduce the exposure of workers to latex proteins and chemicals are required. U.S. FDA approval of latex skin testing extract is anticipated in the near future, and this extract will improve the accuracy and safety of latex testing in the United States. For medical investigators, the focus of current research is on the continued characterization of the major latex allergens. Elucidation of these molecules will improve the diagnosis of latex allergy by ensuring that serologic (e.g., RAST) and skin test reagents contain all the relevant allergens. Allergen characterization also may lead to the development of protein or peptide vaccines for use as immunotherapeutic agents to broaden the treatment options for affected persons.

74 HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Oren J. Cohen, M.D., and Anthony S. Fauci, M.D.

The acquired immune deficiency syndrome (AIDS) was recognized in 1981, when five unusual cases of *Pneumocystis carinii* pneumonia (PCP) occurring in young homosexual men from Los Angeles were reported to the Centers for Disease Control and Prevention (CDC) (1). An infectious etiology as the cause of AIDS was later suggested by geographic clustering of cases, links among cases by sexual contact, mother-to-infant transmission, and transmission by blood transfusion. The depletion in numbers and function of T-helper cells further suggested that a lymphotropic agent might be responsible. Indeed, a human T-lymphotropic retrovirus that was immunologically related to human T-cell leukemia virus type I (HTLV-I) was detected in lymph node tissue from a French patient who was at risk for AIDS (2). This virus, later named *lymphadenopathy-associated virus*, or LAV, proved identical or highly related to the virus subsequently isolated at the National Cancer Institute termed *HTLV-III* (3,4) and in San Francisco termed *AIDS-associated retrovirus* (ARV) (5). These viruses were subsequently cloned and characterized and now are known as *human immunodeficiency virus type 1* (HIV-1). Molecular and seroepidemiologic studies have consistently demonstrated a near-perfect correlation between the development of AIDS and infection with HIV-1.

Scientific advances in understanding the pathogenesis of HIV infection have proceeded with unprecedented speed. Elucidation of the viral replication cycle led to the rational development of potent antiretroviral agents. Appreciation of the intimate relationship between HIV and the human immune system continues to guide efforts aimed at the prevention and treatment of HIV infection (6). Despite the rapid scientific advances that have been made, the brisk pace of the HIV/AIDS epidemic has continued largely unchecked in most parts of the world. Prevention efforts and the availability of antiretroviral therapies have blunted the expansion of the epidemic in the United States and Western Europe; however, expansion of the epidemic continues in sub-Saharan Africa and Southeast Asia and is now burgeoning in India and in the former Soviet republics.

EPIDEMIOLOGY

Global Pandemic

The global HIV pandemic ranks among the most devastating infectious scourges in human history. Approximately 300 cases of AIDS had been reported by the end of 1982; by the beginning of 1999, more than 33 million people worldwide were living with HIV (Fig. 74.1), and 14 million deaths attributable to HIV infection had occurred since the beginning of the epidemic (7). During 1998 alone, nearly six million persons worldwide acquired HIV infection, and 2.5 million deaths from HIV infection occurred; these statistics highlight the continued expansion of the epidemic on a global scale (7).

Figure 74.1. Global distribution of the estimated number of persons living with human immunodeficiency virus (HIV) infection as of December 1999. [Source: Joint United Nations Program on HIV/AIDS (UNAIDS)].

Phylogenetic analysis of HIV proviral sequences worldwide reveals three major genetic groups of HIVs, the M (major), N (new), and O (outlier) groups. These three HIV groups are most closely related to simian immunodeficiency virus (SIV) sequences (SIVcpz) harbored by chimpanzees of the subspecies *Pan troglodytes* troglodytes (8). The relatively rare O group viruses are concentrated in West Africa in Cameroon, Gabon, and Equatorial Guinea. Group N viruses were isolated in 1998 in two persons from Cameroon (9). Within the M group, related HIV variants are classified into *clades*, or subtypes (currently designated A–J) according to their degree of genetic similarity (10). At the nucleotide level, viral subtypes differ from each other by about 14% in their *gag* (viral core) coding sequences and by about 30% in their envelope coding sequences (10). Subtype C viruses are the most common worldwide, whereas subtype B viruses predominate in North America and Western Europe.

Zoonotic transmission of a retrovirus from chimpanzees to humans in sub-Saharan Africa is the most plausible explanation for the genesis of the HIV epidemic (8). From central, western, and eastern sub-Saharan Africa, the epidemic spread to North America, Latin America, Western Europe, Southeast Asia, and southern Africa. Currently, the heaviest burden of the epidemic is concentrated in southern Africa, India, and Southeast Asia. Although only 10% of the world's population live in sub-Saharan Africa, 70% of the worldwide population who acquired HIV infection in 1998 live there. Of all AIDS deaths since the beginning of the AIDS epidemic, 83% have occurred in sub-Saharan Africa. In the southern African countries of Botswana, Namibia, Swaziland, and Zimbabwe, 20% to 26% of the population between the ages of 15 and 49 years are infected with HIV. The epidemic is also expanding rapidly in South Africa; 15% of new infections in the entire African continent in 1998

occurred in South Africa.

Nearly 1% of the adult population in India is infected with HIV. Although this seroprevalence is lower than in many affected countries, it makes India the country with the largest number of HIV-infected persons (approximately four million). Most HIV infections in India occurred during the 1990s. Thus, an extraordinary burden of HIV-related morbidity and mortality lies ahead in India because the epidemic there is in its early stages. Alarmingly, among women attending a sexually transmitted disease clinic in Pune, India, nearly 14% tested positive for HIV, despite the fact that more than 90% were married and monogamous (11).

Societal changes are fueling the spread of HIV in Eastern Europe and central Asia. Increasing availability and use of illicit drugs and a burgeoning sex-worker population in the republics of the former Soviet Union have contributed to a 25-fold increase in rates of syphilis in the 1990s (7). Although the absolute number of HIV infections in the region is small, the rate of increase is extremely rapid. In this regard, the cumulative number of HIV cases reported in the region increased more than fivefold between 1995 and 1997, with Ukraine, Russia, and Belarus accounting for about 90% of all new cases (12). HIV seroprevalence rates are as high as 70% among injection drug users in the Chinese provinces of Yunnan and Xinjiang, which border poppy-rich regions of Asia. Current estimates place the burden of HIV infections at 300,000 to 400,000 in China, and this number appears to be growing rapidly.

In the United States, between 600,000 and 800,000 persons are infected with HIV (13). Although the incidence of new infections declined substantially in the late 1980s as a result of successful prevention efforts, a plateau of about 40,000 new HIV infections per year has persisted through the 1990s (13). The availability of highly active antiretroviral therapy (HAART) in developed countries led to substantial reductions in the death rate due to AIDS (14,15). Unfortunately, no such benefit has reached the developing world, where AIDS-related mortality continues to exact a devastating toll. In fact, the nine African nations with an HIV seroprevalence greater than 10% will experience a decline in average life expectancy of 17 years by the year 2015. Instead of an average life expectancy that would have been on a trajectory to reach 64 years in the absence of HIV, it will decline to only 47 years (7). Infant mortality rates are rising sharply in these countries as well, largely as a direct result of HIV infections. Finally, most developing countries do not have adequate resources to provide for a growing population of AIDS orphans; 20% to 30% of all children under the age of 15 have been orphaned in nine sub-Saharan countries (16).

Transmission

The transmission of HIV occurs by exposure of the oral, rectal, or vaginal mucosa during sex, by inoculation (i.e., through transfusion of contaminated blood products, use of contaminated equipment during injection drug use, or maternal–fetal circulation), or by breast-feeding. Sexual transmission accounts for more than 90% of HIV infections worldwide. In developing countries, most infections occur as a result of heterosexual contact, with a male-to-female ratio of approximately 1. In the United States and Western Europe, the vast majority of HIV infections that occurred early in the epidemic were associated with homosexual contact. Specifically, unprotected receptive anal intercourse was identified as the strongest risk factor for acquisition of HIV infection in men who reported having sex with men. The demographic characteristics of the epidemic have shifted considerably over the years, with a higher percentage of new infections occurring in injecting drug users and their sex partners. Minority populations are disproportionately affected by HIV; in 1998, AIDS rates per 100,000 population were 66.4 for blacks, 28.1 for Hispanics, and 8.2 for whites (17). Women are also increasingly affected by the HIV epidemic; in the United States, the percentage of AIDS cases occurring in women increased from 7% to 23% between 1985 and 1998 (17). Fewer than 50% of AIDS cases in the United States that occurred in 1998 were in men who have sex with men (17). Behavioral risk factors also shifted over time. In a cohort of men who have sex with men recruited in 1992 through 1994, only 15% of HIV seroconversions that occurred were due to unprotected anal intercourse; many seroconversions appear to occur following activities previously considered to be of lower risk, including oral sex (18).

Transmission of HIV is dependent on a large number of behavioral and biologic factors. The per-contact probability of male-to-female HIV transmission during vaginal sex is approximately 0.1% to 0.2% (19,20); receptive anal intercourse is associated with a considerably higher (i.e., about 0.8%) risk of transmission (18). Not surprisingly, considerable heterogeneity exists in per-contact risk, with some persons becoming infected after only one or several exposures, and others remaining uninfected despite frequent exposure (18,21,22). Some of the many variables that influence the probability of HIV transmission include the genetic background of the potential host, the size and infectiousness of the inoculum, and the local environment in which the exposure occurs. Factors that result in physical disruption of the exposed mucosa, such as the use of vaginal dessicants or the presence of genital ulcer disease, can enhance viral transmission (23,24).

IMMUNE SYSTEM MOLECULES NECESSARY FOR HIV ENTRY

Human immunodeficiency virus enters cells through interactions with the CD4 molecule and one of a number of seven-transmembrane G protein–coupled chemokine coreceptors. In 1984, CD4 was identified as the major receptor for HIV fusion and entry (25,26). Although transfection of CD4 into CD4-negative human cells renders them infectable with HIV (27), murine cells remain resistant to HIV infection despite expression of human CD4. This result suggested that other factor(s) were necessary for HIV fusion and entry, although the identity of these additional factors remained elusive for several years.

In late 1995 and early 1996, several lines of investigation into diverse areas of HIV pathogenesis converged, revealing the identity of several cofactors necessary for HIV entry (Fig. 74.2). Investigators studying HIV suppressor factors secreted by $CD8^+$ T cells reported in 1995 that the CC chemokine macrophage inflammatory protein (MIP)-1a, MIP-1b, and RANTES (regulated on activation, normal T cell expressed and secreted) were major components of $CD8^+$ T cell-derived HIV suppressor activity (28). These chemokines inhibited the infection of activated $CD4^+$ T cells by certain strains of HIV-1, HIV-2, and SIV. Of note, these CC chemokines selectively inhibited infection of cells by different strains of HIV-1. They potently inhibited infection by viral strains that infect macrophages and peripheral blood mononuclear cells [i.e., macrophage (M)-tropic strains] but not strains that infect T-cell lines and peripheral blood mononuclear cells [i.e., T-cell (T)-tropic strains]. In a somewhat unrelated line of investigation, a gene was identified that allowed HIV envelope-mediated cell fusion in the presence of CD4 (29). The encoded protein, called *fusin* (later renamed *CXC chemokine receptor 4*, or CXCR4), is a seven-transmembrane G protein–coupled chemokine receptor. This receptor, together with CD4, was required for cell fusion with envelopes from T-tropic strains of HIV, but was not used by M-tropic envelopes.

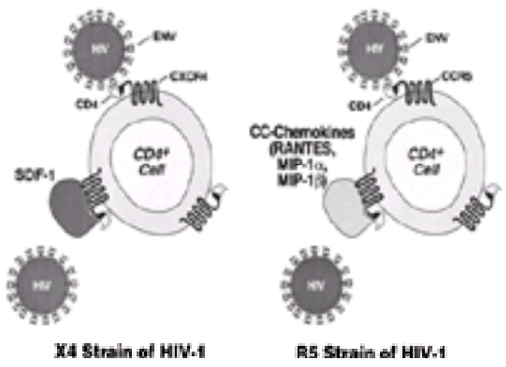

Figure 74.2. Model of human immunodeficiency virus (HIV) coreceptor (CCR5 and CXCR4) utilization and inhibition of HIV entry by coreceptor ligands. Entry of R5 strains of HIV is blocked by the CCR5 ligands macrophage-activating factor (MIP-1)a, MIP-1b, and regulated on activation normal T-cell expressed and secreted (RANTES). Entry of X4 strains of HIV is blocked by the CXCR4 ligand stromal cell–derived factor-1 (SDF-1).

In a separate line of research, Paxton and co-workers were studying a population of persons who had been exposed to HIV-infected partners but remained uninfected (i.e., “exposed-uninfected,” or E-U) (22). They identified two subjects whose $CD4^+$ T cells were refractory to infection with M-tropic strains of HIV *in vitro* but who were easily infectable with T-tropic strains. In addition, cells from these persons produced high levels of CC chemokines, which had been identified as suppressors of infection with M-tropic strains of HIV. Subsequently, a new CC-chemokine receptor, CCR-5, was identified; interestingly, the natural ligands that bind to this receptor were identified as MIP-1a, MIP-1b, and RANTES (30,31). In light of the previous work showing that the CCR5 ligands inhibit cellular entry of M-tropic strains of HIV, the obvious question that arose was whether CCR5 might function as a coreceptor for such strains. A series of five papers simultaneously showed this to be the case (reviewed in 32). Other chemokine receptors, including CCR1, CCR2b, and CCR3, were identified in these reports as potential coreceptors for certain HIV strains. Other chemokine receptors have been shown to be potential HIV coreceptors (reviewed in 32); however, CCR5 and CXCR4 appear to be the most physiologically relevant coreceptors for HIV entry. Strains of HIV are now classified according to their coreceptor utilization preferences; strains that use CCR5 for entry (i.e., most M-tropic strains) are referred to *as R5 strains*, and those that use CXCR4 (i.e., most T-tropic strains) are referred to as *X4 strains* (33).

The interactions between the HIV envelope, CD4, and the relevant coreceptor molecule that is necessary for HIV entry are complex. The HIV envelope glycoprotein (gp) first binds to CD4; this interaction creates a high affinity binding site for the HIV coreceptor as a consequence of a conformational change in the envelope (34,35 and 36). Although signal transduction through the chemokine receptor is not necessary for coreceptor activity (37,38), it may have important effects on viral replication after viral entry (39,40).

REPLICATION CYCLE OF HIV

Interactions between the surface envelope glycoprotein of HIV and the cell surface CD4 molecule and an appropriate coreceptor molecule (generally a seven-transmembrane G protein– coupled receptor; see preceding) result in fusion of viral and cell membranes, with entry of the virion contents into the cellular cytoplasm.

Viral reverse transcriptase (RT) is a product of the polymerase (*pol*) gene, and it synthesizes proviral DNA from the viral RNA genome. Cellular $tRNA^{lys}$ is utilized as a primer for the reverse transcription process. Like RT, RNase H is a *pol* gene product that is necessary for degradation of genomic RNA as viral cDNA is synthesized. Proviral DNA becomes associated with the viral matrix protein (a *gag* gene product), integrase (another *pol* gene product), and RT in a preintegration complex. Nuclear localization signals are present within the gag matrix protein; in addition, the viral Vpr protein appears to play an important role in targeting the preintegration complex to the nucleus (see later). Integrase cleaves chromosomal DNA and facilitates proviral integration.

Transcription of HIV genes is regulated by cis- and trans-acting sequences. The long terminal repeat (LTR) region of HIV DNA contains a TATA box as well as 3 Sp1 binding sites, which function as the major cis-acting transcriptional regulatory sequences. A transcriptional enhancer region is located just upstream from the Sp1 sites, consisting of two nuclear factor-kB (NF-kB) binding sites. These sites represent a prime example of the way HIV is able to utilize the milieu of immune activation (i.e., NF-kB levels are upregulated during T-cell activation) toward its own replicative advantage.

The Tat protein of HIV-1 enhances transcription of viral RNA by binding to the trans-activating response (TAR) region of the viral LTR. The mechanism by which Tat enhances transcription appears to be through its association with cellular factors, including cyclin-dependent kinase Cdk9 and cyclin T1; the complex of Tat and these cellular factors enhances the rate and processivity of RNA polymerase II–mediated transcription (reviewed in 41).

Transcripts of HIV can be grouped into two classes: Multiply spliced RNAs primarily encode regulatory HIV gene products, such as Tat, Rev, and Nef. Unspliced and singly spliced RNAs contain the Rev-responsive element (RRE); these RNAs encode Gag, Pol, and Env products as well as Vif, Vpr, Vpu, and a single-exon form of Tat. Rev binds to the RRE and forms multimers; Rev stabilizes RRE-containing transcripts through a posttranscriptional mechanism, facilitates their transport from the nucleus to the cytoplasm, and enhances their translation (reviewed in 42).

Assembly of new virions requires a number of coordinate biochemical processes. The Gag matrix domain targets the 55-kd Gag polyprotein to the plasma membrane of the infected cell (43) and also facilitates the incorporation of envelope glycoprotein molecules (44). The Gag nucleocapsid domain captures two copies of genomic HIV RNA, which are incorporated into the forming virion (45). The capsid protein associates with cyclophilin A; capsid-mediated incorporation of cyclophilin into the virion may promote uncoating of the viral core after entry into a target cell and is necessary for viral infectivity (46). The viral protease cleaves the Gag-Pol fusion protein; further cleavage of the intact Gag protein by the viral protease yields the viral core proteins that are necessary for virion assembly and maturation. Finally, the maturing virion buds from the cell surface, with envelope glycoproteins protruding outward from the lipid bilayer that is taken from the infected cell.

The HIV genome also encodes a number of other gene products that facilitate the viral replication cycle at a number of different stages. The Nef protein becomes detectable early after transcriptional activation of the HIV provirus. *Nef* mutants of HIV-1 exhibit attenuated pathogenicity, although the mechanisms responsible for this effect remain to be precisely elucidated. Nef downregulates cell surface expression of CD4 by inducing this molecule's endocytosis and lysosomal degradation (47). Other examples of viral receptor downregulation by animal retroviruses are known; teleologically, such an effect is thought to represent a viral strategy aimed at preventing superinfection of target cells. Nef also downregulates major histocompatibility (MHC) class I molecules (48), and this effect may allow HIV-infected cells to evade killing by HIV-specific cytolytic T-lymphocytes (CTLs) (49). Finally, Nef induces secretion of proinflammatory chemokines from HIV-infected macrophages; these chemokines are in turn capable of inducing chemotaxis and activation of resting T cells, an effect that could enhance the availability of suitable HIV targets (50).

Nef also associates with a variety of cellular serine-threonine as well as tyrosine kinases (reviewed in 51). Nef-associated kinase activity enhances serine phosphorylation of gag matrix protein, which in turn facilitates membrane dissociation of the reverse transcription complex during viral entry. These Nef-related effects may be responsible for the enhanced virion infectivity associated with Nef. Finally, Nef can form a complex with the z-chain of the T-cell receptor; this interaction enhances expression of Fas and Fas ligand, sensitizing cells to apoptosis (52,53).

Vif is detectable in the cytoplasm of HIV-infected cells; the protein appears to associate with the plasma membrane and with the cytoskeleton as well (54,55). Vif renders cells permissive for HIV infection, likely by overcoming the activity of an endogenous inhibitor of HIV replication, the identity of which remains undetermined (56). Vif may also be incorporated into virions; it may fulfill roles in virion maturation as well as proper processing of the gag p55 precursor. Products of reverse transcription are unstable in *vif*-defective viruses (57), and the reverse transcription process itself may be inefficient in the absence of Vif. Because Vif does not appear to participate directly in the reverse transcription complex, a defect in the early stages of the viral replication cycle is implied.

Vpu is an integral membrane phosphoprotein. Biologic activities that have been attributed to Vpu include induction of CD4 degradation in the endoplasmic reticulum (58), downregulation of MHC class I molecule synthesis (59), and enhancement of viral particle release from the plasma membrane of infected cells (60).

Despite the absence of a nuclear localization signal, the Vpr protein of HIV-1 localizes mainly in the nucleus of infected cells and facilitates nuclear transport of the preintegration complex (reviewed in 61); this property confers on HIV-1 the ability to infect nondividing cells, such as macrophages. Vpr is incorporated into virions through its interaction with the p6 gag protein. Virion-associated Vpr can arrest the cell cycle at the G2 stage and induce apoptosis in $CD4^+$ T cells (reviewed in 61). These effects are dependent only on viral entry, and not on replication, suggesting a role for defective as well as infectious virions in contributing to $CD4^+$ T-cell dysfunction and death (62).

PATHOGENESIS OF ACUTE INFECTION

The earliest events that occur following exposure to HIV involve the transport of virus from the site of exposure to lymphoid tissue. In a macaque model of SIV sexual transmission, bone marrow–derived dendritic cells (DCs) in the vaginal mucosa were the first cells to contain SIV DNA, which became detectable 2 days after vaginal exposure. In subsequent examinations of lymphoid organs, the pattern of appearance and spread of SIV mirrored the course taken by DC on migrating from peripheral tissues to lymphoid organs (63). In addition to serving as direct targets of HIV infection, DCs are also capable of retaining infectious virions on their surface for extended periods (64). This property is mediated by DC-SIGN [dendritic cell-specific intercellular adhesion molecule-3 (ICAM-3) grabbing nonintegrin], a DC surface molecule that normally interacts with ICAM-3 on the surface of T cells (65). DC-SIGN also binds with high affinity to the HIV-1 gp120; however, the protein does not serve as an entry coreceptor but rather enhances the viability of surface-bound virions (66). Thus, the role of DCs in the initiation of HIV infection includes capturing virions at sites of entry, carrying HIV to the paracortical regions of lymphoid organs and delivering virus to $CD4^+$ T cells that become activated through their interaction with DCs. In fact, active viral replication occurs in DC–$CD4^+$ T-cell conjugates that are formed *in vitro* (67). Similar conjugates of DC and $CD4^+$ T cells containing HIV antigen have been identified *in vivo* in tonsil biopsy specimens from persons infected with HIV (68), in the peripheral blood in low quantities (64), and in the submucosal tissue after vaginal exposure to SIV (63).

Macrophages and $CD4^+$ T cells are key targets of HIV infection. The viral determinant of cellular tropism maps to the gp120 envelope protein of HIV-1, mostly to the third variable region (V3 loop) (69) that is also the major determinant for coreceptor use (70). Changes in viral phenotype have been observed at different stages of HIV infection. CCR5-utilizing viruses are preferentially transmitted during primary infection and predominate at most stages of infection (71). In about 50% of HIV-infected persons, the appearance of CXCR4-utilizing isolates late in the course of disease heralds accelerated $CD4^+$ T-cell decline and clinical disease progression (72,73). This transition may occur by mutation of only a few amino acid residues predominantly in the envelope V3 loop (74,75). Given the high error rate of RT and the rapid kinetics of HIV replication, the surprising failure of such mutants to emerge until late in the course of the disease process indicates a change in the selective advantage of such a mutation during the course of disease progression. The nature of such a selective advantage is currently unknown; however, it may relate to the ability of X4 viruses to gain cellular entry through an expanded repertoire of coreceptor molecules.

The mechanisms responsible for the restriction of R5 viruses during primary infection is the subject of intense investigation. Freshly isolated Langerhans cells (resembling mucosal DCs) express CCR5, but not CXCR4, on their surfaces (76); this finding suggests that infection of DCs may be a necessary first step in acute infection and that this step is restricted by the expression pattern of HIV coreceptors on DC; however, HIV-pulsed DCs from persons who lack a functional *CCR5* gene are capable of transmitting infection to $CD4^+$ T cells *in vitro* (77). Thus, although infection of DC may be dependent on specific HIV coreceptor expression, the ability of DCs to trap virions on their surface and infect $CD4^+$ T cells that they encounter is at least in part a coreceptor-independent phenomenon.

In animal models of SIV infection, virus can be detected in the peripheral lymph nodes within 1 week of infection (63,78,79). Most of the SIV RNA at this time is associated with individual productively infected cells in lymph nodes. This production of virus by individually infected cells in lymphoid tissue precedes and likely is responsible for the peak of viremia. Coincident with the appearance of SIV-specific immune responses, a decrease in the frequency of productively infected cells is seen during the second week after infection. By 4 weeks after infection, viremia decreases as a result of further elimination of productively infected cells by SIV-specific cell-mediated immune responses and clearance of circulating virions by the formation of immune complexes consisting of virus, antibody, and complement that are

trapped within lymphoid tissue germinal centers (78,79).

Cross-sectional studies in patients evaluated soon after acute HIV infection are similar to the findings in the SIV model (Fig. 74.3). The kinetics of HIV viremia and HIV-specific immune responses in peripheral blood parallel those in the SIV model (80,82 and 83). Data from lymph node biopsies obtained from acutely infected individuals suggest that the SIV model is valid in depicting the early events associated with HIV infection in lymphoid tissue as well (84). In the weeks to months following acute HIV infection, a sharp decline in the frequency of productively infected cells is evident in lymphoid tissue. Germinal center formation within lymphoid follicles becomes pronounced, and viral RNA corresponding to extracellular virions complexed with antibody and complement is detected in the network of follicular dendritic cell (FDC) processes (85,86 and 87). Although the immune system is capable of efficient elimination of a substantial number of productively infected cells in lymphoid tissue, the earliest interactions between virus and host virtually ensure viral persistence. In this regard, massive numbers of virions trapped within the germinal center FDC network as well as latently infected cells, which harbor proviral DNA but do not express viral proteins (and thus elude the immune response), represent potentially continuous sources of virus for *de novo* infection of $CD4^+$ T-lymphocytes that are resident in or migrating through lymphoid tissue (88,89,90 and 91).

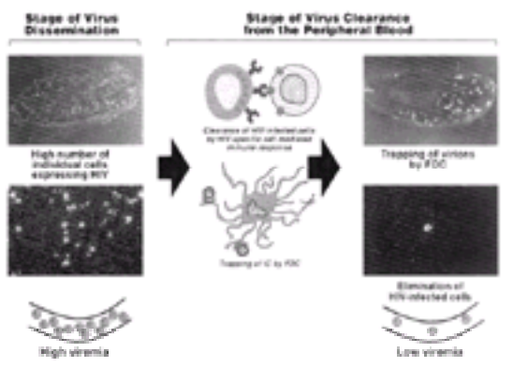

Figure 74.3. Cell-mediated and humoral immune mechanisms involved in the downregulation of viremia following primary HIV infection. Before the emergence of human immunodeficiency virus (HIV)-specific immune responses, large numbers of individual productively infected cells are found in lymph nodes (left; low- and high-power photomicrographs of an *in situ* hybridization assay for HIV RNA in a lymph node), resulting in high levels of plasma viremia. Emergence of cytotoxic T-cell responses against HIV leads to elimination of a large number of productively infected cells (photomicrograph, lower right). In addition, HIV-specific antibodies combine with virions to form immune complexes (IC); complement (C') binds to the immune complexes, which then are trapped in the follicular dendritic cell (FDC) network of expanding germinal centers by complement receptors (photomicrograph, upper right).

VIRAL DISSEMINATION

Like many other invading microorganisms, HIV is transported by antigen-presenting cells to lymphoid tissue. In the case of HIV, however, the host immune system is unable to control and eradicate the infection completely. In fact, in an impressive example of subversion of the immune system, HIV utilizes the activated milieu of lymphoid tissue toward its own replicative advantage. Close contact between immune effector cells as well as high levels of proinflammatory cytokines are characteristic of the lymphoid tissue microenvironment; these conditions favor viral replication in several ways. Activated $CD4^+$ T-lymphocytes migrating through lymphoid tissue serve as ideal targets for *de novo* infection with HIV (91,92). Activation signals such as those delivered by proinflammatory cytokines, found in abundance within activated lymph nodes, are potent inducers of HIV replication in latently infected cells (93,94) and also are able to increase the pool of activated cells that are susceptible to HIV infection (92,95,96 and 97).

Viral dissemination throughout lymphoid tissue is a fundamental pathogenic event during the early phase of HIV infection. Lymphoid tissue remains the most important reservoir of infection throughout the entire course of the disease. The early chronic stage of HIV disease is characterized by heavy concentration of viral load in lymphoid tissue. In this regard, the frequency of infected cells in lymph nodes exceeds that in peripheral blood by fivefold to tenfold; differences in levels of viral replication are generally tenfold to 100-fold (87,98,99). Up to 25% of $CD4^+$ T-lymphocytes present in lymph node germinal centers harbor HIV DNA, further emphasizing the role of lymphoid tissue as a critical reservoir for HIV *in vivo* (88). The continuous state of rapid high-level turnover of plasma viremia derives in large measure from viral replication in lymphoid tissue (100,101).

The concentration of viral load in lymphoid tissue is due in part to the normal process of follicular hyperplasia within lymphoid germinal centers following antigenic challenge (85,102). Expansion of the FDC network within hyperplastic lymphoid follicles is an efficient mechanism for viral trapping via interactions between antibody and complement-coated virions with complement receptors or adhesion molecules on the surface of FDCs (103,104).

During the course of HIV disease progression, there is a shift in the lymphoid histopathologic pattern from follicular hyperplasia to follicular involution (87). This shift in histopathology is associated with important changes in viral distribution. Disruption of the FDC network is characteristic during this period, leading to a decrease in the efficiency of viral trapping in germinal centers and a consequent increase in plasma viremia (87). Sequestration of infected cells within lymphoid tissue also becomes less efficient during follicular involution, leading to an increase in the frequency of infected cells in the peripheral blood. As the $CD4^+$ T-lymphocyte count falls below 200 cells per microliter, there is a tendency for viral load to increase more rapidly in the peripheral blood compartment, leading to equilibration between lymph node and peripheral blood.

Destruction of lymphoid tissue certainly is a major mechanism responsible for the severe immune dysfunction and loss of the ability to inhibit viral replication observed in advanced-stage HIV disease. The ability to maintain an effective immune response to HIV is severely impaired in the absence of intact lymphoid tissue architecture. As a consequence, increased cell-associated viral RNA becomes evident in the paracortical regions of lymph nodes, reflecting increased viral replication. Thus, during progression of HIV disease, there is a reversal in the predominant forms of virus in lymph nodes, with progressive diminution of the extracellular form (i.e., trapped virus) and an increase in cell-associated virus (i.e., cells expressing HIV) (87). In the advanced stage of disease, there is almost total dissolution of lymphoid architecture. Follicular involution, fibrosis, frank lymphocyte depletion, and fatty infiltration herald complete loss of functional lymphoid tissue, contributing to the state of immunodeficiency and the dramatically enhanced susceptibility to opportunistic infections. Disruption of the lymphoid microenvironment during the course of HIV infection remains an enigmatic process with considerable implications for future therapeutic interventions. Productive infection of FDCs by HIV may occur, particularly in the late stages of HIV infection (105); however, most data suggest that productive infection of FDCs is rare during the period of intermediate stage disease, when dissolution of the FDC network begins (104,106). Of note, some of the HIV-related pathologic changes that occur in lymphoid tissue may be at least partly reversible during potent antiretroviral therapy (107,108).

IMMUNE RESPONSES

Similar to most pathogens, HIV induces a broad array of host immune responses in an infected person. A central unanswered question of pathogenesis is how HIV is able to continuously replicate and cause the inexorable decline in immune system function in the presence of these immune responses.

Humoral Immune Responses

Antibodies against the viral core protein p24 develop within weeks of acute HIV infection and may play a role in the decline of plasma viremia associated with primary infection. Loss of anti-p24 antibodies is associated with progression of HIV disease (80,109,110).

Antibodies that neutralize HIV infectivity may be responsible for at least partial control of viral replication *in vivo* (109,110). Neutralizing antibodies may be type specific (i.e., specific for one viral isolate) or group specific (i.e., specific for a broad range of viral isolates). Most type-specific neutralizing antibodies recognize the V3 region of the HIV envelope gp120 protein (111). Neutralizing anti-V3 loop antibodies may prevent conformational changes within gp120 necessary for HIV entry or for cell–cell fusion (112). Group-specific neutralizing antibodies recognize epitopes within the HIV envelope gp41 protein (113), discontinuous conformational epitopes around the CD4 binding site of gp120 (114), or carbohydrate determinants (115). Both type- and group-specific neutralizing antibodies are more efficient in neutralizing laboratory strains of HIV grown in T-cell lines compared with primary isolates grown in peripheral blood mononuclear cells (PBMCs); this is likely due to differential exposure of the V3 loop and CD4-binding domain epitopes among these isolates (116,117). Some neutralizing antibodies interfere with the interaction between the HIV envelope and CCR5, thereby inhibiting cellular entry of R5 strains of HIV (118,119).

Neutralizing antibodies appear to be prognostically relevant to the course of HIV infection (120). The regularity with which viral variants emerge that resist neutralization

suggests that such antibodies are potent impediments to viral replication (121). In nonhuman primate models, neutralizing antibodies are associated with slow rates of disease progression (122) and accelerate clearance of both infectious and noninfectious virions (123); furthermore, passive transfer of SIV-neutralizing antibodies can protect macaques against a subsequent viral challenge (124,125 and 126).

Some anti-HIV antibodies bind to immunoglobulin G (IgG) Fc receptor-positive cells and sensitize them to mediate antibody-dependent cellular cytotoxicity (ADCC) against HIV-infected or HIV-coated cells (127,128). Most of these antibodies are directed against HIV envelope gp120 or gp41 proteins. $CD16^+$ natural killer cells are important mediators of ADCC (129), and monocytes may also mediate this activity (130). Anti-HIV ADCC antibodies develop soon after primary infection and are detectable throughout the course of HIV disease, with some decrease in titers with the onset of AIDS (131). ADCC may also represent an immunopathogenic immune response that may be responsible for $CD4^+$ T-cell depletion during the course of HIV infection. In this regard, a combination of high levels of plasma viremia with high HIV envelope-specific ADCC activity is correlated with rapid $CD4^+$ T-cell depletion; this correlation may reflect ADCC-mediated "innocent bystander" killing of gp120-coated, but uninfected, $CD4^+$ T cells (132).

Cellular Immune Responses

CYTOTOXIC T-LYMPHOCYTES

Classic MHC class I-restricted, HIV-specific, CD8 CTL responses against a variety of HIV target proteins have been demonstrated in HIV-infected persons (133,134). Using standard cell culture methods, a high frequency of HIV-specific CTLs and CTL precursors (up to 1% of peripheral blood T cells) has been observed in asymptomatic HIV-infected patients (135,136). Using human leukocyte antigen (HLA)–peptide tetramers, the true frequency of HIV-specific CTLs may be up to an order of magnitude greater than that detected by standard functional assays (137,138).

A critical role for CTLs in the suppression of viral replication in HIV-infected persons is suggested by the close correlation between the emergence of an HIV-specific CTL response and downregulation of viremia following acute infection (82,83), the association of vigorous HIV-specific CTL responses with slow progression of HIV disease (139,140 and 141), and the decline in HIV-specific CTL activity with disease progression (133,135). Quantitative studies revealed an inverse correlation between the frequency of HIV-specific CTL and levels of plasma viral load (138,142) and between the CTL frequency and the rate of $CD4^+$ T-cell decline (142). A beneficial role for HIV-specific CTLs is also suggested by their presence in the peripheral blood of persons who are frequently exposed to HIV and yet remain uninfected (143,144). Studies in nonhuman primates have demonstrated that monkeys subjected to $CD8^+$ T-cell depletion manifest diminished control of plasma viremia during primary SIV infection (145); in addition, $CD8^+$ T-cell depletion during the chronic phase of SIV infection leads to a prompt and profound increase in levels of viral replication (145,146).

The quality of the HIV-specific CTL response is also an important determinant of the efficacy of these responses in controlling viral replication. The specificity of CTL responses may determine in part their salutary role; in this regard, CTL responses against viral core proteins in particular have been associated with a decreased risk of disease progression (140). CTL recognition of immunodominant HIV epitopes presented by certain MHC class I alleles may result in potent anti-HIV activity (147) and may explain in part the association of certain MHC class I alleles with slower progression of HIV disease (reviewed in 148). Furthermore, the ability to recruit an HIV-specific CTL response composed of a diverse group of T-cell receptor Vb families that recognize multiple epitopes is associated with better control of viral replication and an improved prognosis compared with a narrow CTL response (149,150).

The loss of HIV-specific CTL activity in patients with progressive disease is likely a result of several factors. Viral proteins such as Tat, Nef, and Vpu can downregulate cellular expression of MHC class I molecules that are necessary for CTL recognition of infected cells (48,59,151). Increased expression of killer inhibitory receptors also may inhibit CTL activity (152). Another mechanism responsible for the loss of CTL activity is the selective accumulation of $CD8^+DR^+$ HIV-specific CTLs that lack the interleukin (IL)-2 receptor and are defective in clonogenic potential (153). Finally, the ability of HIV to escape CTL responses by viral mutation or by exhaustion of CTL clones due to high concentration of antigen helps explain the loss of CTL-mediated control over viral replication (154,155).

The host CTL response against HIV is constrained by the ability of the MHC class I alleles to bind to various viral epitopes, and the virus is constrained by the degree to which an escape mutation impairs viral fitness (156,157 and 158). These host–virus dynamics are extraordinarily complex given the large number of permutations of viral epitopes and MHC class I alleles. Viral mutations within CTL recognition epitopes (i.e., "escape mutants") are associated with increased levels of viral replication and progression of HIV disease (159,160 and 161). Viral escape mutants may thrive because of the release of CTL control over their replication and also may inhibit CTL responses against the preescape viral epitope (162,163 and 164). A mathematic model of CTL–virus dynamics was provided by Nowak and co-workers, who described disease progression as a result of viral sequence variation that escapes an immunodominant CTL response and shifts the host response toward a weaker epitope (165). In this scenario, disease progression may be the result of fitness of viral escape mutants outpacing the plasticity of the host CTL response, with slow progression resulting from CTL plasticity overpowering viral escape mutants with limited fitness.

$CD8^+$ T-CELL-DERIVED SOLUBLE SUPPRESSOR FACTORS

A variety of soluble antiviral factors are elaborated by $CD8^+$ T cells. CD8 antiviral factor (CAF) (166,167) is noncytolytic, inhibits viral replication at the level of HIV LTR transcription (168,169) and lacks identity to known cytokines (170). Although CAF activity is non-MHC restricted, its activity is maximal in a syngeneic system (171). CAF activity decreases with disease progression, but it remains potent in long-term nonprogressors (172,173).

The combination of RANTES, MIP-1a, and MIP-1b (the natural ligands for CCR5) are also important soluble antiviral factors, and are secreted by CD8+ T cells as well as by other cell types (28,174). These CC chemokines inhibit viral replication primarily at the level of cell entry. Emerging data support a role for CC chemokines in protecting against HIV infection and disease progression (175,176,177 and 178). Macrophage-derived chemokines (MDC) can potently suppress replication of R5 as well as X4 strains of HIV *in vitro* (179); the role of MDCs in controlling HIV replication *in vivo* is uncertain. Finally, IL-16 has been reported to be a soluble antiviral factor (180). IL-16 inhibits HIV transcription and can potently suppress HIV replication when it is expressed in HIV-infected T cells (181,182); furthermore, IL-16 production has been correlated with protection against disease progression in HIV-infected persons (183,184).

$CD4^+$ T-CELL RESPONSES

The HIV proteins contain helper T-cell epitopes that may be presented by MHC class II alleles (185,186). Recognition of these epitopes by $CD4^+$ T cells results in secretion of cytokines and cellular proliferation. These responses may be associated with abortive infection in persons exposed to HIV but who remain uninfected (187), and they decrease with HIV disease progression (185,186). An inverse correlation has been found between the magnitude of HIV-specific $CD4^+$ T-cell response and levels of plasma viremia (188); these data are consistent with the observed inverse correlation between CTL activity and plasma viremia as well (138). The fate of HIV-specific $CD4^+$ T cells during the course of HIV infection is controversial. Some evidence suggests that these cells are usually depleted in the early stages of disease and that initiation of potent antiretroviral therapy during acute HIV infection may prevent this loss and lead to more effective immunologic control of viral replication (188). Other data suggest that HIV-specific $CD4^+$ T cells are present throughout the course of HIV disease and that their frequency actually declines during HAART-induced viral suppression (189).

CYTOKINES AND HIV DISEASE: DYSREGULATION OF CYTOKINE PRODUCTION

Cytokines that are generated during the host immune response to an infection play an important role in determining the outcome of the infectious process. Dysregulation of the host cytokine network is characteristic of all phases of HIV infection. Many of the observed alterations in cytokine production contribute to HIV pathogenesis by further stimulating viral replication, suppressing the ability of the immune system to mount an efficient antiviral response, and inducing cytokine-mediated cytopathic effects (6,190,191).

Infection with HIV is associated with increased expression of proinflammatory cytokines; high levels of tumor necrosis factor (TNF)-a, IL-1b, and IL-6 are secreted by PBMCs and macrophages from HIV-infected subjects and are found at elevated levels in serum, cerebrospinal fluid, and tissues (reviewed in 191,192). High levels of expression of these cytokines as well as interferon (IFN)-g (193,194) and IL-10 (194), are particularly evident in lymphoid tissue, a major site of HIV replication throughout the course of disease (85,87,88,98).

Another major disruption in the cytokine pattern observed in HIV disease is a progressive loss in the ability to produce immunoregulatory cytokines such as IL-2 and IL-12, which are critical for effective cell-mediated immune responses because they stimulate proliferation and lytic activity of CTLs and natural killer (NK) cells. In addition, IL-12 is essential for stimulating the production of T helper (TH)-1 type cytokines, including IL-2 and IFN-g, which favor the development of cell-mediated immune responses. The T-helper cell type 1 (Th1) limb of cellular immune responses is impaired during the course of HIV infection; although the cause of this TH1 defect in HIV infection is multifactorial, it may derive in part from the ability of the HIV envelope to induce IL-10 production in monocytes and thereby inhibit IL-2 secretion (195). Some investigators have proposed that a dominance of TH2-like responses (i.e., secretion of IL-4, IL-5, and IL-10) characterizes progression of HIV disease (196). Most studies, however, suggest that cytokine dysregulation during the course of HIV infection is complex and cannot easily be classified in terms of TH1

and TH2 polarity (194,197,198).

Effects of Cytokines on HIV Replication

Soluble factors produced by activated PBMCs (93), macrophages (199), and B cells (200) can dramatically upregulate HIV expression in acutely and chronically infected cells of the lymphocytic and macrophage lineage (Fig. 74.4). Cytokines that have been reported to upregulate HIV replication *in vitro* include IL-1b, IL-2, IL-3, IL-6, IL-7, IL-12, IL-15, IL-18, TNF-a, TNF-b, and the colony stimulating factors (CSF) macrophage (M)-CSF and granulocyte-macrophage (GM)-CSF (reviewed in 191; see also 201,202,203,204,205 and 206). IFN-a, IFN-b, and IL-16 (184,207,208) are primarily suppressors of HIV production, whereas other cytokines, such as IL-4 (209), IL-10 (210,211), IL-13 (212), IFN-g (213,214), and TGF-b (215,216), reduce or enhance viral replication, depending on the infected cell type and the culture conditions. The effects of a particular cytokine are often greatly influenced by the activity of other cytokines present in the lymphoid tissue microenvironment (211,217,218).

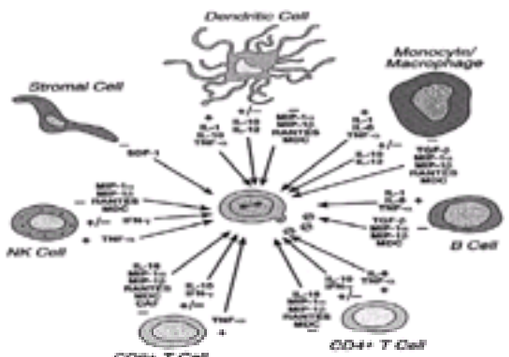

Figure 74.4. Cytokine networks that regulate human immunodeficiency virus (HIV) replication. Cytokines that enhance viral replication (+), inhibit viral replication (–), and enhance or inhibit viral replication depending on the conditions (+/–) are shown.

Proinflammatory cytokines, particularly TNF-a, are considered the most potent HIV-inducing cytokines, and their mechanism of action is relatively well understood. Both TNF-a and IL-1b activate the cellular transcription factor nuclear factor (NF) kB (219,220), a strong inducer of HIV LTR-mediated transcription. IL-6 increases HIV expression primarily by a posttranscriptional mechanism; however, IL-6 can synergize with NFkB-inducing cytokines to enhance HIV transcription (217). The production of HIV by macrophages or PBMCs stimulated with physiologic inducers of proinflammatory cytokine production, such as bacterial endotoxin or IL-2, can be partially or nearly completely abrogated by the addition of anti-proinflammatory cytokines (221,222), neutralizing antibodies to the cytokines (201), or receptor antagonists (ra), such as IL-1ra (201). In cultures of HIV-infected macrophages, the viral-suppressive activity of several cytokines, such as IL-10 and TGF-b, is attributable largely to their ability to inhibit the secretion or activity of HIV-inducing proinflammatory cytokines (215,221,222). HIV production by infected T cells is sensitive to both the anti-proinflammatory and the anti-proliferative activity of such cytokines (223).

Chemokines, or chemoattractant cytokines, are produced by numerous cell types and may influence HIV replication by binding to chemokine receptors that also serve as HIV coreceptors (224). Chemokine production, induced during inflammation, is enhanced by CD40 ligand stimulation (225) and by several cytokines, including TNF-a, IL-1b, IL-2, and IL-15 (226). Chemokines that bind to CCR5 suppress HIV replication *in vitro* in PBMCs from asymptomatic HIV-infected persons harboring predominantly R5 strains of HIV (174) but not in PBMCs from persons with more advanced disease harboring predominantly X4 strains of HIV (174,227). Similarly, HIV isolates obtained longitudinally from persons with rapid disease progression exhibit reduced sensitivity to inhibition by CCR5 ligands *in vitro* over time (227,228). Ligation of chemokine receptors in different cell types may have different effects on HIV replication; CC chemokines inhibit replication of R5 strains of HIV in $CD4^+$ T cells but actually may enhance replication of these strains in monocytes and macrophages (229,230). Unanticipated effects of manipulating the chemokine–chemokine receptor axis also have been observed, including CC-chemokine-mediated upregulation of CXCR4 expression and enhancement of replication of X4 strains of HIV *in vitro* that is dependent on intracellular signal transduction (39,40).

ROLE OF CELLULAR ACTIVATION IN HIV PATHOGENESIS

The end result of HIV infection is profound immunodeficiency; however, paradoxically, HIV infection is associated with hyperactivation of the immune system throughout most of the course of disease. HIV subverts the immune system by inducing immune activation and utilizing this milieu toward its own replicative advantage (6,191,231).

The replicative cycle of HIV infection is achieved most efficiently in activated cells (232,233 and 234). Cytokines that induce T-cell activation can contribute further to viral replication by inducing a state of productive infection in latently infected resting T cells (235). Several lines of evidence suggest that HIV replication *in vivo* is dependent on antigen-driven activation of $CD4^+$ T cells. HIV-infected persons with intercurrent infections experience transient increases in plasma viremia that correlate with the degree of induced immune activation (236); similar observations have been made in HIV-infected persons who received immunizations against various pathogens (95,96 and 97).

Analysis of viral quasispecies and immune responses within lymphoid tissue from HIV-infected persons reveals that, within individual splenic white pulps, a restricted number of individual antigen-specific immune responses occurs (defined by the analysis of T-cell receptor Vb gene usage), and each of these areas contains a single or limited number of HIV quasispecies (237). These data support the theory that, within the context of individual antigen-specific immune responses, a single quasispecies of HIV, which was present at initiation of the reaction, spread among the newly activated T cells. Thus, it is likely that the continuous daily production of HIV occurs in newly activated $CD4^+$ T cells that are being driven by antigen-specific activation (237,238).

IMMUNE DYSFUNCTION DURING HIV INFECTION

The pathogenesis of HIV disease is a complex, multifactorial process (191,231). A wide array of immune system deficits is associated with HIV infection; abnormalities in the function of all limbs of the immune system, including T- and B-lymphocytes, antigen-presenting cells, NK cells, and neutrophils, have been described.

$CD4^+$ T Cells

$CD4^+$ T-cell dysfunction and depletion are hallmarks of HIV disease. The proximate cause of the susceptibility to opportunistic infections observed with advancing disease is the defects in T-cell number and function that result directly or indirectly from HIV infection. In addition to the decrease in IL-2 production and IL-2 receptor expression, the percentage of $CD4^+$ T cells expressing CD28 (i.e., the major costimulatory receptor that is necessary for normal activation of T cells) is reduced during HIV infection compared with cells from uninfected persons (239). $CD28^-$ cells do not respond to activation signals and express markers of terminal activation, including HLA-DR, CD38, and CD45RO (240). In addition, $CD4^+$ T cells from HIV-infected persons express abnormally low levels of CD40 ligand (241).

A variety of mechanisms, both directly and indirectly related to HIV infection of $CD4^+$ T cells, are likely responsible for the observed defects in T-cell function. Interference with CD4 expression by HIV gp120 (242), Nef (47), and Vpu (58) may impair the ability of the infected $CD4^+$T cell to interact with appropriate MHC class II molecules. Preferential infection by HIV of $CD4^+$ memory cells or the preferential susceptibility of these cells to the cytopathic effects of HIV infection may explain in part the loss of memory responses to soluble antigens and the consequent increase in the risk of infection with opportunistic organisms (243,244).

The relatively small fraction of T cells that is infected with HIV in seropositive subjects at any given time militates against direct infection as the sole mediator of the immunopathogenesis of HIV infection (see later) (98). In addition, $CD4^+$ T-cell dysfunction is evident even in the early stages of HIV infection, before quantitative depletion of this key cellular subset (245). A role for HIV envelope in the immunopathogenesis of HIV disease has been suggested by a number of studies (reviewed in 246). The presence of measurable levels of circulating soluble gp120 in HIV-infected subjects (247) and the accumulation of high concentrations of virions (both infectious and defective) in lymphoid tissue (85,87,248) underscore the potential for envelope to contribute to T-cell dysfunction in a process distinct from infection of $CD4^+$ T cells.

The HIV envelope glycoproteins bind with high affinity to the CD4 molecule and to a number of chemokine coreceptors. Intracellular signals transduced by HIV-1 envelope have been implicated in several immunopathogenic processes, including anergy (249,250), syncytium formation (251), apoptosis (252), and inappropriate cell

trafficking (253). The molecular mechanisms responsible for these abnormalities include dysregulation of the T-cell receptor phosphoinositide pathway (254), p56lck activation (255), phosphorylation of focal adhesion kinase (256), activation of caspase-3 (257), downregulation of the costimulatory molecules CD40 ligand and CD80 (258), and activation of the mitogen-activated protein (MAP) kinase and *ras* signaling pathways (259). Most of these aberrant signals were presumed to result from interactions between HIV envelope glycoproteins and CD4; however, more recently, it has become clear that HIV envelope also may transduce intracellular signals through coreceptor molecules such as CCR5 (253,256,260) and CXCR4 (261).

Direct Infection as a Cause of $CD4^+$ T-Cell Depletion

The observations that $CD4^+$ T cells are the principal targets of HIV infection *in vivo* and that HIV infection of $CD4^+$ T cells *in vitro* causes cytopathicity led to a reasonable assumption that direct infection of $CD4^+$ T cells *in vivo* results in their depletion. Quantitative studies of the frequency of HIV-infected cells *in vivo* suggest, however, that single-cell killing by direct infection with HIV may not be the predominant mechanism of $CD4^+$ T-cell depletion (98,262). Although it increases with disease progression, the frequency of HIV-infected peripheral blood $CD4^+$ T cells rarely exceeds 1 in 100, even in patients with AIDS (262). Viral burden and levels of virus expression are far greater in lymphoid tissue compared with peripheral blood (87,88,98); however, these levels, even in lymphoid tissue, do not appear to be sufficiently high to account for $CD4^+$ T-cell depletion solely by direct mechanisms.

Multiple mechanisms of cell death appear to be operative after infection of a $CD4^+$ T cell with HIV. Accumulation of reverse-transcribed viral DNA in the cytoplasm (263), interference by viral RNA with normal cellular RNA processing (264,265), intracellular interactions between the viral envelope gp120 and CD4 molecules (266), compromise of cell membrane integrity by the budding virions (267), and HIV-induced increases in the concentration of intracellular monovalent cations (268) all may play roles in $CD4^+$ T-cell killing.

In addition, HIV-infected cells may die as a consequence of viral-specific immune responses that occur before the cell succumbs directly to viral infection. Multiple effector mechanisms may be involved in the killing of HIV-infected cells, including CTL responses, ADCC, and NK cell responses.

Indirect Mechanisms of $CD4^+$ T-Cell Depletion

SYNCYTIUM FORMATION

The molecular events associated with viral entry that lead to fusion between the viral coat and cell membrane involve the interaction of the HIV envelope glycoprotein, CD4, and a co-receptor molecule. Similar events may occur when an infected cell bearing HIV envelope glycoprotein molecules on its surface encounters an uninfected $CD4^+$ cell with an appropriate coreceptor. Fusion between infected and uninfected cells, resulting in multinucleated giant cells, or syncytia, has long been observed *in vitro* (269,270). Syncytia have been observed only rarely in tissues obtained from HIV-infected persons (102); thus, it is unlikely that syncytium formation is a major pathogenic mechanism of $CD4^+$ T-cell depletion *in vivo*.

AUTOIMMUNITY

Autoimmunity may occur during the course of HIV infection as a result of molecular mimicry by viral components. Highly homologous regions exist in the carboxy terminus of the HIV-1 envelope glycoprotein and the amino terminal domains of different HLA-DR and DQ alleles (271). Sera from a substantial number of HIV-infected persons react with the shared determinant of gp41 and MHC class II: These sera can inhibit normal antigen-specific proliferative responses and also eliminate class II–bearing cells by ADCC (272). Similar instances of molecular mimicry between HIV-1 envelope constituents and host proteins, which may result in pathogenic autoimmune responses, include the collagen-like region of complement component C1q-A (273), MHC class I heavy chains (274), HLA-DR4 and DR2 alleles (275), variable regions of the T-cell receptor a-, b-, and g-chains (275), Fas (276), functional domains of IgG and IgA (275), denatured collagen (277), and a number of nuclear antigens (278). Finally, immune recognition of normal cellular components may be induced by their association with HIV; such phenomena may be responsible for the emergence of CTLs that are specific for autologous $CD4^+$ T cells (279).

INNOCENT BYSTANDER PHENOMENA

Immune responses that target HIV determinants on infected cells also may contribute to the elimination of uninfected cells with HIV proteins (e.g., gp120) bound on their surface. Targeting of such “innocent bystander” cells by antibody and cellular immune responses has been described (127,280).

HIV-MEDIATED INHIBITION OF HEMATOPOIESIS

Failure of normal hematopoiesis is an obvious candidate mechanism to account for depletion of $CD4^+$ T cells during HIV infection. A subset of $CD34^+$ progenitor cells express CD4 and HIV coreceptors and are infectable *in vitro* with HIV-1 (281,282). Furthermore, a substantial minority of HIV-infected patients with severe $CD4^+$ T-cell depletion have a reservoir of HIV-infected $CD34^+$ progenitor cells (283).

Although the role of direct infection of $CD34^+$ progenitor cells in CD4+ T-cell depletion remains controversial, a large body of evidence suggests that viral proteins and HIV-induced cytokines can impair the survival and clonogenic potential of these cells (284,285). The subnormal mobilization of $CD34^+$ cells into the peripheral blood following treatment with GM-CSF in HIV-infected persons provides further evidence of reduced hematopoietic capacity and reserve in HIV infection (286).

Disruption of the thymic microenvironment (287) and HIV-induced thymocyte depletion also may contribute to the failure of $CD4^+$ T-cell production. Thymic epithelial cells normally secrete IL-6, which in turn can increase HIV replication in infected cells (288). Subpopulations of thymic $CD3^-CD4^-CD8^-$ cells (i.e., “triple negative” cells) are susceptible to infection with HIV *in vitro* (289), and thymic $CD3^-CD4^+CD8^-$ progenitor cells from HIV-infected patients are infected *in vivo*. Finally, uninfected thymocytes from HIV-infected persons are primed for apoptotic death, suggesting that indirect mechanisms of defective thymopoiesis are operative as well (290).

APOPTOSIS

Aberrant intracellular signals transduced by HIV may prime $CD4^+$ T cells for apoptosis, resulting in depletion of these cells during the course of HIV infection. Acute infection of T cells with HIV *in vitro* can induce apoptosis (291), and T cells from HIV-infected patients undergo enhanced rates of apoptosis *in vitro* compared with normal T cells, particularly following activation (292,293). Cross-linking of CD4 followed by ligation of the T-cell receptor is sufficient to induce apoptosis, suggesting that uninfected $CD4^+$ T cells can be depleted inappropriately on encountering antigen if CD4 had been cross-linked by gp120 (252).

Both Fas-dependent and Fas-independent pathways of apoptosis may be triggered by HIV. HIV-mediated Fas-independent apoptosis of $CD4^+$ T cells was shown *in vitro* by several groups (294,295); enhanced susceptibility of $CD4^+$ T cells to Fas-dependent apoptosis has been reported as well. Mechanisms that may contribute to this susceptibility include upregulation of Fas and Fas ligand (296,297); upregulation and activation of caspase-1 (298), caspase-3 (257), and caspase-8 (299); activation of cyclin-dependent kinases (300); and downregulation of the anti-apoptotic Bcl-2 protein (301). Viral gene products that have been associated with enhanced susceptibility to apoptosis include the viral envelope (252,296,302), Nef (52,53), Tat (296), and Vpu (303).

The susceptibility of uninfected “bystander” cells to apoptosis is a possible mechanism by which a large number of cells may be eliminated during HIV infection. In fact, studies in lymphoid tissue from HIV-infected persons suggest that most apoptosis occurs in uninfected bystander cells (304,305). Macrophages are efficient mediators of $CD4^+$ T-cell bystander apoptosis. HIV-induced upregulation of Fas ligand expression on macrophages and enhanced secretion of TNF-a from these cells appear to be responsible in part for this phenomenon (306,307). Another mechanism of bystander apoptosis may involve upregulation of CD62L on lymphocytes by HIV (308). These HIV-exposed lymphocytes home to lymph nodes and undergo apoptosis on signaling through homing receptors such as CD62L, CD44, and CD11a (309).

It remains uncertain whether HIV-induced apoptosis plays an important role *in vivo* in $CD4^+$ T-cell depletion. The frequency of apoptotic $CD4^+$ and $CD8^+$ T cells as well as B cells is significantly higher in lymphoid tissue from HIV-infected persons compared with uninfected controls (304,310). The relationship between the frequency of apoptotic cells and the stage of HIV infection remains controversial. Some data indicate a positive correlation between the stage of HIV disease and susceptibility of peripheral blood T cells to apoptosis (311), and another study demonstrated low frequencies of apoptotic cells in HIV-infected long-term nonprogressors (312). Other studies, however, found no correlation between apoptosis and stage of disease (302,304). Compelling evidence that apoptosis may play a role in HIV pathogenesis comes from animal models wherein an increased frequency of apoptosis in $CD4^+$ T cells is seen in primates infected with pathogenic strains of SIV but not in primates infected with nonpathogenic strains of SIV (313).

CLINICAL FEATURES

Studies prior to the advent of HAART revealed that the median time between primary HIV infection and the development of AIDS was approximately 10 years (314). In the acute and early stages of the disease, symptoms resulting from immune hyperactivation predominate; however, with the inexorable depletion of $CD4^+$ T cells that characterizes disease progression, overt cellular immunodeficiency and its many complications develop (Fig. 74.5). The 1993 CDC classification of HIV infection consists of clinical categories and quantitative $CD4^+$ T-cell categories (Table 74.1) (315).

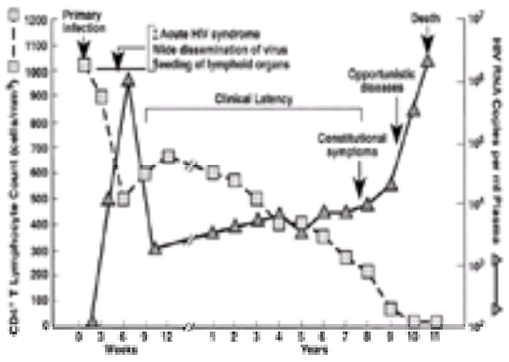

Figure 74.5. Natural history of human immunodeficiency virus (HIV) infection. High levels of viremia during acute infection often are associated with a sharp decline in $CD4^+$ T-cell numbers in the peripheral blood. Emergence of HIV-specific immune responses results in downregulation of viremia and partial recovery of the $CD4^+$ T-cell count. A long period of clinical latency ensues during which levels of plasma viremia may remain relatively low, and the $CD4^+$ T-cell count declines slowly. As the $CD4^+$ T-cell count falls below 200 cells per microliter, the risk for opportunistic diseases increases. In the late stages of disease, sharp increases in viremia and sharp declines in $CD4^+$ T-cell counts occur. (Adapted from Fauci AS, Pantaleo G, Stanley S, et al. Immunopathogenic mechanisms of HIV infection. *Ann Intern Med* 1996;124:654, with permission.)

CD4 Cell Categories	Clinical Categories* A: Asymptomatic, Lymphadenopathy, or Acute Infection	B: Symptomatic,* Not Category A or C	C: Clinical AIDS*
>500/μL (>29%)	A1	B1	C1
200–499/μL (14–28%)	A2	B2	C2
<200/μL (<14%)	A3	B3	C3

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency.
* Categories A3, B3, and C1-3 are defined as AIDS.
† Examples of these symptoms include bacillary angiomatosis; thrush; vulvovaginal candidiasis that is persistent, frequent, or poorly responsive to therapy; cervical dysplasia or carcinoma in situ; constitutional symptoms such as fever or diarrhea of greater than 1-month duration; oral hairy leukoplakia; multidermatomal or recurrent herpes zoster; immune thrombocytopenic purpura; listeriosis; pelvic inflammatory disease; and peripheral neuropathy.
‡ Candidiasis of the esophagus or respiratory tract; invasive cervical cancer; extrapulmonary coccidioidomycosis; extrapulmonary cryptococcosis; cryptosporidiosis; enteropathy; cytomegalovirus infection; herpes simplex: with mucocutaneous ulcer longer than 1-month duration, or bronchitis, pneumonitis, or esophagitis; extrapulmonary histoplasmosis; HIV-associated dementia; wasting syndrome; isosporiasis; Kaposi sarcoma; central nervous system lymphoma; non-Hodgkin's lymphoma; pulmonary tuberculosis; disseminated *M. tuberculosis*, *M. avium*, or *M. kansasii* infection; nocardiosis; *Pneumocystis carinii* pneumonia; recurrent bacterial pneumonia; progressive multifocal leukoencephalopathy; recurrent *Salmonella septicemia*; extrapulmonary blastomycosis; toxoplasmosis.

TABLE 74.1. AIDS Surveillance Case Definition for Adults and Adolescents

DIAGNOSIS AND LABORATORY MONITORING

Serologic tests for antibodies to HIV form the mainstay of laboratory diagnosis of HIV infection. A solid-phase enzyme immunoassay (EIA) containing most HIV antigens has a sensitivity of greater than 99.5% for the detection of antibodies to HIV. Although the EIA is extremely sensitive, false-positives are not uncommon in a number of underlying conditions; therefore, a positive EIA test must always be followed by a confirmatory test. A western blot assay is the most reliable confirmatory serologic test for the diagnosis of HIV infection. A negative western blot demonstrates the absence of reactivity against HIV components. A positive test demonstrates reactivity to at least two of the following HIV proteins: p24, gp41, gp120, and gp160 (316). Indeterminate tests may be the result of reactivity to antigens that cross-react with HIV determinants; however, indeterminate results may also be a reflection of recently acquired infection and an evolving antibody response. Therefore, clinical follow-up and repeat serologic testing are essential in these cases.

The ideal laboratory marker of HIV disease activity should be easily and reproducibly measurable in all persons who have the disease. Furthermore, it should worsen with progression of disease and improve with positive responses to therapy. Although no ideal marker currently exists, several have been of critical importance in the clinical management of patients, especially with regard to establishing standards of care for initiation of antiretroviral therapy and prophylaxis against opportunistic infections.

Markers of Immune Depletion and Immune Dysregulation

Because $CD4^+$ T cells are the primary targets of HIV infection and because depletion of $CD4^+$ T cells is the immunologic hallmark of HIV disease progression, measurement of $CD4^+$ T cells should be an excellent marker of HIV infection. Indeed, studies of the natural history of HIV infection demonstrated that the $CD4^+$ T-cell count is a powerful predictor of the short-term risk of developing an AIDS-defining illness (317,318). $CD4^+$ T-cell counts frequently increase in response to antiretroviral therapy, and this salutary response has been used as a criterion in the licensing of new anti-HIV drugs.

Markers of generalized immune activation such as serum levels of b_2-microglobulin and neopterin are valid markers of HIV disease progression (319) but are now largely of historical interest only. Other immunologic markers of disease activity include levels of soluble TNF receptors (320), proliferative responses of T cells to anti-CD3 antibodies *in vitro* (321), delayed-type hypersensitivity response to recall antigens *in vivo* (322), and the percentage of peripheral blood $CD8^+$ T cells bearing the activation marker CD38 (323).

Markers of Viral Load

Before the development of currently available sensitive molecular techniques for the quantitation of HIV RNA molecules, direct culture of HIV from plasma or mononuclear cells was found to correlate with stage of disease (324,325). Changes in levels of culturable plasma viremia further serve as reliable indicators of activity of antiretroviral agents (326); however, these assays are extremely labor intensive and less sensitive than currently available molecular diagnostic tests. Measurement of p24 antigenemia is a relatively insensitive assay; however, positivity of a p24 antigen test does herald accelerated decline in $CD4^+$ T-cell counts and the likelihood of progression to AIDS (327).

The frequency of HIV-infected cells can be quantified by using polymerase chain reaction (PCR) for the detection of HIV-1 DNA, and this measurement has some predictive value with regard to HIV disease progression (262). Measurement of cell-associated HIV mRNA in peripheral blood, although technically demanding, has been shown by several groups to serve as an independent predictor of disease progression. Particularly impressive is the ability of this marker to predict disease progression in patients with early stage HIV disease and relatively high $CD4^+$ T-cell counts (328). Determination of the splicing pattern of HIV mRNA in PBMCs can add further predictive value with regard to disease progression. In this regard, a disproportionate increase in unspliced HIV mRNA is most predictive of accelerated loss of $CD4^+$ T cells and clinical disease progression (329). Furthermore, decreases in levels of unspliced HIV mRNA in lymphoid tissue correlate well with decreases in plasma viremia during antiretroviral therapy (100). This finding, combined with the fact that HIV mRNAs are orders of magnitude more abundant in lymph node mononuclear cells compared with peripheral blood mononuclear cells, supports the concept that changes in plasma viremia during antiretroviral therapy are reflective of changes in cell-associated viral mRNA production in lymphoid tissue (100).

The ability to assess the level of viral replication with quantitative assays of HIV RNA in plasma (i.e. plasma viremia) has revolutionized the use of laboratory markers for HIV disease. Measurement of the $CD4^+$ T-cell count yields information regarding the degree of immunodeficiency and short-term risk of opportunistic disease (i.e., a reflection of the damage already sustained by the immune system). In contrast, quantitation of HIV RNA in plasma yields information that predicts the rate and severity of immune deficiency. Technology currently available for reproducible measurement of plasma viremia in clinical specimens includes PCR, nucleic acid sequence based amplification (NASBA), and branched DNA (b-DNA) assays. PCR and NASBA are both cycle-based target amplification systems, whereas b-DNA is a

single-step signal amplification system that uses multiple HIV-specific nucleic acid target probes, each of which can be bound to an amplifier molecule containing multiple oligonucleotides. Each oligonucleotide in this array in turn can hybridize to an enzyme-labeled complementary probe, and detection is accomplished by addition of substrate. Each of these assays (PCR, NASBA, and bDNA) is able to detect as few as approximately 20 to 50 molecules of HIV RNA per milliliter of plasma, and each has a dynamic range of several orders of magnitude.

The enhanced sensitivity of molecular amplification assays compared with conventional viral detection techniques and the application of these assays to lymphoid tissue led to the observation that substantial levels of viral replication occur, even during the early, asymptomatic stages of HIV infection (87,330,331). The predictive value of plasma viremia as a valid, independent marker for disease progression was demonstrated in the Multicenter AIDS Cohort Study, where subjects were stratified by quartiles according to baseline plasma viremia levels (Fig. 74.6). The proportion of patients who progressed to AIDS within 5 years after entry into the study with plasma viremia levels in the lowest through highest quartiles was 8%, 26%, 49%, and 62%, respectively (332). Further validation of the use of plasma viremia measurement as a predictor of disease progression was provided by the AIDS Clinical Trials Group, which found that baseline measurements of plasma viremia as well as changes in viremia over time were predictive of disease progression (333,334). The combination of $CD4^+$ T-cell counts with measurements of plasma viremia has the greatest predictive power for HIV disease progression. In this regard, the likelihood of developing AIDS within 3 years given a plasma HIV RNA level of more than 30,000 copies per microliter is 33% with a $CD4^+$ T-cell count of more than 500 cells per microliter, 43% with a CD4+ T-cell count of 351 to 500 cells per microliter, 64% with a count of 201 to 350 cells per microliter, and 86% with a count of fewer than 200 cells per microliter (335). Given a $CD4^+$ T-cell count of 351 to 500 cells per microliter, the likelihood of developing AIDS within 3 years increases from virtually nil with a plasma viral load of fewer than 3,000 copies per milliliter, to 8% with a viral load of 3,000 to 10,000 copies per milliliter, to 16% with a viral load of 10,000 to 30,000 copies per milliliter, and to 43% with a viral load more than 30,000 copies per milliliter (335).

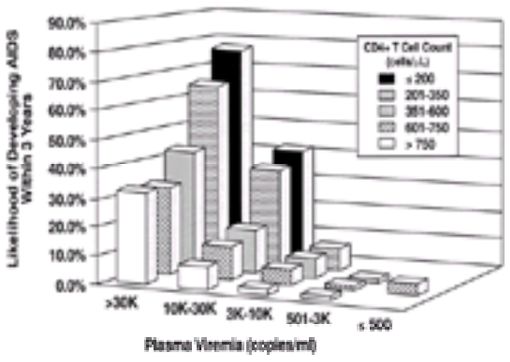

Figure 74.6. Likelihood of developing AIDS within 3 years, given the indicated levels of plasma viremia and peripheral blood $CD4^+$ T-cell counts.

The impressive decreases in plasma viremia during combination antiretroviral therapy reported by many groups suggested that this measurement might serve as a valid marker not only for predicting progression but also for monitoring therapy in HIV-infected persons. The link between decreased plasma viremia in patients receiving therapy and improved clinical outcome was established by the Veterans Affairs Cooperative Study Group on AIDS (336). Finally, data indicating that decreases in plasma viremia during therapy are reflective of decreases in viral replication in lymphoid tissue further validate the use of plasma viremia as a laboratory marker of a critical aspect of HIV pathogenesis (100).

Levels of plasma viremia become predictive of disease progression after stabilization of viremia (i.e., achievement of a viral load "set point") in the months following primary HIV infection. Mellors and co-workers found that the level of plasma viremia at 6 months following seroconversion was significantly higher in patients who developed AIDS within approximately 5 years of follow-up (74,000 HIV RNA copies/mL) compared with levels in those who did not develop AIDS during the same period (19,000 HIV RNA copies/mL) (337). A plasma viremia level of greater than100,000 HIV RNA copies per milliliter at 6 months following seroconversion was associated with an odds ratio of 10.8 for the development of AIDS. Schacker and co-workers found that levels of plasma viremia obtained 0 to 4 months after seroconversion were highly variable and did not correlate with subsequent clinical outcome; however, the level of plasma viremia at 4 to 12 months after seroconversion was a strong predictor of $CD4^+$ T-cell depletion during follow-up (338).

The development of sensitive, quantitative assays for plasma viremia and the ability of this marker to predict progression of disease and to serve as an indicator of therapeutic efficacy have added an important dimension to decisions regarding initiation and maintenance of antiretroviral therapy in HIV-infected patients. The variation in plasma viremia by several orders of magnitude in patients with early stage HIV disease with similar $CD4^+$ T-cell counts allows for the initiation of early therapeutic intervention in those who are most likely to have disease progression. Current recommendations regarding the initiation and maintenance of antiretroviral therapy rely heavily on the two best laboratory markers for HIV disease progression: the $CD4^+$ T-cell count and the level of plasma viremia (339,340).

Acute Infection

Although more than half of primary HIV infections (and perhaps up to 90%) are accompanied by symptoms, most of these infections are not recognized in the acute setting (341). The differential diagnosis of primary HIV infection is extremely broad given the variable presentations associated with the syndrome. Fever, rash, pharyngitis, and lymphadenopathy are common during primary HIV infection, as they are in many "flulike" and "mononucleosis-like" illnesses (342). Myalgias, arthralgias, diarrhea, nausea, vomiting, headache, hepatosplenomegaly, weight loss, thrush, and neurologic symptoms also may occur. Among patients who develop symptoms during primary HIV infection, the mean duration of symptoms is 3 weeks (343).

Plasma HIV RNA levels vary widely in the setting of primary HIV infection, from thousands to millions of copies per milliliter (338). After reaching a peak, plasma HIV RNA levels decline by about 6.5% per week over a 4-month period (338). A steep decline of 5.2 cells per microliter per week occurs in the peripheral blood $CD4^+$ T-cell count over the 5 months following primary infection (338). The peak level of HIV RNA may have prognostic value (337), and persistently high levels after 4 to 6 months add to the predictive power toward more rapid progression of disease (337,338).

Early Stage Disease

The natural history of HIV infection includes a long period (i.e., about 10 years) of clinical latency between the time of primary infection and the development of symptoms indicative of advanced immunodeficiency. Even during the period of clinical latency, many patients experience fatigue as well as generalized lymphadenopathy. Syndromes indicative of depressed cell-mediated immunity in HIV infection, which are not AIDS defining, generally begin to appear as the $CD4^+$ T-cell count falls below 500 cells per microliter. Examples include oropharyngeal and recurrent vulvovaginal candidiasis, bacillary angiomatosis (usually due to infection with *Bartonella henselae*), recurrent or multidermatomal herpes zoster, listeriosis, infections due to *Rhodococccus equi*, pelvic inflammatory disease, oral hairy leukoplakia associated with Epstein–Barr virus (EBV), cervical dysplasia (usually associated with human papillomavirus infection), constitutional symptoms such as unexplained fever or diarrhea lasting more than 1 month, idiopathic thrombocytopenic purpura, and peripheral neuropathy (315).

Late-stage Disease

As the $CD4^+$ T-cell count falls below the level of approximately 200 cells per microliter, the loss of integrity of cell-mediated immune responses allows ubiquitous environmental organisms with limited virulence (e.g., *Pneumocystis carinii* and *Mycobacterium avium*) to become life-threatening pathogens. Conditions indicative of severely depressed cell-mediated immunity from HIV infection constitute the CDC surveillance case definition of AIDS. These conditions include fungal infections (e.g., esophageal or pulmonary candidiasis, extrapulmonary cryptococcosis, histoplasmosis, or coccidioidomycosis, and pulmonary or extrapulmonary *Pneumocystis carinii* infection), viral infections (e.g., cytomegalovirus retinitis, esophagitis, pneumonia, myelitis, pancreatitis, or adrenalitis; and herpes simplex virus bronchitis, pneumonia, esophagitis, or chronic skin ulcers), bacterial and mycobacterial infections (e.g., pulmonary tuberculosis, extrapulmonary infection from any mycobacterium, recurrent bacterial pneumonia, and recurrent *Salmonella* septicemia), protozoal infections (e.g., gastrointestinal syndromes from infection with *Cryptosporidium* or *Isospora*; and toxoplasmic encephalitis), neoplasia (e.g., invasive cervical cancer; Burkitt, immunoblastic, or primary central nervous system lymphoma; and Kaposi sarcoma), as well as HIV-related encephalopathy, progressive multifocal leukoencephalopathy (due to reactivation of JC virus), and wasting syndrome (315). HIV-associated diseases indicative of severe impairment of cell-mediated immunity but not included in the current case definition of AIDS include chronic microsporidiosis, gastrointestinal infection with *Cyclospora cayetanensis*, disseminated *Penicillium marneffei* infection (endemic to Southeast Asia), cerebral or disseminated *Trypanosoma cruzi* infection (endemic to Latin America), relapsing or chronic visceral leishmaniasis, anal carcinoma, and EBV-positive cases of leiosarcoma, leiomyosarcoma, and Hodgkin disease (344).

The degree to which an infection or reactivation syndrome can be considered opportunistic can be inferred by the $CD4^+$ T-cell counts at which it occurs (318). Oral candidiasis and tuberculosis tend to occur as the $CD4^+$ T-cell count falls into the 250 to 500 cells per microliter range. Cryptosporidiosis generally does not occur until the $CD4^+$ T-cell count is fewer than 200 cells per microliter. *Pneumocystis carinii* pneumonia, disseminated *Mycobacterium avium* complex infection, cryptococcosis, and toxoplasmosis are indicative of more severe immunodeficiency. At the more extreme end of the opportunistic disease spectrum, cytomegalovirus (CMV) retinitis is usually diagnosed after the $CD4^+$ T cell count has fallen below 50 cells per microliter. The steep increase in the risk of developing AIDS-defining illnesses associated with a $CD4^+$ T-cell count of fewer than 200 cells per microliter led to the 1993 revision of the CDC definition of AIDS, which includes a low $CD4^+$ T-cell count (<200 cells/µL) as an AIDS-defining criterion (315).

The incidence of AIDS-defining illnesses in industrialized nations has decreased sharply since 1996. In the United States, the AIDS mortality rate decreased by 47% between 1996 and 1997 and 20% between 1997 and 1998 (17,345). These decreases in AIDS-associated mortality can be attributed to a number of factors, including continued progress in prophylaxis against opportunistic infections (Table 74.2) (346), improved access to health care, and improved antiretroviral therapies (see later).

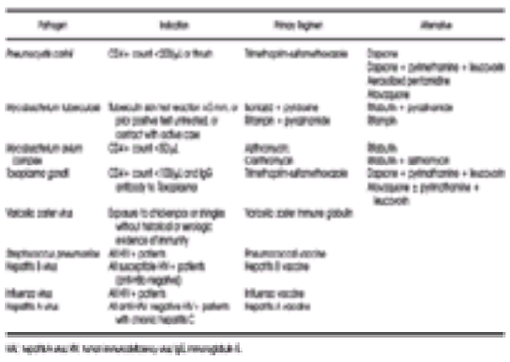

TABLE 74.2. Prophylaxis Recommendations to Prevent Opportunistic Diseases

Determinants of the Rate of Disease Progression

Myriad host and virologic factors determine the extremely variable rates of disease progression that are observed among HIV-infected persons. A small percentage of HIV-infected persons experience no evidence of disease progression over a prolonged period; these long-term nonprogressors provide clues regarding factors associated with disease progression. Although most cases of long-term nonprogressive HIV infection may be associated with attenuated strains of HIV (347,348), most data suggest that viral attenuation is rare among long-term nonprogressors and that host factors play a dominant role in determining the state of nonprogression (139,349,350 and 351).

Host genetic factors strongly influence the rate of disease progression in HIV infection. Numerous different mechanisms may be responsible for the observed associations between certain HLA haplotypes and different rates of HIV disease progression (reviewed in 148). The ability of certain HLA molecules to present immunodominant viral epitopes effectively to generate cell-mediated immune responses may explain an association with slow disease progression. Conversely, other HLA molecules may promote immunopathogenic responses associated with more rapid disease progression.

Mutations in the *CCR5* gene have a large impact on the ability of HIV to be transmitted and on HIV disease progression in HIV-infected persons. A 32-base pair (bp) deletion in the *CCR5* gene (*CCR5-D32*) results in the production of a truncated version of the receptor that is not expressed at the cell surface and therefore does not serve as a functional coreceptor for HIV infection (352). Molecular epidemiologic studies in HIV-uninfected populations have found that about 20% of white persons of northern and western European background are heterozygous for this mutation and 1% are homozygous; the frequency of the *CCR5-D32* allele appears to be exceedingly rare in Asian and African populations (353,354). Among HIV-infected white persons, no subjects homozygous for *CCR5-D32* were initially identified, suggesting complete protection from infection; however, rare cases of infection of homozygous individuals subsequently have been reported, likely reflecting transmission of non-R5 strains of HIV. Although *CCR5-D32* heterozygotes are not protected against HIV infection, they are afforded a modest degree of protection against disease progression and are overrepresented among cohorts of HIV-infected long-term nonprogressors (354,355,356,357 and 358). The mechanism of delayed disease progression in *CCR5-D32* heterozygotes may involve a lower viral load "set point" following acute HIV infection and a slower rate of $CD4^+$ T-cell depletion (355). These effects may be due to a decrease in expression of CCR5 on $CD4^+$ T cells from *CCR5-D32* heterozygotes (359,360), allowing less efficient spread of HIV infection to new target cells (361); however, it is clear that *CCR5-D32* is not the sole determinant of delayed progression of HIV disease (358).

Mutations in chemokine receptor and chemokine genes other than *CCR5-D32* also can confer protection against HIV infection or partial protection against disease progression. A rare point mutation in the *CCR5* gene (m303) results in a premature stop codon, preventing the expression of a functional coreceptor; the *CCR5D32/m303* genotype confers a high degree of resistance to HIV infection, similar to that afforded by homozygosity for *CCR5-D32* (362). Polymorphisms in the CCR5 promoter also influence rates of disease progression (363,364,365 and 366). Polymorphisms in the *CCR5* gene can be grouped into a number of haplogroups based on an evolutionary-based classification system; interestingly, several of these haplogroups have race-specific effects on HIV disease progression (365,366). A mutation in the *CCR2* gene involving a conservative amino acid change in a transmembrane domain of the receptor results in a significant delay in disease progression among HIV-infected persons (367,368 and 369); this effect may be related to the ability of the mutant form of the CCR2 protein to form heterodimers with CXCR4 and CCR5, thus limiting the functional availability of these important HIV coreceptors (370).

A polymorphism in the RANTES promoter is associated with enhanced transcription of the RANTES gene; not surprisingly, this polymorphism is also associated with a slower rate of HIV disease progression (371). A mutation in the 3' untranslated region of the *SDF-1* gene, *SDF1-3'A*, also plays a role in protecting against disease progression in HIV-infected persons (372). Homozygosity for the *SDF1-3'A* allele may be associated with high levels of expression of SDF-1, which may occupy CXCR4 and thereby inhibit replication of X4 strains of HIV. Consistent with this hypothesis, the protective effect of the *SDF-1* mutation is observed late in the course of HIV disease, when T-tropic strains may predominate. Downregulation of coreceptor expression or upregulation of chemokines also may recapitulate phenotypes similar to those created by the genetic polymorphisms described previously (22,175,176,177 and 178,360).

Qualitative and quantitative features of the host immune response that is mobilized against HIV are important determinants of the rate of disease progression as well. In this regard, studies of long-term nonprogressors suggest important roles for CTL, $CD8^+$ T-cell suppressor factors, $CD4^+$ T-helper responses, ADCC, and neutralizing antibody responses in protecting against HIV disease progression (see Immune Responses).

UNIQUE ASPECTS OF PEDIATRIC HIV DISEASE

Since the implementation of routine screening for HIV infection in blood products, pediatric HIV infection has been transmitted through two primary routes: perinatal transmission and sexual transmission to adolescents. Each mechanism establishes a unique clinical situation, with challenges in treatment and understanding pathogenesis.

Perinatal HIV disease transmission is particularly important. If no antiretroviral prophylaxis is used in a country with little breast-feeding, 20% to 30% of infants born to HIV-infected women will be infected. Of those infections, 30% to 50% occur *in utero*, whereas the remainder are thought to occur at the time of delivery (peripartum). If the mother breast-feeds, an additional 10% to 15% of children may become infected. Antiretroviral therapy can be effective at preventing transmission. Vertical transmission rates as low as 2% to 3% have been reported using combination antiretroviral therapy of the mother and RT inhibitors in the child. Cesarean section may also reduce transmission rates, particularly if optimal antiretroviral therapy is not possible. Breast-feeding substantially diminishes the positive benefits of perinatal prophylaxis.

Once HIV is established in an infant, virus replication rapidly achieves very high levels. HIV RNA concentrations of a million or more virions per milliliter are typical. This high level of replication probably reflects a combination of an immature neonatal immune system that responds poorly to HIV and the large number of $CD4^+$ lymphocytes found in infants and thus available to the virus. Newly infected adults also have a burst of early, high-level replication. Adults control the virus within a few months, whereas most infected infants continue to have high viral loads for years.

Infants tend to sort into two categories: rapid and slow progressors. Patients in the rapid progressor cohort develop early opportunistic infections, particularly *P. carinii* pneumonia and *Candida* infections, encephalopathy, wasting, and recurrent invasive bacterial infections. Children who go through the first year of life with no serious

events and their $CD4^+$ lymphocyte count intact may live for years with no problems. Their progression appears much like the adult disease, with a typically slow onset of symptoms. Unfortunately, there is no good way to predict early in life which children will have rapid or slow progression. Both groups have high viral loads, and although the rapid progressor group on average has a higher level of HIV replications, there is enough overlap between the cohorts that HIV viral RNA concentrations are not prognostically useful as they are for adults. One unique aspect of HIV disease in children is its effect on growth. Children have symmetric delays in weight and height growth so that they appear “normal” (correct weight for height) but younger than their calendar age.

Antiretroviral therapy in children is challenging for several reasons. Infants do not take any medicines easily, and many parents of HIV-infected children have difficulty remembering to give the medicines. Many of the medications are not available in liquid preparations that can be titrated to the infant or child's size, and some of those that are available as liquids have unpleasant tastes. Children may have unique pharmacokinetics that do not mimic the adult situation as a result of enzymatic immaturity, lack of gastric acidity, or other problems. Finally, the high viral load found in young children may mean resistance to the antiretroviral drugs can develop relatively quickly. In addition, some infants may inherit virus quasispecies with high levels of resistance from their mothers, particularly if their mothers have had prolonged previous antiretroviral therapy.

The issues in adolescence are somewhat more straightforward. Many infected adolescents acquired their HIV sexually; so the infection when found is typically proximate to the time of infection. The virus may be less genetically diverse, the reservoirs of infection less established. These potential therapeutic advantages are counterbalanced by the fact most adolescents are not compliant patients. Many do not take their medications regularly, they miss appointments, and they disregard medical authority figures. Peer interactions often mean more than communications from adults. Therefore, there is an important social overlay to the management of HIV in teens.

ANTIRETROVIRAL THERAPY

Recent progress in understanding the pathogenesis of HIV disease, combined with the development of potent antiretroviral agents, has resulted in an abundance of treatment options for HIV-infected patients. The recognition that virus continuously replicates in lymphoid tissue throughout the course of HIV infection, even during the clinically latent stage, strengthened the rationale for early intervention (87,88). Quantitative estimates of the extraordinary rate of viral replication *in vivo* further strengthened the rationale for early therapy with combination antiretroviral regimens (373,374 and 375). Combinations of antiretroviral agents that are capable of profoundly suppressing levels of plasma viral load for prolonged periods are referred to as *highly active antiretroviral therapy*, or HAART. Significant declines in AIDS-related morbidity and mortality rates are due in large measure to the wide use of HAART (14,15). Optimal use of antiretroviral agents, however, remains a rapidly evolving field, with many obstacles that need to be addressed.

Viral Replication Cycle and Antiretroviral Agents

Several steps in the viral replication cycle can be targeted by agents that are either currently available or under investigation (Fig. 74.7). Currently available antiretroviral drugs target either the viral RT or protease enzyme; however, investigational agents that target the entry and fusion step of the viral replication cycle, as well as agents that target the viral integrase, are in various stages of development. Another promising strategy targets the conformational changes in gp41 that are necessary for fusion of HIV with the target cell membrane (376).

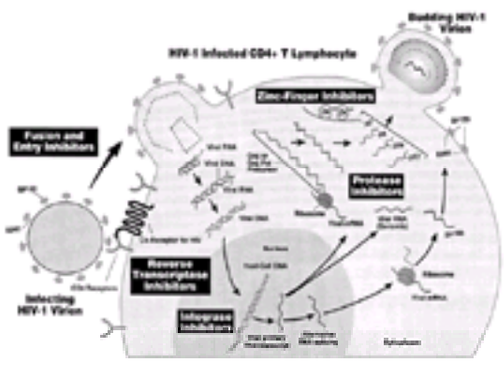

Figure 74.7. Targets of antiretroviral therapy. Drugs that are currently licensed for use in human immunodeficiency virus (HIV) infection include reverse transcriptase inhibitors and protease inhibitors. In development are inhibitors of HIV entry and fusion, inhibitors of HIV integrase, and zinc finger inhibitors.

Inhibitors of viral RT were the first agents to be developed for the treatment of HIV infection; they remain important components of the anti-HIV therapeutic armamentarium. Most RT inhibitors are nucleoside analogs; these agents act as DNA chain terminators by virtue of their structures that lack the 3' hydroxyl moiety necessary for chain elongation. Nonnucleoside RT inhibitors are also used clinically. RT inhibitors as a group suffer from several disadvantages, including their association with multiple neurologic and hematologic side effects, the rapidity with which they select for resistant viral variants when used alone, and their lack of effect on cells already infected with HIV, which no longer require RT to complete the viral replication cycle.

The HIV-1 protease cleaves the Gag precursor polyprotein into the p24 and p17 virion components necessary for viral infectivity. Development of HIV-1 protease inhibitors based on the crystal structure of the protease was a triumph for rational and targeted drug design (377,378). The combination of agents that can inhibit *de novo* infection of cells (i.e., RT inhibitors) with agents that lead to the release of defective, noninfectious virions from cells already infected by HIV (i.e., protease inhibitors) results in potent antiviral activity. Protease inhibitors, in combination with RT inhibitors, have rapidly become the drugs of choice for the treatment of HIV infection.

Integration of reverse-transcribed viral DNA (provirus) into the host DNA is facilitated by the viral enzyme integrase. The determination of the crystal structure of integrase (379) has stimulated a search for inhibitors of this enzyme, which hopefully will lead to the availability of clinically useful agents.

Targeting the “accessory” proteins of HIV has been hampered by the difficulty in delineating the precise biochemical activities of these proteins. A clinical trial of the Tat antagonist Ro24-7429 failed to demonstrate antiviral activity for this agent (380); however, agents targeting the HIV-1 Rev and Nef proteins are being developed.

Delineation of the role of chemokine receptors as HIV entry cofactors and of the role of the chemokine ligands of these receptors as potential inhibitors of HIV cellular entry led to the development of new therapeutic strategies (381). Chemokine analogs that bind to HIV coreceptors and prevent entry of virus without transducing an intracellular signal represent an attractive class of compounds because they are unlikely to elicit inappropriate inflammatory signals. Such a strategy is highlighted by molecules that bind to CCR5 and block infection of cells with R5 strains of HIV without delivering intracellular signals (reviewed in 382). Several small molecules (AMD3100, a bicyclam; T22, a peptide derivative of polyphemusin II; and ALX40-4C, a highly cationic oligopeptide) that compete with SDF-1 for binding to CXCR4 have also been developed. These compounds bind specifically to CXCR4 and inhibit cellular entry of X4 strains of HIV; they also inhibit SDF-1-mediated intracellular calcium mobilization (reviewed in 382). Finally, molecular genetic approaches have been taken to prevent cell surface expression of HIV coreceptors, thus recapitulating the *CCR5D32* phenotype (383,384).

Another therapeutic strategy that inhibits HIV fusion and entry is targeted at the requisite conformational changes within the HIV envelope glycoproteins (385). After interaction with CD4, dramatic conformational changes occur in both the gp120 and gp41 envelope components. Within gp41, a central trimeric coiled coil structure is formed; this structure is essential to the process of fusion with the cell memebrane, and represents an excellent therapeutic target (386,387). In fact, a peptide, T20, which prevents the assembly of the coiled coil structure, has shown promise as a clinically useful antiretroviral agent (376).

Treatment of Primary HIV Infection

Treatment of HIV infection before its wide dissemination to lymphoid tissue and hence prior to establishment of the viral load “set point” is an approach supported by current understanding of the pathogenesis of early events in HIV infection (388). Unfortunately, the pool of resting, latently infected $CD4^+$ T cells appears to be established during the earliest stages of acute infection; this process is not abrogated even by initiation of therapy during the symptomatic phase of acute infection (389). Although these data militate strongly against the possibility of eradicating HIV before its wide dissemination during primary infection, the window of opportunity for treatment of primary HIV infection actually may extend to 12 to 18 months following acute infection; this possibility is based on the persistence of high numbers of productively infected cells in lymphoid tissue during this period, despite attainment of the apparent set point of plasma viremia (84).

A trial of zidovudine therapy versus placebo given for 6 months following primary HIV infection revealed that patients assigned to active treatment maintained higher CD4+ T-cell counts, lower levels of plasma viremia, and slower progression to minor clinical endpoints (e.g., oral candidiasis, herpes zoster, and oral hairy leukoplakia) over a mean follow-up period of 15 months (390). Treatment of patients with recent (i.e., within 90 days) HIV infection with a combination of zidovudine, lamivudine, and a protease inhibitor can suppress plasma viremia to fewer than 20 HIV RNA copies per milliliter for a prolonged period (>2 years) (391); initiation of HAART during acute HIV infection may prevent the loss of HIV-specific $CD4^+$ T-cell proliferative responses (188).

Treatment of Chronic HIV Infection

Early studies of zidovudine monotherapy demonstrated improvements in laboratory markers of HIV disease activity and delayed progression of disease in both symptomatic patients and in asymptomatic persons with relatively low $CD4^+$ T-cell counts (reviewed in 392). Subsequent studies demonstrated that combination therapy with two nucleoside analogs was generally superior compared with monotherapy (393,394,395 and 396).

More potent combination antiretroviral drug regimens, such as zidovudine plus lamivudine, which are capable of prolonged suppression of viral replication, became available in 1995 (397). The addition of protease inhibitors to the antiretroviral armamentarium in 1996 resulted in a dramatic enhancement in the ability to suppress viral replication. The protease inhibitors saquinavir, ritonavir, indinavir, nelfinavir, and amprenavir are all potent antiretrovirals, particularly used in combination with nucleoside analog RT inhibitors (NRTIs). Such combination therapy is now considered the treatment of choice for HIV infection (339). When used in combination with NRTIs, protease inhibitors typically suppress plasma viral load to undetectable levels in the majority of patients for more than 48 weeks. In addition, significant reductions in the rate of progression to AIDS or death have been demonstrated for indinavir and ritonavir (398,399).

The decision to initiate antiretroviral therapy should be made jointly by patient and physician. The decision should be driven in part by data regarding the natural history of disease progression at various levels of $CD4^+$ T-cell counts and plasma viral loads (332,335). Treatment is indicated for patients with symptomatic HIV disease regardless of $CD4^+$ T-cell count and viral load (339). Treatment for asymptomatic patients is generally indicated when the $CD4^+$ T-cell count is below 350 cells per microliter or the plasma viral load is greater than 30,000 copies per milliliter as determined by a bDNA assay (339); however, some physicians and patients choose to initiate antiretroviral therapy earlier or later than recommended in official guidelines. Risks and benefits to early initiation of antiretroviral therapy are presented in Table 74.3; however, unfortunately, no data are yet available regarding the effects of early initiation of HAART on delaying disease progression or improving survival.

Potential benefits
Control of viral replication and mutation; reduction of viral burden
Prevention of progressive immunodeficiency; potential maintenance or re- construction of a normal immune system
Delayed progression to AIDS and prolongation of life
Decreased risk of selection of resistant virus
Decreased risk of drug toxicity
Possible decreased risk of viral transmission
Potential risks
Reduction in quality of life from adverse drug effects and inconvenience of current maximally suppressive regimens
Earlier development of drug resistance
Transmission of drug-resistant virus
Limitation in future choices of antiretroviral agents due to development of resistance
Unknown long-term toxicity of antiretroviral drugs
Unknown duration of effectiveness of current antiretroviral therapies

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus.

TABLE 74.3. Risks and Benefits of Early Initiation of Antiretroviral Therapy in the Asymptomatic HIV-Infected Patient

Many treatment options now exist for the HIV-infected patient. A regimen should be selected that will afford a high likelihood of long-term profound suppression of plasma viral load and a significant increase in the CD4+ T-cell count. Many other factors deserve consideration, including the pill burden associated with a particular regimen, dosing frequency, food requirements, convenience, toxicity, and drug interaction profile. Recommendations regarding specific regimens can be found in Table 74.4 and in the Department of Health and Human Services/Henry J. Kaiser Foundation Guidelines for the Use of Antiretroviral Agents in HIV-Infected Adults and Adolescents on the worldwide web at *www.hivatis.org*.

TABLE 74.4. Recommended Antiretroviral Agents for the Treatment of Established HIV Infection

A change in the antiretroviral regimen may be indicated when a suboptimal reduction in viremia occurs after initiation of therapy, when viremia reappears after suppression to undetectable levels or increases from a nadir of suppression, or when the $CD4^+$ T-cell count declines significantly. When any of these events occur, it is important to determine whether the underlying cause may be drug intolerance or difficulty with adherence to the drug regimen, suboptimal drug levels due to malabsorption or drug–drug or drug–food interactions, or development of drug resistance. If drug resistance is suspected, it is appropriate to change the regimen entirely to drugs that have not been used previously and to which cross-resistance is not anticipated. More targeted changes within a drug regimen may be guided by the use of resistance assays (see later); however, this approach requires further clinical validation. If a regimen is changed because of intolerance or toxicity, it is appropriate to substitute one or more alternative drugs of the same potency and from the same class of agents as the agent suspected to be causing the problem.

Although sustained suppression of viral load is achievable in a high proportion of patients treated with HAART regimens in the clinical trials setting (i.e., nearly 80% at 2 years) (400), only 50% or fewer respond adequately in urban clinic settings (401,402). Predictors of success include lower baseline viral load, higher baseline $CD4^+$ T-cell count, initiation of therapy with multiple drugs simultaneously, and adherence to the drug regimen (400,401,402,403,404,405 and 406). Although the use of HAART regimens has greatly improved the prognosis for HIV-infected persons (14,15), a large number of challenges to the optimal treatment of HIV infection remain.

Adherence

Antiretroviral regimens are complex, consist of multiple agents, and must be taken indefinitely in most cases. Many of the drugs have significant side effects and toxicities (see later). The sheer number of pills required in many regimens (i.e. >20 pills per day) poses a significant challenge to adherence even for the most committed patients. In addition, many antiretroviral agents, particularly protease inhibitors, have complex dosing requirements in relation to food intake.

Lapses in adherence provide windows of opportunity for virus replication and enhance the probability of the emergence of drug-resistant virus. In the INCAS drug trial of nevirapine, zidovudine, and didanosine, missed doses of antiretroviral drugs on 28 or more days during the 52-week study significantly predicted a lower likelihood of achieving durable viral suppression (403). In a study of antiretroviral therapy in an urban clinic setting, missed clinic appointments were significantly associated with failure to suppress viral load over a 1-year period (402).

Side Effects and Toxicites

Gastrointestinal disturbances, such as nausea, vomiting, or diarrhea, are commonly induced by several of the NRTIs and by all of the protease inhibitors. Peripheral

neuropathy may be caused by most of the NRTIs, and rash and Stevens–Johnson syndrome may occur with the use of any of the nonnucleoside reverse transcriptase inhibitors (NNRTIs). Protease inhibitors have a number of drug specific toxicities, such as the association of nephrolithiasis and indirect hyperbilirubinemia with indinavir; nausea, vomiting, and diarrhea and paresthesias with ritonavir; nausea and diarrhea with saquinavir; and diarrhea with nelfinavir. In addition, several class-specific adverse effects are associated with the use of protease inhibitors. In this regard, numerous metabolic derangements involving lipid metabolism are of serious concern with the use of protease inhibitors. Triglyceride and cholesterol levels may become elevated to dangerously high levels. Insulin resistance, hyperglycemia, and even frank diabetes mellitus may occur. Additionally, peripheral fat wasting in the setting of central fat accumulation as well as “buffalo humps” reminiscent of Cushing disease may occur (407,408 and 409). These metabolic derangements may be related to homology between HIV protease and two proteins, cytoplasmic retinoic-acid binding protein type 1 and low-density lipoprotein (LDL) receptor–related protein, that regulate lipid metabolism (410). Finally, a large number of drug interactions may occur with the use of NNRTIs and protease inhibitors, all of which alter cytochrome P-450 metabolism.

Resistance

Failure or loss of suppression of plasma viremia in the setting of good adherence and adequate drug absorption may be due to the emergence of drug-resistant virus. A single nucleotide substitution at position 103 of the RT gene can significantly reduce the activity of the NNRTIs against HIV replication. Similarly, a single nucleotide substitution at position 184 of the RT gene confers resistance to lamivudine. Resistance to some of the NRTIs, such as zidovudine, follows a relatively orderly sequential path whereby accumulation of serial mutations in the RT gene confers increasing levels of resistance to the agent (411); for other drugs in this class, the pathways to resistance are less clear.

Resistance to protease inhibitors is a complex phenomenon that has important implications for drug therapy. The HIV protease is a 99 amino acid protein; that over half of these residues have been reported to be associated with drug resistance is testimony to the genetic plasticity of HIV. Some of these mutations are strongly selected under the pressure of protease inhibitor therapy; however, even when drugs select for unique mutations associated with drug resistance, a great deal of *in vitro* and clinical cross-resistance may still be observed between drugs (412,413). Other mutations are compensatory in nature and can partially restore replicative fitness that is lost with primary mutations. In fact, distant mutations in the protease cleavage site in the HIV p7/p1 core components create a more optimal substrate for a protease enzyme that is compromised by protease inhibitors (414).

Genotypic and phenotypic resistance assays are now available from commercial sources (415). Genotypic assays generally provide information about the presence of mutations in HIV genes (i.e., RT and protease) that may have been selected for during drug therapy. Phenotypic assays evaluate the replication of virus or of a viral construct containing genes from the patient's virus in the presence of antiretroviral drugs. Interpretation of these assays is fraught with difficulty (415). The tests are insensitive to minor viral variants that may be important *in vivo*. In this regard, viral variants harboring resistance mutations to drugs given in the past may be present at frequencies well below the limits of detectability using these assays. Thus, although a positive resistance assay argues strongly that a particular drug will be ineffective, a negative test by no means assures the drug's utility (415).

Preliminary data suggest that resistance testing can be used to optimize the design of antiretroviral regimens. In this regard, one study demonstrated that viral load suppression over a 3- to 6-month period was superior when genotypic resistance assays were used in helping to formulate antiretroviral regimens (416). Another study showed that phenotypic drug resistance may be detectable before viral load rebound becomes evident during drug treatment (417). These data suggest that drug resistance assays will likely be an important adjunct in the formulation of antiretroviral regimens in the future.

Persistent Viral Replication

The beginning of the HAART era saw a great deal of optimism that, with prolonged suppression of viral load, eradication of HIV infection might be possible. Chun et al., however, reported the presence of unintegrated HIV DNA in lymphocytes from HAART-treated patients who had experienced sustained suppression of plasma viral load for an average of 10 months; because of the short half-life of unintegrated viral DNA, this finding argued strongly that ongoing low-level HIV replication was occurring in spite of undetectable levels of plasma viral load (418). Support for this same conclusion came from studies showing persistence of HIV transcription in PBMCs from patients with sustained suppression of plasma HIV viral load (419,420). In addition, two other studies demonstrated evolution of proviral DNA in patients receiving HAART with undetectable viral loads, again indicating ongoing viral replication (421,422). Finally, the rapid rebound of plasma viral load that occurs after cessation of HAART following prolonged suppression of plasma viremia also likely indicates ongoing replication during HAART (423,424).

Persistent viral replication in the setting of apparently effective HAART may be due to intermittently suboptimal drug levels (425,426), poor penetration of drugs into various tissue compartments such as genital secretions (427,428), or suboptimal potency of the drug regimen. Clearly, more potent antiretroviral agents that are capable of inhibiting a broader array of HIV target gene products would be welcome additions to the antiretroviral armamentarium. In this regard, inhibitors of the viral entry and fusion process are in clinical trials (376), and inhibitors of the HIV integrase are in development.

Latent Reservoirs of HIV Infection

On initiation of HAART, plasma viral load declines in several phases (373,374 and 375). The first phase of rapid exponential decay reflects the short half-life of free virions and of recently infected virus-producing cells. After the first several weeks of therapy, a slower second phase of viral load decay occurs with a half-life of approximately 14 days. This phase of decay is thought to reflect attrition of longer-lived, chronically infected cells (429). Extrapolation of this decay suggested that treatment of HIV infection with a potent combination drug regimen that completely suppresses viral replication for approximately 3 years may eradicate infection (429). A practical limitation of this estimate is the assumption of complete suppression of viral replication, which is beyond the capability of currently available HAART regimens (418,419,420,421 and 422).

Another major limitation of the time-to-eradication estimate is the presence of a reservoir of latently infected resting $CD4^+$ memory T cells that persists during HAART. HIV may enter resting $CD4^+$ T cells, and a limited degree of reverse transcription of the viral genome may occur in these cells. This period of preintegration latency may last hours to days; in the absence of an activation signal, the viral nucleic acid loses its capacity to initiate a productive infection. If these cells become activated, however, reverse transcription may proceed to completion, followed by nuclear import, and by integration of proviral DNA into cellular DNA (232,233 and 234). In most $CD4^+$ T cells that become infected with HIV in the *in vitro* setting of a sufficient degree of activation, integration and productive infection occur, followed by cell death. A small fraction of productively infected $CD4^+$ T cells may escape cell death and revert to a resting state in which HIV infection is latent (i.e., postintegration latency). Chun and colleagues estimated the size of this latent reservoir of HIV *in vivo* by examining highly purified resting $CD4^+$ T cells from both blood and lymph nodes of HIV-infected persons. Using a PCR assay specific for integrated proviral DNA, they estimated that the frequency of latently infected resting $CD4^+$ T cells was approximately 0.05%. This frequency was quite similar in the peripheral blood and lymph node compartments (90,430), reflecting the fact that resting memory $CD4^+$ T cells may circulate continuously between various lymphoid tissue compartments. Subsequent micro-coculture analysis revealed that approximately one tenth of latently infected resting $CD4^+$ T cells harboring integrated HIV DNA carried replication-competent HIV (90).

Although the size of the pool of latently infected resting $CD4^+$ T cells *in vivo* harboring replication-competent HIV appears to be quite small, it may nevertheless constitute the most important obstacle to eradication of HIV infection. Latently infected cells are not subject to elimination by the host immune response because of the absence of expression of viral antigens on the cell surface. Furthermore, integrated proviral DNA cannot be targeted by currently available antiretroviral agents. Therefore, the natural half-life of latently infected resting $CD4^+$ T cells may be the rate-limiting step in eradicating HIV infection. These suppositions are substantiated by several independent studies that attempted to recover replication-competent HIV from cells of patients receiving HAART for prolonged periods. In these studies, virus was recovered from $CD4^+$ T cells in essentially all patients receiving HAART with levels of plasma viremia that were below the limit of detectability for up to 94 weeks (418,431,432). To estimate the half-life of this pool of latently infected resting memory $CD4^+$ T cells, Finzi and colleagues performed longitudinal analyses of the number of these cells harboring replication-competent HIV in 20 patients receiving HAART whose plasma viral load remained suppressed to fewer than 200 copies per milliliter over a mean of 14.4 months (433). The decay of the latent pool of $CD4^+$ T cells was extremely slow, with an estimated half-life of 44 months; given a conservative estimate of the size of the latent pool, this leads to an estimated time-to-eradication of 60 years in patients receiving HAART (433). It is possible, however, that the half-life of the latent pool was overestimated if transient low-level viral replications were reseeding the reservoir over the course of the study. As more potent HAART regimens become available, more accurate assessments of the decay of the reservoir of latently infected cells should be possible.

Strategies aimed at long-term control of HIV infection will need to focus on the pool of latently infected cells that represent a long-lived reservoir capable of “reigniting” viral replication during periods of suboptimal antiretroviral therapy. Antiretroviral regimens that are highly potent and more easily administered should be part of such a successful strategy; however, this approach could be combined with interventions, such as IL-2 therapy, aimed at activating latently infected cells in the setting of HAART as well as enhancing HIV-specific immune responses (235). In this situation, latently infected cells might be driven to a state of productive infection and die; infectious virus released from these cells would be unable to infect new cells under the cover of HAART. In fact, Chun and colleagues found that patients who received IL-2 in addition to HAART had a significantly lower frequency of latently infected $CD4^+$ T cells harboring replication-competent virus compared with patients who received HAART alone (434). The mechanism of this effect is under investigation; however, unfortunately, even patients who harbored a frequency of latently infected cells that was below the limits of detection experienced prompt viral rebound when HAART was discontinued (435). These data highlight the importance of other reservoirs of smoldering virus replication or latently infected cells in the body (436,437).

CONCLUSION

Within a relatively short time, AIDS has emerged as a leading cause of morbidity and mortality worldwide. As the epidemic matures and plateaus in certain parts of the world, it emerges and accelerates in others. The extraordinary burden of the epidemic that has devastated sub-Saharan Africa will likely next be realized in India, central Asia, and Eastern Europe.

The pathogenesis of HIV infection is a complex, multifactorial process involving viral and host factors. HIV is a formidable opportunist of the human immune system, as illustrated by its ability to utilize several receptors to gain entry into its target cells. Furthermore, HIV is uniquely able to utilize the milieu of an activated immune system to its own replicative advantage; thus, activation and mobilization of the immune response, which are intended to thwart the virus, rather fuel its replication and spread.

Advances in the treatment of HIV infection have been made at a pace that is unparalleled in the study of human viral diseases. Nevertheless, some sobering obstacles remain to the optimal treatment of HIV-infected persons. More than 90% of HIV-infected persons live in the developing world, where expensive combinations of antiretroviral agents are far beyond the capacities of local per capita health care expenditures. Even in developed countries, it is clear that, although HAART regimens have vastly improved the prognosis of HIV-infected patients, they are not curative, and their use is fraught with difficulties including numerous toxicites and drug interactions. To deal effectively with HIV infection, new antiretroviral agents that target different stages of the viral replicative cycle will be needed, as well as immunorestorative strategies that will allow more complete reconstitution of the immune system in the setting of effective antiretroviral therapy.

75 EPSTEIN-BARR VIRUS

David A. Thorley-Lawson, Ph.D.

Epstein-Barr virus (EBV) was the first candidate human tumor virus to be identified. Since its discovery, it has been found in a number of important malignancies, primarily of B lymphocytes (Burkitt, Hodgkin, and immunoblastic lymphoma) and mucosal epithelium (nasopharyngeal and gastric carcinoma). It also is the accepted cause of infectious mononucleosis. Despite its pathogenic potential, the virus infects virtually the entire human race and persists benignly within the vast majority of individuals for their whole lives. In the last few years, tremendous strides have been made in understanding how EBV causes cells to grow, but only recently have we begun to understand why. EBV latently infects resting B lymphocytes, in the nasopharyngeal mucosal epithelium, and causes them to proliferate so that they can differentiate into resting memory B cells–the site of life-long persistent infection. When this process becomes deregulated, malignancies can arise. This chapter discusses benign infection and the known EBV-associated diseases. We describe how EBV has interwoven its biology with that of the mature B lymphocyte, first to establish and then to maintain a persistent infection within the B-cell arm of the immune system. The virus achieves this despite an aggressive and ongoing immune response against the virus and virus-infected cells. This model is used as a basis for discussing the origins of the EBV-associated diseases.

History and Background

EBV is classified as a g herpesvirus and has a tropism for B lymphocytes. It was discovered through its association with Burkitt lymphoma (BL) (1), a common tumor of children in tropical Africa. The distribution of BL closely follows that of hyper- and holoendemic malaria (2). This led to the suggestion that BL might be caused by an infectious agent spread by the malarial mosquito. Subsequently, BL tumor cells were propagated in tissue culture and a fraction of the cells found to contain viral particles that resembled, morphologically, members of the herpesvirus family (3). Thus was discovered the first candidate human cancer virus. It is ironic to note that, almost four decades later, no causal link has been demonstrated between malaria and either EBV transmission or BL development and that the role of EBV in BL remains a mystery.

After the virus was identified, there followed a series of elegant studies exploiting immunofluorescence assays that used human sera to detect viral antigens expressed by BL tumor cells (4). It was discovered that people developed antibodies to EBV during the course of infectious mononucleosis (IM) (5). This established the causative role of EBV in IM. Subsequently, a strong association was found between elevated antibody titers to EBV and the development of nasopharyngeal carcinoma (NPC), whereas a weaker association also was found with Hodgkin disease (HD) (4). Both associations have subsequently been confirmed by more sophisticated immunohistochemical and molecular biologic techniques.

In parallel with the studies on disease association, other investigators uncovered the fundamental biologic properties of the virus that established it as a *bona fide* tumor virus. The virus was isolated from EBV-positive cell lines (6) and from the throat washings (7) and peripheral blood cells of infected individuals (8). No matter the source, the virus was capable of infecting normal B lymphocytes in culture and causing them to proliferate indefinitely. This process is called immortalization or growth transformation. The cells do not produce infectious virus; therefore the infection is latent. These studies established that EBV alone has the capacity to drive the proliferation of normal cells, thus accounting for its being a risk factor in the development of neoplastic diseases. Immortalization is a powerful experimental tool not only for studying EBV latency, but also for studying human biology. It allows the rapid establishment of cell lines from any individual of interest for subsequent biochemical and/or genetic studies.

Finally, it has been shown in certain New World monkeys (9), severe combined immunodeficiency disease (SCID)/hu mice (10), and in individuals who are immunosuppressed (11,12 and 13), EBV can directly give rise to B-cell tumors. These tumors contain EBV and resemble the proliferating cell lines obtained by infection *in vitro*.

Because EBV is (a) so ubiquitous, (b) capable of driving cellular growth, and (c) infects B lymphocytes, it has been suggested as a candidate causative agent for a number of neoplastic and autoimmune diseases. It is now accepted that EBV has a role in gastric carcinoma (14) and rare T/natural killer (NK) cell lymphomas (15). More controversial and yet to be substantiated is its involvement in invasive breast carcinoma (16), hepatocellular carcinoma (17), and systemic lupus erythematosus (18). Earlier suggestions that EBV plays a role in rheumatoid arthritis and chronic fatigue syndrome are generally discredited (19,20).

Since the time of its discovery, the focus on EBV has been its ability to transform B cells and its relationship to human cancer. Only in recent years has it become apparent that EBV has a less-threatening side. It infects >90% of the human population, persists for their whole lives, and in the vast majority of cases, remains benign. Persistent infection is demonstrated by the continuous presence of infected B cells in the peripheral blood and the shedding of infectious virus in saliva (21). The virus persists by establishing a latent infection in resting memory B cells (22). Here the virus is invisible to immunosurveillance and not a pathogenic threat to the host because no viral genes are expressed (23).

Recent advances in our understanding of the molecular biology of growth transformation *in vitro* and the specificity of viral infection *in vivo* allow a synthesis that begins to explain how EBV establishes and maintains a persistent infection and what the risk factors are that lead to EBV-associated disease.

EPSTEIN-BARR VIRUS INFECTION IN THE HEATHY HOST

Most studies of primary infection have been performed on IM patients on the assumption that IM is simply an amplified version of asymptomatic infection (24). This is untrue (see later). IM is a pathologic, atypical form of primary infection. Normally, EBV does not aberrantly deregulate the behavior of infected B cells *in vivo*. It initiates, establishes, and maintains persistent infection by subtly using various aspects of normal B-cell biology. Ultimately this allows the virus to persist within memory B cells for the lifetime of the host (25,26).

Entering the B Cell: The Earliest Events in Primary Epstein-Barr Virus Infection

It is generally believed that EBV is spread through salivary contact (27). The lymphoid system that surrounds the nasopharyngeal region includes the adenoids and tonsils and is called Waldeyer ring. Together with the overlying epithelium, it forms a continuous structure referred to as the lymphoepithelium (28). The epithelium is invaginated to form crypts, below which resides the lymphoid tissue (Fig. 75.1). Deep in the crypts, the epithelium can be very thin. It is likely that the virus, in saliva, enters the crypts (Fig. 75.1) and crosses the thin layer of epithelial cells to infect B cells that reside below. What happens next is assumed to recapitulate what is seen *in vitro*. EBV infects resting B cells *in vitro* and drives them to become latently infected, proliferating B blasts (29,30). This form of latency is referred to as the growth program (31) or latency III (32). The only population that expresses the growth program in tonsils are naive B cells (33); therefore the target of the incoming virus is the

resting naive B cells that reside in the mantle zone immediately below the epithelium (Fig. 75.1).

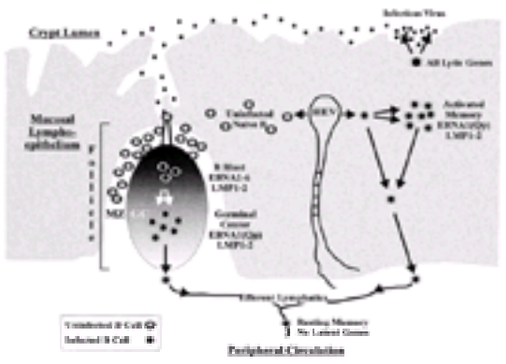

Figure 75.1. A representation of mucosal lymphoepithelium in the nasopharyngeal region. The events and structures depicted here are described in detail in the text and in diagrammatic form in Fig. 2. *MZ*, mantle zone; *GC*, germinal center.

Because the target for EBV infection is a resting cell, the virus must initiate latent gene transcription in a quiescent environment. It infects cells through the interaction of the viral glycoproteins gp350/220 with CD21 (34) and gp42/gH/gL with major histocompatibility complex (MHC) class II (35). CD21 is the receptor for the C3d component of complement and forms part of a multimeric signal-transduction complex with CD19, CD81(TAPA-1), and Leu-13 (36). Cross-linking of surface molecules by the viral glycoproteins provides the signal to move the resting B cells from G_0 to the G_1 phase of the cell cycle and allows expression of the first latent proteins (EBNA2 and EBNALP) (37). EBNA2 is a transcription factor that activates the promoters necessary to produce all nine of the latent proteins expressed in the growth program [reviewed in (38)] (Table 75.1). The result is that the infected B cell becomes an activated lymphoblast and begins to proliferate. The nine latent proteins include six nuclear proteins [EBV nuclear antigens (EBNAs)] and three membrane proteins [latent membrane proteins (LMPs)]. The presence of EBNA2 is diagnostic for the growth program (Fig. 75.1 and Fig. 75.2B). Several of the latent proteins have potent growth-promoting activity and can act as oncogenes. These include EBNA2 (39), EBNA3c (40), and LMP1 (41).

Latent Gene[a]	Function
EBNA1	Tethering and replication of the viral genome
EBNA2	Transcription of latent viral and cellular genes
EBNA3/EBNA3a	Unknown
EBNA4/EBNA3b	Unknown
EBNA5/EBNALP	Augmentation of EBNA2 function
EBNA6/EBNA3c	Cell-cycle progression
LMP1	Cell survival/TNFR family-type signaling
LMP2a/TP1	Cell survival/BCR-type signaling
LMP2b/TP2	Unknown
EBER1[b]	Unknown
EBER2[b]	Unknown
BARF0/BART[c]	Unknown

[a] Where more than one nomenclature is used the alternates are given.
[b] Small nonpolyadenylated RNAs. No protein.
[c] No known protein to date.

TABLE 75.1. The EBV Genes Expressed in Latently Infected Cells

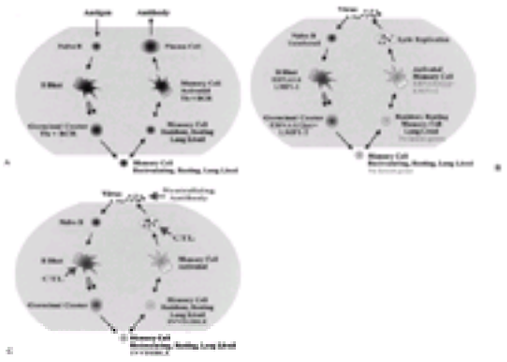

Figure 75.2. A diagrammatic representation of the current model of the establishment and maintenance of Epstein-Barr virus (*EBV*) persistent infection. *The gray shaded area* represents the lymphoepithelium. **A:** The major events involved in the response of naive B cells to antigen. The details are described in the text. **B:** How EBV has exploited normal B-cell biology, shown in **A**, to establish and maintain infection. The cells labeled in *blue* represent the major pathway involved in establishing a persistent infection. The *orange* cells represent the major pathway involved in long-term maintenance. The details are described in the text. Note that the overall consequence of all this activity is that the numbers of latently infected recirculating memory B cells remain extremely stable for many years. **C:** The major targets of the immune response. Note that despite these potent responses, the virus continues to be shed, and B blasts expressing the growth program are continuously present in the lymph nodes such as the tonsil.

In addition to the nine latent proteins, EBV-infected lymphoblasts express two small nonpolyadenylated RNAs, termed EBER1 and EBER2 (42), and a set of transcripts, derived from the Bam A fragment of the genome, called BARF0 or BART (43). [EBV genes are named from their locations on the *Bam*HI restriction map of the viral genome, where the largest fragment is A. Thus, BZLF1 is the ***Bam*HI**, **Z** fragment, **L**eftward reading **F**rame number **1**. Commonly studied genes also are identified by colloquial names (e.g., BZLF1 is referred to as ZEBRA or Zta).] The function of these genes is unclear. The EBER transcripts are important because they are by far the most abundant RNAs found in latently infected cells and are routinely used as targets for *in situ* hybridization studies to identify EBV-infected cells in normal tissues and tumors.

The latent genes are transcribed from the viral genome, which exists as a covalently closed episomal circle. The linear genome forms this circle when the infected cell begins proliferating (44). The status of the viral genome in a tissue provides a considerable amount of useful information. Linear genomes indicate viral replication. Circularized genomes indicate latently infected cells that have proliferated at some time in their history (45,46). The number of discrete joint fragments (TR, or terminal repeat analysis) is a measure of how many independent clones are present in the tissue. This latter technique is used to establish the clonal origin of the virus in tumors (46).

EBV-infected, proliferating lymphoblasts resemble, morphologically (47) and phenotypically (48,49), normal B cells that have been activated to become B blasts by antigen. Normal B cells need antigen, T-cell help, and lymphokines to achieve this activated, proliferating state; however, EBV is able to perform the task alone. Therefore the complex machinery of viral latent gene expression found in the growth program is specifically designed to induce a normal, activated phenotype.

It is apparent then that EBV has evolved a transcriptional program that ensures that EBV will efficiently and predictably establish latency and initiate cell growth as soon as it encounters a resting naive B cell in the lymphoepithelium of the nasopharynx. This growth-promoting transcription program puts the host, in which the virus intends to persist, at risk for developing neoplastic disease. Therefore the virus must use this program because it is essential. We now believe that the virus must drive the latently infected naive B cells to proliferate so that they are in the correct differentiation state, activated B blasts, to differentiate into resting, latently infected memory cells where the virus can persist for life.

The Making of a Memory B Cell

To understand how latently infected, naive B lymphoblasts expressing the growth program can become resting memory B cells, with no viral gene expression, it is first necessary to describe how a normal naive B cell becomes a memory cell. EBV infection occurs in the mucosal lymphoepithelium of the pharynx; therefore the biology of mucosal B cells is most relevant to our discussion.

Environmental antigens are sampled directly through the epithelium (28). Naive B cells extravasate through high endothelial vesicles (HEVs) (Fig. 75.1) in the lymphoepithelium and migrate to the mantle zone surrounding the follicles (50). If they encounter antigen, they become activated B blasts that migrate into the follicles and proliferate to form germinal centers (Fig. 75.1 and Fig. 75.2A) (51,52). During this time, the B cells switch the isotype of the immunoglobulin (Ig) they produce and randomly mutate the immunoglobulin genes. For these cells to survive, they need to receive two signals, one from antigen-specific T helper (Th) cells, and one through the B-cell receptor (BCR) for antigen. If Th cells are not available or the mutated immunoglobulin no longer binds antigen, the cell will die (53). Thus B cells expressing the highest-affinity BCR are selected. The cells that survive ultimately have two fates, depending on the length and type of exposure to Th cells and specific lymphokines (54). They can either terminally differentiate into antibody-secreting plasma cells that migrate into the epithelium (55) or become long-lived memory B cells. Memory B cells, as the name implies, carry immunologic memory and are responsible for a heightened secondary response on reexposure to the specific antigen. The maintenance of B-cell memory is not passive. Memory B cells rarely divide (56) but need frequent signaling through the BCR (57,58) and by Th cells (59) to survive.

Establishing a Persistent Infection: Access to the Memory Compartment

From the preceding discussion, we know that two events must happen for EBV-infected naive B lymphoblasts, expressing the growth program, to become memory cells. First, the latent genes that drive proliferation must be turned off, and second, the cells must receive the requisite survival signals. How the EBNA2-driven growth program is turned off is unknown; however, it is clear (Fig. 75.1 and Fig. 75.2B) that germinal center cells, carrying latent EBV, express only three of the nine latent proteins, EBNA1, LMP1, and LMP2a (60). This form of latency is referred to as the default program (61) or latency II (32). LMP1 is a membrane protein that acts as a ligand-independent, constitutively activated receptor (62) delivering T-cell help. It does this by engaging the TRAF and TRADD molecules (63,64), which normally transmit signals for members of the CD40/TNFR family of surface molecules (65). The interaction of CD40 ligand on Th cells with CD40 on B cells is the mechanism by which the Th cell delivers its rescue signal to the B cell. Thus LMP1 is able to deliver a Th-cell signal in the absence of either antigen or Th cells.

LMP2a also is a membrane protein, and it delivers a constitutive ligand-independent BCR signal (66). LMP2a contains the same signaling motifs (ITAMs) (67), as the a and b chains of the BCR. These motifs allow it to engage members of the src family of nonreceptor protein tyrosine kinases usually used by the BCR when it signals after binding cognate antigen. The BCR produces two types of signals. One type is required simply to ensure the survival of resting B cells (57). The other leads to cellular activation, proliferation, and ultimately differentiation into immunoglobulin-secreting plasma cells (51,52). The two signals, therefore, may be referred to as survival and activating, respectively. LMP2a is able to provide the survival but not the activating signal.

By expressing LMP1 and LMP2a, the virus ensures that the B cell will get the BCR (LMP2a) and Th (LMP1) signals necessary for it to survive a germinal center and exit as a resting memory cell into the peripheral circulation (Fig. 75.1 and Fig. 75.2B) (22). EBNA1 also is expressed in the default program because it is essential for retaining the viral genome by tethering it to cellular DNA so it can be replicated (68). For EBNA1 to be expressed without the other EBNAs, the Q promoter is used (69). EBNA1 transcription from Qp, in the absence of EBNA2, is diagnostic for the default program.

EBV Persistence in the Peripheral Memory B Cell Compartment

EBV, in the peripheral blood, is found only in resting cells (23) that have undergone germinal center differentiation (i.e., classic memory B cells) (22,70). The virus is distributed evenly among memory B cells expressing the different switched immunoglobulin isotypes. The frequency of infected cells for any individual is very stable for years. In a population of healthy carriers, it ranges from 5 to 500 for every 10^7 B cells, with a mean of 50 per 10^7 (71). This is about one infected cell per milliliter of blood, for a total of 2.5×10^6 infected cells in the entire body of an average individual. The stability in the number of EBV-infected cells and their random distribution in the memory compartment suggest that the host may not recognize these cells as infected. The number may be maintained through the normal homeostatic mechanisms that keep the levels of memory B and other lymphoid subsets stable. This stability will continue unless something perturbs the system.

Careful quantitative analysis suggests that most of the infected cells in the peripheral blood do not transcribe any of the genes for the known latent proteins (23; D. Hockberg and D.A. Thorley-Lawson, unpublished observations. However, the messenger RNA (mRNA) for LMP2a (72) is often present, probably due to long-lived transcripts. Therefore the final resting place of persistent EBV is a resting memory B cell that is not subject to immunosurveillance because the immunogenic latent genes are not expressed (Fig. 75.2B and Fig. 75.2C). This cell is not a threat to the host because the growth-promoting latent genes are not expressed. This type of latency is referred to as the true latency program.

Maintenance of the Persistent Infection: Using Long-Term Memory

Latently infected, resting, memory B cells in the periphery need to receive the Th and BCR signals necessary to maintain their survival as memory cells. To do this, it is believed that they transit back through the nasopharyngeal lymphoepithelium where they become activated and express the default program (Fig. 75.1 and Fig. 75.2B) (61). Again LMP1 and LMP2 give the necessary survival signals.

The last component of persistent infection is the continuous shedding of infectious virus into the saliva. Memory B cells, transiting the nasopharyngeal lymphoid tissue, must occasionally initiate virus replication and release the virus back into the crypts. B cells replicating the virus in the lymphoepithelium have plasma cell morphology (73,74). This would suggest that, in some circumstances, the activated, latently infected, memory B cells differentiate into plasma cells and release virus (Fig. 75.2B).

The growth program allows EBV to gain access to the memory compartment. Once the persistent infection is established, cells expressing the growth program are no longer essential, but continue to pose a threat to the host. As the immune response attempts to clear most viruses, it tends to select for strains with altered epitope sequences that can no longer be recognized. The opposite is true for EBV. It has conserved the sequences of growth program latent proteins that are recognized by cytotoxic T lymphocytes (CTLs) (75). As discussed in the ensuing sections, the virus has done this to ensure that aberrant cells expressing the growth program are rapidly killed and do not threaten the health of the host.

IMMUNOLOGIC RESPONSES TO THE INFECTION

Immunologic responses to EBV infection can be divided into those that arise during acute infection and those that continue during persistent infection. Responses to acute infection have been studied only in IM. It is assumed, but not known, that these events typify all primary infections.

Humoral Response

HISTORY

Early work on EBV exploited the observation that infected individuals produce antibodies against discrete components of the virus and virus-infected cells. These antibodies define the EBNA, EA-R, EA-D, MA, and VCA antigens (4). EBNA is detected in the nucleus of latently infected cell lines (76). It consists of six discrete components (Table 75.1). EA-R (early antigen-restricted) and EA-D (early antigen-diffuse) define antigens present in cells that are producing virus. R and D describe the pattern of staining seen within the cells. EA consists of a large number of proteins, many of which are involved in initiating replication of the viral genome. Their expression is independent of viral genome replication (4). MA (membrane antigen) and VCA (viral capsid antigen) also are present in cells producing virus, but their expression is dependent on replication of the viral genome (4). MA is present on the cell membrane and the viral envelope and is a complex composed mostly of glycoproteins that play key roles in virus binding and infection. The major components are two heavily glycosylated proteins of 350,000 and 220,000 molecular weight (gp350/220), which are the major targets of neutralizing antibodies to the virus (77). VCA is expressed in the cytoplasm and is a complex of structural proteins that includes components of the capsid and MA present in the cytoplasm of the cells. Measurement of anti-VCA antibodies is the most common, virus-specific, serologic test for the presence of EBV.

ACUTE INFECTION

IM is characterized by a unique profile of antibody responses (4). These include antibodies to EA, VCA, MA, and the EBNAs, with the exception of EBNA1. A definitive diagnosis of acute EBV infection requires the detection of IgM antibodies to VCA in the absence of anti-EBNA1 antibodies. Why anti-EBNA1 antibodies do not appear during acute infection is a mystery.

PERSISTENT INFECTION

Once the infection is established, the serologic profile stabilizes with significant IgG antibody titers to EBNA1, VCA, and MA, including neutralizing antibodies. Antibodies to EA and the other EBNAs decline but remain detectable. The definitive diagnostic serology for a healthy EBV carrier is IgG antibodies to VCA and EBNA1 (4).

Cellular Responses

ACUTE INFECTION

IM is characterized by the appearance of large numbers of virus-specific CTLs, most of which are CD8 positive (78,79) and recognize proteins of the lytic cycle (80). The CTL response rapidly becomes focused on single epitopes (81). In one case of IM, 44% of all $CD8^+$ T cells were specific for a single peptide of the BZLF1 protein (82) that initiates lytic replication of the virus. Only 1% to 2% of the $CD8^+$ T cells were specific for latent proteins.

PERSISTENT INFECTION

As with the humoral response, the CTL response declines and then stabilizes as the acute infection recedes. The response remains highly focused, however, with the dominant epitopes being from lytic proteins (83), particularly the immediate early transcriptional transactivating proteins such as BZLF1 (84,85). Typically 1% to 5% of all $CD8^+$ T cells are specific for a single epitope of a lytic protein, whereas <1% respond to the latent proteins (86). The peptide used is dependent on the presenting MHC class I molecule. For example, individuals who are human leukocyte antigen (HLA)-B8 focus on single peptides from the BZLF1 and EBNA3a proteins (87).

The CTL response to the latent proteins is particularly strong against the EBNA3 family of proteins (87), and most infected individuals mount responses to these proteins. Responses to EBNA2 and the LMPs are detected much less frequently, and responses to EBNA1 are essentially undetectable. The strong focus on the EBNA3s confirms the notion that the key role of the CTL response to latently infected cells is to destroy those expressing the potentially pathogenic growth program, the only program in which the EBNA3s are expressed (Fig. 75.2C). One consequence may be that cells expressing the default latency program, in which only EBNA1 and the LMPs are expressed (Table 75.2), may not be under aggressive immunosurveillance. This includes latently infected germinal center and memory cells (60). The latent proteins of the default program may have evolved to be less immunogenic to protect these critical intermediates of persistent infection from destruction by CTLs. The reduced immunosurveillance of cells expressing the default program may be important in understanding why tumors that express this program, such as HD and NPC (see later), can escape immunosurveillance.

Form of Latency	Tissue/Tumor	Genes Expressed*
Growth program (Latency III)	Normal tissue	EBNA1-6
	MLN naive activated B cells	LMP1-2
	Tumors	EBER 1-2
	Immunoblastic lymphoma	BARF0
	PTLD	
	XLP	
	AIDS	
Default program (Latency II)	Normal tissue	EBNA1(Gly)*
	MLN: germinal center	LMP1-2
	MLN: activated memory B cells	EBER 1-2
	Tumors	BARF0
	Hodgkin disease	
	Burkitt lymphoma†	
	T/NK lymphoma	
	Nasopharyngeal carcinoma	
Latency program	Normal tissue	EBER1-2
	PBL: Resting memory B cells	BARF0
	MLN: Resting memory B cells	

MLN, mucosal lymph nodes; PBL, peripheral blood lymphocytes.
* The expression of EBER and BARF0 transcripts has not been systematically studied in lymphoid tissues.
† In this form of latency, EBNA1 is expressed from a promoter referred to as Qp, which is different for the promoter used in the growth program (Cp) and Wp).
‡ BL is listed, although only EBNA1 is expressed. It is our assumption that BL is derived from a cell that originally expressed the default program.

TABLE 75.2. The Viral Genes Expressed in the Different Forms of Latency and the Infected Tissues Where They Occur

One striking aspect of the CTL reactivity profile is the absence of clones recognizing EBNA1 (87). EBNA1 contains a large repetitive domain, consisting of repeated glycine and alanine residues, that prevents the protein from being processed for presentation on MHC class I molecules (88). It is has been suggested that this represents a mechanism of immune avoidance by the virus and has led to proposals that the site of persistence expresses only EBNA1 (24,89,90). As discussed earlier, however, the site of persistence is the memory B cell (22,25,26) that, in the blood, does not express the EBNA1 gene (91) and, in the lymph nodes, does expresses EBNA1, but always with LMP1 and LMP2 (60), both of which can be processed for presentation to CTLs. Therefore the default transcription program for persistence is EBNA1 + LMP1 + LMP2, not EBNA1 alone. A more mundane explanation for the stability of EBNA1 may be its tethering function (68), which is essential for genome replication. The stability of EBNA1 may simply reflect the importance of having sufficient EBNA1 protein to ensure retention of the viral genome.

Role of the Immune Response

Although antibodies are produced to a wide variety of latent and lytic proteins, it is certain that most play no role in curtailing acute infection or regulating persistent infection. Only neutralizing antibodies are likely to play a role by preventing the dissemination of infectious virus (Fig. 75.2C). Even this response appears inadequate, however, to prevent the continuous production and shedding of infectious virus into the saliva of persistently infected individuals (21).

CTLs against lytic antigens are probably focused on immediate early proteins to ensure destruction of lytically infected cells before they produce infectious virus (Fig. 75.2C). The importance of this response is demonstrated when the CTL response is suppressed. Immunosuppressed patients shed increased levels of virus in their saliva (92) and have cells replicating virus in their blood (23), an event never seen in healthy carriers.

Because the CTL response to latent proteins focuses so aggressively on the EBNA3s, cells expressing the growth program must be their major target. This conclusion is again borne out by studies of the immunosuppressed who are at risk for developing B-cell lymphomas that express the growth program (93,94), not the default program (see later).

THE EPSTEIN-BARR VIRUS–ASSOCIATED DISEASES

So far we have discussed the current ideas of how and where EBV establishes and maintains a persistent infection and the key immunologic responses that regulate it. The following sections discuss the major EBV-associated diseases. Because the etiology of these diseases is not well understood, we attempt to place each of them in the context of the preceding discussion.

Infectious Mononucleosis

Most people in the world become infected with EBV at a very early age, usually in the first years of life (4). Primary infection of children is rarely recognized because it is usually asymptomatic (95). In Western and economically advanced countries, infection is frequently delayed into adolescence or adulthood, when it can cause IM (96). Reported incidence rates range from two to 2,000 per 100,000 (97), but these estimates are inaccurate because they do not take into account the age-related occurrence of the disease and the socioeconomic dependence of the age of primary EBV exposure. IM is exclusively a disease of EBV-negative adolescents and adults, and in this group, 20% to 50% of primary EBV infections result in IM (97). The intensity of the disease varies but can last for weeks or months before finally resolving (98).

IM is characterized clinically by the insidious onset of malaise, sore throat, fever, and lymphadenopathy. There is a characteristic lymphocytosis (99) (>4,500/mm^2 with >51% lymphocytes on differential count) and the production of IgM heterophile and autoantibodies with no specificity for EBV. A subset of the heterophile antibodies recognizes sheep and horse erythrocytes (100). This is the basis of the Paul-Bunnell-Davidsohn agglutination or monospot test, the most widespread diagnostic test for acute IM. Taken together, these three indicators constitute a diagnosis for IM (98).

The lymphocytosis is characterized by the appearance of large numbers of “atypical” lymphocytes (99). These are not infected B cells but predominantly $CD8^+$ T cells, with a minor $CD4^+$ component, and account for the inversion of the CD4/CD8 ratio seen in IM patients compared with healthy individuals (78). The atypical T cells express HLA class II MHC, CD38, and CD45RO (82), all markers of activated T cells, and die rapidly in culture (101). Originally they were thought to represent a nonspecific response that paralleled the production of heterophile antibody; however, it is now known that they represent a vigorous CTL response to the virus (79)

(see later). This response can, during the height of the disease, involve up to half of all the T cells in the body (82). Presumably this explosion of T cells is responsible for resolving the infection, but the ensuing destruction of infected tissue leads to the fever and malaise characteristic of IM.

The normal course of EBV infection involves the precisely regulated expression of transcription programs that allow latent EBV to gain access to and persist within the long-lived memory compartment (Fig. 75.1 and Fig. 75.2B) (60). This process is normally asymptomatic, as observed in the primary infection of young children, which is not associated with lymphocytosis or heterophile antibody (95). By contrast, IM is a chaotic mixture of inappropriate infection. IM patients shed very high levels of infectious virus in their saliva. B cells that are latently infected or replicating the virus (73,74) are present abundantly throughout the tonsils of IM patients, at levels 100- to 1,000-fold higher than those in healthy carriers (102). Many of the latently infected cells express the growth program (103), and most of them represent expanded clones of memory cells (104). Memory cells expressing the growth program are never found in the tonsils of healthy carriers (33,60). Their presence in IM indicates that the tight regulation of the growth program has been contravened, allowing infectious virus to spread beyond the usual boundaries that restrict it to only infecting naive B cells. The result is the inappropriate infection of memory B cells. Directly infected naive B cells can differentiate through a germinal center into memory and therefore do not accumulate as proliferating clones in the tonsil. Directly infected memory cells, however, cannot undergo this differentiation program and therefore accumulate as clones driven to proliferate by the viral growth program. The process is so disrupted that cells expressing the growth program are even found in the peripheral blood (105), an event that is never seen in healthy carriers (72) and is very rare even in the immunosuppressed (23). The viremia is so systemic that B cells in the periphery are being directly infected to become proliferating lymphoblasts. These cells cannot escape the cell cycle through differentiation and continue to expand until as many as 0.1% to 10% of the B cells in the peripheral blood are EBV positive (106). It has been speculated that these cells may be responsible for the production of the low-affinity IgM heterophile antibody characteristic of IM.

It is often incorrectly assumed that IM is an amplified version of typical asymptomatic infection (24). It is now clear that IM is actually a pathologic condition, demonstrating atypical infection, and is not representative of the well-ordered set of host/virus interactions that characterize normal acute infection. It is likely that IM is immunopathologic in nature, meaning the disease symptoms are caused by the inflammatory response of the immune system rather than by the virus itself. The age dependence of symptoms has led to the suggestion that IM is a disease of a mature immune response. What this means mechanistically is less clear. Another explanation has been suggested, based on animal studies on the memory CTL response (107). Early in life, the CTL response to new infections is by naive T cells. These produce high-affinity CTLs that efficiently clear the virus infection and then become memory CTLs. As the organism ages, memory CTLs accumulate to a variety of pathogens. Exposure to a novel infection later in life is more likely to reactivate cross-reacting memory CTLs than naive CTLs. These CTLs are of lower affinity and may produce an ineffectual response, allowing extensive viral replication and spread, resulting in a massive inflammatory response that lasts until the virus is finally brought under control.

As time passes and the symptoms of IM regress, less virus is shed into the saliva, and infected B cells expressing the growth program disappear from the peripheral blood. The ensuing events, however, are strikingly different from infection with most other viruses. Shedding of EBV does not stop, but stabilizes and continues for life at a lower, steady rate (21). B cells expressing the growth and default programs persist in the nasopharyngeal lymph nodes (60), and latently infected memory cells, expressing the latency program, remain in the blood for life at levels that stay remarkably stable (22,71). At the same time, levels of neutralizing antibodies (4) and CTLs also stabilize (81) and continue at significant levels for the lifetime of the host. It is apparent therefore that the immune response ameliorates but never clears the infection. An equilibrium is established between the immune response and the various states of viral latency, allowing the virus to persist and be shed at stable levels, without causing significant impairment to the host.

Immunoblastic Lymphoma in the Immunosuppressed

TRANSPLANTATION

Lymphoproliferative disorders are a relatively common consequence of iatrogenic immunosuppression associated with organ transplantation. They are collectively defined as posttransplantation lymphoproliferative diseases (PTLDs). The use of this common rubric hides the heterogeneity of these disorders. PTLDs are of B-cell origins and almost always are EBV positive, but no clearly identified marker defines PTLDs as a discrete entity.

PTLDs have been known since the advent of immunosuppression in organ transplantation, but became noticed only with the introduction of the powerful immunosuppressant cyclosporin A (108). A large number of factors influence the incidence and onset of PTLDs, including the types, combinations, dosing levels, and lengths of immunosuppressants used (109), the virologic status of the recipient, the nature of the organ, and the setting of the transplant (110). For example, rates tend to be high in intestinal and heart/lung transplant recipients (15% to 20%) and low in bone marrow transplants (<1%) (111) receiving comparably high doses of cyclosporin A. Rates of PTLDs in bone marrow recipients jump from <1% to 10% to 20% if the bone marrow is depleted of T cells, suggesting that donor T cells play a critical role in controlling the EBV-driven lymphoproliferation (112). PTLD is particularly problematic in EBV-negative recipients (113) who develop a primary infection, frequently with organ-derived virus. This makes children a particularly high-risk group for PTLD. Onset of PTLD is typically less than 1 year after transplant for EBV-negative recipients and all bone marrow recipients. For EBV-positive recipients, receiving solid organs, onset time is several years (114).

PTLD lesions are heterogeneous in terms of locality, morphology, and responsiveness to therapy (115). They range from atypical polyclonal B-cell expansions, which more precisely resemble polymorphic B-lymphocyte hyperplasia, to aggressive non-Hodgkin lymphomas that are classified histologically as high-grade immunoblastic lymphomas. The tumors are frequently multifocal, with the hyperplasia tending to be limited to lymph nodes, whereas the high-grade lymphomas frequently localize in the gastrointestinal tract, the central nervous system, or the grafted organ itself (110). Individual foci may be clonal or multiclonal, and separate lesions within the same patient may be of different clonal origin. PTLDs usually express the growth program (116). Consequently, the tumors will frequently regress if immunosuppression is reduced or withdrawn completely (117) or when EBV-specific CTLs of donor origin are infused into the patient (118). Cells expressing more restricted forms of latency also may be present (119), and a subset of cells within the tumor are replicating the virus (120).

The virus found in the tumors is usually of recipient origin, in the case of solid organ transplants, but of donor origin for bone marrow transplants. This suggests that replacement of the hematopoietic system during bone marrow transplantation includes transfer of the capacity to maintain a persistent EBV infection (121). This phenomenon has been interpreted as evidence that the B-cell system is solely responsible for the maintenance of persistent EBV infection.

It is general believed that PTLDs represent the uncontrolled expansion of B cells expressing the growth program because of reduced immunosurveillance by virus-specific CTLs. This is consistent with the oligoclonal origin of the tumors, the increased risk of tumor development with increasing immunosuppression, and the responsiveness of the tumors to reduced immunosuppression. This unchecked growth provides a proliferating population of cells at risk for secondary genetic alterations that cause the cells to become more malignant (122). This type of progression is consistent with the observation that later-arising variants of the tumors become resistant to reductions in immunosuppression and tend to be more malignant as they move from oligoclonal to clonal (115). At this point, the virus is probably no longer the driving force behind the cellular proliferation, and the tumors are more likely to spread to extranodal sites, suggesting that the B cells are highly abnormal and no longer subject to the restraints that keep proliferating B cells within lymph nodes.

The cellular and molecular mechanisms underling these processes are not well understood. The obvious explanation is that immunosuppression causes more infectious virus to be produced. This leads to an increased number of directly infected B cells expressing the growth program, as seen in IM. Unlike IM, however, the CTL response is suppressed so these cells grow out of control, resulting in PTLD. However, it cannot be that simple. Immunosuppression does lead to a dramatic increase in the levels of shed virus, yet prophylaxis with inhibitors of viral replication, such as acyclovir, have little or no effect in preventing PTLD (111,123). Even though the levels of virus-infected cells, in the blood of the immunosuppressed, increase on average about 50-fold (23), the overall regulation of the system of persistence remains intact, such that all of the infected cells in the blood are still resting, memory cells (23). Unlike IM, cells expressing the growth program are rare or absent. Furthermore, PTLDs are often oligoclonal, implying only a few independent events, not the wholesale infection and expansion of EBV-infected B cells seen in IM. Taken together, this suggests that PTLD arises from the rare aberrant behavior of extant latently infected cells rather than from the new infection of B cells.

PTLD does not arise from the latently infected naive B cells expressing the growth program in the nasopharyngeal lymphoepithelium. A limited study of PTLDs revealed that none expressed surface IgD, and most had switched immunoglobulin isotypes, indicating that they are memory cells (124). Because memory cells expressing the growth program are not derived by direct infection, they must come from the pool of latently infected memory cells expressing either the default or latency programs. Some event(s) must occur that pushes latently infected memory cells to turn on the growth program and proliferate. Normally such cells would be destroyed by CTLs, but they would be free to expand in the immunosuppressed. Presumably this transition is an atypical and therefore rare event, because it is not part of the normal biology of EBV persistence. This would explain why PTLD involves a limited number of clones, not wholesale expansion of EBV-infected B cells, and why the early lesions of PTLD are so susceptible to reduced immunosuppression.

The nature of the signal that causes this transition is unknown, but hints come from animal models. It has been observed that xenotransplantation of peripheral lymphocytes from EBV-positive donors into SCID mice results in a high incidence of EBV tumors that bear resemblance to PTLDs (10). This occurs in part because the memory CTLs do not become activated in the transplanted animal. Interestingly, it has been reported that tumor development requires the presence of Th cells (125). PTLDs are known to be heavily infiltrated with such T cells (126). The EBV-associated superantigen (SAG) (127) may be important here. SAGs are able to recruit and activate Th cells in an antigen-independent fashion. PTLDs and the SCID tumors may arise because Th cells interact with latently infected memory cells expressing the SAG. The Th cells may then deliver signals that cause the latently infected memory B cells to switch on the growth program inappropriately. These cells are free to

grow because the environment lacks the CTLs that usually destroy them.

Another feature that the SCID tumors have in common with PTLDs is the presence, within the tumor, of a heterogeneous mixture of B-cell types. This includes actively proliferating lymphoblastoid cells and more differentiated plasmacytoid cells that have stopped proliferating and may support viral replication (128).

Once oligoclonal expansion of cells expressing the growth program has been initiated, the more aggressive clones take over. More malignant, clonal PTLD has been associated with mutations of p53, c-*myc*, and bcl-6. Chromosomal abnormalities also have been reported, including rare cases in which the specific translocations associated with BL (see later) are observed. However, no consistent pattern of mutations or translocations has been found, suggesting either that a wide range of events can result in the malignant progression or that the key events await identification.

ACQUIRED IMMUNODEFICIENCY SYNDROME

Two types of EBV-associated lymphomas have been observed in human immunodeficiency virus (HIV)-infected individuals (93,129). The first tends to occur relatively early in the course of the disease and resembles BL (see later). From 30% to 40% of these tumors are EBV positive (130). The second type of lymphoma closely resembles those found in allograft patients and arises late in the disease, around 4 to 5 years after HIV infection. They are immunoblastic lymphomas and express the growth program (93). They probably arise by a mechanism similar to that of PTLDs, involving aberrant expression of the growth program in the absence of effective CTL immunosurveillance. Like PTLDs, they are morphologically heterogeneous. Based on histology and EBV TR analysis, they can be either polyclonal or monoclonal lesions, although clonal lesions are more frequent (129). An unusual feature of this disease is that the primary tumor often arises in the central nervous system (CNS) (131). This may be due to neurologic damage, caused by HIV infection, allowing EBV-infected cells access to the immunologically privileged CNS, where they can grow unchecked. B-cell CNS lymphoma in HIV-positive patients is invariably EBV positive and has a poor prognosis.

EBV-positive immunoblastic lymphoma in acquired immunodeficiency syndrome (AIDS) patients began to emerge as a major cause of death after successful prophylaxis for pneumocystis pneumonia was developed. This trend has subsequently been halted with the advent of the new HIV therapies (highly active antiretroviral therapy, HAART).

X-LINKED LYMPHOPROLIFERATIVE SYNDROME

X-linked immunoproliferative syndrome (XLP) is a rare X-linked immunodeficiency that results in lymphoma or fulminating IM, culminating in the death of afflicted boys within 1 month of primary EBV infection (11,132). On infection with EBV, the boys typically mount what has been described as a “dysregulated exuberant response” to the virus (133). EBV-infected B cells, $CD8^+$ T cells, and macrophages enter tissues throughout the body, causing massive tissue damage, particularly in the liver and the bone marrow, ultimately resulting in hepatitis and hypoplasia. A common feature of XLP is a pronounced virus-associated hemophagocytic syndrome (VAHS) (133), characterized by widely disseminated histiocytes filled with erythrocyte and nuclear debris. Death is usually associated early on with the accumulation of EBV-infected B cells expressing the growth program in tissues such as the liver (134) or subsequently by the widespread tissue damage of the VAHS. XLP has been fatal in 75% of cases. Surviving boys typically have severely disrupted immune systems, resulting in varying degrees of hypogammaglobulinemia. It has been reported that XLP-associated VAHS has been successfully treated with etoposide and cyclosporin A and cured with allogeneic stem cell transplantation (135).

The XLP gene itself [SH2D1A (136) or SAP (137)], encodes for a small signaling molecule of 128 amino acids that consists essentially of a single SH2 domain with a small C-terminal extension. Before the onset of IM, boys carrying mutations in the XLP gene are not obviously immunodeficient, although several boys have manifested XLP without detectable EBV infection (138). This implies that EBV precipitates an incipient predisposition. What this predisposition may be and how mutations in the XLP gene cause it are currently the focus of intense study. SAP (the XLP gene product) associates with the receptors SLAM (CDw150) (137) and 2B4 (139). SLAM is a self-ligand expressed on T and B lymphocytes and is an important regulator of lymphocyte interactions and activation. 2B4 is a NK-cell recognition receptor. SAP acts as an inhibitory molecule by binding to the cytoplasmic tails of these receptors and blocking their interaction with downstream signaling molecules. This has encouraged speculation that the XLP defect may interfere with NK activity or result in a failure to dampen T-cell responses, resulting in extensive tissue damage. Why these effects would be so specifically precipitated by EBV remains to be elucidated.

Hodgkin Disease

HD is characterized by the presence of unique mononuclear Hodgkin and large multinuclear Reed-Sternberg (HRS) tumor cells infiltrated and surrounded by large numbers of nontumor cells. The infiltrating cells are a mixture of T lymphocytes, plasma cells, and granulocyte that constitute the majority of the tumor mass, such that sometimes less than 1% of the tumor is actually HRS cells. HD is divided into four histologically distinct types based on the relative abundance of infiltrating cells: nodular-lymphocyte predominant (lp), nodular sclerosis (ns), mixed cellularity (mc), and lymphocyte depleted (ld) (140,141). Together HDns, HDmc, and HDly are referred to as classic HD, whereas HDlp is believed to be a distinct entity. HDns is the most common, followed by HDmc. HDld and HDlp are relatively rare. The incidence of HD peaks at around age 25 to 30 years, with HDns being the predominant form. The incidence then decreases till around age 45 years, when it again begins to increase, with HDmc contributing more significantly to the incidence (142).

HRS cells frequently express CD30, CD70, and CD25, but the cell-surface phenotype is, in general, quite variable and does not fit any particular lineage. T (CD2, CD4), B (CD19, CD20), and myeloid (CD15) lineage markers may all be expressed on occasion (143,144). However, the immunoglobulin genes from the tumor cells are hypermutated (145), suggesting that HD arises from a germinal center or postgerminal center (i.e., memory) B cell. Classic HD tumor cells have fixed mutations that often cripple the immunoglobulin gene and usually do not express the germinal center marker BCL-6 (146), consistent with a post–germinal center origin. The tumor cells of HDlp, however, show evidence of ongoing hypermutation (145) and express BCL-6 (146), suggesting that this subset of HD may arise directly from an active germinal center cell.

The consistent defect found in HD is the deregulation of the NF-kB system (147). NF-kB is a multipotent transcription factor that exists as a cytoplasmic trimer including the inhibitory molecule I-kB (148). NF-kB activity is tightly regulated through the expression and degradation of its I-kB component. Appropriate cell-surface signaling leads to the degradation of the IkB moiety and activation of the resulting NF-kB dimer. The active dimer translocates to the nucleus, where it is responsible for the activation of many lymphocyte genes associated with function and growth. HD has defects that lead to the accumulation of active NF-kB in the nucleus. In several cases, mutations within the I-kB itself have been observed, leading to loss of inhibitory function. Of the known targets of NF-kB, cytokine genes are common. This could explain the well-documented association of HD with the production of cytokines, including interleukin (IL)-1, IL-6, IL-9, IL-10, IL-13, and tumor necrosis factor (TNF), all of which modulate T- and B-cell functions in ways that could be critically important in tumor development (149). This could take the form of autocrine growth stimulation (IL-6), recruitment of Th cells (IL-13), or suppression of the immune response (IL-10).

HRS cells are not found in healthy lymphoid tissue, and it is unclear how they are formed. The only other condition in which these anomalous cells are consistently found is in the lymph nodes of acute IM patients (74). Patients with acute IM are at increased risk for developing HD later in life, and elevated antibody titers to EBV are a risk factor for HD development (4). Up to 50% of HD tumors are EBV positive, increasing to 100% in developing countries and pediatric cases (149). The virus is clonal by TR analysis. It is present in approximately 90% of HDmc and HDld, 30% of HDns, but rarely in HDlp. The tumor cells express the EBNA1, LMP1, and LMP2 latent proteins and the EBERs and BARTs. EBNA2 and the EBNA3s have not been detected (150,151,152,153 and 154). EBNA1 is transcribed from the Q promoter therefore HD displays the default transcription program found in normal germinal center and memory cells (Table 75.2). Although some level of systemic immunosuppression is a feature of HD, there is no evidence of immune dysfunction playing a role in the development of the tumor. It remains unclear, therefore, why the LMP1 and LMP2 molecules do not serve as targets of immunosurveillance during the early stages of tumor development.

A likely scenario for EBV-positive HD is that the severe disturbance in the regulation of EBV infection during IM (see later) leads to the massive expansion and inappropriate infection of cells with EBV. Cells expressing the growth program are destroyed by the immune system. Latently infected, activated memory cells and germinal center cells expressing the default program of EBNA1, LMP1, and LMP2 are not under such aggressive immunosurveillance, but normally exit the cell cycle and become resting memory cells. The increased numbers of these cells during IM, however, make them potential targets for cellular mutations. Any mutation causing constitutive expression of NF-kB in the nucleus would block differentiation and prevent the cells from exiting the cell cycle. As a result, the cells would continue to express the viral latent genes LMP1 and LMP2. Both deliver survival signals, and LMP1, in particular, activates NF-kB (155) and is oncogenic when constitutively expressed (41). Continued expression of these molecules would favor the survival and development of the tumor. However, a significant fraction of HD tumors are EBV negative, and no obvious differences have been observed between EBV positive and negative HDs to indicate that they might be distinct entities. Therefore HD can arise with or without the virus. It is likely that the virus is a predisposing but not essential event in HD development.

Burkitt Lymphoma

As discussed in the introduction, the association of EBV with BL is as old as the discovery of the virus itself (3). BL has been subdivided into two distinct but related entities, endemic (eBL) and sporadic (sBL). eBL is usually associated with EBV and is better characterized because it occurs at high incidence in certain geographic areas such as equatorial Africa and coastal New Guinea. sBL, as the name implies, is not geographically restricted, is less common than eBL, and is usually EBV

negative.

eBL has a strikingly early age at onset, with a peak median age of 6 to 8 years (156). It has a very high incidence of five to 10 per 10^5/year for the first 15 years of life in the high-risk areas. In these regions, it is not only the most common tumor of young children, but is more common than all other tumors combined (156). sBL appears somewhat later, median age 10 to 12 years (157), and occurs world wide at a much lower frequency, one to two per 10^6/year.

BL most frequently occurs in the jaw and abdomen (156,157). eBL tends to occur more frequently in the jaw, and sBL, in the abdomen. Jaw involvement is more common in younger patients, and abdominal involvement in the older. It is striking that the jaw-associated tumors arise during the time of peak dental development (158). These tumors frequently extend from the mandible to the orbit of the eye. BL rarely spreads to the peripheral lymph nodes, and it has been described as a tumor of mucosa-associated lymphoid tissue (158). This concept is consistent with the biology of EBV, which colonizes the mucosal lymphoid system. All BL tumors have a characteristic morphology consisting of a homogeneous population of “noncleaved” lymphoid cells with amphophilic cytoplasm and clear vacuoles. Interspersed throughout the tumor are histiocyte/macrophages, containing engulfed lymphoid cells, debris, and nuclei, that give rise to the typical “starry sky” appearance of the tumor (157). The morphology of the malignant cells bears a close resemblance to the cells found in the germinal centers of secondary lymphoid tissue. Another indication that the tumor arises from a germinal center is the surface phenotype of the cells. This includes the characteristic lineage markers of B cells (CD19, CD20, and surface Ig) together with specific markers of germinal center cells (CD10 and CD77) (32). Interestingly the immunoglobulin isotype is predominantly limited to IgM. IgD, a marker of naive B cells, is never found, and switched isotypes, such as IgG and IgA, also are uncommon.

As with HD, there is a consistent genetic lesion that defines BL and supersedes the presence or absence of EBV and the distinction between eBL and sBL (159,160). This lesion is the reciprocal translocation of the c-*myc* oncogene on chromosome 8 with one of the immunoglobulin gene loci, resulting in the deregulated activation of c-*myc* (161). In about 80% of BL, c-*myc* is translocated into the heavy-chain locus on chromosome 14 (the common translocation). Less frequently, the translocation is into the k or l light-chain loci (the variant translocations).

The contribution of EBV to BL remains enigmatic. The most compelling evidence for a role remains the relatively high frequency of tumors carrying the virus. Virtually every eBL (>90%) in the high incidence areas contains EBV, which is clonal by TR analysis (162). The frequency of EBV-positive sBL is lower, but still ranges from 15% to 25% in Europe and North America to as high as 50% in South America and 85% in North Africa. In healthy carriers of the virus, the level of virally infected cells varies from one to 100 per 10^6 B cells in all infected subsets, including germinal center cells (60). In IM and the heavily immunosuppressed, the number is higher, but never exceeds 1%. It is apparent therefore that a strong selection pressure favors EBV-positive over EBV-negative B cells becoming BL tumor cells.

The viral gene expression pattern in BL is unique, being limited to EBNA1 from the Q promoter, EBERs, and BARF0. Therefore the only latent protein expressed is EBNA1 (32). Unconfirmed reports have suggested roles for EBNA1 (163) and the EBERs (164) in BL development.

No latently infected normal cellular counterpart has been found that expresses the very restricted pattern of latent genes found in BL. Unlike PTLD and HD, however, the tumor cells of BL will survive and grow in tissue culture. Within 24 hours, a burst of viral replication is observed (3), followed by stable outgrowth of the tumor cells. The tumor origin of the cell lines is confirmed by retention of the diagnostic translocation. With time, the viral phenotype of the cells shifts, such that eventually all of the latent genes associated with the growth program are turned on (32,165). At the same time, the cellular phenotype changes from a germinal center cell to that of an activated lymphoblast. Conversely, if activated lymphoblasts expressing the growth program are molecularly manipulated to turn off EBNA2 while retaining c-*myc* expression, they express the BL/germinal-center phenotype (166). Taken together, these observations suggest that cells expressing the growth program and BL tumor cells are very closely related to each other, despite the apparently stark differences in cellular and viral phenotypes. Based on the model of EBV persistence presented earlier in this chapter (Fig. 75.2B), we must conclude that BL is a tumor of latently infected germinal-center cells that have switched from the growth program of the B-cell blast to the default program.

If EBV-positive BL is derived from latently infected germinal-center cells, what happens to the expression of LMP1 and LMP2? The lack of LMP1 and LMP2 may be characteristic of a specific state of germinal-center differentiation that has yet to be identified, or LMP1 and LMP2 expression may not be consistent with the long-term survival of the tumor cells, or immunosurveillance may select for their downregulation. These possibilities have been discussed at length previously because the only viral protein expressed, EBNA1, cannot be processed for presentation by MHC class I and therefore cannot be recognized by CTLs (88). This has led to a popular model of BL as a tumor derived from a normal counterpart that is the site of long-term persistence and that avoids immunosurveillance by only expressing EBNA1 (24,89,90). As described earlier, it is now clear that this model cannot be correct. EBV persistence involves the complex interplay of different latent transcription programs with stages of B-cell differentiation. Immunosurveillance does not select for a particular program, it just regulates the absolute level of persistent infection.

The cellular phenotype of the BL tumor also has been cited as evidence that the tumor has escaped immunosurveillance against EBV (167). BL tumor cells lack most of the cell-surface molecules, adhesion and accessory, necessary for cognate activation of CTLs. They have also severely downregulated peptide-processing systems and have a low turnover of HLA class I molecules, which makes them inefficient at presenting peptides for CTL recognition. However, it has been pointed out (24) that the same phenotype is seen with EBV-negative BL, which cannot have been under immunosurveillance for EBV expression. This phenotype is typical of a germinal center cell. Last, the immunosurveillance/selection hypothesis for loss of LMP1 and LMP2 is unlikely because all of the other EBV-associated tumors that arise in the immunocompetent express LMP1 and LMP2 (Table 75.2 and Table 75.3), yet manage to grow in the face of the immune response.

Tumor	Origin
Immunoblastic lymphoma—PTLD/AIDS	Peripheral memory B cell expressing the latency program switches to the growth program and grows because of immunosuppression
Hodgkin disease	Upregulated expression of NFκB in a latently infected activated memory or germinal center cell causes a differentiation block and constitutive expression of the default program
Burkitt lymphoma	Upregulated expression of c-myc in a latently infected germinal center cell causes a differentiation block and constitutive expression of the default program with subsequent downregulation of LMP1 and LMP2
Nasopharyngeal and gastric carcinomas	Fortuitous infection of nasopharyngeal mucosal epithelium by locally replicating EBV leads to expression of the default program that cannot be turned off by differentiation because the virus is in the wrong cell type
T/NK lymphoma	Fortuitous infection of T/NK cells in the mucosal lymphoepithelium by locally replicating EBV leads to expression of the default program that cannot be turned off by cellular differentiation because the virus is in the wrong cell type

EBV, Epstein-Barr virus; NK, natural killer.

TABLE 75.3. The Major EBV-Associated Tumors and Their Suggested Origins

Other risk factors for BL are not well understood. There is a remarkable concordance between the distribution of eBL and regions of hyper- and holoendemic *Plasmodium falciparum* malaria (2), although the reason for this is unknown. The immunosuppressive nature of malaria has been cited (165,168), but immunosuppressed individuals develop IL not BL (see earlier). An alternate explanation is that the high antigenic load of malaria results in chronic stimulation of the B-cell system, increasing the risk of genetic abnormalities (169). Support for this theory comes from mouse models in which prolonged stimulation with malarial antigen can generate tumors that carry the characteristic genetic translocation of BL (170). The true explanation may be a combination of the two, as suggested by the emergence of a third group at risk for BL, AIDS patients in the early stages of the disease (129). This may suggest that the predisposing factor for BL is heavy antigenic load, in this case from opportunistic infections, in the presence of limited immunosuppression.

In summary, BL is likely to be a tumor derived from a B cell (after prolonged stimulation with antigen) that becomes arrested in the germinal center because of deregulated expression of c-*myc*. As with HD, EBV is likely to be a predisposing but not essential component in the development of the tumor. Unlike HD, in which expression of LMP1 and LMP2 provides a possible role for EBV in tumor growth, there is no obvious candidate viral gene or genes to account for the role of EBV in the development of BL.

Epstein-Barr Virus and Epithelial Cells

THE ASSOCIATION OF EPSTEIN-BARR VIRUS WITH EPITHELIAL CELLS

It is broadly accepted that EBV is associated with epithelial cell diseases. EBV was found in NPC (4) soon after the discovery of the virus. With the advent of AIDS, an additional EBV-associated epithelial disease, oral hairy leukoplakia (171), was described, in which EBV replicates aggressively in epithelial cells of the tongue. It is important to stress, however, that there is currently no established body of evidence to show that EBV normally infects epithelial cells. Such an association was originally proposed based on a series of studies claiming to detect EBV in normal epithelial cells *in vivo* (172,173 and 174). As a result, EBV infection of lymphoepithelium became part of the accepted view of EBV persistence and is frequently cited in review articles and chapters on EBV [see, for example (24,38)]. Recent attempts to reproduce these findings, by several independent groups, have failed (73,175,176). It is now established that EBV is present in lymphoepithelium

and does replicate there; however, the cells harboring and replicating the virus are B cells, and no evidence of epithelial infection has been found.

NASOPHARYNGEAL CARCINOMA

NPC arises in the posterior nasopharynx. It is a tumor of the mucosal lymphoepithelium, where EBV replicates to be shed into saliva or infect B cells as part of ongoing viral persistence and spreading (Fig. 75.1; Table 75.2). How this normally B-lymphotropic virus gains access to the epithelial cells is not fully understood, but recent studies suggest that a subset of epithelial cell lines can be infected with the virus because of low-level expression of the viral receptor CD21 (177).

NPC is one of the most common tumors in the world, with incidence rates that vary markedly with geographic location (178,179,180 and 181). High-incidence areas congregate around southern China, but the disease also is common among Inuit Eskimos and certain ethnic groups in North and East Africa. In these areas, the incidence rates can be as high as one per 10^3 per year. Age-adjusted incidence rates are about 100 times lower in the rest of the world, although NPC remains the most common carcinoma of young adults. There is an extremely long latency period between the time of primary infection and tumor onset. Most individuals in high-risk areas become infected in the first year of life, but the tumor has a peak incidence only in middle age (40 to 60) years.

In the high-incidence areas, the tumors lack markers of keratinization. They consist of poorly differentiated or undifferentiated epithelial cells [World Health Organization (WHO) types II and III] and are often referred to as lymphoepitheliomas because of the extensive infiltration of the tumor by lymphocytes. EBV is present in virtually 100% of all undifferentiated or poorly differentiated NPCs irrespective of geographic location (182). In the low-incidence areas, the tumors are more often well differentiated (WHO type I), and EBV association is less consistent.

Undifferentiated NPC is the only EBV-associated tumor found in immunocompetent hosts in which the virus association is virtually absolute. Therefore, NPC is a prime candidate for EBV playing a requisite causative role in tumor development. The viral genomes in the tumors are clonal (46), and the tumor cells express the default program (183,184 and 185). EBNA1 from the Q promoter has been detected in all cases, whereas LMP1 is present in about 65% of cases. Currently LMP2 has only been detected by reverse transcription/polymerase chain reaction (RT-PCR). The EBER and BART (186) transcripts also are present. Considerable effort has been expended in trying to establish the existence of NPC-associated strains of the virus, but currently the strains identified represent geographic rather than pathogenic variants (187). NPC has a unique virologic aspect, which is its association with the appearance in the serum of IgA antibodies against antigens of the viral lytic cycle (EA and VCA; see earlier) (4). IgA antibodies are typically associated with secretory immunity at mucosal surfaces. The appearance of these antibodies is curious because it suggests ongoing replication of the virus in the mucosa-associated tumor, yet analysis of tumor biopsies reveals them to be tightly latent, with little evidence of viral replication (188). These antibodies arise well before the tumor is detectable. Screening for these antibodies has been extremely effective as a way to detect individuals at risk for tumor development.

NPC tumor cells have an unusual cellular phenotype. They express a number of B-cell lineage markers not typically associated with epithelial cells, including CD40, CD70, CD80, MHC class II, and bcl-2 (189). This phenotype, together with the marked T-cell infiltration of the tumors, raises the possibility that tumor growth is a consequence of an interaction between the T cells and the epithelial cells, with the epithelial cells behaving in some sense like B cells. The presence of LMP1 and LMP2 in the tumor cells could then be seen as providing rescue/survival signals, similar to the model for HD. Expression of LMP1 in immortalized epithelial cell lines is sufficient to convert them to a fully malignant phenotype (190); however, it is insufficient alone to cause malignant transformation of primary epithelial cells. Thus EBV is only one step in a multistep progression. Patients at risk for developing NPC do not have any known immunodeficiency; therefore the tumor, like HD, is able to develop while expressing LMP1 and LMP2 in the face of an intact immune response.

Currently very little is known about the other risk factors for the development of NPC. A genetic risk factor is strongly suggested by the close linkage of the disease to specific racial types, such as the southern Chinese population This association is sustained, although somewhat diminished, when they move to the United States, and decreases in the offspring of mixed marriages (180). Potential environmental risk factors also have been proposed, most prominently eating salted fish during infancy (191).

In summary, NPC is likely to be a tumor that arises through the fortuitous infection of epithelial cells of mucosal lymphoepithelium due to the continuous presence of infectious virus produced at that site. On entry into the epithelial cell, the virus switches on the default program. Normally the default program would eventually be turned off in a latently infected germinal center or memory B cell when they exit the cell cycle to become resting memory cells. Because the epithelial cell cannot do this, the default program will stay on, constitutively delivering survival signals through LMP1 and LMP2 that may allow further genetic lesions to be tolerated. Therefore, EBV is probably an essential step in a multistep process leading to the carcinoma.

OTHER CARCINOMAS

EBV is associated with rare NPC-like carcinomas at other anatomic sites such as salivary gland carcinoma (192) and gastric carcinoma (193). Like NPCs, these tumors are undifferentiated and consistently EBV positive. Recently EBV has been associated with a subset of metastatic breast cancer (16) and hepatocellular carcinoma (17). In both cases, the tumor cells were negative for the EBER transcripts. Detection of EBERs is routinely used for screening biologic material for the presence of EBV because of the sensitivity of the test. These associations remain to be established, but if true, raise the possibility that association of EBV with carcinoma will need to be reassessed with probes other than the EBERs.

T-Cell Lymphoma

EBV is a B-lymphotropic virus; however, there is compelling evidence that under certain conditions, the virus can gain access to T lymphocytes. Rare EBV-positive T cells have been observed in the tonsils of patients with acute IM (74), and EBV is occasionally found in rare T-cell malignancies (194). These malignancies include T/NK cell lymphomas and VAHS-associated T-cell lymphoma.

The T/NK lymphomas are extranodal of angiocentric type and are also known as lethal midline granulomas. The cellular phenotype of the tumors varies considerably, suggesting that they may arise from different stages of T-cell development. The NK-cell marker CD56 is frequently expressed, suggesting NK cells as a possible precursor of the tumor (195). The tumor cells are universally EBV positive and express the default program of latent genes: EBNA1 from the Q promoter, LMP1 and LMP2 with no EBNA2 expression (15). It is significant that these tumors arise in the region of the body where EBV replication and infection are ongoing, the nasopharyngeal lymphoepithelium. This makes it likely that fortuitous infection of T/NK cells may be the initiating event in the development of these tumors.

VAHS-associated T-cell lymphoma has already been discussed in the context of XLP. T-cell involvement can be of both CD4 and CD8 subsets. The disease can range from polyclonal lymphocytosis to full-blown malignant clonal lymphoma (196). The disease onset is associated with primary EBV infection, suggesting a relationship to the VAHS seen in XLP.

IMMUNOLOGIC INTERVENTION

Three kinds of immunologic intervention to EBV have been proposed and are in various stages of application.

Subunit Vaccine

A subunit vaccine has been developed based on the major viral glycoprotein gp350/220, the major target for neutralizing antibodies (77). Preparations of this glycoprotein in various formats have proved successful in preventing lymphoma development in cotton-top tamarins (197). However, these trials were essentially meaningless because the animals were not infected orally, the known route of virus transmission. Thus they were essentially *in vivo* tests of the already well-established *in vitro* observation that antibodies to these glycoproteins will neutralize virus infection (77). Several major hurdles exist to the successful development of such a vaccine:

1. It is unclear whether a vaccine can provide sufficient protection to prevent the entry of the virus through the mucosa to establish infection of B cells in the lymphoepithelium.
2. NPC develops despite the lifetime presence of strong neutralizing antibodies.
3. The lag period between EBV infection and NPC is four to six decades; therefore, each vaccine trial will take a lifetime to be completed.
4. EBV infection in the developing world occurs within the first year of life, and it may be difficult to establish protective immunity at such an early age.

Peptide Vaccines

The use of peptide vaccines has been proposed to boost cellular immunity (87). The difficulties of this are manyfold.

1. It is unclear how peptide-based immunization for CTL immunity might protect against primary infection. All forms of latency, including cells expressing the growth program, the major CTL target, are manifestly present during persistent infection (60) despite continued CTL surveillance.
2. Most of the tumors arise in immunocompetent hosts, where they grow despite an intact CTL response. It is unclear, therefore, whether boosting this response will make any difference.
3. Each epitope is restricted to a particular MHC class I allele; therefore the epitopes used must be different for each individual.

Adoptive Transfer

Adoptive transfer of cultured, EBV-specific CTLs has been successful in the treatment and prophylaxis of PTLD (118). This is an ideal setting for this type of treatment because the role of CTLs in controlling PTLD is well established, and it allows the control of the disease without risking loss of the graft. However, it should be regarded as a special case (i.e., a virus-driven tumor in an immunologically suppressed environment). It should not be interpreted as a proof of concept for the treatment of other tumors with adoptively transferred CTLs because most tumors arise in the immunocompetent and do not express strong viral antigens.

EBV AND DISEASE: A SUMMARY

From the preceding discussion, it is apparent that some generalizations can be made about the association of EBV with neoplastic disease.

1. The diseases fall into two groups, those that arise from normal infected counterparts (IL, HD, and BL) and those that arise from aberrant infection of cells that reside in or around the mucosal lymphoepithelium, the site of EBV replication, shedding, and infection (NPC and T/NK lymphoma) (Table 75.3).
2. All the tumors that arise in the immunocompetent express the default program (EBNA1 from Q, LMP1, and LMP2) (Table 75.2 and Table 75.3). This program is expressed in normal infected germinal center and activated memory cells in mucosal lymphoepithelium. Taken together, it is apparent that the virus always uses the default program when it needs to ensure the survival of a latently infected cell. This survival/rescue function is the virus-associated risk factor for tumor growth in the immunocompetent. These tumors are frequently heavily infiltrated with T lymphocytes, suggesting that tumor cell/T-cell interactions may be a recurring theme in their pathogenesis.
3. The default program is expressed by both normal and malignant cells in immunocompetent hosts but does not appear to be under aggressive or successful immunosurveillance. This program is important because of its role in viral persistence. Therefore it may have evolved to be poorly recognized by the immune response. When expressed in the appropriate B-cell subsets, it is not a pathogenic threat because the cells switch off the program when they exit the cell cycle. The inability to switch off the program because of differentiation block or expression in inappropriate cell types would support tumor progression while not exposing the tumor to aggressive immunosurveillance.
4. The tumors that arise in the immunosuppressed express the growth program, but they are not tumors of lymphoepithelial naive B cells. The growth program is a potentially life-threatening state of infection, but not when it occurs in the biologically relevant tissue, the lymphoepithelial naive B cells. These cells can exit the cell cycle by differentiation into resting memory cells. Expression of the growth program by other B cells probably occurs aberrantly at some low level. These cells are destroyed by CTLs.

Acknowledgment *I thank Elise Thorley-Lawson for her careful reading of the manuscript and many helpful suggestions in clarifying some of the more complex issues discussed here. This work is supported by Public Health Service grants AI 18757, and CA 65883.*

TUBERCULOSIS

John D. McKinney and Barry R. Bloom

Origins of Tuberculosis and Its Impact on Human Health

Mycobacterium tuberculosis, the bacterium that causes human tuberculosis, is one of humanity's most ancient and formidable microbial adversaries. *M. tuberculosis* likely evolved from a closely related species, *M. bovis*, which is today a common cause of tuberculosis in wild and domestic mammals and a significant cause of zoonotic infection in humans (1). The tubercle bacillus resembles gram-positive organisms, but has a unique, lipid-rich cell wall that renders it stainable only after acid treatment, hence the term “acid-fast bacillus” (AFB) (2). This same impermeable waxy cell wall is one of the properties that renders the organism resistant to antimicrobial therapy and to drying in the environment, and probably to the microbicidal activities of phagocytes. In contrast to most bacterial diseases, infection by *M. tuberculosis* is persistent, even lifelong, and previous infection does not prevent reinfection. Persistent infection can be latent (inactive) or chronic (active). Latently infected individuals do not transmit the disease, but they have a 5% to 10% lifetime risk of reactivating and progressing to full-blown, infectious tuberculosis (3,4). In the words of one epidemiologist, “Following infection, the incubation period of tuberculosis ranges from a few weeks to a lifetime” (5). Immune suppression [e.g., by human immunodeficiency virus (HIV) infection] increases the risk of reactivation (6), but reactivation also is common in individuals who are not obviously immune suppressed. For tuberculin skin test–positive individuals, the lifetime risk of developing disease is about 10%, but the risk increases to nearly 10% *per year* for individuals who are coinfected with HIV. In a clinical study of 294 consecutive autopsies of HIV-positive cadavers in Abidjan, Côte d'Ivoire, tuberculosis was considered the prime cause of death (and the single commonest cause) in 32% and a major contributor in another 15% to 25% (7). In sum, there are currently about 16 million individuals with tuberculosis worldwide, 8 million new cases each year, and if one combines deaths from tuberculosis and acquired immunodeficiency syndrome (AIDS) as a result of tuberculosis coinfection, about 3 million deaths each year (8). By far the greatest burden of tuberculosis is felt in developing regions—particularly sub-Saharan Africa, South-East Asia, and eastern Europe—where infection rates are highest, access to medical care is limited or nonexistent, and HIV coinfection is increasingly common.

On current estimates, the global reservoir of latent tuberculosis is nearly 2 billion infected individuals, approximately a third of the earth's human population (8). Given time, approximately 100 to 200 million of these latent infections will develop into active tuberculosis, yet access to effective treatment to prevent reactivation is limited. In persons who are otherwise healthy, reactivation tuberculosis tends to run an indolent, chronic course. In the years before chemotherapy, it was common for chronically infected individuals to be sputum positive (infectious) for years or even decades (9). Even today, it is not uncommon for an individual with chronic tuberculosis to transmit the infection to scores of contacts without even being aware of the disease (10,11). The insidious and persistent nature of tuberculosis poses special challenges to efforts to control and eliminate the disease in communities, and largely accounts for the overwhelming disease burden caused by tuberculosis today.

Vaccination

Vaccination is the most cost-effective intervention available for the prevention of many infectious diseases. Indeed, it is thanks only to concerted vaccination efforts that smallpox has been eliminated as a cause of human morbidity and mortality (12), soon to be followed by poliomyelitis (13). All the more tragic that despite the introduction of the bacille Calmette-Guérin (BCG) vaccine into global public health use in 1928, a truly effective vaccine against tuberculosis remains elusive. Because nine of ten infected individuals never develop tuberculosis, there is ample evidence for at least partial acquired immunity in tuberculosis. It should be possible, in theory, to develop an effective vaccine to protect everyone. Tuberculosis, however, poses special problems for the design and evaluation of vaccine candidates. The first problem is the inadequacy of acquired immunity in natural infection. Most microorganisms elicit protective responses that lead to the rapid and complete elimination of the pathogen, and the establishment of immunologic memory that protects against reinfection. Neither is true in tuberculosis: long-term persistence of *M. tuberculosis* in the tissues is the rule, relapse and reactivation are common, and first exposure does not prevent reinfection. Thus a vaccine against tuberculosis would have to engender immune responses that are qualitatively or quantitatively more effective than those engendered by natural infection. How to identify the necessary and sufficient immune responses to assure protection is a major scientific challenge. A second problem arises from the unusual difficulty that the persistent nature of tuberculosis infection poses to vaccine evaluation. Most adult cases of tuberculosis are thought to arise from the latent residuals of an infection acquired in childhood. Thus, to be effective, a vaccine given at birth would have to protect against reactivation of disease in adulthood. This lengthy time frame poses daunting operational challenges for the creation and evaluation of vaccine candidates.

The only vaccine against tuberculosis in use today is the live-attenuated BCG vaccine introduced by Calmette and Guérin in 1921. It is currently the most widely used vaccine in the world, with 104 million children receiving it each year. The BCG strain was originally derived from virulent *M. bovis* and attenuated by extensive serial passage *in vitro* between 1908 and 1919 (14). The genetic basis of BCG attenuation remains unclear (15). BCG possesses many of the attributes of an ideal vaccine (16,17). It has a long and excellent record of safety: the case fatality rate is just 60 per billion, which is much lower than that of many other live attenuated vaccines, notably the smallpox vaccine. It is inexpensive to manufacture, as low as U.S. $0.10 per immunization. It can be given at birth, or any time thereafter, and a single inoculation elicits long-lived specific immunity. It is relatively heat resistant and is therefore suitable for even the poorest countries not reached by the “cold chain” that many vaccines require. It generates a characteristic scar, which is useful for epidemiologic surveillance. It provides well-demonstrated protection against the most severe forms of childhood disease, including meningitis and disseminated miliary tuberculosis. But unfortunately, these major advantages are overshadowed by the most important consideration of all: despite its widespread application for decades, the efficacy of BCG vaccination against adult tuberculosis remains controversial. In large case-controlled and randomized placebo-controlled trials, the protection conferred by BCG has varied enormously in different areas, ranging from nil to nearly 80% in the British MRC trial (16,17). Most disturbingly, in the largest field trial yet conducted, involving more than 350,000 individuals in the Chingleput district of India, BCG vaccination was not protective in any adult age group (18). Many theories have been forwarded to explain the extreme variability of BCG efficacy, but convincing evidence is lacking. The fact that BCG is still so widely used, despite doubts about its efficacy, has ethical implications for the evaluation of any new vaccine candidate. To gain acceptance, a new vaccine will have to be compared not just with a placebo control, but with the current BCG vaccines. This requirement will obviously complicate clinical trials of vaccine candidates, as well as increasing costs substantially. Given the solid evidence that BCG protects against severe forms of childhood tuberculosis, it could be argued that a placebo control would be unethical. Addressing these operational and ethical issues will require every bit as much ingenuity as the actual design of a vaccine candidate.

Chemotherapy

The lack of a suitable vaccine has shifted the emphasis to chemotherapy as an important agent in tuberculosis control. Effective multidrug therapy for tuberculosis has been available since the introduction of isoniazid in 1952 (19,20). Unlike many bacterial infections, tuberculosis is always treated with multiple drugs, because monotherapy almost invariably leads to treatment failure and bacterial drug resistance. First-line drugs against tuberculosis are isoniazid, rifampicin, pyrazinamide, and ethambutol. Second-line drugs are streptomycin, kanamycin, ciprofloxacin, cycloserine, capreomycin, and *p*-aminosalicylate. Currently, the U.S. Centers for Disease Control in Atlanta recommends a “short-course” regimen administered in two stages (21). The first, “induction” phase consists of isoniazid, rifampin, pyrazinamide, and ethambutol or streptomycin, given every day for 2 months. This is followed by a “continuation” phase of isoniazid and rifampin given twice weekly for 4 to 7 months.

Second-line drugs are typically given only in cases of drug resistance, which requires much longer treatment—typically 2 years, if there is resistance to isoniazid and rifampin. Short-course chemotherapy can provide a lasting cure for 90% or more of patients who complete therapy (22), despite a significant risk of reinfection in high-incidence areas (23), but 90% cure rates are seldom achieved in practice. The problem is the human element. Without close supervision, most patients will fail to complete the 6 to 9 months of therapy needed to ensure a lasting cure (24,25,26,27 and 28). Patients who default on therapy put themselves at greatly increased risk of treatment failure, relapse, and evolution of bacterial drug resistance. Thus, largely because of treatment nonadherence, resistance to every one of the first- and second-line antituberculosis drugs has emerged in clinical settings. Although the exact numbers remain uncertain, the World Health Organization (WHO) estimates that perhaps 50 million individuals worldwide have been infected with multidrug-resistant (MDR) strains of *M. tuberculosis* resistant to both rifampin and isoniazid (29). Some of these MDR strains are untreatable except with second-line drug regimens, and these are often unavailable in developing countries.

Because treatment failure and emergent drug resistance are the result of incomplete chemotherapy, attention has focused on strategies to improve patient adherence. The WHO advocates a strategy of directly observed therapy short-course (DOTS), in which each dose of medications is directly administered by a health care or social worker (29,30). Although DOTS, administered properly, can improve cure rates substantially, there is a growing realization that DOTS alone, which has been implemented in only 20% of developing regions, is not going to rein in the global epidemic of tuberculosis (31). Given the treatment duration required and its impact on patient adherence, development of faster-acting regimens is a high priority. Here, as in so many other facets of tuberculosis, persistence is the problem. Conventional drugs are rapidly effective against tubercle bacilli growing *in vitro*, but they take much longer to kill bacilli *in vivo* (17,32). Why? Penetration of drugs into tuberculous lesions seems to be adequate (33), so it is unsurprising that *in vivo* killing is not accelerated by simply adding more drugs or increasing drug dosage (34,35), What, then, is the explanation for the observed tolerance of *in vivo* tubercle bacilli to antimicrobials? This area of tuberculosis research has received surprisingly little attention, considering its manifest importance. The answer presumably lies in the physiology and growth state of persistent bacteria *in vivo*, which differ from *in vitro* grown bacteria in many respects (36). Indeed, even the basic carbon metabolism of persistent tubercle bacilli is profoundly altered *in vivo* (37), and these variables could influence the effectiveness of antimicrobials.

Pathogenesis: The Natural History of a Tuberculosis Infection

Tuberculosis is transmitted when an individual with active pulmonary disease coughs, sneezes, expectorates, or speaks, releasing tremendous numbers of very small droplets containing tubercle bacilli. These droplets may remain suspended in the air for many hours before they are inhaled and enter the lung. Infection initiates with the implantation of an inspired particle in a pulmonary alveolus, deep within the terminal ramifications of the respiratory tree. Particles that settle higher in the tree are presumably removed by the mucociliary elevator. To reach the alveoli, particles must be very small, no more than ~5 µm in diameter; a particle of this size could not accommodate more than ten tubercle bacilli. Autopsy studies indicate that most cases of human tuberculosis originate from a single respired particle (38), so the infectious inoculum in tuberculosis is presumably quite small. Bacteria that reach the alveoli are immediately phagocytosed by resident alveolar macrophages (39), professional phagocytes that roam the lung, scavenging and destroying foreign invaders. The tubercle bacillus has evolved to parasitize this otherwise inhospitable cell, and replicates intracellularly within membrane-bound vacuoles. Eventually, the bacterial load overwhelms the parasitized macrophage, which lyses and releases the bacteria. These are ingested by fresh alveolar macrophages and monocyte-derived macrophages that emigrate from the bloodstream, and the cycle begins anew. As the bacillary population grows, a nascent lesion or “tubercle” forms, which remains focalized for perhaps 2 weeks, until the expanding tubercle breaches the parenchyma. Bacteria then escape from the primary lesion and are carried to the regional lymph nodes. There, bacterial replication continues, resulting in pronounced lymphadenopathy, which is characteristic of primary tuberculosis (Fig. 76.1A) but uncommon in postprimary (reactivation or reinfection) tuberculosis (Fig. 76.1C). The parenchymal lesion and associated lymph nodes are known as the “primary complex” or “Ghon complex” (40). From the draining nodes, tubercle bacilli are carried via the thoracic duct to the bloodstream, whence they are disseminated to the extrapulmonary organs and to previously unaffected regions of the lung. Within these metastatic foci, bacterial replication continues until a specific T-cell response emerges at 3 or more weeks after infection. Activation of infected macrophages by T-cell–derived cytokines, such as interferon-g (IFN-g) and tumor necrosis factor-a (TNF-a), curtails further replication of the bacteria. A mature granuloma forms, consisting of a central area of necrotic tissue with large numbers of extracellular bacilli, encompassed by a mantle of macrophages harboring intracellular bacilli (which typically include multinucleate Langhans giant cells), surrounded in turn by a sheath of lymphocytes, consisting mainly of $CD4^+$ and $CD8^+$ T cells (Fig. 76.2). The emergence of *Mycobacterium*-specific T-cell populations is signaled by the development of a delayed-type hypersensitivity (DTH) response to intradermally injected antigens of the tubercle bacillus (tuberculin).

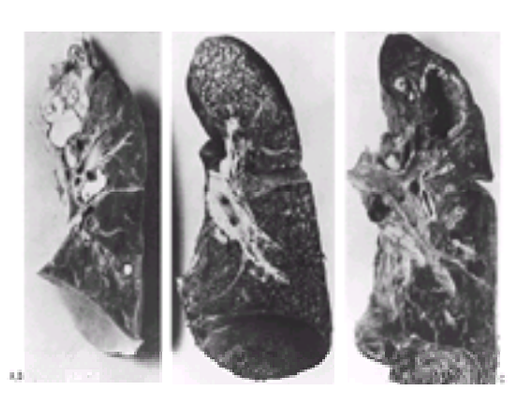

Figure 76.1. A: Primary tuberculosis in a 2-year-old child. A small primary lesion is located in the lower lobe of the left lung. The hilar lymph nodes are greatly enlarged and caseated. **B:** Miliary tuberculosis in an 8-year-old child. Numerous small “millet seed” lesions are evenly distributed throughout the lung. **C:** Postprimary tuberculosis in a 44-year-old woman. A large cavitary lesion is located in the upper lobe of the left lung. The hilar nodes show no appreciable involvement. Figure 76.2. Histopathology of a tubercle at low **(A)** and high **(B)** magnification. A central region of caseous necrosis (*CN*) is surrounded by a zone of epithelioid macrophages (*M*), some of which have fused to form multinucleate Langhans giant cells (*L*). The macrophage zone is encompassed by a mantle of lymphocytes, primarily $CD4^+$ and $CD8^+$ T cells. (Reprinted from Wheater PR, Burkitt HG, Stevens A, Lowe JS. *Basic histopathology: a colour atlas and text*. 2nd ed. Edinburgh: Churchill Livingstone, 1991:28, with permission.)

What happens next depends on the immune status of the host. Most (~90%) healthy individuals will hold the infection in check indefinitely. Indeed, autopsy studies suggest that most tuberculous lesions in humans are completely sterilized over time (41,42,43 and 44). Sterilization of lesions correlates with calcification of the necrotic tissue and walling off of the diseased tissue within a fibrous capsule. This is an important and frequently overlooked point: self-sterilization of pulmonary lesions is common in humans, but it has not been observed in animal models of infection, including mice, rabbits, guinea pigs, and monkeys. The explanation for this species difference is unknown, but it is a critical issue for those studying host mechanisms of defense against tuberculosis. A minority of individuals, ~ 5% of all infected persons, fail to control the infection and develop “primary progressive” tuberculosis within a year or 2 of infection (Fig. 76.1A). It is currently impossible to predict who will or will not develop primary progressive tuberculosis, but those at particular risk include infants, the elderly, and individuals with compromised immunity due to HIV infection, malnourishment, stress, steroid therapy, and genetic deficiencies affecting the immune system. In extreme cases, unrestricted dissemination and multiplication of bacilli can lead to “miliary” tuberculosis affecting the lungs and extrapulmonary organs (Fig. 76.1B). Miliary tuberculosis usually progresses rapidly to a fatal conclusion unless treated promptly. Another ~ 5% of all infected individuals will hold the infection in check initially, only to reactivate after years or even decades of clinical latency. Reactivation gives rise to “postprimary” tuberculosis, which tends to remain focalized at the site of reactivation, most commonly the apex of the lung (Fig. 76.1C). Erosion of a tuberculous lesion into an airway promotes bronchogenic spread of tubercle bacilli within the lungs and expulsion of bacilli from the lungs when the infected person coughs or expectorates. The appearance of bacilli in the sputum is correlated with infectivity, so the identification and aggressive treatment of

“sputum positive” patients is currently the most effective means of preventing transmission.

The pathogenesis of primary versus postprimary tuberculosis differs in several respects. In primary tuberculosis, lymphadenopathy is pronounced, the disease process tends to become generalized by lymphatic and hematogenous dissemination, and caseating necrosis of infected tissue is extensive, with rapid expansion of lesions and little reparative fibrosis (Fig. 76.1A). In postprimary tuberculosis, lymphadenopathy is slight or absent, the disease process tends to remain focalized at the site of reactivation, and lesions typically develop slowly, with extensive fibrosis (Fig. 76.1C). Cavitation, one of the most severe forms of pathology in tuberculosis, is common in postprimary tuberculosis, but rarer in primary tuberculosis. Tuberculous cavities are excavated by the expulsion of liquified necrotic tissue into an airway (Fig. 76.1C). Liquefaction of necrotic tissue, leading to cavity formation, has been linked to an excessive DTH response of the host (45). Cavitation is thus an important example of immunopathology in tuberculosis (46). One of the most striking differences between primary and postprimary tuberculosis is the localization of the disease process. Primary tuberculosis occurs anywhere in the lungs (Fig. 76.3A). In contrast, postprimary tuberculosis is largely restricted to the upper lung fields (Fig. 76.3B); cavities, in particular, are located almost exclusively in the upper lungs (Fig. 76.3C). These clinical observations suggest that acquired immunity is effective in the lower lung but not in the upper lung. Why is the upper lung so vulnerable to tuberculosis? Theories abound, but the problem remains mysterious and little studied (17,47). This neglect is perplexing: “The importance of the problem becomes evident when it is realized that, were it not for the failure of the apices to share equally in the increased resistance of the infra-apical portions, there would be almost no pulmonary tuberculosis in white adults” (48).

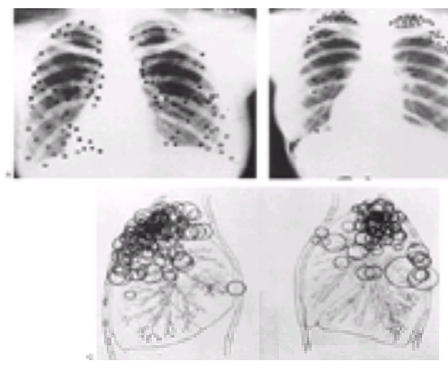

Figure 76.3. A: Location of calcified parenchymal foci (inactive) in 105 individuals with a single primary complex. Foci are randomly distributed throughout the lungs. **B:** Location of parenchymal lesions (active) in 55 individuals with postprimary tuberculosis. Lesions are largely restricted to the upper lung fields. (Reprinted from Medlar EM. The pathogenesis of minimal pulmonary tuberculosis: a study of 1,225 necropsies in cases of unexpected and sudden death. *Am Rev Tuberc* 1948;58:583–611, with permission.) **C:** Location of 268 cavities in 204 patients with postprimary tuberculosis. Cavities occur almost exclusively in the upper lungs. (Reprinted from Sweany HC, Cook CE, Kegerreis R. A study of the position of primary cavities in pulmonary tuberculosis. *Am Rev Tuberc* 1931;24:558–582, with permission.)

It must be emphasized that tuberculosis is a persistent infection. Latent infection can give rise to active disease years or decades after exposure. Established lesions may oscillate between periods of activity and dormancy. Chronic or sporadic disease is the rule, and chronically ill patients may transmit infection for many years, even in cases in which antimicrobials are readily available (Fig. 76.4). The unusual ability of *M. tuberculosis* to maintain this long-term relationship with the host, in which the host survives but continues to shed bacilli over long intervals, is the key to the unparalleled success of this tenacious pathogen.

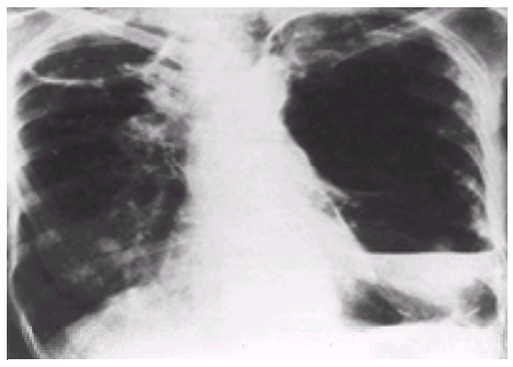

Figure 76.4. Chest radiograph of a 70-year-old woman obtained shortly before her death. “A white woman had cavitary tuberculosis of 41 years' duration. She had bilateral bronchiectasis, cavitation of the right upper lobe, a collapsed left lung, pleural effusion, and an induced left pneumothorax of 36 years' duration. She had received no antituberculous drugs for 28 years from the onset of her illness, and these drugs, when finally prescribed, were taken inadequately. Pleural effusion present for 28 years required aspiration. *Mycobacterium tuberculosis* recovered by culture of sputum was resistant to all antituberculous drugs except streptomycin [which the patient had never received due to allergy].” (Reprinted from Edwards WM, Cox RS Jr, Cooney JP, et al. Active pulmonary tuberculosis with cavitation of forty-one years' duration. *Am Rev Respir Dis* 1970;102:448–455, with permission.)

Animal Models of Tuberculosis and Genetics of Resistance

Among his many “firsts” in the realm of tuberculosis, Robert Koch (49) showed that *M. tuberculosis* will infect, replicate, and cause disease in an astonishing menagerie of mammalian species, including dogs, cats, guinea pigs, rabbits, and mice. Many of these species, with the addition of monkeys, are still used today as animal models of tuberculosis. There is no single ideal animal model of tuberculosis: each model offers unique advantages and shortcomings.

Guinea pigs are exquisitely susceptible to tuberculosis, and uniformly die within 6 to 9 months when infected by the respiratory route with even a minute (five to ten bacilli) inoculum (50,51 and 52). Genetic differences in resistance to tuberculosis were recognized in inbred guinea-pig strains long ago (53), but the biologic basis remains unknown. The reason for the extreme susceptibility of guinea pigs to tuberculosis also is not known, but it is not because of a failure of these animals to control bacillary replication. Indeed, a bacterial load that is fatal to a guinea pig is tolerated by a mouse, notwithstanding the fact that the latter animal has one tenth the body mass of the former (51,52,54). It is tempting to speculate that the difference may reflect the relative contribution of immunopathology to disease in different species, but this has not been proven. Whatever the reason, infected guinea pigs develop a fulminating form of disease that resembles primary tuberculosis in susceptible humans. This has made the guinea pig a species of choice for the evaluation of vaccines against tuberculosis (51). The underlying belief is that a vaccine capable of protecting the highly susceptible guinea pig would also stand the best chance of protecting susceptible humans (i.e., the relevant target for vaccination).

Of the nonprimate animal models of tuberculosis, the rabbit develops pathology that is most faithful to the disease in humans. The classic work of Max Lurie (55) with inbred rabbit lines that he created is the best-studied example of genetic variation in susceptibility to tuberculosis. This difference is manifest at the level of innate resistance to infection, in two ways. First, resistant rabbits require a much larger inoculum of tubercle bacilli to generate a single pulmonary lesion (Fig. 76.5A). Second, growth of the inhaled bacilli in the lungs is delayed by ~4 days in resistant as compared with susceptible animals (Fig. 76.5B). Although the rate of bacillary growth that ensues is similar in both strains, the bacterial load in resistant rabbits never closes the gap (Fig. 76.5B). The rabbit is relatively resistant to tuberculosis and develops a chronic form of the disease that resembles postprimary tuberculosis in humans, although without an intervening period of latency. The rabbit also is the only nonprimate species that routinely develops cavitary lesions, which makes it uniquely valuable for the study of this important pathologic process (46,56,57). Potentially as important is the observation that cavitary lesions are localized in the rabbit in a manner that is reminiscent of apical localization of cavities in humans. In the rabbit, however, cavities are localized to the dorsal/caudal region of the lung, which is the most elevated region of the lung in rabbits because of their four-footed posture and oversized haunches (58). The same localization of cavities to the dorsal/caudal lung fields also is seen in bovine tuberculosis (59). In a daring study that would no longer be ethically acceptable, it was shown that the localization of disease could be shifted by 180 degrees, to the apex of the lung, simply by forcing infected rabbits to stand upright (58). These observations suggest that the rabbit could be developed as a model to study the apical localization of postprimary tuberculosis, an important and sorely neglected problem in the field of tuberculosis research.

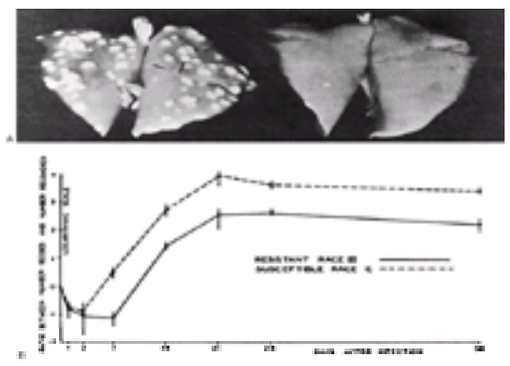

Figure 76.5. A: Lungs of Lurie's genetically susceptible (**left**) and resistant (**right**) rabbits 33 days after inhalation of ~10^4 colony-forming units of *Mycobacterium tuberculosis*. Formation of a single macroscopic tubercle required inhalation of 36 bacilli in susceptible rabbits versus 932 bacilli in resistant rabbits. **B:** Bacterial loads in the lungs of genetically susceptible and resistant rabbits after quantitative airborne infection with *M. tuberculosis*. Bacterial growth is delayed in the lungs of resistant rabbits as compared with susceptible rabbits. *(Reprinted from Lurie MB, Resistance to tuberculosis: experimental studies in native and acquired defensive mechanisms. Cambridge, MA: Harvard University Press, 1964:196* ***(A)****, 201* ***(B)****, with permission.)*

Although the guinea pig and rabbit offer unique advantages for the study of tuberculosis, their utility has been limited by the high cost of purchasing and maintaining these animals, the unavailability of inbred strains, the paucity of species-specific immunologic reagents, and the absence of technologies for generating transgenic and gene knock-out animals. All of these considerations have made the laboratory mouse by far the most intensively studied model of tuberculosis. On the debit side, the pathogenesis of tuberculosis in the mouse bears little resemblance to the disease in humans (60,61). Mice do not generally develop caseating necrosis or liquefaction, lesions do not calcify or encapsulate, and cavitation does not occur, even at late stages of disease. Indeed, mice are relatively resistant to tuberculosis and survive to nearly their normal life span after infection with a small number of bacilli by the respiratory route (62,63). Notwithstanding these shortcomings, the mouse has proven extremely useful for the elucidation of host defense mechanisms against tuberculosis, and many of the lessons first gleaned in the mouse model have been verified subsequently in clinical studies of human patients. A prominent example is the role of reactive nitrogen intermediates (RNI) in resistance to tuberculosis (64,65). It has been known for some time that inbred mouse strains display significant variability in their resistance to tuberculosis (66). In recent years, efforts have been initiated to identify the underlying genetic (67,68).

Monkeys and other nonhuman primates are potentially valuable models of tuberculosis, but their utility has been limited by high cost, ethical considerations, and the difficulty of maintaining colonies of these large animals over the long periods that studies of tuberculosis demand. Rhesus macaques are highly susceptible to tuberculosis and develop a fulminating form of disease (69), but recent studies suggest that cynomolgus monkeys develop a chronic disease that more closely resembles adult-type tuberculosis in humans (70). Importantly, anecdotal evidence suggests that some species of monkeys may provide a model of latent tuberculosis that closely resembles latency, reactivation, and postprimary tuberculosis in humans. This is an exciting possibility, because there is currently no small animal model of tuberculosis latency, and little prospect for the development of one. Over the years, several murine models of latent tuberculosis have been proposed, but these bear little resemblance to the clinical features of latent tuberculosis in humans (62,71,72,73,74,75,76 and 77). Given the importance of latent infection to the epidemiology and pathogenesis of tuberculosis in humans, the primate model is one avenue that deserves further exploration.

Among mammals, humans are uniquely resistant to tuberculosis. This presumably reflects the long history of coevolution of *Homo sapiens* and *M. tuberculosis*. As discussed earlier, ~90% of infected humans never progress to active disease, and humans are the only mammal known to be capable of self-sterilizing tuberculosis lesions. The mechanism(s) responsible for sterilizing immunity is not known, but the species restriction of this phenomenon suggests that animal models might not yield the answer. The native resistance of *H. sapiens* to tuberculosis is illustrated by a tragic accident, the Lubeck disaster of 1929/1930, in which 251 infants were accidentally inoculated with a virulent strain of *M. tuberculosis* rather than the BCG vaccine that was intended (78,79). Of the 251 vaccinees, 72 died of tuberculosis during the first year of life. Of the remainder, 175 infants who were still alive after 4 years of observation showed arrested macroscopic lesions by radiograph. Only four infants escaped infection or suppressed infection so efficiently that macroscopic pathology was not visible. Understandably, the appalling mortality suffered by the Lübeck victims riveted the public eye and cast a pall over the acceptance of the BCG vaccine that persisted for many years. It should not be overlooked, however, that the great majority (175 of 247) of the exposed infants overcame massive infection with highly virulent *M. tuberculosis*, despite having no previously acquired resistance. From this perspective, the Lübeck disaster provides a striking illustration of the native resistance of the human species to tuberculosis.

The question arises why some infected individuals develop disease while others do not. Although environmental factors undoubtedly influence susceptibility to tuberculosis (17), accumulating evidence also points to an important role for genetic factors in resistance to infectious diseases (80). Considering what a powerful selective force *M. tuberculosis* has exerted on certain human populations since antiquity, it seems plausible that races with a longer history of contact would have evolved greater resistance. Although definitive studies are lacking, a wealth of clinical observations suggest that individuals of African origin might be more susceptible than individuals of European origin (10,78,81,82,83,84,85 and 86). This partitioning of resistance along racial lines is historically plausible, because tuberculosis was not introduced to sub-Saharan Africa until the late nineteenth or early twentieth century. Similarly, tuberculosis did not reach remote regions of South America until the mid-twentieth century, but it is now devastating Amerindian populations there. Suggestively, a field study of the native Yanomami of the Brazilian Amazon basin found that in exposed adults, a fulminating form of the disease develops, resembling tuberculosis in children or immunocompromised patients, accompanied by unusually high rates of tuberculin anergy (87).

A role for heredity in human resistance also is supported by twin studies, which point to a greater concordance of risk for tuberculosis among monozygotic than dizygotic twins (88,89,90 and 91). Native resistance may be determined, in part, by the ability to present mycobacterial antigens to T cells. For example: several studies show disproportionate representation of certain human leukocyte antigen (HLA) haplotypes, particularly HLA-DR2, in severe cases of tuberculosis (92,93). In a recent study, mutations at the human *NRAMPI* locus were associated with increased risk of tuberculosis in West African populations (94), although this association was not seen elsewhere (95,96). This is an intriguing observation, because *NRAMPI* allelism in the mouse strongly influences resistance to a number of intracellular pathogens (97), albeit not including *M. tuberculosis* (98,99). Although *NRAMPI* itself might not influence human resistance to tuberculosis, it is possible that naturally occurring polymorphisms at *NRAMPI* are in linkage disequilibrium with a distinct but contiguous resistance locus (68). As discussed later, null mutations in specific cytokine receptors are associated with increased susceptibility to infection with *Mycobacterium* spp. (100,101,102 and 103).

Unraveling the genetic basis of resistance or susceptibility to tuberculosis is an important goal. Despite exposure to a potentially lethal microorganism, 90% of *M. tuberculosis*-infected individuals remain healthy indefinitely. Knowledge of the genetic basis of susceptibility might suggest strategies to extend some measure of protection to the less well endowed 10% who would otherwise develop active tuberculosis. Particularly for immunologists and physicians interested in vaccine development, “it is necessary, therefore, to attempt to gain as clear an understanding as possible concerning the nature, the mechanism and the effects of native resistance in this disease” (104).

Immunoprotection and Immunopathology

Tuberculosis is a classic example of an infectious disease in which the signs, symptoms, and pathology of disease are to a large extent attributed to the host response to the pathogen rather than to direct toxicity of the pathogen itself. But it is also clear that host immunity is essential for resistance to tuberculosis: immune deficient hosts (e.g., HIV-infected individuals) are unable to contain the replication of the tubercle bacillus and succumb more often and more rapidly to infection. A critical question that remains unanswered to this day is whether immunopathology is the unavoidable price paid for protection. It is by no means clear that protection and tissue damage are mediated by distinct mechanisms. Many host defense mechanisms (e.g., generation of reactive intermediates of oxygen and nitrogen) are potentially autotoxic. A multicellular organism can sacrifice some tissue in the struggle to oust a foreign invader, but this gambit is dangerous in the case of pathogens that are not rapidly eliminated. A persistent infection like tuberculosis may lead to gradual, progressive, and eventually overwhelming tissue destruction simply because the host, failing to drive the enemy from the field, cannot disengage. Conversely, there are hints that the “protective” and “tissue-damaging” host responses in tuberculosis may be dissociable to some extent (17,46). The rational design of new vaccines and immunotherapies against tuberculosis will hinge on a fuller understanding of the effector mechanisms responsible for protection and damage.

The “dual nature” of the host response to *M. tuberculosis* was first discovered by Robert Koch in the late nineteenth century, ultimately leading, ironically, to his discredit. Koch (49) won enduring fame when he announced his discovery of *M. tuberculosis*, the etiologic agent of tuberculosis, in a historic address to the Berlin Physiological Society on March 24, 1882. His subsequent reports of a remedy for the disease met with less happy results. In a series of seminal experiments, Koch demonstrated that intradermal injection of a crude extract of the tubercle bacillus (“Old Tuberculin”) into a tuberculous guinea pig caused necrosis and sloughing of the tissue both at the site of injection and at the site of previous infection. This rapid necrotic response, known since as the “Koch Phenomenon,” did not occur when Old Tuberculin was injected into uninfected animals. Encouraged by this demonstration of seemingly beneficial immune modulation, Koch announced to the Tenth International Congress of Medicine, meeting in Berlin in 1890, that he had discovered a substance capable of ameliorating tuberculosis (105,106). At that time, tuberculosis alone was responsible for perhaps one in seven of all deaths in Europe, and no effective treatment was available. So it is hardly surprising that Koch's

announcement of a “cure” met with overwhelming public enthusiasm and acclaim—initially. Unfortunately, clinical studies of tuberculin soon proved that it had little value as a remedy, and could even produce a fatal “tuberculo-shock” in severely affected patients. Although the clinical application of tuberculin was quickly abandoned, the insights painfully gleaned during tuberculo-therapy's vogue laid the foundation for the emerging field of cellular immunology. In modern parlance, the Koch Phenomenon is the first recognized example of the DTH response, which is still considered the touchstone for studies in cell-mediated immunity.

Host Defense

THE ROLE OF THE MACROPHAGE

Koch's (49) histopathologic studies of infected tissues from humans and experimental animals demonstrated that tubercle bacilli growing *in vivo* were localized within large mononuclear cells, which we now know to be macrophages. The recognition that resistance to tuberculosis could be expressed at the level of the infected macrophage came many years later, when Lurie (55) demonstrated that tubercle bacilli grew luxuriantly in macrophages from normal rabbits but were inhibited within macrophages from tuberculous animals. Inhibition was not seen in tissue-culture experiments with highly purified macrophages, whether derived from normal or infected animals, suggesting the involvement of some additional, unrecognized factor. Rich (78) noted the abundance of lymphocytes at the perimeter of tuberculous lesions and suggested that they might play a role in acquired immunity, but he lacked the means to determine their function. In a classic experiment, Chase (107) demonstrated that cutaneous hypersensitivity to tuberculin could be transferred to naive animals by cells (but not serum) derived from the lymphoid organs of tuberculous animals. Mackaness and Blanden (108) demonstrated that antigen-stimulated lymphocytes (now known to be T cells) could trigger macrophages to express nonspecific antimicrobial activity. Evidence that T cells could mediate delayed hypersensitivity responses by secreting diffusible factors (cytokines) was reported independently by two groups in 1966 (109,110). Twenty years later, IFN-g and TNF-a were identified as the key cytokines mediating activation of macrophages to inhibit the intracellular growth of *M. tuberculosis* (111,112).

In the tissues of infected animals and humans, tubercle bacilli are found almost exclusively within cells of the mononuclear phagocyte lineage. This cellular tropism is a puzzle, because tubercle bacilli are highly invasive *in vitro* and will productively infect many cell types. A number of different cell-surface molecules have been implicated in the invasion of macrophages by mycobacteria, including complement receptors, mannose receptor, CD14 [the receptor for lipopolysaccharide (LPS)/LPS-binding protein], Fc receptors, and scavenger receptors (113). Tubercle bacilli that have invaded a resting (unactivated) macrophage replicate exponentially within the confines of a tightly apposed vacuolar membrane. The vacuole apparently divides in synchrony with the bacteria, so it is uncommon to find a vacuole containing more than one bacterium, even in a heavily infected cell (114). Normally, vacuoles containing bacteria or other internalized particles undergo maturation, acidification to pH 4.5 to 5.0, and fusion with lysosomes, where the internalized material is digested. *M. tuberculosis* enters early endosomes and somehow inhibits their maturation, perhaps by inhibition of calcium signaling after phagocytosis (115), perhaps by retention of the actin-binding host coronin “TACO” on the *Mycobacterium*-containing phagosome (116), which is correlated with invasion through cholesterol-rich plasma membrane domains (117). Whatever the precise mechanism, vacuoles containing tubercle bacilli fail to mature, acidify only partially (to pH ~6.5), remain in contact with the recycling endosome network, and fail to fuse with lysosomes (118,119 and 120). The block to phagosome maturation is important for the intracellular survival and replication of *M. tuberculosis* (115,121), presumably because it provides the organism with a more hospitable environment. The *Mycobacterium*-induced block to phagosome/lysosome fusion is reversed by activation of the macrophage with IFN-g and LPS (122,123). By subjecting the bacteria to the harsh environment of the fused phagolysosome, “induced maturation” of *Mycobacterium*-containing vacuoles might play an important role in host defense against tuberculosis.

Murine macrophages activated with IFN-g and TNF-a produce superoxide and other reactive oxygen intermediates (ROIs), as well as nitric oxide and other reactive nitrogen intermediates (RNIs), which inhibit intracellular mycobacteria (124). Early in the course of infection, IFN-g may be provided by natural killer (NK) cells and gd T cells. At later stages of infection, *Mycobacterium*-specific T cells are presumably the most important sources of this key cytokine. Activated macrophages are professional antigen-presenting cells that express both major histocompatibility complex (MHC) class I and II for antigen presentation to $CD4^+$ and $CD8^+$ memory T cells, respectively. Unlike dendritic cells, however, macrophages do not express the costimulatory molecules required to activate naive T cells and initiate an adaptive response (125). Activation and maturation of dendritic cells after uptake of *M. tuberculosis* (126) is therefore likely to play a key role in priming the protective response to infection (127,128).

The importance of both $CD4^+$ and $CD8^+$ T-cell subsets for resistance to tuberculosis is underscored by the extreme susceptibility of knock-out mice that are selectively deficient for either class of T cells (129,130 and 131). In humans, an essential role for $CD4^+$ T cells is suggested by the frequency and severity of tuberculosis in HIV-infected individuals (6). A role for $CD8^+$ T cells in human infection also is likely, as discussed later, but direct evidence is lacking.

Infected macrophages secrete the proinflammatory cytokines TNF-a and interleukin-12 (IL-12). Production of TNF-a and IL-12 is triggered by the interaction of mycobacterial cell-wall components with Toll-like receptors (TLRs) (132,133), which are pattern-recognition proteins displayed on the surface of monocytes and macrophages (134). The IL-12 released from infected macrophages triggers IFN-g secretion by NK cells and T cells (135,136 and 137). Conversely, IFN-g and TNF-a enhance IL-12 release by infected macrophages, generating a potential positive-feedback loop for macrophage activation. Infected macrophages themselves are copious secreters of TNF-a, and are likely responsible for much of the accumulation of TNF-a in tuberculosis lesions (138,139 and 140). Chronic overproduction of TNF-a is thought to be responsible for many of the signs and symptoms of advanced tuberculosis, such as tissue necrosis, fever, malaise, wasting, fatigue, and night sweats (141). Thus TNF-a is thought to play a dual role in tuberculosis, mediating both protection and immunopathology. The importance of the cytokine network in resistance to tuberculosis has been demonstrated in the mouse model by infection of gene knock-out mice lacking IFN-g (142,143), TNF-a (144), TNF-a receptor p55 (145), or IL-12 (146). All of these mutations cause exquisite susceptibility to infection with *M. tuberculosis*. In humans, naturally occurring mutations in the genes encoding the IL-12 receptor (102,103) or IFN-g receptor (100,101) are associated with increased susceptibility to infections by *Mycobacterium* spp. (80).

Tubercle bacilli growing *in vitro* and in cultured macrophages are relatively resistant to ROIs but susceptible to RNIs (124). The contribution of these two antimicrobial mechanisms of macrophages to host defense is underscored by studies with gene-disrupted mice (65). Mice defective in the phagocyte oxidase responsible for ROI production ($phox^{-/-}$ mice) show moderately increased replication of *M. tuberculosis* at early stages of infection, but eventually stabilize bacterial numbers (147,148). In contrast, mice defective in the nitric oxide synthase responsible for IFN-g–inducible RNI output ($NOS2^{-/-}$ mice) are unable to curtail replication of *M. tuberculosis* and die rapidly (147,149). The “nonredundancy” of these two macrophage effector mechanisms in host defense is clear when one compares the response to different pathogens (65). For example, although $NOS2^{-/-}$ mice are more susceptible than $phox^{-/-}$ mice to infection with *M. tuberculosis*, the opposite is true of mice infected with another intravacuolar bacterium, *Salmonella typhimurium* (150). Why this difference? One possibility is that tubercle bacilli have evolved effective mechanisms to evade or counterattack by ROIs, but are less adept at dealing with RNIs. Several mechanisms have been identified that could contribute to the ROI resistance of tubercle bacilli: (a) invasion of macrophages via the CR1 or CR3 complement receptors does not trigger the oxidative burst (which might be true of other receptors, as well); (b) mycobacteria shed lipoarabinomannan (LAM) and sulfatides that inhibit ROI production; (c) LAM also is an efficient scavenger of ROIs; (d) mycobacteria produce superoxide dismutase and catalase, enzymes that detoxify ROIs. Mechanisms of resistance to RNIs are less well defined, but are likely to exist, because mycobacteria are capable of persistence *in vivo* despite exposure to potentially lethal RNIs (64,65,151). The role of RNIs in human tuberculosis remains controversial, in part because conditions that will reproducibly trigger NO release from human macrophages have been difficult to establish. Direct quantification of NO production in human lung granulomas also poses a technical challenge. Definitive proof may await the identification of human genetic deficiencies in NOS2 (64,65,152).

A ROLE FOR CYTOTOXIC T CELLS?

RNI and, to a lesser extent, ROI production by activated macrophages is currently the only genetically proven mechanism of defense against tuberculosis. Other mechanisms undoubtedly exist, because IFN-$g^{-/-}$ mice are notably more susceptible to tuberculosis than are $NOS2^{-/-}$, $phox^{-/-}$, or $NOS2^{-/-}$ $phox^{-/-}$ mice (64; J. McKinney, unpublished observations). As suggested earlier, IFN-g–induced maturation and lysosome fusion of bacteria-containing vacuoles might contribute to host defense, although this remains to be proven. All of the mechanisms described so far are mediated by the parasitized macrophage itself. However, recent studies suggest that cytotoxic T lymphocytes (CTLs) also may provide a “lethal weapon” against *M. tuberculosis*. Lysis of infected human macrophages by $CD8^+$ CTLs is correlated with a significant reduction (~50%) in the viability of the intracellular bacteria (153). Antigen recognition by these $CD8^+$ T cells is restricted by CD1, a family of nonclassic MHC I–like molecules that present nonpeptide antigens including mycobacterial lipids (154). Whereas CD1-restricted double-negative T cells ($CD4^-$ $CD8^-$) are capable of lysing infected human macrophages *in vitro*, only those expressing surface CD8 are capable of killing the intracellular tubercle bacilli. Killing by CD1-restricted $CD8^+$ T cells is apparently mediated by granulysin, a component of the cytotoxic granules of T cells and NK cells (155). Granulysin is directly toxic to *M. tuberculosis* and other microbes, including gram-positive and gram-negative bacteria, fungi, and protozoa (156). Access of granulysin to intracellular mycobacteria is dependent on the pore-forming molecule perforin, which also is a component of cytotoxic granules. Tubercle bacilli exposed to granulysin develop striking surface protrusions and blebs, suggesting that disruption of cell-wall integrity is the mechanism of killing. Genetic confirmation of the role of granulysin in host defense against tuberculosis awaits the identification of a mouse homolog and, if possible, specific human genetic deficiencies. In this context, it is noteworthy that perforin knock-out mice show normal resistance to tuberculosis during the early, acute phase of infection (157,158), although they may be less able to contain bacillary growth during later, chronic stages of disease (156,159). It also is relevant that CD1 molecules capable of presenting mycobacterial lipid antigens have not been identified in the mouse (154).

A ROLE FOR B CELLS?

Serum therapy for infectious diseases became the vogue after the discovery by von Behring and Kitasato in 1890 (160) that immune serum could transfer protection against tetanus and diphtheria. Innumerable claims were made that serum from immunized animals or healthy tuberculin-positive humans could transfer protection in

animal models and in human clinical trials. Little of this evidence would stand up to the more critical standards of contemporary science. It is certainly true that infection with *M. tuberculosis* elicits an antibody response, predominantly against lipid and carbohydrate antigens found in the cell wall. However, human genetic deficiencies resulting in agammaglobulinemia have not been associated with increased susceptibility to mycobacterial infections. In the mouse model, μ chain (immunoglobulin M) knock-out mice, which are B-cell deficient and do not produce antibodies of any class, were reported to be more susceptible to tuberculosis (161); others, however, disagreed (162). In another study, opsonization of tubercle bacilli with specific monoclonal antibodies (mAbs) prolonged survival of mice infected by the respiratory route, although there was no effect on bacillary numbers in the lungs (163).

Even if antibodies do not make a significant contribution to naturally acquired immunity to tuberculosis, a question that merits consideration is whether the B-cell response could be harnessed to provide protection (for example, by vaccination) (160). This issue has been largely ignored by immunologists. Because human infection is initiated by the implantation of small numbers of tubercle bacilli in the airways, it is possible that the presence of mucosal antibodies in the respiratory tree could prevent or diminish infection of the lung, or ameliorate the early stages of infection. For example, mucosal antibodies could promote the expulsion of inhaled bacilli from the lungs or alter their trafficking in the bronchoalveolar epithelium or associated lymphoid tissue. The question is not whether humoral immunity is important for the resolution of natural infection: the weight of evidence suggests that it is not. Rather, the question is whether humoral immunity could be manipulated to provide a level of protection beyond that engendered by natural infection. This issue merits greater attention and study, particularly by those interested in development of vaccines against tuberculosis.

Development of New Vaccines

In the past several years, more than 100 tuberculosis vaccine candidates and antigens have been tested in small animal models. The nature of the different vaccine concepts has been discussed elsewhere (164,165 and 166) and is summarized briefly here:

Subunit vaccines, consisting of protein, lipid, and carbohydrate antigens in various formulations, have the potential to be specific, defined, and safe. Their disadvantage is limited persistence *in vivo* and whether they can induce lasting cellular immunity.

DNA vaccines encoding a variety of *M. tuberculosis* antigens have shown significant protection in mice, in some cases rivaling the protection conferred by BCG. Advantages include ease of production, low cost, and the ability to induce long-lasting cellular immune responses. Current approaches to increasing immunogenicity include delivery of the DNA in adjuvants and altering the nucleotide composition of the vectors. Duration of protection, safety, and heterogeneity of responses remain important issues. In a recent study, tuberculosis relapse after chemotherapy of infected mice was prevented by postexposure vaccination with a DNA vaccine encoding the 65-kd antigen; significantly, this effect was not obtained with BCG (167). These observations suggest the exciting possibility that DNA vaccination might be useful in preventing reactivation of latent tuberculosis—an enormous reservoir of contagion for which no effective or practicable intervention currently exists.

Microbial vectors other than mycobacteria, including attenuated strains of *Salmonella* and vaccinia expressing mycobacterial antigens, are being tested in animal models. The former has the potential to induce mucosal immunity, and the latter, to induce CTLs.

Live attenuated mycobacteria vaccines are under development, including nonpathogenic species (*M. vaccae* and *M. habana*) and recombinant BCG expressing immunodominant antigens of *M. tuberculosis*. It is noteworthy that the MRC vaccine trial in the United Kingdom demonstrated *M. microti* to be as protective as BCG (about 80% in both cases), even though tuberculin skin test conversion occurred in only a small fraction of individuals vaccinated with *M. microti* (168). In addition, attenuated strains of *M. tuberculosis*, including auxotrophic mutants and other mutants defective for virulence in mice, are being evaluated for safety and immunogenicity. An important point in the era of widespread AIDS is that auxotrophic mutants of *M. tuberculosis* have been shown to be as protective as BCG in immune-competent mice, yet safe in immune-deficient mice, in which BCG infection is lethal (169). Live-attenuated *M. tuberculosis* vaccines have the advantage of expressing a wide range of relevant antigens, as well as the persistence and adjuvanticity associated with mycobacteria, but their safety in immune-deficient individuals, their potential toxicity, and the persistence of the responses they engender have yet to be evaluated.

Future Priorities

The massive burden of tuberculosis has not been addressed by appropriate mobilization of scientific or political resources, although encouraging efforts in this arena have been initiated recently. Although almost every aspect of the pathogenesis of tuberculosis and the immunologic mechanisms required for protection versus tissue damage will require further study, we outline several priorities that we believe to be of greatest urgency.

Development of new and faster-acting drugs, particularly targeting persistent infection, whether active or latent. With the complete genome of two isolates of *M. tuberculosis* now complete (170), and with genome sequencing of nonpathogenic mycobacteria including BCG under way, a range of unique targets for drug development will shortly become available. Identification of potential drug targets will be accelerated by the advent of new technologies for identifying genes that are selectively expressed *in vivo*, such as DNA microarrays (171), “selective capture of transcribed sequences” (SCOTS) (172), and “molecular beacons” (173). Novel drugs that could shorten the effective duration of therapy from the current 6 to 9 months head the list of priorities for drug development, because patient noncompliance with lengthy chemotherapy regimens is currently the most formidable obstacle to successful treatment. New strategies for chemoprophylaxis of latent infections are also urgently needed. Current chemoprophylaxis regimens, although effective, are not used because the duration of treatment required (3 to 6 months) is too difficult and costly to implement on a large scale. Development of a simple, effective, and affordable chemoprophylaxis regimen that could be administered to all individuals who are skin-test positive (i.e., presumably harboring latent infection) would have an enormous impact on future case rates. In the absence of such an intervention, some 200 million new cases of reactivation tuberculosis can be expected to arise among the estimated 2 billion individuals who currently harbor latent infection. Indeed, an effective and widely implemented intervention against latent infection is the only hope for truncating the centuries-long intrinsic epidemic cycle of tuberculosis (Fig. 76.6).

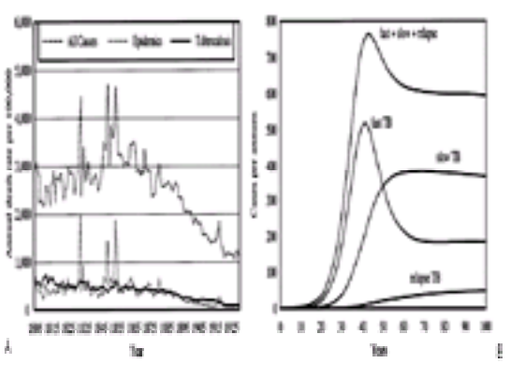

Figure 76.6. Tuberculosis epidemics have slow intrinsic dynamics. **A:** Death rates, New York City, 1804 to 1930, due to all causes, epidemic diseases, and tuberculosis. The urban death rate from tuberculosis was constant at ~500 per 100,000 throughout most of the nineteenth century. Incidence began to decline around 1885, concomitant with a steep decrease in overall deaths rates attributed to advances in public health. (Redrawn from Condran GA. Changing patterns of epidemic disease in New York City. In: Rosner D, ed. *Hives of sickness: public health and epidemics in New York City.* New Brunswick, NJ: Rutgers University Press, 1995:27–41, with permission.) **B:** Numeric simulation of a tuberculosis epidemic initiated by entering one infectious case at time zero into a susceptible population of 200,000. The simulation illustrates the relative contribution of three types of disease to the overall incidence: fast (progressive primary), slow (postprimary), and relapse tuberculosis. A fourth type, exogenous reinfection, is not included in the model, but would presumably increase the peak level and duration of the epidemic. (Redrawn from Blower SM, McLean AR, Porco TC, et al. The intrinsic transmission dynamics of tuberculosis epidemics. *Nature Med* 1995;1:815–821, with permission.)

Development of immunologic correlates and surrogate markers of protection will be essential for the evaluation of vaccine candidates. It is no longer conceivable that multiple vaccine candidates will be evaluated in large prospective, randomized phase III clinical trials, with disease prevention as the sole end point. If the immunologic responses required for protection were known, multiple vaccine candidates and immunization protocols could be evaluated and optimized in relatively small phase II clinical trials. The validity of these immunologic correlates as “surrogate markers” for protection could then be evaluated in phase III efficacy trials. The use of validated surrogate markers as end points of immunization would permit optimization and ranking of multiple vaccine candidates in small, short-term clinical studies without the necessity of carrying out large, multiyear efficacy trials.

Development of a rapid, sensitive, specific, and inexpensive diagnostic test would be of enormous value in permitting early treatment and prevention of transmission. Currently, diagnosis of pulmonary tuberculosis in developing countries is by clinical presentation and microscopy of sputum stained for AFB. These methods are neither sensitive nor specific, nor do they detect bacterial drug resistance, which is increasingly prevalent. In industrialized countries, sputum cultures can

increase sensitivity and specificity, and permit the identification of drug resistance, but diagnosis can be delayed by many weeks and requires relatively specialized equipment and technical skills. A simple, rapid, and inexpensive serologic or molecular test for tuberculosis would do much to ensure that everyone received prompt and appropriate treatment; a diagnostic that detected drug resistance also would contribute enormously to preventing the spread and further evolution of drug-resistant strains.

Development of international collaborations for research and clinical trials would ensure that progress is made in the most efficient and equitable manner possible. The vast majority of tuberculosis patients reside in the developing world, whereas the vast majority of tuberculosis research is carried out in the industrialized world. Evaluation of new drugs and vaccines will require international collaborative partnerships aimed at building infrastructure for basic and clinical research in the countries that are hardest hit, as well as establishing epidemiologic field sites where phase I to IV clinical trials can be carried out effectively. This will require investments in capacity building, international travel, workshops, and conferences, and a commitment to long-term international collaborations. Most important, these collaborations must involve technology transfer and appropriate training of visiting scientists to ensure that the necessary skills are represented "on site."

Addressing market barriers to development of drugs and vaccines. The fact that tuberculosis has become predominantly a Third World disease is a powerful disincentive to the industrialized world to invest in development of drugs and vaccines against tuberculosis. Without collaborations between the public and private sectors, it is difficult to see how new interventions will be developed. Two models have been suggested. The first, a "pull" mechanism, would provide assurance to companies that there would be public-sector financing for purchase and distribution of an effective drug or vaccine, if one were developed. Assurance of a market with the opportunity for at least a small profit is critical for a company to invest in research and development for a new intervention, because the cost of bringing a new drug to market is estimated to be US$ 350 to 500 million. The second mechanism would "push" the development of new interventions by public sector investment in research and development; this approach is of particular relevance for small biotechnology companies that might otherwise not have sufficient resources for such an effort. Either approach would require close collaboration between government research and overseas development agencies, pharmaceutical and vaccine companies, and other private sector concerns, such as foundations and nongovernmental organizations (NGOs). An inspiring recent example of this model is the Global Alliance for Vaccines and Immunization (GAVI), which was established as a result of a major donation from the Bill and Melinda Gates Foundation. The success of this and similar enterprises will hinge on the development of true and equitable partnerships between the industrialized world and the scientists and leaders of the developing world.

LEPROSY

Robert L. Modlin, M.D.

Leprosy provides an extraordinary model for investigating the regulation of immune responses to microbial pathogens. First, the disease still poses a significant health and economic burden on developing countries. Second, because leprosy affects primarily the skin, sampling of the site of disease activity is readily feasible. Finally, and perhaps most important, leprosy presents a clinical/immunologic spectrum, providing an opportunity to study resistance versus susceptibility to widespread infection. By studying the immune response in leprosy, it is possible to gain insights into mechanisms of immunoregulation in humans.

At one end of the leprosy spectrum, patients with tuberculoid leprosy typify the resistant response that restricts the growth of the pathogen (174). The number of lesions is few and bacilli rare, although tissue and nerve damage are frequent. At the opposite end of this spectrum, patients with lepromatous leprosy represent susceptibility to disseminated infection. Skin lesions are numerous, and growth of the pathogen is unabated. These clinical presentations correlate with the level of cell-mediated immunity against *Mycobacterium leprae*. The standard measure of cell-mediated immunity to the pathogen is the Mitsuda reaction or lepromin skin test, a 3-week response to intradermal challenge with *M. leprae*. The test is positive in tuberculoid patients but negative in lepromatous patients (175). Most contacts of lepromatous patients develop protective immunity, as the majority have positive lepromin skin tests but do not develop overt disease.

Perhaps more than any other human disease, leprosy exemplifies the fascinating paradox of the inverse relationship between cell-mediated and humoral responses at the two poles of the spectrum. Cell-mediated immune responses are strong in tuberculoid but not in lepromatous patients; humoral responses including anti–*M. leprae* antibodies are most elevated in patients with the lepromatous form of the disease. This dichotomy can best be explained by the pattern of cytokines produced by T cells at the site of infection.

The Th1/Th2 Paradigm

Studies of murine T-cell cytokine patterns have revealed a paradigm of cellular immunology, the existence of two subsets that differentially regulate immune responses (176). T cells that produce IL-2 and IFN-g, termed Th1 cells, could be envisioned as contributing to cell-mediated immunity; whereas T cells that produce IL-4 and IL-5, termed Th2 cells, augmented humoral responses. In murine models of intracellular infection, resistant versus susceptible immune responses appear to be regulated by these two T-cell subpopulations (177,178 and 179). Th1 cells preferentially activate macrophages to kill or inhibit the growth of the pathogen, resulting in mild or self-curing disease. In contrast, Th2 cells facilitate humoral responses and inhibit some cell-mediated immune responses, resulting in progressive infection.

By the study of leprosy lesions, it became apparent that this paradigm has applicability to human disease in general and to skin immune responses in particular. Initially, IL-2 was detected in leprosy lesions by using mAbs and immunoperoxidase techniques (180,181). An order of magnitude greater number of IL-2–containing cells were present in tuberculoid lesions as compared with lepromatous lesions. By *in situ* hybridization, it became readily apparent that IFN-g mRNA also was more strongly expressed in tuberculoid lesions (182). These early studies indicated that the "Th1" cytokines were most prominent in the form of leprosy that is characterized by cell-mediated immunity to the pathogen.

To probe more fully the patterns of cytokines in lesions at the extremes of the spectrum of leprosy, polymerase chain reaction (PCR) was used to analyze the local cytokine pattern (183,184). The following strategy was devised and proved useful: (a) RNA was extracted from biopsy specimens; (b) polyadenylated mRNAs were reverse transcribed to obtain cytokine cDNAs; and (c) those cDNAs were detected with high sensitivity by PCR by using cytokine specific primers.

The striking observation was that clear differences in cytokine PCR profiles were observed between tuberculoid and lepromatous lesions, and those differences were consistent across lesions of all patients: IL-2 and IFN-g mRNA were markedly higher in tuberculoid lesions, whereas IL-4, IL-5, and IL-10 were characteristic of lepromatous lesions. The cytokine patterns that were detected in the leprosy lesions are remarkably similar to the Th1 and Th2 patterns of murine $CD4^+$ cells. Th1-like cytokine mRNAs were abundant in tuberculoid lesions, which are basically self-healing and characterized by resistance to growth of *M. leprae*. In marked contrast, Th2-like cytokine mRNAs were abundant in lepromatous lesions, correlating with immunologic unresponsiveness to *M. leprae*. Therefore, investigation of leprosy permitted the delineation of comparable human Th1 and Th2 responses in response to a single pathogen, which correlate with the clinical course of the infection.

Earlier immunoperoxidase and immunofluorescence studies had indicated differences in the CD4/CD8 ratio at the poles of the leprosy spectrum (180,181,185,186 and 187). The data from these studies indicated that in tuberculoid leprosy lesions, the $CD4^+$ population predominated with a CD4/CD8 ratio of 1.9:1, whereas in the lepromatous lesions, the $CD8^+$ population predominates with a CD4/CD8 ratio of 0.6:1. Furthermore, $CD4^+$ cells in tuberculoid lesions mark as T-memory cells ($CD45R0^+$) (188). The majority of $CD8^+$ cells in lepromatous lesions are $CD28^-$, indicating that they are of the T-suppressor phenotype (188). Of $CD4^+$ cells cultured directly from tuberculoid lesions, one in 60 react to *M. leprae* antigens (188). $CD8^+$ cells from lepromatous lesions fail to proliferate to antigen, but can be activated by *M. leprae* to inhibit proliferative responses by $CD4^+$ cells and are termed "T-suppressor cells" (189,190).

The patterns of cytokine secretion of these clones revealed the existence of subsets of both $CD4^+$ and $CD8^+$ T cells (191). All of the *M. leprae*–specific $CD4^+$ clones obtained from tuberculoid patients produced IL-2, IFN-g, and granulocyte-macrophage colony-stimulating factor (GM-CSF), but little or no IL-4 or IL-5, similar to the pattern of cytokines characteristic of murine Th1 cells. These clones also lacked helper activity for antibody formation; we therefore designated them "type 1" $CD4^+$ T-cells. CD4+ T cells that recognized tetanus toxoid, in comparison, produced low levels of IFN-g and IL-2, but high levels of IL-4 and IL-5, a pattern similar to that of Th2 cells. These clones were found to have B-cell helper activity and were designated "type 2" $CD4^+$ T cells. Thus functionally different $CD4^+$ T cells from strongly antigen-reactive donors can be subtyped into two groups, similar to the murine counterpart, based on cytokine patterns.

Similarly, it was possible to define subpopulations of $CD8^+$ T cells based on their cytokine patterns. The majority of the $CD8^+$ alloreactive T-cytotoxic clones tested secreted IFN-g, but made no detectable IL-4 or IL-5. Of particular interest, the pattern of cytokine production by the $CD8^+$ T-suppressor cells from leprosy lesions was characterized by high levels of IL-4 and low levels of IFN-g. Based on patterns of cytokine secretion, particularly of IL-4, the data suggest that the human CD8 population also can be divided into two functional subsets, that we designate "type 1" and "type 2" $CD8^+$ T cells.

The inverse relationship between cell-mediated immunity and humoral immunity in the spectrum of leprosy can best be explained according to these cytokine patterns. The abundance of IL-2 and IFN-g produced by $CD4^+$ in tuberculoid lesions is likely to contribute to the resistant state of immunity in these patients. IFN-g is well known to enhance production of reactive oxygen and nitrogen intermediates (192) by macrophages and to stimulate them to kill or restrict the growth of mycobacteria (193,194) and other intracellular pathogens (195). IFN-g also augments expression of HLA-DR and intercellular adhesion molecule (ICAM)-1, which facilitates T cell–accessory cell interaction (196). IL-2 may contribute to the host defense by inducing the clonal expansion of immune activated cytokine–producing T cells and

augments the production of IFN-g (197).

In contrast to the set of cytokine mRNAs present in tuberculoid lesions that might be involved in cell-mediated immunity and inflammation, those found to be increased in lepromatous lesions might be expected to contribute to the immune unresponsiveness and failure of macrophage activation in these individuals. In particular, IL-4 was increased in lepromatous lesions and produced by CD8+ T cells. IL-4 likely contributes to the elevated anti–*M. leprae* antibodies in lepromatous patients through its role in differentiation and immunoglobulin class switching of B cells (198), as well as its ability to stimulate Th2 proliferation (199). IL-4 also has a negative immunoregulatory effect on cell-mediated immunity, which could lead to enhanced bacterial growth.

Innate Immunity: The Role of IL-12 and Toll-like Receptors

Of particular interest to immunologists is the delineation of factors that influence the T-cell cytokine pattern. The innate immune response is one important factor involved in determining the type of T-cell cytokine response. Innate immunity pertains to those cells that have been preprogrammed to respond to foreign molecules. The cells of the innate immune response include macrophages, NK cells, and mast cells. Innate immunity can be contrasted to acquired immunity that involves the selection and expansion of immune cells with the development of memory. The acquired immune response involves T and B cells. Cells of the innate immune response release cytokines, which in turn bias the cytokine profile of the acquired T-cell response.

The ability of the innate immune response to induce the development of a Th1 response is mediated by release of IL-12, a 70-kd heterodimeric protein (200,201 and 202). For example, in response to an intracellular pathogen, macrophages release IL-12, which acts on NK cells, and later T cells, to release IFN-g. The presence of IL-12, IL-2, and IFN-g, with the relative lack of IL-4, facilitates Th1 responses. In contrast, in response to allergens or extracellular pathogen, mast cells or basophils release IL-4, which, in the absence of IFN-g, leads to differentiation of T cells along the Th2 pathway. It is intriguing to speculate that keratinocytes may also influence the nature of the T-cell cytokine response. Keratinocytes can produce IL-10, particularly after exposure to UVB (203). The released IL-10 can specifically downregulate Th1 responses, thus facilitating the development of Th2 responses.

The role of innate immunity in human host defense is perhaps best exemplified in leprosy. The local production of IL-12 in lesions correlated with cell-mediated immunity, being strongest in type 1 cytokine–containing tuberculoid lesions, and weaker in the type 2 cytokine–expressing lepromatous lesions (204). One characteristic of IL-12 is its potent T-cell growth factor activity. T-cell proliferation to *M. leprae* was dependent on the endogenous production of IL-12, in that proliferation could be blocked by the addition of neutralizing IL-12 antibodies. IL-12 induced proliferation of the $CD4^+$ type 1 cells from tuberculoid lesions but not the $CD8^+$ type 2 cells from lepromatous lesions. Therefore, a mechanism by which IL-12 may contribute to cell-mediated immunity in skin is through the preferential expansion of differentiated T cells committed to the type 1 cytokine pattern.

An exciting breakthrough in our understanding of innate immunity to microbial pathogens has been the identification of a human homolog of a *Drosophila* gene product known as Toll, which is responsible for protecting flies from bacterial and fungal pathogens (205,206). Activation of *Drosophila* Toll leads to activation of NF-kB–like kinases, and induction of a series of antifungal peptides, including metchnikowan, defensins, cecropins, and drosomycin. Mammalian TLR family members also are transmembrane proteins containing repeated leucine-rich motifs in their extracellular portions, similar to other pattern-recognition proteins, and a cytoplasmic portion that is homologous to the IL-1 receptor, and hence could trigger intracellular signaling pathways.

Human TLR4 mRNA expression was detected on cells of the immune system, monocytes, macrophages, dendritic cells, gd T cells, Th1 and Th2 ab T cells, and B cells (205). Expression of a dominant active form of TLR4 in monocytes and T cells led to induction of cytokine genes including IL-1, IL-6, and IL-8, as well as activation of NF-kB.

Perhaps the most interesting finding regarding mammalian TLRs is their ability to mediate responses to microbial ligands, lipids, and glycolipids including LPS (133,207,208,209,210,211,212,213,214,215,216,217 and 218). Experiments have led to the exciting finding that microbial lipoproteins trigger host responses through TLRs (133,215). By studying the bacterial cell-wall components that stimulate IL-12, microbial lipoproteins, specifically the *Mycobacterium tuberculosis* 19-kd lipoprotein, the *Borrelia burgdorferi* OspA lipoprotein, and the 47-kd lipoprotein of *Treponema. pallidum* were found to induce IL-12 in macrophages and that induction was dependent on the lipid moiety because deacylated lipoproteins had no activity. The induction of IL-12 was dependent on TLR2, because an mAb to TLR2 completely blocked IL-12 release, and transfection of a dominant negative TLR2 construct inhibited IL-12 promoter activity. Transfection of TLR2 into 293 cells conferred reactivity to microbial lipoproteins. Furthermore, lipoproteins induced iNOS activity and NO production through TLRs, indicating activation of a direct and powerful microbicidal activity. This discovery is relevant to the skin immune response, given that the lipoproteins were derived from two important cutaneous pathogens, *B. burgdorferi* and *T. pallidum*, as well as mycobacterial species that also are a significant cause of skin disease. Other microbial products that activate via TLRs include bacterial peptidoglycan (214,219), *S. aureus* lipoteichoic acid (219), and lipoarabinomannan from rapidly growing mycobacteria (220). Thus Toll proteins represent a host defense mechanism that has been conserved over hundreds of millions of years of evolution.

CD1 and the Universe of Nonpeptide T-cell Antigens

The model of antigen presentation to T cells has centered on the ability of T cells to recognize foreign or self-peptides in the context of MHC class I and II molecules. A new advance in our understanding of T-cell biology has been the demonstration of T-cell recognition of nonpeptide antigens. In one system, gd T cells were shown to recognize isopentenyl pyrophosphate and related structures in the isoprenoid family (221). The ability of gd T cells to recognize these antigens may occur in a manner independent of antigen-presenting molecules. In a second system, ab T cells have been shown to recognize lipid and lipoglycan antigen in the context of CD1 molecules (222,223 and 224).

The human cluster of differentiation I (CD1) gene family consists of five nonpolymorphic genes, CD1*A*, –*B*, –*C*, –*D*, and –*E*, mapped to a cluster on chromosome 1 (225). Human CD1 has a unique tissue distribution, with CD1a, -b, and -c present on thymocytes but not peripheral blood T cells. Human CD1 are also present on professional antigen-presenting cells including dendritic cells, Langerhans cells, and mantle zone B cells. The structural homology of CD1 with class I and class II molecules suggests an antigen-presenting function; however, the amino acids encoded in the predicted antigen-binding site, the a1 and a2 domains, are extremely hydrophobic.

A striking finding was that a unique function of human CD1 was the ability to present nonpeptide antigen to T cells. Specifically, human CD1b and CD1c have been shown to present lipid and lipoglycan antigens to T cells. To date, all the CD1-restricted T cells that have been derived recognize nonpeptide antigens of mycobacteria, specifically *M. tuberculosis* and *M. leprae* (222,223 and 224,226,227). Three major antigens have been elucidated, derived from the cell wall of mycobacteria: mycolic acids, lipoarabinomannan and glycosylated mycolates (GMMs). Mycolic acids are branched long-chain fatty acids that are specifically found in mycobacteria. Lipoarabinomannan contains an arabinose head, branched mannose core, and phosphatidylinositol, which contains two fatty acids: tuberculostearic acid and palmitic acid. For lipoarabinomannan, the data suggested that T-cell recognition was at the level of the branched mannose core.

Investigation of human leprosy has provided direct evidence for the involvement of the CD1-restricted T cells in host response to infection. CD1a, -b, and -c were expressed on dendritic cells in the granulomas within the skin lesions of leprosy patients. Furthermore, the frequency of $CD1^+$ cells correlated with the level of cell-mediated immunity to *M. leprae*, being tenfold more abundant in the granulomas of patients with the immunologically responsive tuberculoid form of the disease, as compared with the unresponsive lepromatous form (228). It is likely that these differences are related to the level of GM-CSF in the lesions, being greater in the tuberculoid lesions. In addition, IL-10, which is specifically found at the site of infection in the lepromatous form, has been shown to downregulate CD1 expression (229). Further evidence for a role of CD1 presentation of antigens in immunity to mycobacterial infection *in vivo* includes the isolation of CD1-restricted T cells from patients with mycobacterial infection. Initially, a CD1b-restricted, *M. leprae*–specific T-cell line was derived from a cutaneous leprosy lesion (224), and more recently, *M. tuberculosis*–reactive CD1-restricted T-cell lines from the peripheral blood of patients with tuberculosis (153).

The study of CD1-restricted T cells from patients with mycobacterial infection as well as normal healthy donors has revealed certain shared functional features. First, all the CD1-restricted T-cell lines isolated produce high levels of IFN-g, but little or no IL-4 on stimulation with mycobacterial antigen. This Th1 cytokine pattern can directly contribute to cell-mediated immunity against intracellular infection by enhancing T-cell proliferation and macrophage activation. Second, CD1-restricted T cells also show a high degree of cytolytic activity against antigen-pulsed macrophages. Furthermore, these T cells can lyse macrophages infected with virulent *M. tuberculosis*. The induction of cytotoxicity is dependent on antigen presentation and T-cell recognition, because lysis was blocked by antibodies to CD1b. Lysis of highly infected macrophages can contribute to host defense either directly by killing the bacteria or indirectly by dispersing the pathogen and thereby allowing freshly recruited macrophages to take up and more effectively dispose of the bacteria (230).

Two mechanisms of cell-mediated cytotoxicity differentially contribute to the outcome of infection with intracellular pathogens. $CD4^-CD8^-$ (DN) CD1-restricted T cells lyse targets through the Fas/Fas-ligand pathway; whereas the lysis of targets by $CD8^+$ cells depends on the release of granules containing perforin and granzymes. However, only the $CD8^+$ subset of CD1-restricted T cells kills the intracellular *M. tuberculosis* during the lysis of the target cell. Although the DN T cells may have an immunoregulatory role by reducing the local cellular infiltration and thereby limiting tissue damage, the $CD8^+$ T cells may have the greatest impact in combating intracellular pathogens (153).

There is an intriguing linkage between the direct antimicrobial effect of $CD8^+$ CTLs (including those that are either CD1 or MHC class I restricted) and their expression of granulysin (231), a 9-kd protein component of CTL granules (232). Granulysin inhibited the growth of a broad spectrum of pathogenic bacteria, fungi, and parasites *in vitro*. Granulysin directly killed extracellular *M. tuberculosis*, and in combination with perforin, the pore-forming molecule that colocalizes with granulysin in CTL, caused a dramatic decrease in the viability of intracellular *M. tuberculosis*. Scanning electron micrographs of granulysin-treated *M. tuberculosis* revealed lesions in the surface ultrastructure indicating alteration of membrane integrity, leading to the death of the organism. These studies defined a new mechanism by which T cells can directly contribute to immunity against microbial pathogens.

Conclusion

By studying the skin lesions of leprosy, it is possible to gain insight into immunoregulatory mechanisms in humans. The generation of cell-mediated immunity to microbial pathogens involves two arms of the immune system, the innate and the adaptive response. We have learned that microbial ligands activate cells of the innate immune response through TLRs, a family of proteins that have been highly conserved from *Drosophila* to humans. Activation of the innate response can lead to a direct antimicrobial pathway, but also may serve to amplify the adaptive T-cell response. In particular, by the release of IL-12, the innate system can instruct the adaptive T-cell response toward the Th1 cytokine pattern, the pattern of cytokines required for effective cell-mediated immunity. T cells, once activated, also can mediate an antimicrobial activity through the release of granulysin. Our studies provide evidence that both peptide and nonpeptide antigens can stimulate such T cells. In leprosy, the T cells and monocytes cooperate in granulomas to deal with the invading pathogen. It should be possible to use this knowledge to develop new strategies both to prevent and to treat cutaneous infections such as tuberculosis and leprosy, as well as other infectious, malignant, and autoimmune conditions.

The genome sequence of the laboratory strain H37Rv was determined by the Sanger Centre (Cole ST, Brosch R, Parkhill J, et al. Deciphering the biology of *Mycobacterium tuberculosis* from the complete genome sequence. *Nature* 1998;393:537–543. Available online at http://www.sanger.ac.uk/Projects/M tuberculosis. The genome sequence of a recent clinical isolate, strain CDC1551, was determined by The Institute for Genomic Research (TIGR), available online at http://www.tigr.org/tdb/CMR/gmt/htmls/Background.html

77 CRYOPATHIES: CRYOGLOBULINS AND CRYOFIBRINOGENEMIA

Peter D. Gorevic, M.D.

A number of cold-related hypersensitivity syndromes have been grouped together under the term *cryopathies* and include such diverse conditions as Raynaud phenomenon and the paroxysmal cold hemoglobinurias (255). Several of these disease entities are treated in detail in other chapters of this volume. This review focuses on the various forms of cryoglobulinemia and cryofibrinogens, with specific emphasis on molecular mechanisms and associated clinical symptom complexes.

CRYOGLOBULINS

Cryoglobulins are immunoglobulins that undergo reversible precipitation in the cold (Fig. 77.1) (93,141,425). Early studies showed that this phenomenon is a concomitant of immune complex formation (156) and also occurs in patients with multiple myeloma (414). Subsequent clinical series established that cryoglobulinemia can accompany a wide variety of disorders, but can also occur in an apparently “essential” or idiopathic form (42,135,169), which is now known to be significantly associated with hepatitis C virus (HCV) infection.

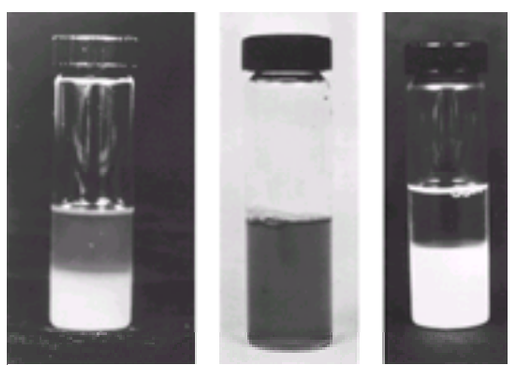

Figure 77.1. Serum of a patient with a 30-year history of clinical cryoglobulinemia. A gelatinous precipitate is apparent when the serum is kept at 4°C overnight (**left**), and dissolves completely when it is rewarmed to 37°C (**center**). The isolated cryoprotein (**right**) is composed of immunoglobulin M (IgM) and IgG.

The immunochemical classification first suggested by Brouet et al. (42) has been adopted in many clinical reports. Type I cryoglobulins consist of a single component, almost invariably a monoclonal immunoglobulin, usually IgM or IgG. Mixed cryoglobulins are cold-precipitable rheumatoid factors (RFs), usually IgM, which form cryoprecipitates by virtue of complex formation with polyclonal IgG at low temperatures (210,231). This RF may be monoclonal (type II) or polyclonal (type III) and, similar to classic RFs seen in rheumatoid arthritis, has specificity for the Fc portion of IgG (325). Generally, type I cryoglobulins are found in diseases in which malignant B-cell transformation has occurred, whereas type III cryoglobulins may be found in a large number of disorders in which hyperglobulinemia, hyperimmunization, and immune complex formation have been documented (Table 77.1) (135). The relative frequency of single-component and mixed cryoglobulins has varied considerably when large numbers of sera have been screened for cryoglobulinemia (Table 77.2) (42,135,169,253,362,368). In recent series, the incidence of type II cryoglobulins has increased dramatically compared with that in older studies (Table 77.2), reflecting the greater use of immunofixation for typing (49), and recognition of the often striking clonality of the humoral immune response in many patients with mixed cryoglobulinemia (MC) associated with chronic HCV infection (338). In addition, the IgG component of type II cryoglobulins also may be found to be oligoclonal when analyzed by IgG subclass or in isofocusing studies (262,263).

Type I	24.5	38.1	9.6	5.0	5.9	3.4
Type II	25.5	13.5	36.5	72.0	62	62.2
Type III	50.0	48.4	53.9	23.0	32	34.4

TABLE 77.2. Relative Frequency of Different Types of Cryoglobulins

Isolation and Characterization

Methodologic guidelines for the isolation and characterization of cryoglobulins have recently been published (49,137,178). Cryoproteins are isolated from blood that has been allowed to clot at 37°C. The serum is removed and kept for a variable period at 4°C. Most type I cryoglobulins yield copious flocculent, and occasionally crystalline, precipitates that appear within 24 hours of exposure to the cold, whereas type III cryoproteins are usually gelatinous, occur in lower amounts, and may require up to a week to be apparent. These differences reflect the homogeneity or immune complex nature of these proteins, respectively, as well as the relative quantities present in blood. Although considerable overlap may occur, the majority of type III cryoglobulins are present at concentrations of less than 1 mg/mL (i.e., cryocrits <1% volume of serum collected), whereas type I cryoglobulin concentrations are often greater than 5 mg/mL (i.e., cryocrits >1%, and occasionally 20% to 40% or more) (Table 77.3) (42).

Cryoglobulin Type	<1 mg/mL (%)	1-5 mg/mL (%)	>5 mg/mL (%)
Type I	10	30	60
Type II	20	40	40
Type III	80	20	0

Type III cryoglobulins, at concentrations up to 80 μg/mL, may be found in 40% of normal individuals (76).

TABLE 77.3. Cryoglobulin Levels

The temperature at which cryoprecipitation starts, as well as the rate at which it occurs, may vary considerably among individuals and even in the same individual when assessed at different times. This appears to be a function of a number of different factors, including heterogeneous mechanisms responsible for cryoprecipitation (Table 77.4) and concentration effects (141,179,194,425). In general, the greater the concentration of cryoprotein in serum, the higher the maximal temperature at which precipitation begins to take place (391). Among cryo-IgMs, 1,000- to 10,000-fold differences of insolubility were found when different proteins were compared (236). Cryoglobulins with high (i.e., greater than room temperature) thermal amplitudes may cause unusual clinical findings (e.g., purpura in atypical locations), be missed because of rapid precipitation during clotting, or cause *ex vivo* laboratory artifacts (137,379,419). Occasionally, type I cryoproteins may gel in the syringe shortly after venipuncture if care is not taken to keep the sample at 37°C. Typically, cryoprecipitation occurs over a temperature range less than 10°C (141,425). Once precipitated, the cryoprecipitate dissolves completely on rewarming to core body temperature, and this process can generally be repeated again and again (Fig.77.1). Cryoglobulins are purified by low-speed centrifugation in the cold, followed by repeated washing in cold physiologic saline solution at neutral pH. The purification may be monitored by assessing the disappearance of contaminating serum proteins from the reprecipitated protein by immunodiffusion at 37°C against, for example, antisera specific for albumin. [In rare instances, albumin may be specifically complexed to the cryoglobulin (see later) (174,244).] Mixed cryoglobulins may lose material on reprecipitation in saline (141,416), a feature that has suggested in turn the importance of serum factors (possibly including fibronectin, low-density lipoprotein, and C1q), which may act as cryoprecipitagogues (151).

Monoclonal cryoglobulins
V region determinants (primary amino acid sequence) (4,60,131,396)
Nucleation reactions (333,383)
Altered protein-solvent interactions at low temperatures (235,236)
Aggregation due to electrostatic and dispersion forces (14,61,186,241)
Extension of normal solubility phenomena (239)
Concentration effects (391)
Deficient carbohydrate side chain (sialic acid residues) (149,427)
Monoclonal immunoglobulin serving as both antibody and antigen (IgRF, IgM-IgM) (142,318,374,402)
Mixed cryoglobulins
Cold-precipitable rheumatoid factors (IgM, IgA) (210,231,408)
V region determinants (133,189,396)
Cryoprecipitagogues in serum (? fibronectin, C1q) (151)
Deficient carbohydrate side chains (425,427)

TABLE 77.4. Mechanisms of Cryoprecipitation

The pH and solute effects on cryoprecipitation are similarly variable (141,425). Loss of precipitability with various solvents and mild denaturing agents has been taken as an indication of the importance of immunologically nonspecific noncovalent interactions in determining cryoprecipitation, especially in regard to type I cryoglobulins. In some instances, occupancy of the antigen-binding site (94) or modification of electrostatic interactions (195) can prevent aggregation. Other factors may include nucleation reactions (333,383), aggregation caused by electrostatic and dispersion forces (14,61,186,241), temperature-induced conformational changes (237,241,318), altered protein/water interactions (235), abnormal stability of disulfide bonds linking heavy chains (332,334), deficient carbohydrate side chains (notably sialic acid) (425,427), nonimmunologic binding to other serum proteins (161,205), and differences in variable (V) region primary amino acid sequence (4,60,131,396). All have been implicated in specific instances (Table 77.4). Most cryoglobulins remain cryoprecipitable in the pH range from 5.0 to 8.5; that is, they are least soluble at physiologic pH, and undergo dissociation and/or dissolution beyond this range (141,425). Rarely strict pH (14,328) or calcium (298) dependence of cryoprecipitation has been demonstrable.

After repeated washing in cold saline solution, purified cryoglobulins may be further characterized by immunoelectrophoresis against antisera specific for immunoglobulin light and heavy chain isotypic determinants. More sensitive techniques are agarose or composite agarose polyacrylamide gel electrophoresis, immunofixation, capillary zone or two-dimensional gel electrophoresis techniques, and immunoblotting with isotype and light chain–specific antisera (49,62,137,262,338,368). These techniques, as well as detailed immunochemical and structural studies in individual patients, have shown that occasional mixed cryoglobulins may be biclonal, oligoclonal, or a mixture of monoclonal and polyclonal components, thus blurring the classic distinction between types II and III (368). Further characterization has included sizing by analytic ultracentrifugation and dissociation on gradients or by gel filtration (210,231). These methods have been widely used for the study of mixed cryoglobulins and have clearly demonstrated that the phenomenon of cryoprecipitation in types II and III cryoglobulinemia is dependent on immunologically specific complexing of the constituents of the cryoproteins (357). Ultracentrifugal analysis has shown that IgM and IgG components may not circulate as 22S complexes, as do classic RFs, but rather as individual 19S and 7S IgM and IgG, with relatively low affinity for each other at core body temperatures. Affinity of cryoIgM RF for IgG may increase significantly as the temperature is lowered, resulting in complex formation and aggregation (41). Cryoprecipitation can be demonstrated only in density-gradient fractions containing both IgM and IgG (Fig. 77.2) and is not a property of the isolated components. Furthermore, pooled normal IgG may be substituted for the IgG component of the mixed cryoglobulin, and cryoprecipitation will occur when the temperature is lowered, whereas this is not seen when the IgM component is substituted for by an unrelated noncryoglobulin monoclonal or polyclonal IgM (231).

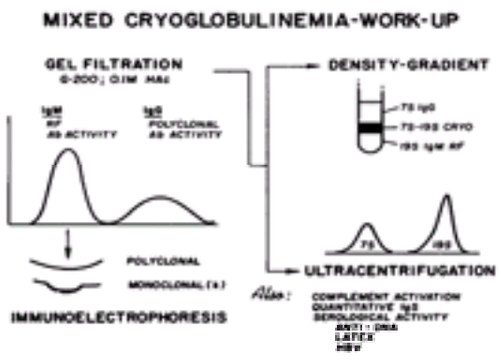

Figure 77.2. Workup of mixed cryoglobulins may include (a) ultracentrifugal analysis (**bottom right**) which generally yields two distinct peaks at 37°C, corresponding to 19S immunoglobulin M (IgM) and 7S IgG, although additional peaks may be evident if complexes form or if IgA or C1q is also present; (b) density-gradient centrifugation (**top right**): 19S IgM and rheumatoid factor are found in the heavier fractions of the gradient, but cryoglobulin formation at a lower temperature occurs only at the interface tubes containing both IgM and IgG; and (c) gel filtration under dissociating conditions (**top left**): IgM and rheumatoid factor activity can be shown in a high-molecular-weight peak on various columns, which can then be tested by immunoelectrophoresis (**bottom left**) against antisera to μ, k, and l determinants to define whether it is monoclonal (type II) or polyclonal (type III); most type II cryoglobulins are IgMk. Additional studies may include quantitation of serum immunoglobulins, complement activation, or a search for specific serologies in dissociated and fractionated material.

Type I cryoglobulinemia may be due to immunologically specific, temperature-sensitive interactions in which the monoclonal immunoglobulin is both antibody and antigen (142,318,374,402). Demonstration of this mechanism is difficult because antibody and antigen may be of the same isotype. Dissociation and fragmentation of the cryoprotein may be required to show that the Fab fragment and not the Fc portion of the molecule retains specific binding in the cold (142,318). Such studies have shown binding to other species of molecule (e.g., albumin, lipoprotein, transferrin) in some instances (161,174,244). Immunologically specific binding to the Fc fragment or light chains of other immunoglobulin molecules of the identical isotype, that is, demonstrating a mechanism analogous to that of IgG RF, has been shown in other cases.

Isolated cryoglobulins may be quantitated by reference to the volume of serum from which they are isolated as a *cryocrit* (analogous to the hematocrit) or as an absolute value, determined by various protein assays (137,142,178).

Simple Cryoglobulins

LIGHT CHAINS

In one series, 3% of Bence Jones proteins (BJPs) were found to be cryoprecipitable (229). Only a small number of these proteins have been studied in any detail, and all were obtained from the urine of patients with multiple myeloma (15,152,207,380). Limited sequence and serologic studies have failed to show clear-cut k/l or V-region subgroup specificity (59,183,229,230). Four of six l cryo-BJPs studied by amino acid sequence analysis had unblocked amino termini, an incidence that contrasts with that of 20% among l BJPs in general (230). One well-characterized k cryo-BJP was found to form crystals at 4°C and to belong to the VIII subgroup by sequence analysis (59,265). However, whereas the VIII subgroup is extremely common among type II cryoglobulins (see later), it does not appear to be particularly enriched among type I cryoproteins.

In one well-studied example, the isolated l light chain of an IgG1 myeloma protein was found to be cryoprecipitable, whereas the parent molecule was not. Only the dimeric form of the light chain underwent reversible temperature-induced conformational changes in the cold, and proteolysis of the intact light chain caused loss of cryoprecipitability (183). Two cases of subacute vasculopathy associated with l light chain crystals have been reported (356).

IMMUNOGLOBULIN G

Approximately 3% to 10% of IgG M components are cryoprecipitable, occurring both in individuals with established multiple myeloma and in others without clear-cut underlying plasma cell dyscrasia (42,135,169). A small percentage of type I IgG cryoproteins also are crystalglobulins (95) and, as such, have provided useful tools for x-ray diffraction analysis of immunoglobulin structure (102).

Among IgG cryoglobulins, several investigators have shown that determinants of cryoprecipitability may reside in the variable region of the molecule and are retained in some instances by peptic $F(ab')_2$ fragments, but not by Fc or Fc-related digestion products (317,318 and 319,383). In other instances, cryoprecipitation cannot be localized to specific enzymatic fragments (208,272). Different series have provided conflicting data regarding abnormal k/l or IgG subclass ratios among IgG cryoglobulins (4,42,385,396). Chemical analyses have shown, however, that most of these monotypic proteins have V_hI heavy chains and unblocked light chains (396). In one series, idiotypic cross-reactivity of several IgG cryoglobulins was shown serologically (5). Temperature-induced conformational changes can occur in the Fab portion of such molecules, which may in turn lead to aggregation and cryoprecipitation. One mechanism for the latter is interaction with the Fc portion of IgG (142,318,319). In other proteins, small amounts of soluble polymers may act as nucleation centers for cold precipitation or crystal formation. Such precipitates also may be obtained with Fab or $F(ab')_2$ fragments but not Fc, indicating the association of the former to be the primary event (334,383).

Structurally abnormal IgG cryoglobulins also have been described. Abnormalities reported include extra disulfide bonds linking heavy chains (333), formation of unusual fragments after enzymatic digestion (279), a lack of sialic acid residues (149,426), and, in one case, a deletion in the hinge region of the molecule (88). Aberrant immunoglobulin and c-*myc* gene rearrangements have been found in some patients (285). In other instances, no structural abnormality or specific antibody activity can be identified, and it must be assumed that cryoglobulinemia is simply due to unfavorable interactions with solvent in the cold, presumably reflecting tertiary structural groupings (208). More than 30 cases of crystal cryoglobulinemia of monotypic proteins have been reported (95,143), again mostly in patients with multiple myeloma (19,387). Clinical associations have included vasculitic purpura (143,244,278), skin ulcers (143,244), glomerulitis (95), pyoderma gangrenosum (407), erosive arthritis (192,278), severe Raynaud phenomenon (143), and corneal deposits (139,187). Crystalglobulins may form tubular structures that can be visualized *in vitro* by electron microscopy (35,290,355,407) and that also can be identified in myeloma and mononuclear cells (198). In one instance, Fab and $F(ab')_2$ fragments cryoprecipitated to form tubular structures similar to the parent molecule on cooling (383); in another IgG3 crystalglobulin, the Fc fragment was necessary for cryoprecipitation (3). Instances of crystalglobulins formed by specific complexing of IgG to albumin have been reported (174,244).

IMMUNOGLOBULIN M

From 10% to 20% of macroglobulins are cryoprecipitable (42,135,169). Detailed studies of a series of monotypic IgM cryoglobulins failed to provide a specific physicochemical basis for cryoprecipitation. No major differences were found between noncryoglobulin IgM molecules by spectroscopy (238), hydrodynamics (241), solute variation (236), or immunochemical analysis (240), and this lack of specific structural determinants has been borne out by limited sequence studies (131). Based on these findings, it has been suggested that cryoprecipitation among many of these molecules may be an extension of a normal solubility phenomenon (239). This observation appears to be corroborated in the marked relation between viscosity and temperature among sera of patients with Waldenström macroglobulinemia (regardless of the presence of clinical cryoglobulinemia) when varying levels of IgM are compared (391).

IMMUNOGLOBULIN A

Rare examples of monotypic IgA cryoglobulins have been identified, some of which caused gelation of serum (295,346), or were found also to be pyroglobulins (i.e., to precipitate at temperatures >56°C) (397,398). Similar to IgG type I cryoglobulins, cryogel formation has been localized to the $F(ab')_2$ fragment in some instances (295).

Mixed Cryoglobulins

The incidence of *type II* cryoglobulins in recent series has increased with greater appreciation of the prevalence of this form of cryoglobulinemia (Table 77.2) (42,135,169,253,362,368). In addition to lymphoproliferative disorders and cryoglobulinemia associated with HCV infection, associations with Sjögren syndrome (371,392) and other forms of chronic hepatitis (347) have been noted in a number of case reports and small clinical series. The large majority (>95%) of type II cryoglobulins contain IgM molecules with k light chains (Table 77.5).

"Essential": cryoglobulinemia
Waldenstrom macroglobulinemia
Sjogren's syndrome (371)
Autoimmune diseases (rheumatoid arthritis, lupus, polyarteritis, polymyositis) (214,215)

TABLE 77.5. Diseases Associated with "Monoclonal" IgM-polyclonal IgG Mixed Cryoglobulins

IgA/IgG mixed cryoglobulins have been described in association with cold-induced urticaria (219,389) and glomerulonephritis (400).

Serologic, structural, and genetic studies have provided the basis for this striking enrichment of k light chains among type II cryoglobulins. Initial investigations of a small group of monoclonal antiglobulins, some of which were isolated from the blood of patients with lymphoma or macroglobulinemia, indicated that these proteins could be divided into three groups by using antisera developed against individual IgM K proteins and rendered antiidiotypic by rigorous absorption with normal IgM and noncryoglobulin IgM M components (50,188). The Wa and Po groups defined 60% and 20%, respectively, of these proteins by hemagglutination inhibition. About 20% could not be classified with these antibodies (188).

Amino acid sequence studies of the variable sequence region (V_{REGION}) light chain of a number of these monoclonal RFs have shown that proteins belonging to the Wa group invariably have light chains belonging to the V_kIIIb subsubgroup (133,189). The V_kIII subgroup constitutes approximately one third of the normal k light-chain pool, and about half of these proteins can be typed as V_kIIIb by serologic or sequence analysis. The rest are V_kIIIa or untypable (227). Whereas 60% to 70% of monoclonal IgMk autoantibodies are V_kIIIb, only 8% of non-RF IgM paraproteins belong to this subsubgroup (189,291). Furthermore, complete V_{REGION} sequences of a small number of these proteins have established striking homology that extends through the third hypervariable region of the light chain (133,196,291). In contrast, the Po group is less well defined. Although none of these proteins are V_kIIIb, a significant percentage also appear to belong to the V_kIII subgroup (189). Two Po-positive proteins completely studied to date shared four of six heavy- and light-chain hypervariable sequences, although they differed significantly when framework sequences were compared (51,52).

Monoclonal and polyclonal antibodies to mixed cryoglobulin cross-reactive idiotypes (MC CRIs) have been used to analyze relationships between MC and other rheumatic and lymphoproliferative diseases (136). Antibodies have been obtained by generating hybridomas to IgMk isolated from mixed cryoglobulins, or as polyclonal antisera raised to synthetic peptides corresponding to specific hypervariable region or framework sequences. MC CRIs may be light- or heavy-chain specific or may depend on the association of heavy and light chains for expression; light- and heavy-chain CRIs were found frequently to be associated with each other, suggesting that combination is not random. Some CRIs depend on the integrity of the antigen-binding site for expression; binding of others to V-region determinants is only partially or not inhibited by antigen. Whereas two to three MC CRIs account for virtually all type II IgMk cryoproteins, the expression of these CRIs among noncryoglobulin or RF paraproteins and in the normal serum IgM pool is quite low. MC CRIs are particularly prevalent in primary Sjögren syndrome, CD5-positive B-cell chronic lymphocytic leukemia (CLL), some non-Hodgkin lymphomas (NHLs), and monoclonal cold agglutinin disease (136). In these disorders, CRIs may be demonstrable both in the fluid phase and on the surface of B cells, either in peripheral blood or in tissue lesions (e.g., glandular tissue of patients with Sjögren syndrome). In long-standing rheumatoid arthritis, although MC CRIs are prevalent, they constitute only a small proportion of the RF pool quantitatively, which may be skewed away from these idiotypes (326). In contrast, in Sjögren syndrome, the bulk of IgM RF is accounted for by these CRIs, and serial measurements have been used to monitor for the lymphoproliferation that occurs with increased incidence in this disorder (136,339,372). These observations suggest that most type II IgMk RFs resemble "natural" autoantibodies, which are often IgM, low affinity, polyreactive, prevalent in the fetal repertoire, and commonly found to have CRIs; however, unlike other "natural" autoantibodies, MC IgM are not known to be polyreactive, and do not appear to be synthesized specifically by CD5-positive B cells (78,281).

MC CRIs have been correlated with specific heavy- and k light-chain V genes, and the roles played by somatic mutation, diversity and/or joining segment use, and recombination in determining idiotype defined at the molecular level. Most V_kIII light chains are encoded by two genes, designated *Kv328* and *Kv325* (A27 locus or k IIIb gene), accounting for the (a) and (b) subsubgroups and the Wa and Po groupings that were previously defined serologically. Kv325 is significantly associated with expression of a specific V_H1 heavy-chain gene, designated V_H*7*83 (51p1); other MC V_kIII-associated idiotypes (Po, Bla) are linked to increased expression of V_H3 or V_H4 subgroup genes (136). Overall, skewing of the V_H gene repertoire to some subgroups (notably V_H4) has been noted among autoantibodies. Specific genes (e.g., V_H4.21) are highly associated with autoantibodies; this gene accounts for virtually all monoclonal cold agglutinins, as well as some polyreactive RFs and anti-DNA antibodies (280).

Type II IgM RFs manifest a high degree of specificity for human and primate IgG (141). Selectivity also is seen in the pattern of reactivity with different IgG subclasses and fragments, which appear to vary from one cryo-IgM to another (175). The relative contribution of the IgG subclasses to the polyclonal IgG fraction isolated from mixed cryoglobulins also varies from protein to protein (77,175) and is significantly different from the pool of noncryoprecipitable IgG remaining in serum from the same individual; specific increases in IgG1 and IgG3 have been reported in older and more recent studies (77,263,416). Generally, however, reactivity is greatest with intact IgG, less so for Fc fragments, and has been reported to be nonexistent for isolated Fab fragments (175). Two thirds of cryoglobulins react selectively with the staphylococcal protein A-binding site at the interface between C_H2 and C_H3 (325).

Type III cryoglobulins are associated significantly with a variety of disorders in which immune complexes may occur (Table 77.1) (42,135,169). These cryoproteins may be complex and may also have a significant nonimmunoglobulin content. In some cases, this has been correlated with the presence of other proteins or specific antigens enriched in the cryocomplex relative to serum levels. These other proteins include various complement components, notably C1q, which may be especially important in cryoglobulin formation in the sera of patients with systemic lupus erythematosus (SLE) (148,352), and fibronectin, which appears to be a significant constituent of serum cryoprecipitates in some patients with connective tissue disease (24,106,332), as well as those found in high incidence in the joint fluid of patients with rheumatoid arthritis (53). DNA, as well as enrichment of anti-DNA and anti-Ku antigen antibodies, and idiotype/antiidiotype complexes, have been found in type III cryoglobulins associated with SLE (305,411). Hepatitis B surface antigen (HBsAg) occurs in cryoprecipitates isolated from the sera of patients with chronic hepatitis (223,367) or extrahepatic syndromes associated with hepatitis B virus (HBV) infection (110,138,166).

Familial Cryoglobulinemia

Type III cryoglobulinemia may rarely occur as a genetic disorder. IgM/IgG cryoglobulins with RF activity have been reported in several kindreds (32,81,268,345). One family was asymptomatic, and the cryoproteins were detected on routine screening (399). In other families, several members were affected by recurrent purpura or membranoproliferative glomerulonephritis. In one kindred, two brothers were found to have a cold-precipitable RF and depletion of the early components of complement without apparent symptoms (345). Detailed studies of one family provided evidence for an idiotype on the IgM component of the cryoglobulin that was inherited in an autosomal dominant fashion (269,270). An unusual form of cryoglobulinemia has also been described in three siblings affected by dysgammaglobulinemia type I, an immunodeficiency disorder characterized by high levels of IgM and IgD but decreased or absent IgA and IgG. In these individuals, the cryo-IgM, which was polyclonal, was itself found to have anti-IgM activity, leading in turn to the conclusion that cryoglobulin formation was due to self-association of this class of immunoglobulin (413).

Experimental Cryoglobulinemia

A murine model of cryoglobulinemia characterized by severe leukocytoclastic vasculitis of the ears, tail, and footpads, and glomerulonephritis associated with deposition of immune reactants, complement activation, and electron-dense deposits (wire looping) was developed with IgG3-producing hybridomas obtained from MRL-lpr/lpr mice (145,172). This strain spontaneously develops a lupuslike syndrome characterized by high levels of IgG3 cryoprecipitating RFs; hybridomas transfer disease to nonautoimmune mice in 5 to 10 days (145,337). Murine IgG3 has a predilection for cryoprecipitation because of an intrinsic tendency to self-associate by Fc/Fc interactions that appear in part to be glycosylation dependent (276). However, not all IgG3 are cryoglobulins, and this activity appears to depend on V-region electrostatic charge and may be potentiated by IgM RF directed to IgG3 (28,29). RF activity of IgG3 monoclonal cryoglobulins and the formation of IgG3/IgG2a immune-complexes initiates cutaneous vasculitis, whereas cryoprecipitability of the IgG3 is sufficient for nephritogenicity, which can thus be dissociated in this system (173,306). Exact correlations between specific features of renal pathology and V and C domain primary structures were identified in a murine model for

cryocrystalglobulinemia (307). In this model system, disease can be prevented by monoclonal antiidiotypic antibody and is inhibited by noncryoglobulin IgG3; antiadhesins (ICAM-1/LFA-1) selectively attenuate the cutaneous vasculitis, which depends on neutrophil/endothelial cell interactions for expression (172,173,350).

Glomerulonephritis with pathologic and ultrastructural features (hyaline thrombi; mesangial and subendothelial deposits) resembling glomerulonephritis seen in cryoglobulinemia has been induced in mice by short-term injection of human type II cryoglobulins (121)

Antibody Activities in Cryoglobulins

Enrichment of a number of antibody activities and, in several instances, the presence of specific antigens in cryoprecipitates, have been demonstrated in various diseases associated with cryoglobulinemia (Table 77.6). These examples have provided the basis for the supposition that mixed cryoglobulins are pathogenic immune complexes and not just epiphenomena. Elevated levels of antibodies to specific antigens associated with Epstein-Barr virus (EBV) infection, or to HCV (see later), as well as persistence of viral genome demonstrated by molecular techniques in patients with MC, have been taken as evidence for ongoing infection (12,118). In other instances (e.g., cryoprecipitates associated with subacute bacterial endocarditis or poststreptococcal glomerulonephritis), evidence for the presence of specific exogenous antigenic determinants, or even enrichment of antibody activity, remains inconclusive (165,213).

Antibody	Antigen
Antiglobulin (IgM) Fc specific	DNA (34,305,309,411) Ku antigen
Antinuclear (IgM) (34,309,411)	Hepatitis B virus (110,138)
Lymphocytotoxic (IgM) (412)	Epstein-Barr virus (393)
Cold agglutinins (IgM) (132,214)	Renal tubular antigens (181)
Smooth muscle (IgM) (90)	Bacterial products (395)
Mitochondrial (IgM) (120)	Hepatitis C virus
Renal tubular antigens (IgM) (181)	
Pemphigus (IgM) (249)	
Albumin (IgM) (344)	
Lipoprotein (low density) (IgM) (165,204,291)	
α-Fetoprotein (IgM) (179)	
Intestinal microorganisms (IgM) (395)	
Streptolysin O (IgM) (334)	
VDRL (IgM) (378)	
Epstein-Barr virus (IgM) (393)	
Cytomegalovirus (IgM) (335), (IgM) (390)	
Hepatitis B surface antigen (IgM) (110,120,138,200,223,304,367)	
Toxoplasma (IgM) (75)	
Coccidioidin (IgM) (126)	
Candida (turnwald) (IgM)	
Hepatitis C virus (see Table 77.11)	

TABLE 77.6. Antibody Activity and Antigens Detected in Cryoglobulins

The simultaneous occurrence of cryomacroglobulinemia and cold agglutinin disease has been reported in chronic cold agglutinin disease, CLL, and primary macroglobulinemia (216,296). About 5% of Waldenström macroglobulins are also cold agglutinins. Cryoglobulins with cold agglutinin activity are most commonly IgMk and have specificity for the I-i antigen system; non–I-i or Pr (protease-sensitive)-specific proteins also have been described (64,417). Monoclonal cold agglutinins may occur in lymphomas, Kaposi sarcoma, severe combined immunodeficiency disease with B-cell proliferation, and rarely, mycoplasmal pneumonia (296). Cold agglutinins with anti-I specificity are usually k, whereas those specific for i are commonly l; one third of anti-i cold agglutinins are cryoprecipitable (294,296).

Consistent with experience in other types of cryoglobulinemia, different molecular mechanisms for cryoprecipitability have been identified in individual cases of cold agglutinin disease. In two instances, the thermal properties of the protein were found to be dependent on binding to carbohydrate moieties found on the red cell membrane and on the cryoagglutinins themselves (370,401). Fab_{μ} and $Fc_{\mu 5}$ fragments of an IgM l cold agglutinin associated with Waldenström macroglobulinemia were found to undergo self-association in the cold that was inhibitable by sialyllactose or by neuraminidase treatment (401). These observations imply immunologic specificity for sialic acid residues as a necessary mechanism for cryoprecipitability. In another instance, both cryoaggregation and cold agglutinin activity of IgMk macroglobulin was found to depend on binding to *N*-acetylneuraminosyl–containing carbohydrate residues (370). More rarely, IgM/IgG cold agglutinins that are type II mixed cryoglobulins have been described (132); most type II cryoglobulins, however, do not have cold agglutinin activity (135).

Phlogistic Potential of Mixed Cryoglobulins

Clinical symptoms suggestive of immune complex disease, that is, cutaneous vasculitis and glomerulonephritis, have been associated with both single-component (26,68,260) and mixed cryoglobulins (42,68,135,169). Nevertheless, the occurrence of cryoglobulins in normal subjects (76,178), in apparently asymptomatic individuals (286,399), as well as in association with diseases and in individual patients not manifesting immune complex symptoms (345,399), suggests that other factors, analogous to those recognized for immune complexes in general, are necessary for the clinical expression of disease. These may include the level and composition of the cryocomplexes, complement activation, specific antibody activities, efficiency of clearance of immune complexes from the circulation and binding to specific receptors, direct interaction with cell types important in inflammation (including mononuclear cells, basophils, and platelets), and direct effects leading to the generation of other inflammatory mediators (including coagulation factors, kinins, and leukotrienes) (365).

Patients with cryoglobulinemia frequently have a characteristic complement profile in blood, consisting of depletion of early components (C1q, C4) in the presence of relatively normal C3 and factor B levels (Fig. 77.3) (147,360). The presence of C1q in cryoproteins occurring in SLE (148,352) and mixed cryoglobulinemia (147,360) may be responsible for the often undetectable levels of this component in the serum of some patients.

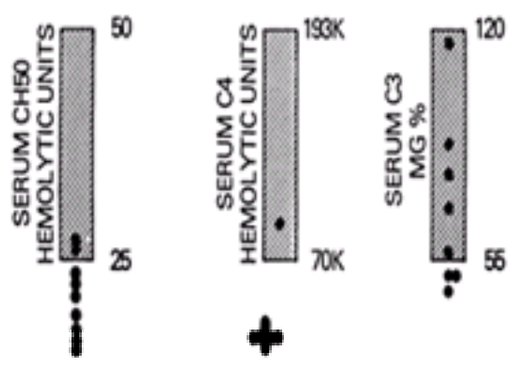

Figure 77.3. The characteristic complement profile of serum in mixed cryoglobulinemia includes depression of C4 and CH (measured here in hemolytic units) and normal or depressed levels of C3 (measured as mg/dL). The *hatched bars* indicate normal range for these determinations, with the upper and lower limits defined numerically (*K*, thousand). (From Hamburger MI, et al. Mixed cryoglobulinemia: association of glomerulonephritis with defective reticuloendothelial Fc receptor function. *Trans Assoc Am Physicians* 1967;93:104, with permission.)

Despite these findings, hypocomplementemia in association with cryoglobulinemia only poorly correlates with clinical symptoms and has been found in asymptomatic “healthy” individuals (399). Temperature-dependent activation of both the classic and alternative pathways of complement *in vitro* has been reported among mixed (IgM/IgG, IgM/lipoprotein) (9,154,206) and monoclonal (IgG) cryoglobulins (74,292). Activation of the alternative pathway has been correlated with the presence of IgA in mixed cryoglobulins (394) and with an IgG3 monoclonal cryoglobulin occurring in a patient with membranoproliferative glomerulonephritis (292). Among IgM/IgG mixed cryoglobulins, fractionation experiments have established that the majority of anticomplementary activity is associated with IgM RF (18). Nevertheless, *in vitro* studies indicated that IgM RF/IgG immune complexes may not fix C3 and C4 efficiently in spite of fluid-phase complement activation, and bind poorly to erythrocyte complement receptor 1 (CR1) (418). *In vivo* turnover studies have indicated that hyposynthesis and increased catabolism of C4 contribute to the low level of this protein in blood (315). *In vitro* studies suggest an alternative explanation: inability to activate C3 due to regulation of classic pathway C3 convertase by C4-binding protein and C3b inactivator (154). Dissociation of the thermal properties of cryoprecipitation and complement activation has been noted in specific instances in which it has been studied (314).

How cryoaggregates generate vasoactive substances and proinflammatory mediators to produce tissue lesions is unclear. That such mechanisms might be operative in some patients is suggested by elevated levels of complement fragments with anaphylatoxin activity (C3a, C5a) in serum (234) as well as the ability of isolated cryoproteins to activate basophils (233) or Fc receptors on neutrophils (164), cause platelet aggregation (71), and interact with kallikrein-kinin (180) *in vitro*. These mechanisms may be most relevant to the pathogenesis of disease in the peripheral vascular beds, where increased protein concentration and skin temperatures

significantly below core levels might facilitate the occurrence of such molecular events and cell interactions (113).

Increased production of immunoglobulin (232) and RF (341) by peripheral blood mononuclear cells correlates generally with elevated levels of cryoglobulin in the fluid phase of blood, although some patients are found to be significantly hypogammaglobulinemic (135). In one case of mixed cryoglobulinemia associated with Sjögren syndrome, *in vivo* turnover studies indicated that hypogammaglobulinemia was due to increased catabolism of IgG complexed with the IgM RF (392). In other studies, turnover of a monoclonal IgG cryoglobulin (2) and the IgG components of type II mixed cryoglobulins (267) were normal. IgG Fc receptor function, assessed by clearance of IgG-sensitized autologous erythrocytes or the kinetics of ingestion of IgG-coated material by circulating monocytes, has been found to be abnormal in some patients, particularly those with active nephritis or neuropathy (267,311). Similarly, CR1 numbers were decreased when peripheral blood erythrocytes were analyzed with a monoclonal antibody to this receptor (72). Defective immune adherence and elimination of immune complexes may lead to trapping in tissues, resulting in clinical vasculitis or nephritis (217,312).

Clinical Features of Cryoglobulinemia

Monotypic cryoglobulins are more likely to be associated with acrocyanosis, retinal hemorrhage, severe Raynaud phenomenon, and arterial thrombosis. By contrast, vascular purpura and joint symptoms are more typically seen in patients found to have type II or III cryoglobulins (Table 77.7) (42).

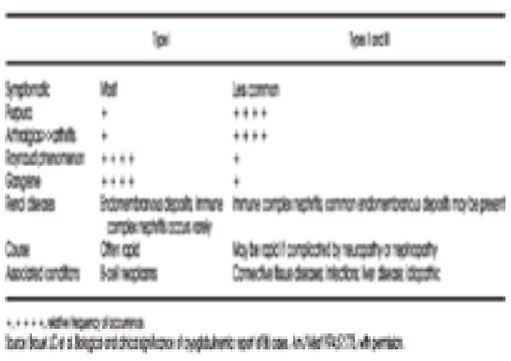

TABLE 77.7. Contrasting Clinical Features of Simple and Mixed Cryoglobulins

A syndrome of purpura, arthralgias, and nephritis associated with mixed cryoglobulins was delineated in 1966 (231), the clinical and laboratory aspects of which have been expanded and corroborated in a number of case reports and series since then (Table 77.8 and ,Table 77.9) (123,134,135,253). These patients constitute from 25% to 62% (42,253) of large series of patients found to have cryoglobulinemia.

TABLE 77.8. Clinical and Laboratory Features of Mixed Cryoglobulinemia

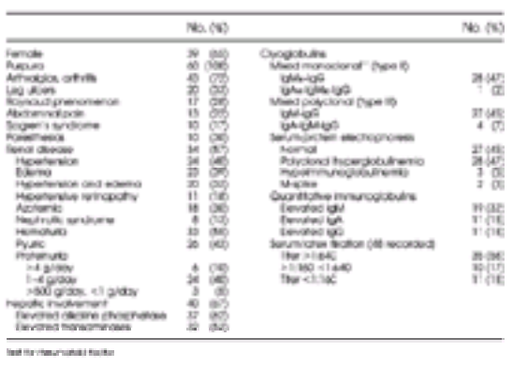

TABLE 77.9. Mixed Cryoglobulinemia (60 Patients)

SKIN

Cutaneous symptoms are especially common in these disorders, most often occurring as vascular purpura (76). The histology of these lesions is characteristically that of a leukocytoclastic angiitis (76,231), although different histologic patterns have been delineated in some instances (68). Occlusion of small vessels by hyaline thrombi may occur in cutaneous lesions of patients with type I disease (17), and in skin ulcerations complicating mixed cryoglobulinemia (27). However, care must be taken in handling biopsy specimens to exclude artifacts caused by cryoprecipitation *ex vivo*. Characteristic cutaneous manifestations of type I cryoglobulinemia are ischemic necrosis of the helix of the ear and other exposed parts on cold exposure, and livedoid vasculitis; hyperkeratotic spicules also have been observed in areas exposed to cold (40). Positive immunofluorescence showing cryocomplex constituents (monotypic or mixed) in vessel walls has been noted in some reports and used as evidence for an etiologic role for the cryoglobulin in the pathogenesis of the skin lesions (68,242,260). Often, however, results of these studies are negative.

Cold-induced urticaria may be a prominent feature in some patients. This symptom has been reported in 15% of patients with type I and in 10% of patients with type III cryoglobulinemia (42), and has been associated particularly with IgA/IgG mixed (219,389) and IgG monoclonal cryoglobulins (73,74,177). In the latter, a direct pathogenic role for the cryoprotein in the production of the skin lesions has been suggested on the basis of (a) cold-dependent complement activation *in vitro* as well as *in vivo* during an episode of cold-induced urticaria (74), (b) passive transfer experiments in which urticarial lesions can be induced by cold at skin sites sensitized directly by the cryoglobulin, and (c) positive immunofluorescence for IgG in urticarial skin lesions showing leukocytoclastic angiitis (73,384). The vast majority of patients affected by cold urticaria, however, do not have cryoproteins in their blood.

JOINTS

Although articular manifestations are common in types II and III cryoglobulinemia, frank arthritis, erosive disease, and progressive joint deformity are distinctly unusual (42,135,169). Nonspecific radiographic findings have been noted in small series (404), and rare arthrocenteses have yielded a noninflammatory joint fluid. More severe arthritis, associated with intraarticular cryocrystalglobulinemia of an IgG paraprotein, also has been reported (192,278).

NERVOUS SYSTEM

In early series, neurologic symptoms were reported to affect about 20% of patients with mixed cryoglobulinemia, most commonly in the form of a mild sensorimotor neuropathy seen as dysesthesias (135). Neuropathy may be subclinical, may result in symptoms that cause the patient to seek medical attention, or may develop later in the disease. More recent series reported prevalence rates up to 90% on the basis of symptoms, electrophysiologic findings, or nerve biopsy results, the latter of which may be positive in some instances even when nerve-conduction velocities are normal (58,115,128,130,266,376,377). Neuropathy may be symmetric and mainly sensory, patchy and asymmetric, or present as a mononeuritis multiplex. In addition to axonal degeneration, vascular changes may be prominent among endoneurial vessels, and can range from chronic vasculopathy, ischemia due to occlusion, to frank necrotizing vasculitis (130,266,376). Antimyelin antibodies have been implicated in some cases (366). In contrast to peripheral involvement, central nervous system disease due to cryoglobulinemia is rare (288). Instances of pseudotumor cerebri (96) and cerebrovascular events due to vasculitis (6) have been described.

RENAL DISEASE

From 30% to 60% of patients with MC initially have or develop renal involvement (42,135,169,253). The typical clinical picture is that of chronic glomerulonephritis and may consist of edema due to nephrotic-range proteinuria and hypertension, which is frequently severe (Table 77.9). Rarer presentations are acute renal failure, renal tubular acidosis, and papillary necrosis. Urinalysis shows proteinuria, hematuria, and red cell casts (70,135,361).

Pathologic findings are in many respects typical of an immune complex glomerulonephritis, but with several distinctive features (Table 77.10). In a large clinical series, about two thirds of patients with renal involvement were found to have membranoproliferative glomerulonephritis, and one third had mesangial proliferative glomerulonephritis (361); focal glomerulitis and purely membranous changes also have been described (42,135). Membranoproliferative glomerulonephritis has also been found in rare cases of monoclonal cryoglobulinemia in patients with chronic lymphocytic leukemia (259) or lymphoma (312), or occurring without apparent underlying disease (26,139,157,171). Here, renal deposition of IgG/anti-IgG complexes has been implicated in some instances (135). About one third of biopsy specimens from patients with MC contain large occlusive eosinophilic thrombi in small blood vessels and/or in a subendothelial or intramembranous distribution in glomeruli (361). The presence of these hyaline thrombi may suggest the diagnosis of cryoglobulinemic nephropathy even before the protein is detected in blood; their presence correlates only poorly with prognosis. From 15% to 30% of biopsy specimens have an associated renal vasculitis, which postmortem studies have indicated to be focal and segmental. Tarantino et al. (361) stressed the presence of a monocytic infiltrate in glomerular capillary loops and suggested an important pathogenic role for these cells, analogous to that indicated from studies of experimental serum sickness.

Membranoproliferative glomerulonephritis, type I (42,70,135,361)
Increased mesangial matrix
Focal glomerulitis
Membranous glomerulonephritis
Endocapillary proliferation (382)
Nodular subendothelial, intramembranous, or intraluminal deposits (hyaline thrombi) (111)
Positive immunofluorescence (IgM > IgG; C') (42,135,361)
Along glomerular basement membranes
Intraluminal thrombi
Monocytic infiltration of glomerular capillary loops (70,361)
Focal fibrinoid renal arteritis (135,361)
Interstitial infiltrate of plasma cells and/or lymphocytes
Fibrillar or tubular structures in deposits (109,111)
Crystalline inclusions in endothelial cells

TABLE 77.10. Renal Pathology

Immunofluorescence studies are positive in almost all cases and provide evidence for localization of cryocomplex components in tissue lesions (i.e., IgM > IgG > C') (42,135,361). In addition, specific MC CRIs have been demonstrated in glomerular immune deposits by using the polyclonal anti-Wa reagent or newer monoclonal antibodies (342). Particularly striking may be positive fluorescence corresponding to intraluminal thrombi in peripheral subendothelial deposits or in vessel walls at sites of vasculitis (382). Ultrastructural studies confirm the presence of electron-dense immune deposits along glomerular basement membranes. Several reports also noted the presence of distinctive fibrillar or tubular structures in deposits (109,111), reminiscent of the ultrastructure of some cryocrystalglobulins that have been examined electronmicrographically (290,355).

HEPATIC INVOLVEMENT

A number of early reports noted an association between clinical cryoglobulinemia and inflammatory liver disease (36,101,202). The latter is often subclinical, recognized by hepatomegaly and/or mildly elevated liver enzyme levels, and occasionally appreciated only at postmortem examination (135,202). Pathologic studies reveal a spectrum of lesions in different patients, ranging from minimal triaditis to chronic active hepatitis and/or cirrhosis. Most commonly, a chronic persistent hepatitis, often with a striking mononuclear cell infiltrate, is seen (36,202,252). Mixed cryoglobulins also may be found in patients with acute and chronic hepatitis and inflammatory bowel disease (ulcerative colitis, Crohn ileocolitis) without other clinical manifestations of cryoglobulinemia (101,120,201,223).

HEPATITIS C VIRUS AND MIXED CRYOGLOBULINEMIA

Since 1990, after the identification of the causative agent of “non-A non-B” hepatitis, a number of well-described case reports and clinical series corroborated an association between HCV infection and cryoglobulinemia (Table 77.11). Most of these studies originated from areas in southern Europe known to have a high incidence of HCV-associated hepatitis (30,55,82,92,114,211,246,283,359,406). Both types II and III mixed cryoglobulins have been found in several series (Table 77.10), whereas small surveys of type I cryoglobulinemia did not reveal a significant incidence of HCV antibody or HCV RNA. Overall, the prevalence of cryoglobulins in HCV infection has ranged from 13% to 54% (44,63,153,204,212,415), and the incidence of HCV associated with MC has ranged from 42% to 98% (93).

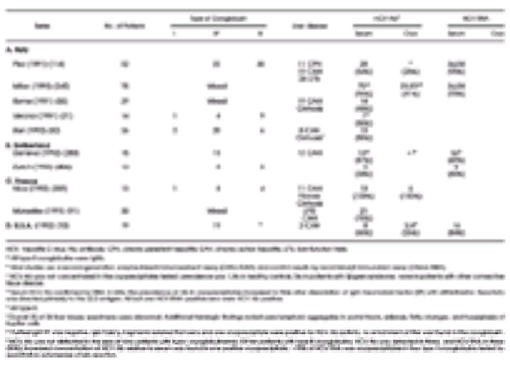

TABLE 77.11. Hepatitis and Cryoglobulinemia

By analogy to previous studies (Table 77.6), an etiologic role for HCV-containing immune complexes has been inferred in reports of concentration of HCV antibodies (HCVAbs) and/or HCV RNA in the cryoprecipitates of patients with MC (10,31,49,114,261). Most HCVAb activity directed to standard linear recombinant antigens used in commercial assays appears to be associated with the IgG fractions of mixed cryoglobulins (329). Of some interest has been the increased prevalence of HCV RNA compared with HCVAb in cryoprecipitates. RNase insensitivity of the HCV RNA in the cryoprecipitates suggested the possibility that they might contain antibodies to conformational determinants on the intact virion that are not recognized by standard assays for nucleocapsid or nonstructural protein antigens (10); alternatively, antibody activity may be directed to HCV quasispecies hypervariable regions that may be complexed in the cryoprecipitates or are not recognized in standard assays (13,190). An etiologic role also is suggested by the presence of HCV viral RNA and viral antigens in skin (11,320) and renal lesions (321) of patients with

cryoglobulinemia.

Several reviews have summarized an increasing spectrum of extrahepatic disease associated with HCV infection (144,191,228,410), including rheumatologic (405), cutaneous (69,146), and renal (85,331,344) manifestations that overlap with and extend descriptions of the clinical and pathologic features of cryoglobulinemia before appreciation of this association (Table 77.12). These series and case reports have expanded the articular (43,197,308), renal (80,254), cutaneous (98), and neurologic (86,364) disease manifestations that may be associated with, or that may occur in HCV infection apparently without cryoglobulinemia. More problematic have been reports associating HCV infection with other rheumatologic disorders, such as Sjögren syndrome and polyarteritis nodosa, where conflicting results have been obtained from different geographic areas (Table 77.12) (191,381); although HCV may be significantly associated with lymphocytic sialoadenitis (289) and sicca syndrome (176), most of these patients do not have other immunologic or clinical features of Sjögren syndrome. Overall, two large surveys from France (one multicenter and one a single monocenter cohort) reported prevalences of 19% to 23%, 15% to 17%, 11% to 12%, and 9% to 17% for joint disease, skin manifestations, sicca, and neuropathy, respectively, among patients with chronic HCV infection (45,47).

TABLE 77.12. HCV: Autoimmunity, Immunologic/Musculoskeletal Diseases, and Lymphoproliferation

Laboratory Findings

Serologic evidence of IgM RF activity (135) and selective depletion of the early components of the classic pathway of complement are characteristic although not invariable (360). For these studies, care is necessary in the processing of whole blood, as exposure to the cold for periods of time may allow cryoprecipitation to occur before the serum is separated, and cause complement activation *in vitro*. Rarer artifacts are pseudoleukocytosis and pseudothrombocytosis on Coulter analysis due to precipitation of cryoprotein in aggregates with the dimensions of white blood cells or platelets (137). Elevation of the erythrocyte sedimentation rate due to rouleaux formation also may be seen (391). In different series, disease activity, presumably due to active vasculitis, has been reflected in blood levels of endothelial cell markers and a fragment of the basement membrane antigen, laminin (125,369); anti–endothelial cell antibodies have been reported among HCV-infected patients with cryoglobulinemia (see also Table 77.8 and ,Table 77.9) (46).

A phenomenon that has been termed cold-dependent activation of complement (CDAC) is prevalent in HCV-infected persons (373). In CDAC, CH50 is low after cooling to 4°C overnight; C4 protein is normal, even though hemolytic C4 is low. CDAC was found in 28 (41%) of 69 HCV-infected sera, and none infected by hepatitis B virus. More than half of CDAC sera show cryoprecipitation, and 35% of samples with cryoprecipitation also showed CDAC. CDAC appears to represent a complement abnormality that may correlate somewhat with liver damage and response to treatment with interferon-a (IFN-a) (273). The mechanism responsible for this phenomenon is not understood, but may be consequent to HCV/antibody/mRF complexes with differing stoichiometry (403).

Similar to other chronic viral infections, in several of which [e.g., EBV, cytomegalovirus (CMV)] cryoglobulins and RF activity may be prevalent (Table 77.1), other autoantibodies have been found to occur with increased frequency in patients chronically infected by HCV (45,47,65,282,375). In general, the prevalence of autoimmune phenomena greatly exceeds that of autoimmune disease. Thus most ANAs are low titer and lack identifiable antigen specificity, most anticardiolipin antibodies are not associated with anti-b_2 glycoprotein 1 or clinical thrombosis (150,200,274), and, although thrombocytopenia secondary to hypersplenism is common in end-stage liver disease, autoimmune thrombocytopenia also may occur (Table 77.12) (23,150,158). The relative contributions of upregulation of specific germ-line genes encoding autoantibodies versus virus, or viral antigen-driven, autoimmune responses to these phenomena remain to be defined (327).

Studies that have addressed the possible contributions of viral versus host factors to the expression of autoimmunity in the setting of chronic HCV infection and hepatitis have yielded inconclusive results. Although skewing to a 2a genotype has been seen in some surveys of cryoglobulinemic patients, most studies have not revealed significant correlations with specific genotypes or subtypes of HCV compared with appropriate controls (79,122,275,343,409,421,422 and 423). A role for HLA restriction of cellular or humoral immune responses in HCV infection is suggested by increased expression of HLA antigens by infected hepatocytes (20); the fact that HLA class I–restricted cytolytic cells specific for HCV core, E1/E2, and NS2 proteins have been identified among liver-infiltrating lymphocytes, and can be expanded from peripheral blood with antigen (155,416); and increased levels of soluble HLA class I antigens in blood (209). Nevertheless, two studies that examined HLA antigens in patients with HCV-associated mixed cryoglobulinemia produced somewhat discordant results (16,199).

Lymphoproliferative Disease

Laboratory evidence of clonal B-cell proliferation in patients with type II cryoglobulinemia includes selective V-region gene use of heavy and light chains of the circulating monoclonal IgM, based on protein sequencing and the prevalence of MC CRI, increased numbers of IgMk-bearing B cells in peripheral blood, increased numbers of cells producing V_kIIIb-positive antiglobulins, evidence for immunoglobulin gene rearrangement among peripheral B cells (221), and increased numbers of clonal or oligoclonal lymphoid or plasmacytoid aggregates in bone marrow, assessed immunohistologically or by fluorescence-activated cell sorter analysis (FACS) (90,136,221,251,293,303). Interestingly, B-cell proliferation in the livers of patients with chronic hepatitis and cryoglobulinemia is distinct from that occurring in the peripheral compartment, or possibly in lymph nodes (84,322), in that hepatic B cells are more often CD5 positive (252), do not appear to be associated with HCV RNA, and do not appear to be significantly skewed to RF or MC RF V-region gene use (218,323). Clonal B-cell proliferations in peripheral blood are common among HCV-infected patients with or without evidence of type II cryoglobulinemia (124), and may regress with effective antiviral therapy (221). Limited V-region sequence analysis of monoclonal B-cells from patients with HCV-associated immunocytomas, or isolated from peripheral blood by using anti-CRI have confirmed skewing to kv325/51p1 gene use and intraclonal diversity consistent with antigen stimulation (78,170).

It has been recognized for many years that patients with type II mixed cryoglobulins may be found to have, or may develop, overt B-cell lymphoproliferative disease (42,135,136,168,293). Thus initial evaluation of such patients may include a computed tomography (CT) scan of the abdomen to look for organomegaly or significant retroperitoneal adenopathy, and a bone marrow examination that might include FACS analysis. An increased prevalence of HCVAb and/or HCV RNA among patients with NHL has been reported from a number of geographic areas in Italy since 1994, confirmed from France, Japan, the United States, Romania, and Turkey, but has not been universally corroborated (103). Limited studies have suggested that NHL in this setting of chronic infection may be analogous to mucosa-associated lymphoid tissue (MALT) tumors that develop after chronic *Helicobacter pylori* infection, and that the development of malignant lymphoid cells may be antigen driven (87,170). HCV-specific mechanisms that may potentiate oncogenesis in this setting include biologic effects of the core protein in modulating apoptosis and cell transformation (226), and direct interactions between envelope protein 2 (E2) and CD81, a cell-surface receptor on B (and other) cells, which may potentiate activation and proliferation (287); a correlation between lymphomagenesis and T(14;18) translocation also has been reported (424).

Clinical Course

Long-term follow-up studies of patients with essential mixed cryoglobulinemia indicated that in the absence of renal disease or progressive neurologic involvement, symptoms may remain static over prolonged periods (Fig. 77.4) (135,168). Patients need to be monitored closely, however, as some progress to clear-cut autoimmune or lymphoproliferative disease (134,284). In one recent series, NHL developed in five of 13 patients (123). The clinical course of patients with renal involvement is highly variable, with an overall 5-year survival rate of more than 60% (250). Fewer than 10% of patients have acute nephritis and have rapidly progressive renal failure with a poor outcome. The more common clinical picture is that of chronic glomerulonephritis, which may be recognized incidentally during evaluation for hypertension or cutaneous vasculitis. In a large clinical series, in 30% of patients with renal disease, acute renal failure developed at some point in their course, 7% progressed to chronic insufficiency, and only one (0.02%) of 44 patients required dialysis (361).

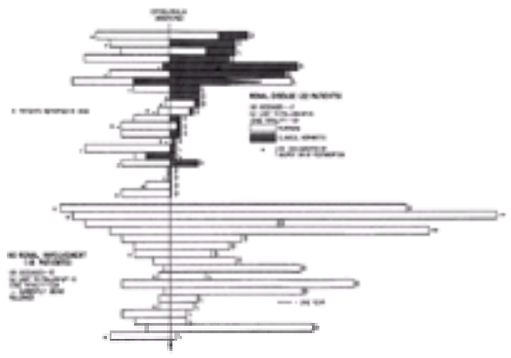

Figure 77.4. Long-term follow-up of 40 patients with “essential'` mixed cryoglobulinemia. *GN*, glomerulonephritis. (Updated from Gorevic PD, et al. Mixed cryoglobulinemia: clinical aspects and long-term follow-up of 40 patients. *Am J Med* 1980;69:287, and Gorevic PD. Mixed cryoglobulinemia: an update of recent clinical experience. In: Ponticelli C, Minetti L, D'Amico G, eds. *Antiglobulins, cryoglobulins, and glomerulonephritis*. Hingham, MA: Martinus Nijhoff, 1986:179–192.)

Treatment

Patients with mild cutaneous symptoms may require no therapy at all or can be managed symptomatically. A low-antigen diet was found to benefit stable purpura and to improve liver function and immune complex clearance function in a study involving 24 patients, nine with type II and 15 with type III cryoglobulinemia (37,117). Some patients may benefit from short courses of high-dose corticosteroids, and/or cytotoxic agents (6,191). High-dose intravenous gamma globulin (IVIG) has been reported to result in renal failure in one case of mixed cryoglobulinemia (22), and therefore should be used with caution; nevertheless, it led to disappearance of cutaneous vasculitis in a separate report (39), and appears to be well tolerated in others.

Immunosuppressive therapy has generally been reserved for patients with renal or progressive neurologic disease or other major organ involvement. Aggressive treatment of renal disease due to cryoglobulinemia may be necessary in the few patients in whom acute renal failure develops early or in those in whom nephrosis or progressive azotemia develops later (80,129,361). Adequate control of hypertension is particularly important in the group of patients with stable chronic renal disease (361). Because early reports indicated little benefit of corticosteroids alone in these patients (248), many have been treated with cytotoxic agents combined with high-dose steroids (129). Monthly pulse methylprednisolone has been used to reverse deteriorating renal function in uncontrolled studies (89). Cytotoxic agents that have been found to be effective include melphalan, chlorambucil, and cyclophosphamide (7,93). Purine analogs (2-chlorodeoxyadenosine; fludarabine) have been reported to be efficacious for refractory disease (105). Patients with end-stage renal disease can be maintained by dialysis (361) or can undergo transplantation; in some patients with mixed cryoglobulinemia, however, disease quickly recurs in renal allografts (160).

The effects of plasma exchange on the laboratory and clinical manifestations of cryoglobulinemia were studied in several series and case reports (129,316). Plasma exchange is rarely effective alone and is usually combined with cytostatic drugs (112) to suppress a rebound phenomenon that may develop about a week after each exchange (1). Treatment schedules and exchange volumes have varied greatly between reports, and controlled trials with sham apheresis have not been attempted. Cryopheresis, in which autologous plasma depleted of cryoprecipitable protein is returned to the patient, or cryofiltration using large-bore membranes, has been advocated by some investigators (1,162,340). Plasma exchange effectively lowers the cryocrit and other immune complex assay parameters, and may lead to improvement in measures of reticuloendothelial clearance, but has a variable effect on antiglobulin activity and complement levels (96). It may be particularly useful in the short-term management of cold-induced symptoms in type I cryoglobulinemia, and may benefit renal disease (107) or neurologic involvement (129) in patients with mixed cryoglobulinemia. Proof of efficacy of IFN-a was shown in an initial study involving seven patients with type II mixed cryoglobulinemia reported 2 years before the description of HCV (38), and has been confirmed in a number of series since 1991 (Table 77.13) (99,184). IFN-a has been used mostly in the setting of stable disease, is active for both types II and III HCV-associated cryoglobulinemia, but has not been shown to be efficacious for acute, progressive, or life-threatening presentations; appropiate therapy for cryoglobulinemia in patients coinfected with HBV or human immunodeficiency virus (HIV), or in the posttransplant (liver, kidney) patient with HCV-associated cryoglobulinemia, has not been established. IFN appears to be most effective for cutaneous vasculitis, and may be useful for glomerulonephritis, even after other therapies have failed (256,324), or combined with apheresis (182). Crossover studies have shown superior efficacy to corticosteroids with regard to virologic, biochemical, and clinical parameters (83,193). Although an antiviral effect has been implicated, it is not clear whether the beneficial responses observed also may be due to the antiproliferative or immunomodulatory effects of this drug; thus regression of clonal B-cell proliferation (221) and gammopathy (330), even in the absence of cryoglobulinemia, has been seen, and IFN-a may be effective therapy for HCV-negative cryoglobulinemia (57). Similar to the general experience in chronic HCV, although many patients respond to IFN-a, some are unable to tolerate the drug (277), relapses are frequent, and sustained responses off treatment are rare (Table 77.13). Ribavirin appears to be an effective modality for the treatment of mixed cryoglobulinemia associated with HCV, either as a monotherapy (100), or combined with IFN-a. Combination therapy has largely replaced the use of IFN-a alone because of higher response rates; similar to IFN-a, the effectiveness of ribavirin may be consequent as much to its immunomodulatory as to its antiviral effects (271). Additional treatment strategies may be expected to result from better understanding of the ways by which HCV succeeds in evading IFN-induced antiviral responses (363).

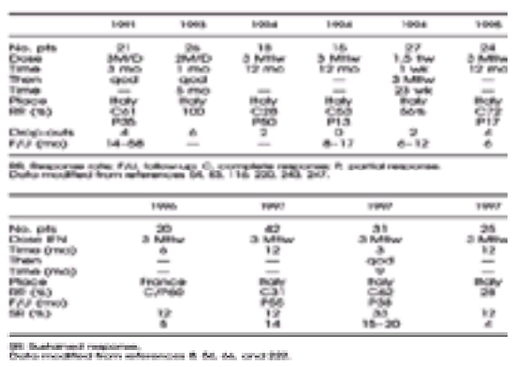

TABLE 77.13. Efficacy of IFN-a Monotherapy for Mixed Cryoglobulinemia Associated with HCV

The goal of specific therapies directed to immune abnormalities characteristic of cryoglobulinemic states has great appeal, stimulated by the introduction of biologics for the treatment of other immunologic and lymphoproliferative diseases. For the cryopathies, these include the therapeutic potential of monoclonal anti-CRI antibodies as generic agents that may downregulate specific antibody production, or help to clear specific immune complexes from the circulation (5,136), other monoclonal antibodies targeted to specific B-cell subsets (420), and agents that may interfere with complex formation between the IgM and IgG components of mixed cryoglobulins at the level of the antigen-binding site (302).

CRYOFIBRINOGENEMIA

The term *cryofibrinogenemia* has traditionally been used to refer to the presence of reversibly cold-precipitable protein in anticoagulated blood that can be shown antigenically or functionally to be fibrinogen (300,349). Cryoglobulinemia is excluded by the absence of a comparable precipitate in a paired sample of serum and the fact that immunoglobulin is not a significant component of the isolated cryofibrinogen. Plasma is collected in citrate, oxalate, or ethylenediaminetetraacetic acid (EDTA) (but not heparin) at 37°C and allowed to stand overnight at 4°C. Blood should be collected rapidly and sufficient anticoagulant added (e.g., 9:1, vol/vol blood/citrate) to avoid *in vitro* induction of fibrin formation. Thrombin inhibitors such as hirudin (1 to 5 units/mL) also may be added to citrated blood during collection to inactivate any formed thrombin (354). Although older reports noted the presence of “trace” amounts of cryofibrinogen in the plasma of “healthy” controls, these precautions were not routinely observed (224). Consequently, the presence of significant amounts of cryofibrinogen in normal plasma should be considered problematic and unlikely. In contrast, normal plasma that is freeze/thawed forms a major cryoprecipitate containing fibrinogen, fibrin, and fibronectin, and that is enriched in factor VIII and von Willebrand factor. This preparation has been used as replacement therapy for patients with von Willebrand disease, hemophilia A, or afibrinogenemia.

Clinical Features

In older and recent screening surveys, cryofibrinogen was reported in about 3% of random blood samples from hospitalized patients or healthy blood donors (33,349).

Prominent clinical associations include neoplasms and thromboembolic disease. Neoplastic states seen in association with cryofibrinogenemia are multiple myeloma, various solid malignancies (notably prostatic carcinoma), and leukemia. Thromboembolic disease may occur as occlusion of major vessels with secondary ischemia and gangrene, myocardial infarction, or stroke. Other associations noted in some large series have included pregnancy-at-term, use of oral contraceptives, diabetes mellitus, thrombotic vasculopathy (25), Raynaud phenomenon, cold-induced urticaria, pseudotumor cerebri, IgA nephropathy (264), and connective tissue diseases (33,224,349). Rare cases of apparently essential or familial cryofibrinogenemia also have been described (25,300,378).

Mechanisms

Fibrinogen-containing precipitates may form in plasma by at least two distinct mechanisms, neither of which requires the presence of a structurally abnormal fibrinogen. Both mechanisms yield cryoprecipitates consisting of fibrinogen, fibrin, and fibronectin in varying ratios (Fig. 77.5) (257).

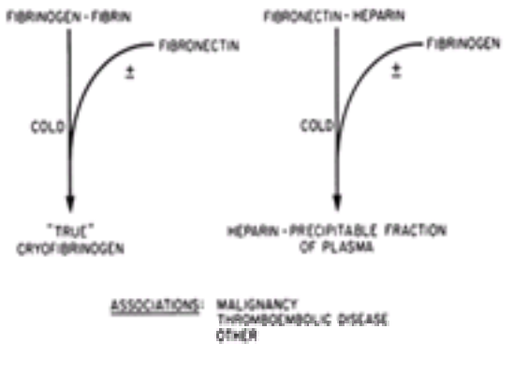

Figure 77.5. Pathogenic mechanisms for the formation of cold-insoluble fibrinogens.

HEPARIN-PRECIPITABLE FRACTION

The phenomenon in which the addition of a sulfated mucopolysaccharide such as heparin to plasma leads to a cryoprecipitate was first described as a concomitant of endotoxemia. It has since been found in a variety of other clinical states (348). The inciting event is the formation of cryoprecipitable complexes between heparin and fibronectin, although with reduced threshold and increased amounts in the presence of fibrinogen. Fibrinogen is incorporated secondarily during cryoprecipitation, accounting for its variable and sometimes minor contribution (353,358). This form of cryofibrinogen may be seen in the evaluation of any patient who is treated with heparin or who may have heparin in the line from which blood is taken.

FIBRIN COLD INSOLUBILITY

In this entity, the primary event appears to be the formation of complexes between fibrin and fibrinogen, with fibrin being the essential component for cold insolubility. Thus the amount of precipitate obtained will be determined by the relative concentrations of fibrin and fibrinogen, and fibrinogen alone will not cold-precipitate to any significant extent (354). The requisite for this molecular event will be any condition in which increased circulating levels of fibrin may be present, such as frank chronic intravascular coagulation (258). Cryofibrinogens also can be induced in normal plasma by addition of thrombin or thrombinlike enzymes in trace amounts sufficient to generate fibrin at low enough levels (15–30:1 *M* ratios of fibrinogen to fibrin) to prevent polymerization and permit the formation of soluble complexes with fibrinogen (257,354).

Fibronectin is not an essential component of this form of cryofibrinogen, but it is frequently incorporated because it may circulate as a complex with fibrin. Fibronectin itself is cold insoluble and, as noted earlier in regard to cryoglobulins, may act as a nucleus for binding of other proteins (e.g., C1q, IgG) or as a cryoprecipitagogue (53,151,313).

Treatment

Therapy is directly primarily to the underlying disease. The evaluation of thromboembolic disease in a young woman should also include a search for a lupus anticoagulant or antibodies to cardiolipin and, as noted earlier, positive results must be carefully interpreted in the setting of chronic HCV infection (200,274). Heparin has been used for the chronic intravascular coagulation syndrome, with the level of cryofibrinogen reflecting to some extent the response to therapy (258), stanozolol has had some success for the treatment of painful leg ulcers (108).

78 VIRUSES

Michael B.A. Oldstone, M.D., and Persephone Borrow, Ph.D.

VIRAL DISEASES AND THE ORIGINS OF VIROLOGY

Diseases caused by viruses have been described since antiquity, but the identification and description of viruses as infectious agents occurred just over 100 years ago, near the end of the nineteenth century (141). Thus, smallpox and measles made their appearance with the urbanization of cities along the banks of great rivers and the gathering of both people and animals in more restricted areas. Pox marks reminiscent of smallpox are found on the face and neck of the mummy of Ramses V (1158 BC), the earliest illustration of a suspected case of poliomyelitis occurs in an Egyptian stele dating from the eighteenth dynasty (1580–1350 BC), and description of rabid dogs is noted in early Greek and Roman literature. It was not until the late 1890s, however, that viruses were recognized as distinct infectious agents and as dangers to health.

The mid-1800s were the time of discovery of bacteria and the pioneering work of Louis Pasteur, Robert Koch, and their associates. During that period, the laboratory culturing process was developed so that bacteria could be grown, fixed on glass slides, stained, and observed under the microscope. Bacteria were retained on filters with defined pore sizes. After their identification, specific bacteria could be linked with particular disease states. This was the framework in which the first viruses were uncovered. Just before the twentieth century began, Dmitri Iosifovich Ivanovski in Russia and Martinus Beijerinck in the Netherlands demonstrated that the material responsible for a disease of tobacco plants was not retained but was passed through the pores of a Pasteur–Chamberland filter without losing infectivity (reviewed in 141). They found that this soluble residue of filtration could grow on healthy tobacco leaves. Their results constituted the first report of a plant virus, the tobacco mosaic virus. Similarly, Friedrich Loeffler and Paul Frosch in Germany concluded that the agent causing foot-and-mouth disease of cows also passed through porcelain filters and induced symptoms of disease when inoculated into previously healthy cattle. These observations, highly controversial at the time, provided the basis for defining viruses as subcellular entities that could cause distinct forms of tissue destruction, which became marks of specific diseases. Using similar techniques, yellow fever virus was the first virus isolated from humans. This isolation was achieved in 1901; so the twentieth century has seen the isolation, characterization, and understanding of viruses that involve both human and animal populations.

DEFINITION OF VIRAL DISEASES

Many viral infections are recognized as an acute illness. The causative virus enters the body, multiplies in one or more local tissues, and then may spread further through the blood or along nerves. The incubation period of 2 days to 2 or 3 weeks is followed by signs and symptoms of disease and local or widespread tissue damage. Viruses can be isolated from the patient's blood (serum or cells) or secretions for a short time just before and after the appearance of symptoms. The infected host either dies during the acute phase of illness or recovers from the infection and may exhibit life-long immunity to that virus.

Distinct from acute infections are persistent infections in which the immune response fails to completely eliminate the infection from the body, and virus may persist for months or years. Some viruses, for example, human immunodeficiency virus type 1 (HIV-1), persist at high levels and can be recovered throughout the entire course of infection. Although both humoral and cell-mediated immune responses are mounted following HIV-1 infection and play an important role in controlling virus replication, the immune response is not capable of terminating the infection. During the end stages of this infection, T-cell immunity declines, the viral load increases, and death from acquired immunodeficiency syndrome (AIDS) occurs.

A variation of persistent infection is *latent* infection, during which virus may remain in the host or within certain host cells without ongoing productive replication. Activation from latent to productive virus replication can occur, however, to allow virus spread. Latent infection is best exemplified by herpesviruses, for example, herpes simplex virus type 1 (HSV-1), in which reactivation results in cold sores, or varicella zoster virus (VZV), in which reactivation results in shingles. Figure 78.1 illustrates the clinical differences between acute, persistent, and latent infections.

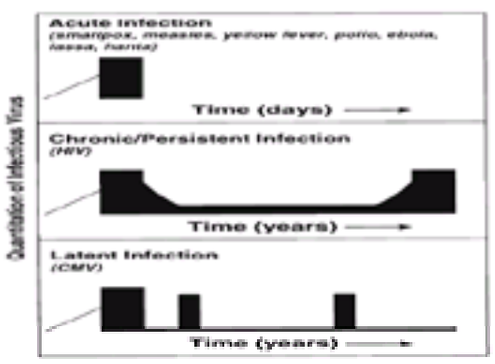

Figure 78.1. Infections caused by viruses differ. Some are acute, with virus elimination occurring in a week or two. Others are chronic, like HIV, which routinely runs a prolonged infectious course, whereas other viruses, like herpes simplex virus, persist in a latent form and infection sporadically reactivates, causing exacerbation of disease. The dark areas indicate the presence of infectious virus. (For more information, see Oldstone MBA. *Viruses, plagues and history*. New York: Oxford Press, 1998.)

Despite attempts to implement the current wealth of information about viral structure, genetics, replication, epidemiology, and pathogenesis in the control of viral diseases, viruses remain the most common cause of acute illness today and are implicated in an ever-increasing number of chronic diseases. How do viruses cause disease? Three mechanisms may be involved. First, the virus or its proteins may be directly toxic to cells, and the virus may kill the host cells it infects. With some viruses, this process serves to release virus particles from within cells to the outside environment. Second, the virus may not kill the cells it infects, but instead it may alter their differentiated functions. By this means, the synthesis of an important product made by a cell may be turned down or turned up; some examples are discussed later. The third way in which injury and disease can follow a viral infection is through the participation of the host's immune response. The antiviral immune response is generated to destroy infected cells or rid them of virus progeny and to remove infectious virus from the host's blood and other body fluids. By destroying virally infected cells or by causing “bystander” damage to surrounding cells, the immune system can damage tissues that are critical for the health of the organism. The immune response thus has potential to cause disease: this is called *immunopathology*. The balance between the protective and destructive processes of the immune system is in large part responsible for the clinical symptoms and signs that accompany virus infections.

The importance of the immune system in regard to viral diseases is thus tripartite. First, it may prevent the establishment and spread of virus infections so that pathologic consequences do not ensue. Prevention occurs when the nonspecific immune defenses are sufficient to block infection or if there is preexisting specific immunity to the virus as a result of vaccination or previous infection. Second, the immune response may combat established virus infections and terminate virus-mediated damage to host tissues. Third, antiviral or autoimmune responses evoked following virus infection may themselves have immunopathologic consequences.

This chapter briefly overviews viruses and their life cycles, giving some examples of their importance in human disease. It goes on to discuss different immune effector mechanisms and what is known from studies in animal models and in humans of their importance in protection against and the pathogenesis of viral diseases. Finally, it outlines strategies viruses have evolved to counter immune defenses.

VIRUS GENOME AND STRUCTURE

Viruses are among the smallest of all microorganisms and have an obligate requirement for intracellular growth because they depend on host cell structural and metabolic components. A virus particle, or *virion*, is composed of the viral genome, which may be single- or double-stranded, segmented or nonsegmented DNA or RNA, complexed with viral (and sometimes host) protein(s) to form the nucleocapsid, which may be filamentous or icosahedral. This nucleic acid and protein assembly may be surrounded by a lipid envelope in which one or more viral proteins are embedded, or it may be a more complex structure (Fig. 78.2). Viruses are classified on the basis of the type of genome they possess and whether the virion is enveloped. Table 78.1 illustrates this point and provides selected examples of human pathogenic viruses in various families. There is great diversity in size and complexity among viruses of different families; whereas poxvirus and herpesvirus genomes encode hundreds of proteins, parvoviruses and arenaviruses encode only four or five proteins. Viruses have relatively few genes, 4 to fewer than 200, compared with other organisms, for example, 5,000 to 10,000 genes for the smallest bacteria and approximately 70,000 to 90,000 genes for a human.

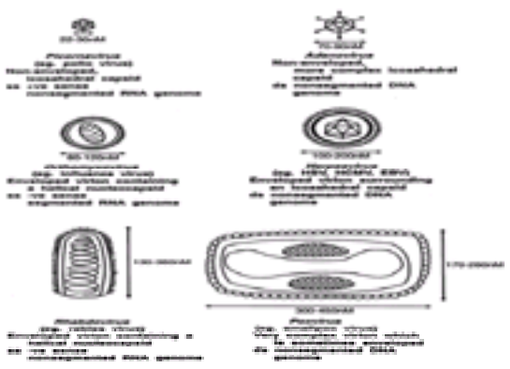

Figure 78.2. Examples of virus structure.

Class/delta	Virus family	Example
DNA viruses		
ds DNA, enveloped	Poxviridae	Smallpox, vaccinia
	Herpesviridae	Herpes simplex types 1 and 2, cytomegalovirus, Epstein-Barr virus, varicella-zoster virus
ds DNA, nonenveloped	Adenoviridae	Human adenoviruses
	Papovaviridae	Human papillomaviruses; JC and BK polyomavirus
ds/ss DNA, nonenveloped	Hepadnaviridae	Hepatitis B virus
ss DNA, nonenveloped	Parvoviridae	Human parvovirus B19 and B19-2
DNA virus with a DNA step in replication		
ss RNA, enveloped	Retroviridae	Human T-lymphotropic viruses I and II; HIV-1 and -2
Other RNA viruses		
ds RNA, nonenveloped	Reoviridae	Colorado tick fever virus, human rotaviruses
ss RNA, positive sense, enveloped	Togaviridae	Rubella virus and many encephalitis-causing alphaviruses
	Coronaviridae	Human coronaviruses
	Flaviviridae	Yellow fever virus, dengue virus, West Nile virus, and other encephalitogenic viruses
ss RNA, positive sense, nonenveloped	Picornaviridae	Poliovirus, coxsackie viruses, human enteroviruses, hepatitis A virus, human rhinoviruses
	Caliciviridae	Norwalk and other gastroenteritis viruses
ss RNA, negative sense, nonsegmented genome, enveloped	Paramyxoviridae	Parainfluenza viruses, measles virus, respiratory syncytial virus
	Rhabdoviridae	Rabies virus, vesicular stomatitis virus
	Filoviridae	Marburg and Ebola viruses
ss RNA, negative sense, segmented genome, enveloped	Orthomyxoviridae	Influenza viruses
ss RNA, ambisense, segmented genome, enveloped	Bunyaviridae	Bunyamwera virus, LaCrosse virus, Rift Valley fever virus
	Arenaviridae	Junin, Lassa, Machupo, LCMV

LCMV, lymphocytic choriomeningitis.

TABLE 78.1. Families Containing Viruses of Pathogenic Importance to Humans

It has been argued that the nucleic acid of viruses may have evolved from normal cell genes. Via gradual mutation, recombination, and reassortment, viruses could have evolved their own genetic structure. Mechanisms by which viruses can mutate are diagrammed in Fig. 78.3. Some viruses may have stayed within the parental host from which they evolved and display symbiotic or near-symbiotic relationships; but, as viruses moved from one host species to another or mutated to form new genetic mixtures, these formerly nonpathogenic viruses may have achieved a high level of virulence. A recent example is that of a primate virus that causes little or no disease in its natural host, the chimpanzee: Its transmission to humans (either through bites, contact with contaminated blood, or consumption of infected animals) is thought to have been the cause of the HIV-1 epidemic (59). Other examples include arenaviruses that produce asymptomatic or almost asymptomatic infections in their natural rodent hosts but on transmission to humans cause Lassa fever or Argentinian hemorrhagic fever and influenza viruses that cause asymptomatic infections in aquatic birds but cause disease in humans.

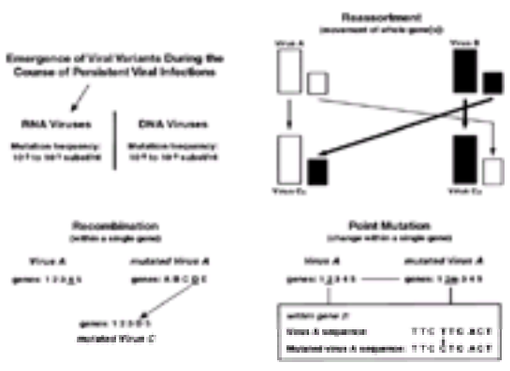

Figure 78.3. Cartoon of the constantly evolving landscape of viruses. **A:** The high mutational rate of RNA viruses. Because the polymerases of RNA viruses lack a proofreading mechanism to correct errors that occur during genome replication (DNA virus polymerases have such a proofreading mechanism), swarms of mutant viruses, making up a quasispecies, are constantly generated, with the fittest viruses selected over time by evolution. Hence, the progeny of a cloned RNA virus is not a clonal population (subst/nt = substitutions per nucleotide). B–D schematically show the three primary ways genetic changes occur in viruses. **B:** Reassortment (i.e., the movement of entire segments of genetic information). Each box represents a separate piece of nucleic acid that may encode one or several genes. **C:** The process of recombination, illustrated here as causing change in a single gene. In this example, gene D from mutated virus A replaces gene 4 of virus A to form new virus C. **D:** Changes introduced within a single gene by point mutation. Alteration of a single nucleotide within a gene can give rise to a new virus with distinct biological properties. Nucleotides depicted: (T) thymine; (C) cystosine; (A) adenine. The example shown is real data from a study using LCMV. Virus A (which represents part of the sequence from Armstrong strain) undergoes a T C mutation at base pair 855. The TTC triplet codes for the amino acid phenylalanine; the mutated *C*TC codes for the amino acid leucine. This single amino acid change allows the mutant virus to cause immunosuppression and establish a persistent infection in adult mice; by contrast, the parental virus does not cause immunosuppression and is readily cleared from adult animals.

VIRUS INFECTION AT THE CELLULAR LEVEL

Virus replication in host cells involves a series of steps. First, the virus contacts the cell to be infected and then attaches to its surface. Second, the virus conveys its genetic material and accessory proteins across the plasma membrane barrier into the cell cytosol. Further uncoating then may need to occur, and the virus may traffic to a particular site in the cell (e.g., the nucleus). Viral gene expression and genome replication then take place. Finally, virion assembly and release of mature virions from the host cell occur.

The first steps in virus infection of a host cell, attachment, and entry are dependent on interactions between virion proteins and specific components of the host cell surface. As illustrated in Table 78.2, different viruses may use cell membrane lipids, carbohydrates, or proteins as binding and entry receptors on host cells. Of the

viruses that bind to protein receptors, a surprisingly large number evolved to use cell membrane proteins that are members of the immunoglobulin superfamily or have immunologic functions as their host cell receptors. One explanation could be that virion binding to these proteins confers some advantage on the virus in terms of immune evasion. For example, in HIV-1, use of the CD4 protein as its primary cellular receptor (46,118) results in this virus infecting $CD4^+$ T cells, which may contribute to impairment of this arm of the antiviral immune response observed in most HIV-1-infected patients (165). In many cases, however, such a link has yet to be demonstrated. In addition to access through classic receptor interactions, viruses sometimes enter cells by other means. For example, infectious virus complexed with antibody can bind to and enter Fc receptor positive cells even though they may not bear specific receptors for the virus.

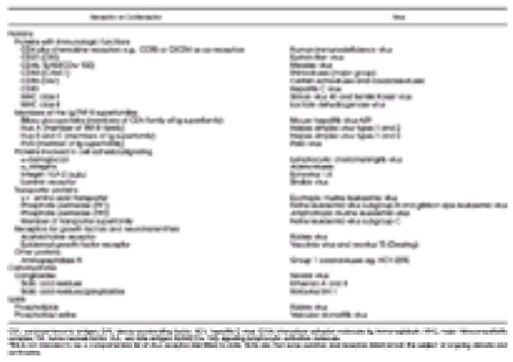

TABLE 78.2. Examples[a] of Host Cell Surface Components Used as Receptors by Viruses

Virion binding to the host cell surface is followed, often within seconds, by virus entry. This is an active, energy-dependent process. For some enveloped viruses, including HIV-1, entry is achieved by a virion protein with fusion function causing the viral envelope to merge with the host cell plasma membrane so that the viral nucleocapsid is released into the cytoplasm. Many other viruses enter the host cell by endocytosis, and then, as the endocytic vesicles move into the host cell and their internal pH drops, virion proteins are triggered to mediate transfer of the virus genome into the cytoplasm. Specific immune response that prevent the establishment and spread of virus infection are thus generally directed against virion structural components, frequently the viral proteins involved in attachment and fusion.

The pattern of expression of specific attachment and entry receptors for viruses on host cells is a key determinant of virus tropism within the host; however, virus replication also may be blocked at subsequent steps in the replication cycle. The virus must be able to traffic within the cell to the site where replication takes place. A major block to HIV-1 replication in resting cells is the inability of the viral replication complex to cross the nuclear membrane into the nucleus, where proviral DNA integration and replication take place. The cell also must provide an appropriate environment for viral transcription, protein production, and genome replication to take place. Viruses may use a variety of strategies for ensuring that their own products are efficiently produced within the host cell. Host cell transcription and translation may be shut off completely, as seen, for example, with poliovirus, or they may be more subtly altered.

Assembly of progeny virions then occurs within the nucleus or the cytoplasm. For enveloped viruses, the virion envelope proteins are inserted into a host cell membrane, in some cases the plasma membrane, and new virions bud from this surface. Virions formed within the cell may be released without cell lysis; in other cases, the host cell is lysed to enable virion release. Virus infection may result in death of the host cell by a number of mechanisms, including shutdown of cellular macromolecular synthesis, toxicity of accumulated viral capsid proteins, syncytium formation, or direct lysis. However not all productive virus infections are lytic, as exemplified by the noncytopathic infections caused by arenaviruses and many retroviruses.

From this brief, generalized account of virus–host cell interactions, it can be seen that immune responses that clear an established virus infection may be targeted against (a) virion structural proteins inserted into the host cell plasma membrane; (b) peptide epitopes of virion structural or nonstructural proteins, which as these proteins are being produced intracellularly, are presented on the cell surface in association with the host's class I major histocompatibility (MHC) molecules; or (c) novel or modified host proteins or epitopes, which start to be expressed as a result of virus-induced alterations in host cell transcription and translation. Immunopathologic damage may result from these responses directed against virus-infected cells or from autoimmune responses induced either to host antigens presented following destruction of host tissues or as a result of virus-induced dysregulation of the immune system.

VIRUS INFECTION, SPREAD, AND PRODUCTION OF DISEASE

After contact with a eukaryotic host, viruses may directly invade deeply into the host, but they frequently undergo an initial round of replication at the site of entry (often the respiratory or gastrointestinal tract). Whereas many respiratory and enteric viruses (e.g., rhinoviruses and rotaviruses) are confined largely to epithelial surfaces, others (e.g., measles) reach subepithelial tissues, where they may infect cells of the immune system, such as macrophages, and be carried to local lymph nodes, where further replication occurs. After primary replication, virus may be disseminated by the blood or lymph, often within infected immune system cells, and cause a systemic infection. Other routes for virus spread are the cerebrospinal fluid and nerves. Viruses show tropisms for distinct host tissues, resulting in characteristic patterns of disease (e.g., skin rashes, pancreatitis or diabetes, orchitis, meningitis).

Disease results from virus effects on host tissues or the immune response to infection. As discussed already, viruses can cause direct damage to cells by a number of mechanisms. Examples of diseases in humans that result from such damage are poliomyelitis, which follows infection of motor neurons in the spinal cord by poliovirus, and some common colds, which follow infection and destruction of nasal epithelial cells by rhinoviruses. Noncytopathic viruses may cause more subtle changes in infected host–cell functions that result in disease (e.g., by affecting cellular “luxury functions”) (reviewed in 47,136). Examples are the murine virus lymphocytic choriomeningitis virus (LCMV), which can cause a persistent infection of growth hormone (GH)-producing cells in the anterior pituitary; in the absence of cytopathologic changes, the virus produces a selective decrease of GH transcription, which results in a failure of the animal to grow because of GH deficiency (96,145,189). Rabies virus is another example; it impairs acetylcholine and other membrane receptor functions in neural cells *in vitro* and *in vivo* without producing a cytopathic effect (100,188). In addition, viruses may transform the cells they infect and may be involved in neoplasia; for example, human papilloma viruses 16 and 18 are associated with more than 90% of human cervical cancers. Because of this association, it has been shown that screening of women to detect papilloma virus in cervical tissue is far more reliable than the conventional Papanicolaou smear. It is estimated that 12% to 20% of all cancers in humans are caused by viruses. Examples of diseases that arise as pathologic consequences of various types of antiviral immune response are discussed later in the chapter as these responses are detailed.

As in an individual cell, virus infections *in vivo* may be acute or persistent. To persist *in vivo*, viruses, in addition to possessing unique component(s) or a strategy of replication that ensures a noncytopathic phenotype, must avoid detection and clearance by the immune system; mechanisms by which viruses achieve this are discussed later.

IMMUNE DEFENSES AGAINST VIRUS INFECTION

Vertebrate hosts possess an armamentarium of complex and interrelated defenses against invasion by viruses and other microbial pathogens. Such defenses may be subdivided into *innate mechanisms* and the *acquired response*. Nonspecific defense mechanisms include physical barriers to virus infection, such as the skin, gastric acid, and the mucociliary system in the respiratory and gastrointestinal tracts, and components of the immune system, including complement, interferons, macrophages, and natural killer (NK) cells, which provide early defenses against virus infection in the nonimmune host. The acquired immune response is characterized by (a) specificity (it is mediated by T- and B-lymphocytes, which have surface receptors capable of distinguishing distinct foreign antigens); and (b) memory (on second contact with a particular antigen, a more rapid immune response of higher avidity is mounted). The effector components of the specific immune response are antibody molecules produced by B cells, cytokines produced by T cells, and cytotoxic T-lymphocytes (CTLs). The specific immune system plays a major role later in the infection and in preventing reinfection. In addition, there is interplay with nonspecific immune effector mechanisms, which are activated during the specific immune response and interact with specific effector mechanisms to mediate virus clearance.

Nonspecific Immune Responses

INTERFERONS

Interferons are the earliest of the known host-induced defenses that operate to control virus infections. Local interferon production occurs within hours of infection, before the development of the inflammatory response. There are three distinct types of interferon (IFN): IFN-a, formed primarily in leukocytes; IFN-b, synthesized predominantly in fibroblasts; and IFN-g, or immune interferon, secreted by stimulated lymphocytes. Normal cells usually do not synthesize detectable amounts of interferons; lymphocytes produce IFN-g in response to stimulation by mitogens or specific antigen, and IFN-a and IFN-b production by leukocytes and fibroblasts is

induced by a variety of agents, including double-stranded RNA, various metabolic activators and inhibitors, and most importantly virus infection. In general, RNA-containing viruses are good interferon inducers, whereas DNA-containing viruses, with the exception of pox viruses, tend to be poor interferon inducers.

Interferons have many biologic effects, including conferring an antiviral effect on host cells, cell multiplication–inhibitory activity, effects on differentiation, and effects on the immune system that include enhancement of cell surface MHC molecule expression, enhancement of NK cell activity, and antibody-dependent cell-mediated cytotoxicity, suppression of antigen- and mitogen-induced leukocyte migration inhibition, and driving the turnover of memory phenotype T cells (which may play a role in the maintenance of immune memory) (186). The various interferons have differential efficiencies in mediating the various effects; for example, IFN-a and IFN-b, are more efficient inducers of an antiviral state in host cells than IFN-g, whereas IFN-g has more pronounced effects on the immune system and potentiates the antiviral activity of IFN-a and IFN-b.

The IFN-induced antiviral state renders infections abortive and in some virus–cell systems protects cells from the effects of virus infection; so more IFN-treated than -untreated cells survive (171). Although the basis of the IFN-induced antiviral state in cells is still not completely understood, there is now some insight into this problem (reviewed in 191). IFNs themselves do not inhibit virus multiplication; IFN binding to cell-surface receptors is followed by induction of the synthesis of proteins, which are the actual effectors of the antiviral state. One of these proteins is the enzyme oligoisoadenylate synthetase, which is activated by the presence of ds RNA to catalyze the formation of a family of oligonucleotides collectively termed 2,5-oligoA. 2,5-OligoA activates RNase L, a ribonuclease that is present in latent form in the cytoplasm of mammalian cells, which cleaves viral and cellular RNA. Although RNase L itself possesses no specificity, it is thought that some specificity may be achieved by the highly localized formation of 2,5-oligoA. A phosphodiesterase also found in IFN-treated cells can regulate this system by cleaving 2,5-oligoA. Another IFN-induced enzyme is a 67-kd protein kinase that, when activated by virus infection or ds RNA, phosphorylates the small subunit of protein synthesis initiation factor eIF2, resulting in inhibition of protein synthesis. Several viruses encode inhibitors of the 67-kd protein kinase (e.g., the VA_1 RNA of adenoviruses) (94,95,146), which may render the virus resistant to IFN. The 2,5-oligoA synthetase and the 67-kd protein kinase system are of different importance in providing the basis for the antiviral activity of interferons against different viruses in different cell types (reviewed in 191). Yet another IFN-inducible gene is the *Mx* gene, which determines resistance to influenza viruses in mice (181). This gene, which is also present in humans, encodes a protein that drastically inhibits primary transcription of influenza virus genes by an unknown mechanism and does not confer resistance against any other virus.

Interferons are thought to be a key component of the *in vivo* antiviral defense mechanisms. Their production is associated with a reduction of virus titers not just locally but throughout the body, suggesting that interferons limit virus production and spread. It is difficult to assess the precise role of IFN in virus infections in humans because primary and secondary immunodeficiency states, where there are defects in IFN production, usually involve multiple immunologic changes. There are some reports of diminished IFN production capacity resulting in repeated or severe infections (e.g., in children with recurrent respiratory infections (79) or patients with acute fulminating viral hepatitis) (109). Moreover, clinical trials have shown that human IFN-a and IFN-b, when inoculated early at high doses, can shorten the course of a number of virus diseases (reviewed in 30,203). In addition, there is strong support from experimental animal models that IFN is a critical antiviral defense mechanism. Treatment of animals with IFN or IFN inducers before or during acute virus infections has protective effects (13), whereas elimination of IFN or IFN receptors increases susceptibility to a number of viruses (16,63,106,128,192).

In addition to their protective role, IFNs may have immunopathologic effects. Clinical trials revealed side effects that included nausea and vomiting, anorexia, fatigue and malaise, and myalgias (157); and it has been suggested that many of the clinical symptoms of influenza virus infections may be caused by IFN. A good example of immunopathologic roles of IFN-g is provided by work with LCMV infection of mice. Anti-IFN treatment of one strain of mice persistently infected from birth with a particular strain of LCMV inhibits liver necrosis, glomerulonephritis, runting, and deaths that normally are seen; and experiments done by Leist et al. (106) showed that treatment of mice with anti-IFN-g antibody would protect them from the lethal, T-cell-mediated choriomeningitis that follows intracerebral inoculation of small doses of LCMV.

NATURAL KILLER CELLS

Natural killer (NK) cells are a subset of non-T, non-B lymphocytes that do not bear antigen-specific receptors generated by gene rearrangement (NK cells develop normally in *RAG* knockout and severe combined immunodeficiency disease, or *SCID* mice). They are a component of the innate immune response and are activated early after infection: They can help to combat virus infection both via cytotoxic activity and via the production of cytokines and chemokines, in particular IFN-g (reviewed in 21). The factors responsible for the activation of NK cell migration, expansion, and effector functions after infection still are not defined completely, but it is thought that soluble mediators such as type 1 IFNs, other cytokines [tumor necrosis factor-a (TNF-a, interleukin (IL)-12, IL-15] and chemokines plus contact with cell surface ligands are involved. In addition to these triggering signals, NK cell activity is tightly controlled by inhibitory signals. These are transmitted by NK cell surface receptors that contain immunoreceptor tyrosine-based inhibition motifs (ITIMs) in their cytoplasmic tails. There are two main classes of receptors on NK cells that can mediate either stimulatory or inhibitory signals: (a) the killer immunoglobulin-like receptors (KIRs) and leukocyte immunoglobulin-like receptors (LIRs) and (b) C-type lectin (Ly49 and CD94-NKG2) receptors (reviewed in 105,114,206). Human KIRs recognize sets of classic human leukocyte antigen (HLA) class I allotypes, and the human CD94-NKG2 receptors bind to the class Ib molecule HLA-E, which is stably expressed at the cell surface only after binding peptides derived from the signal sequences of other HLA allotypes. These receptors thus appear to play complementary roles in surveying the biosynthesis and expression of class I molecules, which can be hampered during viral infections or in certain tumors.

Natural killer cell activity usually peaks rapidly (within hours to days) after virus infection, paralleling levels of virus-induced interferon, and declines as the virus-specific CTL response is induced (around day 7 after infection). It is therefore tempting to speculate that NK cells represent a rapid, nonspecific first line of defense against virus infections, which is superseded by the virus-specific CTL response. The contribution that NKs cell make to early control of virus replication has been demonstrated both in murine and human virus infections by documentation of increased sensitivity to certain viruses in situations where NK cells are depleted or deficient. Mice depleted of NK cells by treatment with antiserum against NK cell markers show greatly increased replication of some viruses, for example, murine cytomegalovirus (MCMV), mouse hepatitis virus (MHV), and vaccinia but not others (e.g., LCMV) (21). Similarly, adoptive transfer of NK cells protected suckling mice from MCMV but not LCMV (28). Beige mutant mice, which have aberrant large granular lymphocyte morphology and reduced NK cell lytic activity, show increased susceptibility to MCMV compared with control mice (173). Similarly, the Chédiak-Higashi syndrome in humans, in which granule-dependent functions including NK cell lysis are depressed, is associated with increased susceptibility to virus infections (121,149,202), and patients in which NK cells are absent also exhibit poor control of certain virus infections. The best documentation of this is for control of primary herpesvirus infections (20). Additional evidence that NK cells have an important role in this infection in humans derives from the finding that human cytomegalovirus (HCMV) has evolved two proteins that are hypothesized to decrease the susceptibility of infected cells to NK cell lysis: gpUL18, a class I homolog that binds to the NK cell inhib itory receptor LIR-1 (44,51,107,160) and gpUL40, which upregulates HLA-E expression (185).

COMPLEMENT

The human complement system comprises more than 20 proteins present in normal serum, which on activation undergo a cascade reaction, generating products that mediate and amplify immune and inflammatory reactions. The complement cascade (see Chapter 30) can be initiated in three ways: (a) by the classical pathway, which is activated by the binding of the C1q subunit of C1, the first complement component to an immune complex; (b) by the alternative pathway, which does not involve antibody (in the latter process, C3b generated by slow spontaneous hydrolysis of C3, is protected on the surface of an activator, e.g., a virion, from factor H, which initiates a cascade of reactions); (c) by the binding of mannan binding lectin to a suitable acceptor with subsequent activation of specific proteases that ultimately activate C3. The later complement components have various biologic activities; for example, C3a and C5a are anaphylotoxins, C3b can attach to receptors present on macrophages and polymorphs and mediate opsonization, and the C5b-9 complex can insert into the lipid bilayer of cell membranes, producing cylindrical membrane lesions similar to those induced by the perforins of CTL and NK cells.

Following virus infection, the classical complement pathway may be activated by complexes of virus and antiviral antibodies or antiviral antibodies bound to viral proteins expressed on the surface of infected cells. Certain viruses are also capable of triggering the classical pathway directly in the absence of antibody; they include retroviruses such as Moloney murine leukemia virus, in which the viral envelope protein p15E is known to bind the C1q component of complement, causing C1 activation (14); Sindbis virus; and Newcastle disease virus (72,196). Other viruses activate complement directly via the alternate pathway, including Sindbis, vesicular stomatitis, measles, and respiratory syncytial (RSV) viruses (179). The alternative pathway also can be activated by cells infected with viruses such as mumps, parainfluenza, herpes simplex, and measles in the absence of antibody, although measles virus-infected cells are not lysed unless immunoglobulin G (IgG) is present (43,176).

Complement thus may be activated *in vivo* at early times after virus infection before the development of the specific immune response and can potentiate the antiviral effects of antibody, which may be particularly important during the early stages of infection when the antibodies present are only of low affinity. Complement mediates its antiviral effects by at least three mechanisms: (a) It produces an acute inflammatory reaction with leukocyte accumulation. (b) Complement activation on the surface of infected cells may result in lysis of those cells. With measles virus-infected cells, activation of the classical pathway alone is not sufficient for cell lysis; it requires activation of the alternate pathway as well (43). (c) Complement activation (with or without antibody) on the virion surface may result in virolysis (damage to or lysis of the membrane of enveloped virions, leading to leakage or destruction of viral nucleic acid (142,168); enhancement of neutralization of virions by antibody; the complement components, perhaps providing extra coverage of the viral proteins involved in viral attachment (7); or opsonization of the virion, allowing it to be more readily destroyed by phagocytes.

Although complement clearly can mediate a number of antiviral effects, its importance in protection against virus disease *in vivo* is uncertain. Mice that were

C3-depleted by treatment with cobra venom factor showed increased severity of Sindbis and influenza virus infections, and a C5-deficient mouse strain showed increased organ titers of Sindbis virus (70,72). Human genetic deficiencies of complement, although predisposing to bacterial infections, do not seem to predispose to virus infections (102).

MACROPHAGES

Macrophages and related cells play a central role in the immune response to viruses, having an essential function in antigen presentation to and the activation of antiviral T cells as well as possessing virucidal, cytotoxic, virustatic, and monokine-secreting potential. Details of antigen presentation and T-cell activation by macrophages and other presenting cell types are covered elsewhere in this book. Here we focus on the other antiviral roles of macrophages.

It is hypothesized that the activation of macrophages and dendritic cells initially is triggered following infection by both endogenous and exogenous signals. Endogenous signals include the presence of necrotic cells, heat shock proteins, and cytokines, such as type 1 IFNs (58). Exogenous signals are thought to be delivered by the binding of components of pathogens to pattern recognition receptors on the surface of macrophages and related cells (81). The best documented of these is the murine Toll-like receptor Tlr4, a signal-transducing receptor activated by bacterial lipopolysaccharide (19); other pattern-recognition receptors have been shown to bind to yeast mannans (10). To date, no mammalian pattern recognition receptors that bind to viral components have been identified; but plant resistance genes with homology to Toll proteins have been described, for example, the *N* gene of tobacco, which mediates resistance to tobacco mosaic virus (197).

Following activation, macrophages secrete a large number of soluble mediators, termed *monokines*, which include IFN (see preceding discussion) and IL-1, which not only is required for the initiation and amplification of T-cell-dependent immune responses and the inflammatory response but acts as an endogenous pyrogen, generating the fever that commonly accompanies virus infections in large mammals. Fever may well have significance in antiviral defense: *In vitro* immune responses are enhanced when cells are cultured at 39°C rather than 37°C (12); and in experiments where virus-infected animals were maintained at low temperatures, disease severity was markedly increased (115,161). These experiments are difficult to interpret, however, because animals undergo complex physiologic changes under these conditions.

Macrophages are also able to destroy virus-infected cells. There is some evidence that cytotoxicity may be mediated in the absence of antibody (33,108), but more common is macrophage-mediated antibody-dependent cell-mediated cytotoxicity (ADCC), a process whereby macrophages are targeted to virus-infected cells by specific antibody bound to Fc receptors on the macrophage surface, introducing specificity into what otherwise would be a nonspecific effector mechanism. In addition, macrophages are able to block cell-to-cell spread of viruses such as herpes simplex in monolayers by a noncytolytic, IFN-independent mechanism. Wildy et al. (200) suggest that arginase secreted by macrophages deprives the cells of arginine essential for the growth of herpes viruses and has a virostatic effect.

The interaction of viruses with free and tissue-fixed macrophages (e.g., Kupffer cells in liver, alveolar cells in lung, and microglia in brain) at early times after infection can be of key importance to the outcome of virus infection. Many viruses multiply within macrophages, and macrophage susceptibility or resistance may determine host susceptibility or resistance, as is illustrated in infections of mice with MHV-3, ectromelia, and HSV. With MHV, the liver macrophages of susceptible mouse strains (e.g., PRI) are destroyed by the virus (93), whereas the virus is not uncoated following adsorption to and penetration into macrophages of resistant C3H mice. A virulent strain of ectromelia productively infects liver macrophages and thus is able to undergo extensive replication in the liver, whereas, in contrast, an avirulent strain could establish only limited infection of liver macrophages and thus could not invade liver cells on a significant scale and produce disease (162,163). Similarly, the age-dependent susceptibility of mice to HSV appears to be closely correlated with changes in the susceptibility of macrophages to infection (123). In humans, dengue virus virulence also has been correlated with the ability of the virus to grow in monocytes (67).

Antigen-specific Immune Responses

ANTIBODY

Antibody responses are mounted following almost all virus infections, and their presence is used as the classic marker for prior exposure to a virus. Antibodies can exert antiviral effects through several distinct mechanisms, some directed against free virions and others against virus-infected cells. Antibody binding to virions can prevent infection of host cells. The antibody may prevent viral attachment to host cell receptors (deposition of complement proteins on the virion surface may contribute to the block of receptor binding, too); alternatively, it may not affect receptor recognition but may alter the capacity of the virion to undergo conformational changes involved in virus entry. Studies with monoclonal antibodies that bind to different epitopes on the influenza virus Hemagglutinin (HA) molecule, the positions of which have been mapped on the three-dimensional structure of the molecule, suggest that antibodies binding to different regions of the molecule mediate neutralization in different ways. Those binding near the tip of the molecule around the cleft that is involved in receptor recognition perhaps block attachment, whereas those binding near the HA_1/HA_2 cleavage site perhaps block entry and uncoating. Yet another monoclonal antibody against the influenza virus HA does not prevent attachment, penetration, or uncoating, but it inhibits viral RNA transcription (156).

Because antibodies are multivalent, they may cause clumping (agglutination) of virions, which not only may prevent virus entry but reduce the number of infectious units. In addition, the formation of virus–antibody complexes promotes uptake and clearance of virus by Fc receptor-positive phagocytic cells (opsonization); again, this process may be enhanced by complement deposition. As described earlier, antibody also may initiate complement-mediated lysis of virions.

One mechanism by which antibody combats virus-infected cells is by antibody- and complement-mediated lysis. The antibody involved may be directed against the envelope proteins of budding viruses, other viral proteins expressed on the plasma membrane, or even neoantigenic determinants. Cells may express sufficient levels of viral antigen to bind immunoglobulin, leading to lysis, from within a few hours after infection. Cooper and Oldstone (43) studied the lysis of human diploid cells infected 48 hours previously with HSV or measles virus, and they calculated that 5×10^6 antibody molecules must be bound to the infected cells to achieve virtually complete lysis: antibody-mediated lysis of infected cells is thus much less efficient than CTL-mediated lysis or ADCC. IgG antibody also may render infected cells targets for ADCC mediated by Fc receptor-bearing cells, including polymorphs, macrophages, and NK/K cells. ADCC was shown by Shore and Romano (174) to be hundreds of times more efficient per antibody molecule than complement-mediated cytolysis and hence might be more relevant *in vivo*.

Antibody bound to the surface of infected cells also can inhibit virus multiplication by mechanisms that do not involve cell lysis (134). Work with measles virus–infected cells has shown that antibody can also “modulate” (i.e., induce elimination of) viral antigens expressed on the cell surface (reviewed in 144). Such modulation interferes with viral assembly and, in the case of measles virus, may inhibit F protein-mediated cell–cell fusion and virus spread. It also may interfere with cytoplasmic events of viral replication; for example, levels of the viral phosphoprotein in the cytoplasm of measles virus-infected cells can be influenced by antibody to cell surface elements. Again, antigenic modulation can occur with significantly less antibody than is required for antibody-dependent, complement-mediated lysis of infected cells. Similar findings have been shown for antibodies and Sindbis virus *in vivo* and for influenza virus *in vitro*.

Antibodies of different classes are of different importance in antiviral defense in certain situations. IgM and IgG are the major classes of antibody responsible for virus neutralization in serum. They are particularly important for controlling viruses that produce systemic disease characterized by a plasma viremia (e.g., yellow fever or poliovirus). Children with severe hypogammaglobulinemia recover normally from measles or smallpox vaccination but are about 10^4 times more likely than normal children to develop paralytic disease after vaccination with live poliovirus vaccine (204). They are also susceptible to echovirus, meningitis, and VZV infection (42,201). The first antibodies to be produced following infection are of the IgM class. The multivalency of this antibody, which, for example, enables complement to be activated when a single IgM molecule is complexed with antigen (not the case with monomeric IgG), compensates somewhat in terms of protective efficiency for the fact that the early antibody response is usually of low affinity. The higher-affinity serum IgG response that develops subsequently may persist, providing protection against reinfection for many years; in addition, IgG antibodies can cross the placenta and confer passive protection on the fetus. Secretory IgA antibody neutralizes viruses on mucosal surfaces, which is of particular importance for resistance to viruses that normally gain entry through the respiratory or intestinal epithelium. In contrast to IgG, IgA does not recruit effector systems such as phagocytic cells or complement but mediates its protective effects by directly preventing virus binding to mucosal surfaces. In addition, secretory IgA does not provide good long-term protection against reinfection. The importance of IgE in antiviral protection is uncertain. It may be involved in some forms of virus-induced immunopathology, possibly contributing to the rashes that accompany certain virus infections by inducing local inflammation, and the wheezing seen in respiratory infections (e.g., with RSV) by inducing bronchospasm. Both these conditions result from a type 1 hypersensitivity reaction in which mast cells with surface-bound IgE are triggered to degranulate when the antibody contacts its specific antigen, releasing histamine and other mediators.

In a number of other instances, the antibody response to virus infection has detrimental effects in addition to or as a by-product of its protective effects. As reviewed by Oldstone (137), the binding of antibody to viral proteins or free virions may result in the formation of circulating immune complexes, which may deposit in the walls of small blood vessels in the skin, joints, and kidney, giving rise, for example, to the prodromal rashes seen in exanthematous virus infections and hepatitis B and to immune complex glomerulonephritis (Fig. 78.4). With persistent virus infections, where virions and viral antigens are continuously generated and antibody responses are frequently of low affinity or are directed against nonneutralizing epitopes, complexes may be deposited for long periods. A classic example is provided by mice persistently infected from birth with LCMV, where circulating immune complexes are progressively deposited in glomeruli (137,143), resulting in certain mouse strains in glomerulonephritis, uremia, and death. Systemic immune complex reactions also may give rise to disseminated intravascular coagulation, which occasionally is seen with yellow fever and other arbovirus hemorrhagic fevers.

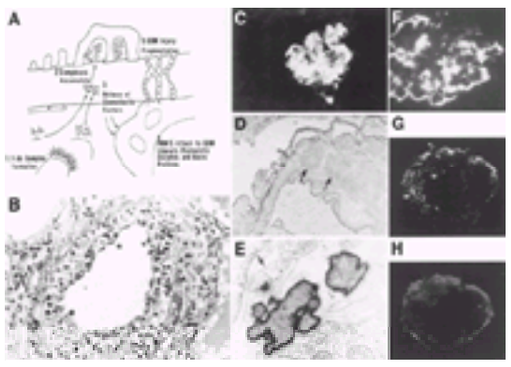

Figure 78.4. Illustration of how disease can be triggered by virus-induced antibody–antigen immune complexes in an experimental small animal model and the subsequent expansion of that information into human disease. **A:** How trapping of virus–antibody (V-Ab) complexes in the kidney can trigger local inflammation resulting in damage to the glomerular basement membrane (GBM). **B–E:** Examples of immune complex disease in mice persistently infected with lymphocytic choriomeningitis virus (LCMV). The immune complex vasculitis seen in arteries of mice persistently infected with LCMV (**B**) was subsequently observed as hepatitis B virus antigen (**G**)/hepatitis B virus antibody (**H**) immune complex deposits in an artery of a patient with hepatitis B virus infection. The deposition of immune complexes in the glomeruli of mice persistently infected with LCMV. **C:** immunofluorescent staining. **D:** Electron microscopy of dense deposits. **F:** The deposition of immune complexes in the glomeruli of mice persistently infected with LCMV is mirrored by Epstein–Barr virus (EBV) antigen-anti-EBV antibody immune complex deposits in a human glomerulus; similar immune complex deposition is also seen in many other human infections, including those with CMV and HIV. **E:** Immune complexes being degraded by a macrophage (*arrow*) in the choroid plexus of a mouse persistently infected with LCMV (For details, see Oldstone MBA. Virus-induced immune complex formation and disease: definition, regulation, and importance. In: Notkins AL, Oldstone MBA, eds. *Concepts in viral pathogenesis.* New York: Springer-Verlag, 1984:204–2097; and Whitton JL, Oldstone MBA. Immune response to viruses. In: Fields BN, et al., eds. *Fields' virology*. Philadelphia: Lippincott–Raven Publishers, 1996:345–374.)

Opsonization of virions by antibody with or without complement may enhance virus infectivity rather than result in virus destruction by phagocytes; this situation is seen, for example, with dengue virus. When persons who are immune to one dengue serotype become infected with a different serotype of the virus, the antibodies they have are cross-reactive and nonneutralizing, and they enhance infection of mononuclear cells by the second virus via an Fc-dependent mechanism (66,67). Another example of the presence of an inappropriate, nonneutralizing antibody response with a detrimental effect is the antibody response to formaldehyde-inactivated paramyxovirus vaccines. These vaccines elicit nonneutralizing antibodies directed against the viral hemagglutinin protein, but they fail to elicit antibodies against the fusion protein, which would control the spread of virus. This process may explain the severe atypical disease that resulted when children vaccinated with inactivated RSV or measles virus vaccines subsequently became infected (119).

Yet another mechanism by which antibodies induced by a virus infection may mediate immunopathology is by reacting against normal host components; this process is called *autoimmunity*. Autoantibody responses can be induced by several mechanisms:

1. As a result of viruses interfering with normal immune regulation, by affecting T-cell control of B-cell responses or causing polyclonal activation of B cells: Some of the antibodies they secrete react with host tissues (reviewed in 2). For example, Epstein–Barr virus (EBV) infects and causes polyclonal activation of B cells (182), and autoantibody production is associated with this infection.
2. By molecular mimicry, which occurs when a viral antigenic determinant is shared with a host antigen, and so a cross-reactive immune response is generated (reviewed in 140) (Fig. 78.5): Fujinami et al. (56) identified an epitope on the capsid protein VP1 of Theiler's murine encephalomyelitis virus (TMEV), antibodies against which cross-react with galactocerebroside, a major component of myelin, and may contribute to the pathogenesis of the demyelinating disease this virus causes in mice. In humans, antibodies directed against a region of the E1b protein of adenovirus 12, which has sequence similarity to A-gliadin, a wheat protein, have been suggested to play a role in the pathogenesis of celiac disease (91).

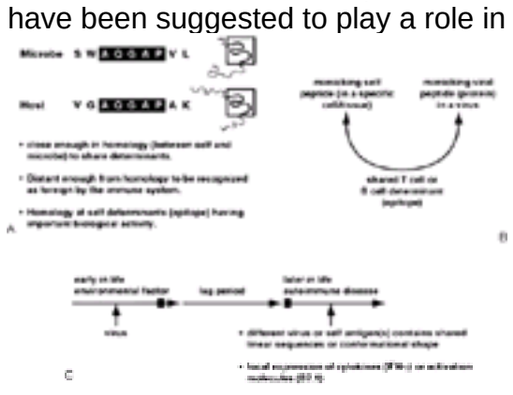

Figure 78.5. Cartoon illustrating the concept and cardinal points of molecular mimicry. **A,B:** How linear or conformational similarity between portions of a microbial protein and a host protein can lead to the induction of an autoimmune response via molecular mimicry. An immune response directed against the microbe (that is recognized as foreign) can cross-react with the self-antigen to cause an autoimmune disease. The anti-self-response initiated in this way may continue long after the triggering microbe has been cleared from the host. **C:** How a virus infection encountered early in life may predispose the host to the subsequent development of autoimmune disease via molecular mimicry. This model is based on observations made in a murine experimental models.

3. If antiidiotype antibodies against the idiotype of antiviral antibodies directed against virion surface components cross-react with proteins on host cells to which the virion can bind; for example, antiidiotypic antibodies of antibodies directed against reovirus type 3 hemagglutinin also recognize a 67-kd protein on lymphoid and neural cells, which may be the b-adrenergic receptor (40,41,48).
4. Virus infection also may lead to host components being rendered immunogenic and exposed to the immune system; this situation could occur if the virus incorporated host antigens into its envelope, if infection led to expression of new or modified host epitopes on the cell surface, or if host antigens that the immune system does not normally encounter were released and presented as a result of virus or immunopathologic damage (epitope spreading).

T-CELL–MEDIATED RESPONSES

T-cell–mediated immunity plays a critical role in virus infections. As discussed, whereas patients with defective antibody production suffer from bacterial infections (6), defective T-cell function frequently is associated with virus infection. Patients with T-cell deficiencies often develop generalized progressive vaccinia if vaccinated and are prone to infections with CMV, HSV, VZV, and measles virus. Measles virus infection of infants with defective thymic function leads to a progressive infection complicated by giant cell pneumonia, without a rash. Although disorders primarily affecting T cells also may result in defective antibody production, it is probable that the susceptibility to virus infections seen in patients who have congenital defects in cellular immunity or who are immunosuppressed results primarily from their inability to generate cytolytic and inflammatory T-cell responses to eradicate intracellular virus.

Both class I MHC–restricted (largely $CD8^+$) and class II MHC–restricted (generally $CD4^+$) T-cell responses are elicited after a virus infection. “Professional” antigen presenting cells, such as dendritic cells and macrophages, process virion proteins and viral proteins derived from infected cells for presentation in association with class II for the induction of $CD4^+$ T-cell responses and in addition possess mechanisms for capturing and presenting exogenous (usually cell-associated) antigens in association with class I for the induction of $CD8^+$ T-cell responses (68). Such “cross-priming” is essential for the induction of $CD8^+$ T-cell responses following virus infection (175). In most cells, however, peptides presented in association with class I are derived exclusively from proteins synthesized within the cell. As viruses replicate intracellularly, peptide fragments of the viral proteins become associated and presented with class I MHC molecules, as do those of normal cellular proteins, and this targets activated $CD8^+$ T cells to interact with virus-infected cells. Identification of the epitopes seen by $CD8^+$ T cells on a number of viruses confirmed that nonstructural internal virion proteins are frequently recognized in addition to virion surface proteins. Such recognition was first demonstrated with influenza virus, where the viral nucleoprotein was shown to be the principal target for T-cell recognition. There are several advantages to the recognition of nonstructural, internal viral proteins by antiviral T cells: (a) It increases the number of potential viral epitopes. (b) These proteins tend to be more conserved between viruses than virion surface proteins. For a number of viruses, T-cell responses have been shown to cross-react between strains or even subtypes (9,101), which may provide some protection against related viruses. (c) If T cells are targeted against the first nonstructural viral proteins produced in an infected cell, as has been shown to occur with herpesviruses, including HCMV, HSV, and VZV, this gives the potential for destruction of the infected cell before progeny virion production is complete, thereby

blocking virus spread.

The recent development of new techniques for quantitating antigen-specific T cells has allowed reassessment of the magnitude and kinetics of virus-specific $CD4^+$ and in particular $CD8^+$ T-cell responses in murine and human virus infections (120). Antigen-specific T cells now can be identified by staining with fluorescent-labeled tetrameric complexes of MHC molecules folded around a specific peptide or, alternatively, on the basis of their ability to produce cytokines in response to antigen stimulation in assays where cytokine-producing cells are quantitated on a single cell basis (either by ELISPOT or by intracellular staining of cells from which cytokine secretion has been blocked using brefeldin A). Using these techniques, it was shown that antigen-specific $CD8^+$ T cells can expand to far higher numbers than previously appreciated during the acute phase of a virus infection. For example, more than 50% of the $CD8^+$ T cells in the spleen of mice were virus specific at the peak of the acute response to LCMV (129,130), and in some patients undergoing acute EBV infection, more than 40% of $CD8^+$ T cells in the peripheral blood were virus specific (32). During chronic virus infections, virus-specific $CD8^+$ T cells may be maintained at high frequencies over long periods. For example, as many as 2% of peripheral blood $CD8^+$ T cells in humans chronically infected with HIV-1 or 10% of $CD8^+$ T cells in macaques chronically infected with SIV may be virus specific (8,103).

There are two principal mechanisms by which T cells contribute to control of virus infections: (a) by playing an inductive/regulatory role in the antiviral immune response and (2) by mediating antiviral effector functions. $CD4^+$ T cells more commonly perform the former role and $CD8^+$ T cells the latter, although each T-cell subset can participate in both functions.

Examples of inductive and regulatory roles principally carried out by virus-specific $CD4^+$ T cells include the recruitment and activation of T cells and cells of the innate immune system (e.g., NK cells and macrophages) at sites of infection and, in some viral infections, provision of help for the induction and maintenance of $CD8^+$ T-cell responses and provision of help to B cells for production of antiviral antibodies. Work with terminally differentiated mouse $CD4^+$ T-cell clones defined two subsets of $CD4^+$ T helper cells (Th1 and Th2) on the basis of their cytokine production patterns; cells that are not fully differentiated may exhibit an intermediate cytokine production profile. Th1 and Th2 $CD4^+$ subsets also exist in humans. Both subsets produce IL-3, granulocyte–macrophage colony-stimulating factor (GM-CSF), and TNF, which regulate the functions of hematopoietic stem cells and macrophages. In addition, Th1 cells produce cytokines such as IL-2, IFN-g, and lymphotoxin (LT), which activate T cells, especially CTLs, NK cells, and macrophages, and have a number of direct antiviral actions on tissues. Th1 cytokine production results in an accumulation of activated mononuclear cells at the site of infection, classically termed a *delayed-type hypersensitivity* (DTH) reaction, in which a number of cell-mediated responses are coordinated to combat the virus infection. By contrast, Th2 cells do not make IL-2, IFN-g, or LT but, instead, produce IL-4, IL-5, and IL-6. These cytokines again have effects on a number of cell types, the most important of which are their effects on B cells: They promote B-cell growth, differentiation, and class switching. Both Th1 and Th2 cells are activated during most immune responses, although one or the other subset may predominate. During virus infections, the Th1 response, which is more directed against intracellular pathogens, frequently predominates.

T cells mediate direct antiviral effector functions by two principal mechanisms. First, they may act as CTLs and lyse virus-infected target cells. For most virus infections studied, CTL lysis has proved to be mediated by $CD8^+$, class I MHC–restricted T cells, although $CD4^+$ CTLs also were identified in a few infections (e.g., in some instances, the human CTL response against measles virus is $CD4^+$-mediated, and human $CD4^+$ CTLs specific for HIV-1 have been documented). Two principal contact-dependent mechanisms are used by lymphocytes (both CTLs and NK cells) to kill infected cells (187). The first involves ligation and trimerization of Fas (CD95) receptors on target cells by Fas ligand (FasL, CD95L) on effector cells. This triggers the activation of caspases in the target cell, which leads to apoptotic cells death. The second mechanism involves the directional exocytosis of specialized granules in the effector cell cytoplasm; these contain a pore-forming protein perforin—that can produce membrane lesions similar to those induced by the complement C9 complex and a series of serine proteases termed *granzymes*. The granzymes, like the caspases, cleave specific target proteins in the cytoplasm and nucleus of the target cell, leading to apoptotic cell death. The second mechanism by which T cells mediate antiviral effector functions is through the production of antiviral cytokines such as IFN-g and TNF-a, which may trigger the clearance of virus from infected cells by noncytopathic mechanisms.

Numerous experiments have been carried out in animal model systems to investigate the roles of particular T-cell subsets/effector mechanisms (e.g., $CD4^+$ versus $CD8^+$ T cells and lytic versus nonlytic viral clearance mechanisms) in both protection and pathogenesis in different virus infections. These experiments have centered on two approaches: (a) *depletion*, in which a component of the immune system is selectively removed or its function is blocked by using specific antibodies or, more recently, by knockout technology; and (b) *reconstitution*, in which T-cell populations (e.g., cytokines) are adoptively transferred and the effects examined. Much less definitive evidence is available about the roles of T-cell responses during human virus infections because here only a correlative approach (i.e., measurement of the activity of different T-cell subsets at different stages of the infection and correlation of their activity levels with protection or pathogenesis) is possible. Summarizing the findings from many studies with different virus infections, it has been shown that the key effector mechanism differs depending on the infection studied, and that each type of effector mechanism has the potential to mediate pathogenesis as well as protection following virus infection. Pathogenic sequelae may occur long after the infection. Because of space constraints, we confine ourselves here to illustrating these points by just a few examples.

Lymphocytic choriomeningitis virus is a natural pathogen of mice, the outcome of infection with which depends, among other factors, on the dose and route of infection and the age of the animal at the time of infection (24). Adult mice inoculated intraperitoneally with moderate doses of virus clear the infection within 7 to 14 days. The animals mount antibody, $CD4^+$, and $CD8^+$-mediated responses to the virus, but it is the latter that is the key protective response. In acute LCMV infection, adoptive transfer of $CD8^+$, MHC class I–restricted virus-specific CTL clones into infected animals results in virus clearance (31); likewise $CD4^+$ cell–depleted animals or mice that lack CD4 or MHC class II are able to control an acute LCMV infection (36,125,158), whereas mice depleted of $CD8^+$ T cells by treatment with a CD8-specific monoclonal antibody fail to clear the virus and become persistently infected (125). Control of virus replication also is impaired in CD8 or b_2-microglobulin knockout mice, although virus clearance eventually is mediated in some of these animals. This is attributed to the action of MHC class II–restricted $CD4^+$ CTL produced in these mutant mice, in which $CD8^+$ T cells are lacking (57,127). The mechanism by which $CD8^+$ T cells mediate control of acute LCMV infection has been addressed using mice deficient in perforin, Fas, FasL, and IFN-g. Acute LCMV infection can be controlled in all except perforin-deficient mice (89,90,184), indicating that perforin-dependent lysis of virus-infected cells is the key effector mechanism by which control of an acute infection with this noncytopathic virus is mediated. This contrasts with results obtained when infections with more cytopathic viruses are studied; for example, clearance of vaccinia virus from mice can occur in the absence of perforin but is highly dependent on IFN-g production (90). It has been hypothesized that lytic clearance mechanisms make a less important contribution to the control of acute infections with cytopathic viruses because in any case destruction of infected cells ultimately is mediated by the virus.

In mice, LCMV can cause persistent as well as acute infections; the requirements for clearance of a persistent LCMV infection differ from those of an acute infection with this virus. First, although virus-specific $CD8^+$ T cells alone can control an acute LCMV infection, for long-term control of persisting virus to be achieved, $CD4^+$ T-cell help is required to sustain the $CD8^+$ T-cell response (15,117,153,184). Recently, the precise number of $CD8^+$ T cells and $CD4^+$ T cells required to clear a persistent LCMV infection have been quantitated (17). The minimum number of cells that need to be adoptively transferred to purge virus and cure a persistent infection is 3×10^6 LCMV-specific $CD8^+$ T cells and 0.7×10^6 LCMV-specific $CD4^+$ T-helper cells. Second, the key effector mechanism by which control of persistent LCMV infection is mediated differs from that of acute infection. Although IFN-g is not required for the clearance of an acute LCMV infection, it plays an essential role in the elimination of persistent LCMV infection (184). Cytokine-mediated “curative” mechanisms also been shown to constitute the means by which other persistent virus infections are cleared, for example, hepatitis B virus replication in a transgenic mouse model (64) and in chimpanzees (65).

Although clearly of key protective importance, $CD8^+$ lymphocytes also can mediate lethal immunopathologic damage in LCMV-infected mice. This situation is seen when adult mice are infected intracranially with the virus or when $CD8^+$ virus-specific CTL clones are transferred into mice persistently infected with LCMV: The animals develop a lethal choriomeningitis. The cause of death here has not been identified with certainty. Lytic damage to the central nervous system (CNS) is not apparent, and it is thought that lymphokine-mediated damage or edema related to the presence of a large cellular infiltrate in the meninges may be involved.

Although class I MHC–restricted $CD8^+$ T-cell responses are of key importance in LCMV-infected animals, in mice infected with another natural mouse pathogen, TMEV, class II MHC–restricted $CD4^+$-mediated responses are also critical determinants of protection and immunopathology. TMEV-infected mice mount $CD4^+$-dependent antibody, $CD4^+$-mediated, class II MHC–restricted DTH, and $CD8^+$-mediated, class I MHC–restricted CTL responses to the virus (37,38,113,166]. Mice depleted of $CD4^+$ T cells before infection with TMEV fail to mount an antiviral antibody response and may die of an acute encephalitic disease within 3 to 4 weeks after infection (195). Th2 cells providing help for antibody production thus have a protective role early after infection. $CD8^+$ T cells also play a role in control of virus replication (26); some mouse strains clear TMEV infection in the acute phase by a process that requires $CD8^+$ T cells and perforin (131,167). Antibody and $CD8^+$ T-cell responses are thought to make different contributions to the control of virus replication in different areas of the brain. Class I–mediated immune responses provide more protection from virus-induced damage in areas with abundant white matter, whereas regions with an abundance of neurons are protected primarily by antibody (49). Mice of strains that fail to clear the virus develop a persistent CNS infection that is associated with chronic demyelinating disease; this is used as a model for multiple sclerosis in humans. It was shown that $CD4^+$ T cells play an immunopathologic role here because mice depleted of $CD4^+$ T cells or treated with anti-class II antibody just before the start of the chronic disease phase developed less severe disease signs than did nondepleted animals (53,195). During the later stages of TMEV infection, the virus-specific DTH response peaks; Th1 cells producing DTH thus have an immunopathologic role in this phase of the infection.

Finally, it should be noted that, as with antibody production, immunopathologic T-cell responses induced after virus infection may be directed against host determinants. The mechanisms by which autoimmune T-cell responses arise are similar to those discussed for autoantibody production. These include interference with immune regulation; molecular mimicry [e.g., a region of the hepatitis B virus polymerase shares six amino acids in common with a region of myelin basic protein that is encephalitogenic in rabbits) (55), and cross-reaction of an HSV-1 gene product with a corneal antigen has been implicated in autoimmune herpes stromal

keratitis in a murine model (209)] (Fig. 78.6); neoantigen generation [e.g., CTLs recognizing cellular neoantigens have been shown to contribute to cardiac injury in mice infected with a myocarditic variant of coxsackievirus B_3) (77)]; and epitope spreading, which has been described in experimental studies of TMEV-induced demyelination and in diabetes (122,190).

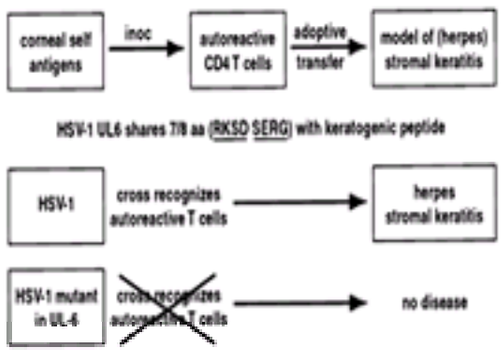

Figure 78.6. Example of induction of an autoimmune disease via molecular mimicry. Cross-reaction between the $CD4^+$ T-cell response to an epitope in the UL6 protein of herpes simplex virus type 1 (HSV-1) and a corneal antigen is implicated in the development of autoimmune herpes stromal keratitis in a murine model. Mutant HSV-1 viruses that lack this epitope do not induce autoimmune disease. (For details, see Zhao Z-S, et al. Molecular mimicry by herpes simplex virus type 1: autoimmune disease after viral infection. *Science* 1997;79:1344; for other examples of molecular mimicry in animal models and human disease, see Oldstone MBA. Molecular mimicry and immune mediated diseases. *FASEB J* 1998;12:1255).

VIRAL STRATEGIES FOR AVOIDING IMMUNE CONTROL

The immune response does not always achieve efficient clearance of virus infections. The rapid rate at which viruses are able to evolve enables them to develop mechanisms to delay or avoid clearance. A surprisingly large number of viruses are able to establish persistent infections in their hosts. The strategies by which viruses achieve these infections can be subdivided into (a) those that affect the induction or maintenance of the antiviral immune response; (b) those that affect the recognition of virions or infected cells by the immune system; and (c) those that interfere with the efficacy of antiviral effector mechanisms. Many viruses use a combination of different immune evasion strategies to maximize their chances of persisting in their hosts.

Viral Interference with the Induction or Maintenance of Antiviral Immune Responses

Viruses may induce a generalized suppression of the host immune response, or they may interfere more selectively with the induction or maintenance of virus-specific T- or B-cell responses. One mechanism by which viruses may produce a generalized immune suppression is through the production of soluble immunosuppressive factors, and the best documented example is the feline leukemia virus envelope protein p15E (116,180). Likewise, the EBV protein BCRF-1 is a homolog of the immunosuppressive cytokine IL-10 that can block the synthesis of IL-2 and IFN-g (75). Alternatively, viruses may replicate within cells of the immune system and impair their function or induce their destruction either by means of direct viral damage or by rendering them targets for immunopathologic damage by the antiviral immune response. For example, certain isolates of LCMV replicate within dendritic cells in lymphoid tissues and may infect a high proportion of these cells at early times postinfection. Although viral replication per se is noncytopathic, it renders the cells targets for destruction by the host virus-specific $CD8^+$ CTL response, which rapidly depletes these cells, leaving the host in a state of generalized immune suppression (23,135). The drawback to a virus persisting in its host by means of induction of a state of generalized immune suppression is that, if the host's immune functions are too severely compromised, it will be susceptible to many other infections that ultimately may result in its death, as occurs in the end stages of human HIV-1 infection when T-cell function is so severely impaired that death occurs from AIDS (104). Many viruses thus have evolved strategies for interfering more selectively with the virus-specific immune response.

If a virus infects its host sufficiently early in life, the virus-specific T cells will be clonally deleted in the thymus as “self”-tolerance is established. The host thus will be unable to mount a T-cell response to eliminate the virus but will be otherwise fully immune competent. This mechanism is the one LCMV most commonly uses to establish persistence during natural infection of its murine host. The virus is passed from mother to offspring *in utero*, and the offspring, having clonally deleted the LCMV-specific $CD8^+$ T cells they require to clear the infection, remain persistent viral carriers for life (151). In humans, neonatal tolerance is thought to play a role in the establishment of chronic HBV infections in children born to HBV-infected mothers (35) and may be among the factors that contribute to poor control of HIV-1 in children who acquire this infection *in utero* from HIV-positive mothers.

Viruses also have evolved strategies that enable them to interfere with the virus-specific T-cell response in adult animals. Virus-specific T cells may be deleted or rendered unresponsive. Both possibilities have been documented in LCMV persistent infection of adult mice (126,208). How antigen-specific T cells are deleted or rendered unresponsive in particular virus infections is not fully understood; it is likely that several different mechanisms may be involved. It is known that when T cells are stimulated in the presence of high concentrations of specific antigen, they may undergo apoptotic cell death. One hypothesis suggests that this occurs because the T cells acquire peptide–MHC complexes from antigen presenting cells and become sensitive to peptide-specific lysis by neighboring T cells (76). Deletion of virus-specific T cells may be induced by this mechanism if high levels of viral antigen are presented by antigen presenting cells. Alternatively, there may be deficits in T-cell stimulation. During viral infection, antigen may be presented to T cells by “nonprofessional” antigen presenting cells that fail to deliver appropriate activating signals, leading to T-cell death or nonfunction. Lack of necessary $CD4^+$ T-cell help for the induction or maintenance of $CD8^+$ T-cell responses also may lead to failure of virus-specific T-cell responses. Results from experimental models clearly demonstrate that to maintain effective $CD8^+$ T cells *in vivo* for more than a few weeks, helper $CD4^+$ cells are required (15,17,117,184). Although it is not clear how $CD4^+$ T cells function to maintain CD8 activity, one factor known to be important is IFN-g (34,52,184). Thomsen et al. (183) noted that removal of B-lymphocytes also interfered with maintaining clearance of virus and allowed infection to persist. It is not clear, however, whether the deficiency observed in the absence of B cells was due to a role for antibody, the interaction of B cells with $CD4^+$ T cells or a failure in antigen presentation by B cells. Indeed, recent data of Homann et al. (73) indicated that there was also a $CD4^+$ T-cell defect in the μMT knockout mice used by these investigators and that adoptive transfer of neutralizing antibodies played no role in limiting the viral infection.

Examples of human virus infections where interference with the induction or maintenance of virus-specific T-cell responses by the mechanisms discussed already may be involved in virus persistence are HBV and HIV-1. In the estimated 10% of persons who develop a persistent HBV infection after infection as adults, the HBV-specific CTL responses that can be detected are extremely weak compared with those seen in patients who clear the virus during the acute phase of the infection, suggesting that many virus-specific T cells may have been deleted or rendered nonfunctional (35). In HIV-1 infection, deficits in the virus-specific $CD4^+$ T-cell response are observed in all but the few patients who control virus replication efficiently over time (165) and have been suggested to result in failure to maintain effective virus-specific $CD8^+$ T-cell responses during this infection (92).

Interference with Recognition of Virions or Infected Cells by the Immune System

Viruses have evolved many strategies for avoiding recognition by the immune response. Two mechanisms that enable viruses to avoid recognition by both humoral and cell-mediated immunity are the establishment of latent infection and replication in immune-privileged sites. Latency is a strategy that is exploited particularly by herpesviruses and retroviruses. In latently infected cells, expression of viral proteins is highly restricted; for example, HSV establishes a latent infection in neurons during which there is thought to be no expression of viral proteins. Under such circumstances, the infected cells are essentially invisible to the immune system and thus are not targeted by immune effector mechanisms. Immune privileged sites are sites that are not readily accessed by the immune system. A surprisingly large number of viruses can persist in the CNS, where the blood–brain barrier restricts the presence of components of the immune system. Other favored sites for virus persistence include the epithelial cells of secretory or excretory glands, where T-cell access is restricted by a basement membrane and microvascular epithelium (e.g.,. the human polyoma viruses BK and JC); also, HCMV persists in the kidney, and both HCMV and EBV persist in the salivary gland.

To avoid recognition by neutralizing antibodies, viruses may undergo antigenic variation. With influenza viruses, which do not persist in individuals, this contributes to the persistence of the virus at the population level (150,194). Lentiviruses, including equine infectious anemia virus (EIAV), visna, caprine arthritis, enteritis virus (CAEV), and HIV, undergo antigenic variation within one host. With the possible exception of EIAV, however, in which sequential episodes of clinical disease associated with viremia correlate with the emergence of variants, this mechanism is probably not essential for persistence (39). Other viruses induce nonneutralizing antibodies; for example, lactate dehydrogenase virus (LDV) has evolved immunogenic epitopes, antibodies against which are nonneutralizing but block the action of neutralizing antibodies. Viruses that can spread by cell–cell contacts avoid exposure of the virion to neutralizing antibody altogether.

Virus-infected cells may avoid lysis by antibody-dependent mechanisms by reduced expression of viral glycoproteins on the cell surface. This action has been

observed to occur with paramyxovirus-, retrovirus-, rhabdovirus-, and arenavirus-infected cells (reviewed in 138). Neurons latently infected with HSV do not express any viral proteins (164), which avoids both B- and T-cell recognition. As mentioned, antibody itself contributes to the removal of viral antigens from the surface of measles virus-infected cells by antibody-induced modulation of viral antigens (87,88).

T-lymphocytes identify cells as being infected by recognizing viral peptides displayed on MHC molecules on the cell surface; T-cell recognition of virus-infected cells can be avoided if viruses replicate within MHC-deficient cells, such as neurons (82,83,159), or if viruses disrupt the antigen presentation pathway in infected cells (reviewed in 139) (Fig. 78.7).

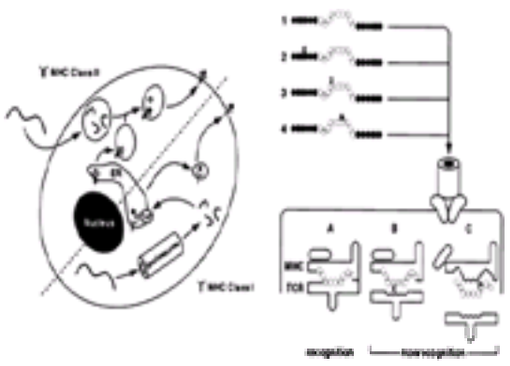

Figure 78.7. Illustratation of how amino acid changes in a viral sequence can alter the processing, presentation, or recognition of viral epitopes by virus-specific $CD8^+$ T cells. **A:** Diagram illustrating the major pathways by which antigens are processed and presented in association with major histocompatibility complex (MHC) class I and class II (for details, see Whitham S, et al. The product of the tobacco mosaic virus resistance gene N: similarity to toll and the interleukin-1 receptor. *Cell* 1994;78:1101). Viruses have evolved strategies to block many different steps in the class I presentation pathway (for details, see text and Whitman S, et al. The product of the tobacco mosaic virus resistance gene N: similarity to toll and the interleukin-1 receptor. *Cell* 1994;78:1101; and Oldstone MBA. How viruses escape from cytotoxic T lymphocytes: molecular parameters and players. *Virology* 234:179, 1997;234:179). **B:** Schematic illustrating the effects that a single amino acid mutation (X, <uftr<) either within a 9-amino-acid class I-restricted epitope (<soc>) or in the viral sequence flanking this epitope (<soc>) may have on epitope processing, presentation and recognition by $CD8^+$ T cells. Row 1 shows a viral polypeptide that is degraded by the proteasome to generate a peptide that is translocated by TAP molecules to the ER, where it binds strongly to a MHC class I molecule. This peptide–MHC complex then binds to a T-cell receptor (TCR) (motif A) and triggers T-cell activation. In row 2, a mutation in the sequence flanking the epitope prevents recognition and processing by the proteasome. In rows 3 and 4, mutations occur within the epitope itself, either at a residue that is involved in contact with the TCR (X) or at an anchor residue (<uftr>) that is critical for peptide binding to MHC. In the former case (motif B), although binding of the viral CTL epitope to the MHC and transport of the complex to the cell surface are not impeded, TCR binding or T-cell triggering does not occur. In the latter case (motif C), the viral epitope does not bind to the MHC class I heavy chain b_2-microglobulin does not lock into place, and a stable MHC-peptide complex is not formed.

Two fundamentally different approaches can be used by viruses to interfere with antigen presentation. The first is used primarily by DNA viruses associated with persistent infections, although there are also some examples of RNA viruses using this approach; they encode gene products that interfere with any of multiple steps along the antigen presentation pathway (reviewed in 139,154). If greater numbers of $CD4^+$ than $CD8^+$ CTLs are generated during a virus infection, this may signal a defect in class I antigen presentation. $CD4^+$ CTLs were found several years ago in human HSV infection (205), although $CD8^+$ CTLs also have been detected (155). By contrast, in most other viral infections studied, including HSV infection of mice (132), $CD8^+$ CTLs are generated. The reason for the generation of $CD4^+$ anti-HSV CTL in humans was unclear until others showed that the HSV ICP-47 protein efficiently blocked antigen presentation in human cells but did so poorly in murine cells (4,54,71,207). The HSV protein ICP-47 inhibits binding of its peptides to TAP, a molecule necessary for translocating peptides from the cytosol into the endoplasmic reticulum (ER).

This strategy is just one of many for interfering with the different steps in the MHC class I presentation pathway that have been described. A number of viruses can downregulate the transcription of class I genes (74) or other components of the class I presentation pathway (e.g., TAP and the LMPs). The cytosolic proteolysis required for epitope generation may be inhibited; for example, the HCMV phosphoprotein pp65 inhibits the generation of HCMV T-cell epitopes (61), and the EBV EBNA-1 protein contains a Gly-Ala repeat that frustrates proteosomal proteolysis (110). As exemplified by the HSV ICP-47 protein described previously, viral proteins also can interfere with the transport of epitope peptides from the cytosol to the ER by the TAP complex. Whereas the ICP-47 protein blocks the peptide binding site on the TAP complex from the cytoplasmic side, the US6 protein of HCMV acts on the ER–luminal side (5,69). Yet another strategy involves preventing the movement of peptide–MHC complexes from the ER to the cell surface. The adenovirus E3/19K glycoprotein was the first viral component shown to inhibit MHC class I antigen presentation (11,29,148,169). This viral protein forms complexes with MHC class I molecules and traps them in the ER; the six amino acid residues terminating the 15-membered cytoplasmic tail of its gp19 component are necessary and sufficient for retention in the ER (80,133). When these last six amino acids (DEKKMP) are transplanted onto the cytoplasmic tail of other membrane proteins that normally travel out of the ER, their ability to leave the ER is aborted. The HCMV US3 protein also binds to MHC class I molecules and sequesters them in the ER (3,86), whereas the MCMV m152 gene product, gp40, causes intracellular retention in the cis-Golgi by a mechanism that is independent of sequences in its cytoplasmic tail (210). Slater and Campbell (177) noted that the MCMV-induced defect in MHC class I synthesis and transport varied in a cell-specific manner, perhaps dependent on the state of differentiation or transcriptional activity of the infected cell. The US2 and US11 proteins of HCMV achieve the same end by a different means: They transfer the MHC heavy chain from the ER into the cytosol, where it is degraded (84,85,199). Finally, if peptide–MHC complexes reach the cell surface, antigen presentation still may be compromised. The MCMV p34 protein is present in a complex with those MHC class I molecules that reach the plasma membrane and may prevent their interaction with the T-cell receptor (TCR) (97); the HIV-1 nef protein downmodulates surface expression of class I molecules (170). Although inhibition of MHC class I antigen presentation by the adenovirus E3 complex was confirmed both *in vitro* and *in vivo* (50,193), none of the HSV, HCMV, MCMV, or HIV proteins have yet been shown to interfere with MHC class I antigen presentation *in vivo*; therefore, their biological significance remains to be established.

The second approach is used by RNA viruses, including any viruses that have an RNA step in their replication cycle. Because of their potentially high frequency of mutation, they can acquire amino acid changes in and around T-cell epitopes that interfere with epitope processing, binding to MHC class I molecules, or interaction with the TCR (reviewed in 25). Mutation in the viral sequence flanking an immunodominant epitope or within an epitope can influence its processing and block association with MHC molecules in the ER (147). For example, a single amino acid change in the p15E protein of murine leukemia viruses can alter the proteolytic cleavage site required for the generation of a $CD8^+$ T-cell epitope. The KSPWFTTL peptide encoded by AKV-MCF is processed correctly, whereas the Friend/Moloney/Rauscher (FMR) peptide RSPWFTTL is not (147). Similarly, Sevilla et al. (172) showed that a single amino acid change in the COO^- flanking region of an LCMV $CD8^+$ T-cell epitope in the Traub strain prevented the processing of this epitope and generation of epitope-specific effector $CD8^+$ CTLs. Interestingly, an *in vivo* consequence of this was the inability to generate sufficient $CD8^+$ CTLs cross-reactive to a self-viral antigen expressed in b cells of the islets to cause diabetes (172).

Viruses can escape recognition by virus-specific CTLs by acquiring mutations that prevent the binding of epitopes to MHC molecules or recognition by the TCR (45). The bound peptide sequence is linear, resulting from proteolytic fragmentation of viral protein synthesized within the cell. Several rules have been established about the structure of these peptides and their binding to MHC as well as the peptide–MHC complex binding the TCR. Studies of endogenously processed viral peptides indicate that they vary in length from 8 to 11 amino acids and display MHC allele-specific motifs. Mutational and crystallographic studies of MHC molecules complexed with viral peptide show that the molecule's flexible conformations allow these 8 to 11 amino acid peptides to bind within the MHC groove once their anchoring residues are fixed (22,60). Analysis of residues flanking the anchoring residue(s) indicated the critical importance of minor pockets of MHC-binding clefts in peptide selectivity, leading to the concept that these structural factors are likely responsible for the preferential selection of specific peptides so often observed in interactions with MHC molecules (78; reviewed in 198). Viral mutation at residues in an epitope that are important for MHC binding can ablate peptide binding to MHC altogether or reduce the affinity of peptide–MHC interaction so that the peptide-MHC complex has an extremely short half-life and is unlikely to trigger T-cell activation. Alternatively, mutations at residues involved in MHC binding can cause peptides to bind to MHC in a distorted conformation so that the TCR contact surface is altered. TCR recognition of peptide–MHC complexes also can be affected by changes in the TCR contact residues of an epitope. Altered peptide-MHC complexes may fail to interact with a particular TCR altogether, or they may be recognized but the T cell may receive a reduced or even a different type of signal when it recognizes this complex. Thus, the responding T cell may be only partly activated, for example, to proliferate but not to perform effector functions (99), or even anergy (178). Presentation of certain mutant peptides to T cells therefore can inhibit the response to the index not just by competing with it for binding to MHC but also by negatively signaling the responding T-cell population: This phenomenon is known as *T-cell antagonism*. Mutations that confer antagonistic properties on epitope sequences have been found in the persisting virus population in chronic HBV and HIV-1 infections (18,98).

Viral variants able to escape $CD8^+$ T-cell recognition have been found in a number of persistent virus infections, including LCMV and MHV-JHM in mice, SIV and HCV in nonhuman primates, and HIV-1 and HBV in humans. It not clear, however, how important is the contribution they make to viral persistence in all of these infections (review in 25). Studies with LCMV have shown that under CTL pressure *in vitro*, it is possible to select for viral variants bearing CTL escape-conferring mutations in all

three of the most immunodominant epitopes recognized in $H2^b$ mice (1,111,112). So long as at least one of these three immunodominant epitopes was not mutated, the virus was cleared efficiently and effectively with the usual kinetics *in vivo* (112). When all three immunodominant epitopes were mutated in the same virus, the host still could mount lower-affinity CTL responses against subdominant epitopes in the virus and control infection, although in this case more time was required to achieve virus clearance (112,124). Thus, under CTL pressure, escape variants can arise, but the host has other options and can bring epitopes lower down the hierarchy into play when immunodominant epitopes mutate. The inference drawn is that, unless a particular antiviral response is restricted to one epitope (for example, in LCMV TCR transgenic mice, where most of the host T cells were directed against a single viral epitope) (152), mutations in dominant CTL epitopes are unlikely to make a major contribution to viral persistence *in vivo*.

This hypothesis receives further reinforcement from recent observations of selection for CTL escape variants in HIV-1 infection (27). Within 15 days after the onset of symptoms of a primary HIV infection, a patient mounted a strong $CD8^+$ T-cell response that was highly focused on a single immunodominant epitope in gp160, at amino acids 30 through 38. Viral variants bearing mutations that conferred escape from recognition by CTLs directed against this epitope were rapidly selected for in the *in vivo* viral quasispecies and by 136 days after onset of symptoms had completely replaced the starting viral population. The kinetics of CTL escape was comparable to that of the emergence of drug-resistant viral variants in patient receiving therapy with a single antiretroviral drug and clearly indicated for the first time the biological significance of $CD8^+$ T-cell control of virus replication during HIV-1 infection *in vivo* (27). In this HIV-infected individual, subdominant CTL responses against other epitopes in gp160 and epitopes in the gag, pol, and nef proteins were subsequently detected (25,27). Because viral variants able to escape recognition by the originally dominant CTL response were selected, the viral load dropped from 200,000 to 300,000 to approximately 10,000 RNA molecules per milliliter. The viral mutations that occurred in this patient were thus not sufficient to block completely the control of virus replication; however, the fact that the viral variants were selected indicates that they must have conferred an *in vivo* replicative advantage on the virus carrying them, which may have contributed to the rapid disease course this patient subsequently underwent. Likewise, Goulder et al. (62) described selection for CTL escape viral variants in two HIV-infected patients during the late stages of disease and hypothesized that the replicative advantage conferred by the escape mutations may have contributed to disease progression.

It is thus unlikely that, during natural infection, selection of CTL escape viral variants generally constitutes the sole mechanism by which viral persistence is achieved, except when a uniquely restricted $CD8^+$ T-cell response is mounted (152). The MHC diversity and breadth of the TCR repertoire in most patients will allow for recognition of viruses, even when one or more of the most dominant epitopes have mutated (112,124).

Viral Strategies for Interfering with the Effector Mechanisms of Clearance

The important role of effector cytokines such as TNF-a and the IFNs produced both during the innate immune response and by virus-specific T cells in controlling many virus infections was discussed already. Therefore, it is not surprising that a number of viruses developed mechanisms for interfering with the function of cytokines. Adenoviruses encode at least four genes that interfere with the effects of TNF. Different members of the poxvirus family encode soluble chemokine and cytokine receptors that bind to and block the activity of factors, including TNF, the IFNs, and IL-1. The *in vivo* importance of a number of these was confirmed in animal models using viruses in which these genes have been deleted. Examples of mechanisms viruses use to avoid control by IFNs were discussed earlier.

In summary, during infection, a multifactorial and complex chess game is played between the host and the virus. A winning immune response overcomes infection, and a winning virus can effectively escape the host's immune surveillance. Defining the parameters and manipulating the players involved promise to be important strategies in the treatment of persistent viral infections.

CONCLUSION

Host defenses against virus infection consist of a broad spectrum of interreacting mechanisms targeted against both free virions and virus-infected cells. These mechanisms are still not yet fully understood, and their relative importance in vivo is even less clear, especially in virus infections in humans. Although these defense mechanisms sometimes mediate efficient virus clearance, viruses have developed strategies to escape immune clearance and therefore can establish persistent infections. Viral etiologies are being implicated in an increasing number of human diseases (e.g., multiple sclerosis, arthritis, diabetes, and chronic fatigue syndrome), making the study of virus–host interactions in animal models and in humans of key importance to increase understanding of all the possible consequences of virus infection.

79 LYME DISEASE

Lisa Glickstein, Ph.D., and Allen C. Steere, M.D.

HISTORY

Lyme disease or Lyme borreliosis, which was first identified 25 years ago (1), occurs in temperate regions of Europe, North America, and Asia (2,3). It is now the most common vector-borne disease in the United States (4). Erythema migrans, the initial skin lesion (5), acrodermatitis chronica atrophicans (6), and Bannwarth syndrome (7), which are now known to be a part of the spectrum of Lyme borreliosis, were each recognized as separate entities in Europe during the early or mid twentieth century. The full spectrum of Lyme borreliosis, however, was not recognized until after the description of this entity in the United States in 1976 (8) and identification of the etiologic agent, *Borrelia burgdorferi* sensu lato, in 1982 (9). *B. burgdorferi* sensu lato has three pathogenic species: *B. burgdorferi* sensu stricto, *B. garinii*, and *B. afzelii* (10,11). Only *B. burgdorferi* sensu stricto strains have been found in the United States. Although all three species have been recovered in Europe, most illness there is due to infection with *B. afzelii* and *B. garinii*. Only the latter two species are found in Asia.

Infection is transmitted to humans by a variety of *Ixodes ricinus* complex ticks (12). In the United States, emergence of this infection in the late twentieth century coincided with reforestation of farmland and consequent increased deer populations, necessary for the natural tick life cycle (13). Expanding human residential communities and decreased hunting have probably also played a role (12). In Europe, Lyme borreliosis is already widely established in the remaining forested areas, and there is little room for spread. Within a span of 22 years, the protean manifestations of the infection were described, the etiologic agent was identified, diagnostic tests and treatments were established, the complete genome of the spirochete was sequenced (14,15), and a vaccine was developed for disease prevention (16).

IMMUNOLOGIC HIGHLIGHTS

B. burgdorferi elicits a complex immune response to multiple spirochetal proteins, including a number of membrane lipoproteins, some of which are upregulated or downregulated during the course of infection. *B. burgdorferi* lipoproteins are potent stimulants of an innate inflammatory immune response. Arthritis resistance is under control of the innate immune system, whereas control of spirochete burden is primarily the function of antigen-specific T and B cells. Failure to mount successful innate or antigen-specific responses leads to chronic infection. A subset of patients with late, active infection may develop chronic, antibiotic treatment-resistant Lyme arthritis, apparently because of molecular mimicry between the dominant T-cell epitope of outer-surface protein A (OspA) bound by DRB1*0401 and related major histocompatibility complex (MHC) molecules and a self-peptide of the adhesion molecule hLFA-1a, which is upregulated in the synovial lesion (17).

EPIDEMIOLOGY

Pathogen Genetics

The genome of *B. burgdorferi* is small (approximately 1.5 megabases), and it consists of a linear chromosome of 950 kilobases as well as 9 linear and 12 circular plasmids (14,15). The genome contains no homologs of the secretion systems, which have been described in other bacteria and which often contain toxin genes or other virulence factors. Instead, the only known virulence factors of *B. burgdorferi* are surface proteins that contribute to spirochete attachment to mammalian cells.

Although all three pathogenic species may cause infection of the skin, nervous system, heart, or joints, the frequency, duration, and severity of the involvement differ. *B. burgdorferi* sensu stricto commonly causes disseminated infection and intermittent or chronic arthritis (18,19). In contrast, *B. afzelii* less often disseminates hematogenously (20) but may cause chronic infection of the skin, acrodermatitis chronica atrophicans (21), which is rarely seen with infection with the other species (10,21,22). Finally, *B. garinii* sometimes causes a severe, chronic neurologic disorder, borrelial encephalomyelitis (21,23), which seems to occur rarely, if at all, with infection with the other species. For the most part, the mechanisms that may account for these differences are not known; however, the sequence of the immunodominant T-cell epitope of OspA bound by the DRB1*0401 molecule is found only in *B. burgdorferi* sensu stricto strains, not in *B. garinii* or *B. afzelii* strains. This may explain why, to date, chronic treatment-resistant Lyme arthritis has been reported only in the United States.

Host Genetics

Even in the United States, where Lyme disease is caused exclusively by *B. burgdorferi* sensu stricto strains, only about 60% of untreated persons develop Lyme arthritis, ranging from brief attacks lasting weeks, to chronic, persistent joint inflammation lasting several years (19). Although multiple host genes probably influence the severity and duration of Lyme arthritis, the only characterized example in humans is the association of chronic, antibiotic treatment-resistant Lyme arthritis with certain class II MHC alleles, including DRB1*0401, 0404, 0101, and 0102 alleles (24). These alleles are also associated with the severity of rheumatoid arthritis (25,26).

The murine model of Lyme arthritis seems to duplicate the acute, infectious phase of joint inflammation but not the later chronic phase seen in genetically susceptible humans. Ankle swelling in (C57BL/6xC3H) mice identified quantitative trait loci on chromosomes 4 and 5, whereas histopathologic score identified unique quantitative trait loci on chromosomes 5 and 11 (27). Candidate genes in these regions include several regulators of the innate inflammatory immune response to bacteria, such as inducible nitric oxide synthase (iNOS), tumor necrosis factor (TNF)-inducible protein-1, and the gene controlling the response to bacterial lipopolysaccharide (LPS) (*Lps*), among others (27).

Environmental

In the northeastern United States, *B. burgdorferi* sensu stricto exists in a horizontal cycle between *Ixodes scapularis* ticks and the field mouse, *Peromyscus leucopus* (2). This mouse is the preferred host for the immature larval and nymphal stages of the tick. The larval ticks acquire *B. burgdorferi* infection from infected mice in the late summer or early autumn. Following overwintering and molting, nymphal ticks transmit the infection back to mice in the early summer; this completes the spirochete life cycle. The nymphal ticks molt into adults and feed and breed on deer in the spring and fall. Thus, deer are important for the life cycle of the tick but not the spirochete (28). Birds may play a role in spreading ticks across geographic regions (29). Humans become infected primarily in May through July as the newly hatched nymphal ticks search for an appropriate host. The prevalence of infected nymphal ticks is directly correlated with the risk of human infection (30).

CLINICAL PRESENTATION

Signs and Symptoms; Physical Findings

After an incubation period of 3 to 32 days, Lyme disease commonly begins with erythema migrans, a slowly expanding, large annular lesion, often with a bright red

outer border and partial central clearing (stage 1: localized infection) (Fig. 79.1) (8,18,31). Within days to weeks, in patients with *B. burgdorferi* sensu stricto infection, the spirochete often spreads hematogenously to many different sites (stage 2: disseminated infection). Such patients may develop secondary annular skin lesions, severe headache, mild neck stiffness, fever, chills, migratory musculoskeletal pain, or profound malaise and fatigue. Even in untreated patients, the early symptoms usually improve within several weeks.

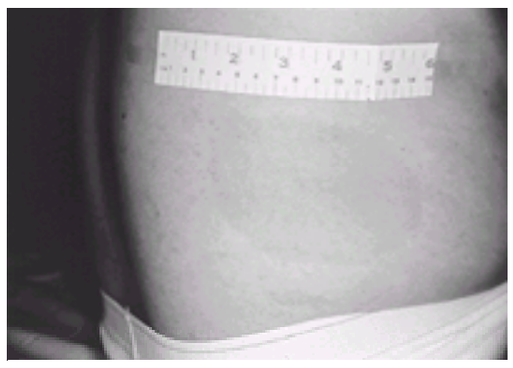

Figure 79.1. A characteristic erythema migrans skin lesion is shown. A 10-day-old lesion has gradually expanded to 10 cm and is beginning to have a brighter red border. (Reprinted from Steere AC, Bartenhagen NH, Craft JE, et al. The early clinical manifestations of Lyme disease. *Ann Intern Med* 1983;99:76, with permission.) (See Color Figure 79.1.)

After several weeks to months, about 15% of untreated patients develop frank neurologic abnormalities, including meningitis, subtle encephalitic signs, cranial neuritis (including bilateral facial palsy), motor or sensory radiculoneuropathy, mononeuritis multiplex, cerebellar ataxia, or myelitis, alone or in various combinations (32,33). The usual pattern consists of fluctuating symptoms of meningitis accompanied by facial palsy or peripheral radiculoneuropathy, lasting weeks to months. In addition, about 8% of untreated patients develop cardiac involvement. The most common abnormality is atrioventricular block (first-degree, Wenckebach, or complete heart block), fluctuating in degree and lasting weeks (34,35). Some patients have more diffuse cardiac involvement, including electrocardiographic changes of acute myopericarditis, left ventricular dysfunction on radionuclide scans, or, rarely, cardiomegaly or pancarditis.

Months after the onset of infection, about 60% of untreated patients develop frank arthritis (stage 3: persistent infection) (19). The typical pattern is of intermittent attacks of oligoarticular arthritis in large joints, especially knees, lasting weeks to months in a given joint. About 10% of patients develop chronic arthritis in knees, defined as 1 year or longer of continuous joint inflammation. Chronic neurologic involvement develops in about 5% of untreated patients months to years after the onset of infection (36). The most common form of chronic central nervous system involvement is a subtle encephalopathy that affects memory, mood, or sleep (37). These patients frequently have evidence of memory impairment on neuropsychological tests and abnormal cerebrospinal fluid (CSF) analyses (36,38). Lyme encephalopathy is often accompanied by an axonal polyneuropathy manifested as either distal paresthesias or spinal radicular pain (39,40).

Laboratory Tests

The diagnosis of Lyme disease is based primarily on the recognition of a characteristic clinical picture, exposure in an endemic area, and an elevated antibody response to *B. burgdorferi* (41). Culture of the spirochete from patient specimens permits definitive diagnosis, but with few exceptions, the procedure yields positive results only from biopsies of erythema migrans skin lesions (42). Therefore, serologic testing is the most practical laboratory test for support of the diagnosis.

For serodiagnosis, the U.S. Centers for Disease Control and Prevention (CDC) recommends a two-step approach in which samples are tested first by enzyme-linked immunosorbent assay (ELISA), and those with equivocal or positive results are tested by western blotting (41). About 20% to 30% of patients with erythema migrans have a positive response in acute samples, and about 70% to 80% have a positive response 2 to 4 weeks later, during convalescence, even after antibiotic treatment (43). After treatment, antibody responses typically remain positive for years, particularly if the disease progressed to late stages prior to treatment. In persons who have illness for longer than 1 month, a positive immunoglobulin M (IgM) response alone should not be used to support the diagnosis. After that time, the great majority of patients with active infection have a positive IgG antibody response, and a single test is usually sufficient. Patients in Europe or Asia with *B. garinii* or *B. afzelii* infection usually have less expansion of the antibody response than is observed with *B. burgdorferi* sensu stricto infection in the United States (44). Therefore, the CDC criteria cannot be used effectively in Europe or Asia.

The major limitation of serologic tests is that they do not clearly distinguish between active or inactive infection. Because culture is usually negative in Lyme disease, it had been hoped that polymerase chain reaction (PCR) testing might serve as a substitute for culture in this infection; however, this test has been readily positive only in joint fluid samples from patients with Lyme arthritis prior to antibiotic treatment. In one study, 70 of 73 joint fluid samples (96%) had positive PCR results using primer-probe sets that detect OspA gene segments (45). PCR testing is much less sensitive in detecting spirochetal DNA in CSF samples in patients with neuroborreliosis (46,47), and there seems to be little, if any, role for PCR in the detection of *B. burgdorferi* DNA from blood or urine samples.

Pathology

After injection into the skin, *B. burgdorferi* is particularly tropic for tissues of the skin, nervous system, heart, and joints, but the specific reasons for these tropisms are not yet known. Histologically, all affected tissues show an infiltration of lymphocytes and plasma cells with some degree of vascular damage, including mild vasculitis or hypervascular occlusion, suggesting that the spirochete may have been in or around blood vessels (48). The synovial lesion, which is similar to that seen in other forms of chronic inflammatory arthritis, shows synovial cell hyperplasia, vascular proliferation, and a heavy infiltration of mononuclear cells (49,50).

In patients with meningitis, CSF typically has a lymphocytic pleocytosis of about 100 cells/mm^3, often with an elevated protein but a normal glucose level (33). Electrophysiologic studies of affected extremities suggest primarily axonal nerve involvement (39,40). Histologically, the lesions show axonal nerve injury with perivascular infiltration of lymphocytes and plasmocytes around epineural blood vessels (51). In several patients with carditis, spirochetes have been demonstrated in the myocardium *in vivo* by endomyocardial biopsy (34).

Acrodermatitis chronica atrophicans, which sometimes follows years after erythema migrans, begins with red violaceous lesions that become sclerotic or atrophic (6). *B. burgdorferi* has been cultured from such lesions as long as 10 years after their onset (52). Histologically, the rete ridges of the epidermis are typically lost, and a mononuclear cell infiltrate and telangiectasia are manifest throughout the underlying dermis (53). Sclerotic lesions may resemble localized scleroderma (54).

Treatment and Prognosis

The various manifestations of Lyme disease usually can be treated with oral antibiotic therapy, except for objective neurologic abnormalities, which seem to require intravenous therapy (8,55). For patients with infection localized to skin or in those with early, disseminated infection, 20- to 30-day courses of oral doxycycline or amoxicillin are usually sufficient. Lyme arthritis often can be treated successfully with either oral or intravenous antibiotic therapy. In most cases, 30- to 60-day courses of oral doxycycline or amoxicillin or 2- to 4-week courses of intravenous ceftriaxone are adequate (56,57). Despite treatment with either oral or intravenous therapy, a subset of patients may have persistent joint inflammation for months or even several years after antibiotic therapy (56). Both nonsteroidal antiinflammatory drugs (NSAIDs) and disease-modifying antirheumatic drugs (DMARDs) have been used with some success if patients have persistent arthritis after 2 months of oral therapy or 1 month of intravenous therapy and if the PCR results for *B. burgdorferi* DNA in joint fluid are negative.

For objective neurologic abnormalities, with the possible exception of facial palsy alone, parenteral antibiotic therapy seems to be necessary. Intravenous ceftriaxone, for 2 to 4 weeks, is most commonly used for this purpose (33,36,57). In patients with high-degree atrioventricular block or a PR interval of greater than 0.3 seconds, intravenous ceftriaxone or intravenous penicillin for at least part of the course and cardiac monitoring is recommended.

The outcome of treatment with these antibiotic regimens is generally excellent, particularly in those with early Lyme disease (58). Objective evidence of relapse is rare. The most common reason for apparent lack of response to antibiotic therapy in Lyme disease is misdiagnosis (59). Patients may have subjective symptoms after Lyme disease, including fatigue, arthralgia, myalgia, headache, or cognitive difficulties, which has been referred to as *post-Lyme disease* or *chronic Lyme disease syndrome* (60,61 and 62). It is similar to chronic fatigue syndrome or fibromyalgia. In these patients, further courses of antibiotic therapy do not lead to sustained improvement.

IMMUNOPATHOLOGY AND IMMUNOBIOLOGY

Humoral Response

To maintain its complex enzootic cycle, *B. burgdorferi* must adapt to two markedly different environments: the tick and the mammalian host. This may be responsible in part for modulation of antigen expression by the spirochete (63,64,65,66,67 and 68). OspA and OspB are expressed primarily by the spirochete within the midgut of the tick (63). When the blood meal is taken, OspC is upregulated (68) and OspA is downregulated (63) as the organism traverses to the tick salivary gland and to the mammalian host. Spirochetes from ticks fed on OspA vaccinated mice died *in situ* prior to transmission into the host (69). The magnitude of the immune response to OspA elicited by the vaccine correlates with protection (16).

In the human host, antibody reactivity develops slowly to an expanding number of borrelial proteins over weeks to months (43,70,71). In a retrospective analysis of serial serum samples from patients followed up throughout the course of the infection (72), the earliest responses were usually to OspC (P23), a fibronectin-binding protein (P45, also called P35), and the flagellar protein (P41). Reactivity with OspE, OspF, P39, and P93 often developed weeks later, and months to years later, patients with arthritis frequently developed responses to OspA and OspB.

Antibodies to the flagellar protein of *B. burgdorferi* (P41) bind to a component of normal human axons identified as chaperonin-HSP60 (73). It is not known, however, whether autoreactivity causes tissue damage or is a secondary epiphenomenon. In the subgroup of patients with antibiotic treatment-resistant Lyme arthritis, the higher the IgG antibody response to OspA, the more severe and prolonged the arthritis (72). This response may be a marker for a critical T-cell response rather than an autoantibody.

Cellular Response

B. burgdorferi contacts immune cells shortly after infection at the site of entry and subsequently in the local lymph nodes, through cell surface receptors, including lipoproteins. Spirochetal lipoproteins OspA and OspB are mitogenic for B cells, macrophages, and g-d T cells, and they induce cytokine production by endothelial cells (74,75 and 76). OspA and other spirochetal lipopeptides of *B. burgdorferi* trigger LPS receptor (CD14) signaling and downstream activation of Toll-like receptor-2 (77,78,79,80 and 81). This pathway then leads to nuclear translocation of NF-kB, which upregulates cytokine production (82,83 and 84). *B. burgdorferi* binds to mammalian cells via integrins, among other pathways (85,86), which is known to upregulate NF-kB and induce interleukin-12 (IL-12), an inflammatory cytokine (87,88). Attachment to dendritic cells leads to phagocytosis, spirochete killing, and antigen presentation (89).

Activation of antigen-specific T cells follows antigen presentation. Proliferative responses of peripheral blood lymphocytes to various spirochetal antigens are significantly greater in patients with Lyme arthritis than in control subjects (90,91,92,93,94 and 95). In addition, cytotoxic $CD8^+$ T cells from both peripheral blood and synovial fluid have been elicited by OspA, OspB, and flagellin (P41) (96). These inflammatory cells may participate in spirochete control. gd T cells may be activated by *B. burgdorferi* (76,90). They also express Fas-ligand and kill activated synovial a-b T cells *in vitro*, suggesting a role in downregulating the immune response (97).

Inflammatory cytokines, particularly interferon-g (IFN-g), predominate in T cells in synovial fluid in patients with Lyme arthritis (98). T-cell clones derived from such patients have a T-helper cell type 1 (Th1) phenotype, characterized by IFN-g production, as opposed to an antiinflammatory Th2 phenotype (99). When *in vitro* recall responses were compared by a sensitive fluorescence-activated cell sorter (FACS) assay, the Th1 to Th2 ratio in synovial fluid correlated directly with the severity of arthritis, such that the higher the ratio, the greater the joint swelling (100). Peripheral blood mononuclear cells from subjects with Lyme disease secrete more IFN-g and less IL-4 than cells from control subjects (101). Proinflammatory cytokine mRNA for IL-1b, IFN-g, and TNF-a is predominant in synovium of patients with chronic Lyme arthritis (102). Finally, TNF-a is produced following *B. burgdorferi*-specific stimulation of synovial fluid mononuclear cells (98,103).

A comparison of cytokine profiles in patients with erythema migrans, a self-limited skin lesion, versus those with acrodermatitis chronica atrophicans, a chronic progressive skin condition, suggested that proinflammatory cytokines, particularly IFN-g, are important in the initial control of the infection (104). Among 27 patients who had erythema migrans alone with no associated signs or symptoms, the major cytokines expressed in T cells and macrophages were the proinflammatory cytokine IFN-g and the antiinflammatory cytokine IL-10. In the 15 patients who had associated signs and symptoms, including headache, elevated temperature, arthralgias, myalgias, and fatigue, a larger number of macrophages and greater expression of macrophage-derived, proinflammatory cytokines, TNF-a, IL-1b, and IL-6, also were found. In comparison, infiltrates of T cells and macrophages in the skin lesions of acrodermatitis patients had little or no IFN-g. Instead, they usually expressed only the proinflammatory cytokine TNF-a and the antiinflammatory cytokine IL-4.

Autoimmune Mechanisms

Joint inflammation in patients with chronic, antibiotic treatment–resistant Lyme arthritis continues after apparent eradication of the spirochete from the joint with antibiotic therapy. In an initial study, T-cell lines from patients with treatment-resistant arthritis preferentially recognized OspA (105). In a larger series, T cells from 32 treatment-responsive or treatment-resistant patients were tested for their reactivity with *B. burgdorferi* proteins in bulk culture (95). The only significant difference was the greater reactivity of treatment-resistant patients with N- and C-terminal fragments of OspA. When OspA epitope mapping was done, the responses of patients with treatment-resistant disease were significantly greater to several OspA peptides, particularly OspA peptide 154-173.

Patients with treatment-resistant arthritis were more likely than the group of treatment-responsive patients to express DR-b1-0401 or several other related alleles (24,95). Independent peptide substitution analysis of DR-b1-0401 allowed development of an algorithm to predict its binding affinity for any sequence of amino acids (106). When the OspA sequence was analyzed according to the algorithm, the best-fit peptide was predicted to be OspA165-173 (17), which was consistent with the observations in patients. Binding was confirmed with affinity studies, and the immunodominance of this peptide was shown by immunization of DR4 transgenic mice with OspA and peptide recall *in vitro* (17). When this sequence was compared with the database of sequenced genetic information (Genetics Computer Group, University of Wisconsin, Madison, Wisconsin), a single human homolog, LFA-1a332-340, was identified that had predicted binding by the 0401 molecule. Using an Elisaspot assay for IFN-g production, synovial fluid T cells from 10 of 11 patients with treatment-resistant Lyme arthritis had reactivity with the OspA or hLFA-1 peptides or, in most instances, with both, whereas patients with rheumatoid arthritis or other chronic inflammatory arthritides recognized neither peptide.

These observations led to the following hypothesis. In genetically susceptible patients, OspA165-173-specific T cells are expanded in the joint. In addition, LFA-1 expression is upregulated on activated T cells as a consequence of T-cell receptor and cytokine signals. After some of these activated T cells undergo apoptosis and are cleared by macrophages, presentation of the cross-reactive hLFA-1 peptide may continue to stimulate OspA165-173-specific T cells, enabling the immune response to continue after the eradication of spirochetes with antibiotic therapy (107). Inflammation, enhanced by inflammatory cytokines, or linked immune responses such as priming of $CD8^+$ cytotoxic T cells, may prolong the episodes of arthritis and lead to destructive joint changes.

This hypothetical autoimmune response occurs only in infected joints, although it is directed against a ubiquitously expressed self-antigen. There is precedent for this apparent paradox in a novel murine model of autoimmune arthritis, where an immune response directed against a housekeeping gene, glucose 6-phosphate isomerase, causes an arthritogenic autoimmune disease (108,109 and 110). Currently, a murine model for chronic, antibiotic treatment–resistant Lyme arthritis does not exist. The chronicity of disease observed in susceptible mice results from persistent infection and cannot be transferred with immune cells alone. DR4 transgenic mice on the B10.M/Sn background do not develop chronic, antibiotic treatment–resistant disease (111). However, the potentially cross-reactive epitope of human or murine LFA-1 is different.

ANIMAL MODELS

Mouse

The plethora of available mouse strains, including genetically modified animals, and the depth of knowledge of the murine immune system have made studies of the mouse particularly valuable in understanding Lyme disease. The mouse does not mimic all aspects of human Lyme disease, as mice do not develop erythema migrans, neuroborreliosis, or autoimmune Lyme arthritis (112). Needle inoculation, the predominant method of infection used in mice, requires a higher infectious dose and transmits cultured organisms with different antigenic expression than tick transmission. Finally, *B. burgdorferi* sensu stricto is more virulent in laboratory animals and humans than *B. garinii* or *B. afzelii* (113); this organism is the most extensively studied in laboratory rodents.

Most mouse strains can be infected with *B. burgdorferi* sensu stricto, strain N40 (Table 79.1) (112). At one extreme, young C3H/He mice develop severe destructive arthritis at all challenge doses, including challenge with fewer than 100 spirochetes (112,114). At the mild end of the spectrum, C57BL/6 mice do not develop arthritis, even at high challenge doses (114). Mice that lack T and B cells because of severe combined immune deficiency (scid) or genetically engineered recombinase deficiency (rag) fail to control spirochete replication (115,116 and 117). Efficient spirochete control is not a factor in C56BL/6 resistance, as even C57BL/6-rag mice do not develop joint inflammation (Table 79.2) (117). Most mouse strains resemble arthritis-resistant C57BL/6 mice (114). At low-challenge doses of *B. burgdorferi* strain

N40, they resist infection, whereas at higher doses, infection occurs without obvious sequelae.

Strain	Arthritis	Spirochete burden	References
Wild type			
C57BL/6 (B6)	None	Low–High[a]	114–117, 126–127
C3H/He	Severe	High	112, 117, 116–117, 119, 124, 131–132, 137, 139–144

TABLE 79.2. Infection and Arthritis Susceptibility in Selected Strains of Genetic Knockout or Antibody-Treated Mice

MURINE INNATE RESPONSES

Mapping of chromosomal regions controlling arthritis severity in C57BL/6 mice implicated innate immune regulators (27). In C57BL/6 mice with the *beige* mutation, which causes gross defects in cell-mediated immunity, severe arthritis follows *B. burgdorferi* infection (118). High natural killer (NK) cell effector functions correlate with severe destructive arthritis, but depletion of NK cells does not alter the disease course in susceptible or resistant mice, suggesting that NK activation results from inflammation but is not pathogenic (119). In mice, *B. burg dorferi* lipoproteins are mitogenic for B cells (120) and monocytes/macrophages (121). Macrophages engulf *B. burgdorferi* and degrade the spirochetes in intracellular compartments (122,123). Although NO was thought to be the main effector molecule produced by macrophages, iNOS-deficiency does not change the course of infection or arthritis severity in susceptible or resistant mice (124).

Proinflammatory cytokines, such as IL-12, enhance macrophage function. In C3H-scid mice, anti-IL-12 treatment limits innate immunity and further exacerbates arthritis (Table 79.2) (125). IL-10, a cytokine produced by both T cells and macrophages, is an antiinflammatory macrophage suppressor. IL-10-deficient C57BL/6 mice have 90% fewer spirochetes than infected C57BL/6 control mice, probably because of sustained macrophage activation (Table 79.2) (126). Consistent with a role for antiinflammatory responses in controlling arthritis, IL-10-deficient mice develop more severe arthritis. IL-6-deficient C57BL/6 mice are also more susceptible to Lyme arthritis (127), suggesting a role for this cytokine in enhancing macrophage function. Innate immunity is the primary determinant of arthritis resistance or susceptibility.

MURINE ANTIGEN-SPECIFIC RESPONSES

BALB/c mice also can be infected with *B. burgdorferi*, and they develop arthritis in a dose-dependent manner (Table 79.1) (128). At low infectious doses, BALB/c mice resist infection; at moderate doses, they become infected and develop mild arthritis; and at the highest doses, they develop more severe arthritis. In early genetic studies of (C3HxBALB/c)F1 mice, susceptibility was dominant and associated with large numbers of spirochetes in tissues (129,130). BALB/c-scid mice develop both a high spirochete burden and severe arthritis and carditis, exceeded only by C3H-scid mice (115,116 and 117). Therefore, BALB/c mice have a similar arthritis-susceptible innate immune response to *B. burgdorferi* as C3H mice, but under normal conditions, antigen-specific T and B cells control spirochete expansion in BALB/c but not C3H mice.

In both C3H and BALB/c mice, depletion of $CD4^+$ T cells substantially inhibits the early immune response, increasing spirochete burdens and arthritis severity (Table 79.2) (131). When signaling through the T-cell costimulatory receptor CD28 is blocked with antibodies directed against CD80 and CD86 (also known as B7-1 and B7-2, respectively), or anti-CD86 alone, arthritis worsens significantly in C3H mice (Table 79.2) (132). Blocking only the CD80/CD28 interaction, however, reduces arthritis severity. CD80 has been shown to inhibit T-cell responses in a negative feedback mechanism, and blocking this signal may prolong the immune response and enhance spirochetal control, suggesting a dominant role for T-dependent responses in C3H mice. In BALB/c mice, in contrast, blockade of both CD28 costimulatory signals decreases arthritis, whereas blockade of either pathway alone does not change disease outcome (133). This suggests that humoral responses that occur in the absence of CD28 costimulatory signals, but not in the absence of T cells themselves, are most important in controlling disease and arthritis in BALB/c mice. *In vivo* expressed *B. burgdorferi* proteins induce antibodies to a 37-kD arthritis-resolving protein that are sufficient to resolve arthritis when passively transferred to infected C3H-scid mice (134,135). Anti-OspA responses are not required for arthritis resolution (135,136).

MURINE CYTOKINES

Inflammatory cytokine production contributes to spirochetal control. Highly susceptible C3H mice have lower IFN-g production early in the infection, whereas the more resistant BALB/c mice produce higher levels of IFN-g initially and then switch to IL-4 production, which presumably attenuates the arthritis (137). BALB/c and C3H mice have equal numbers of *B. burgdorferi*-specific $CD8^+$ T cells (138). Needle inoculation of high doses of spirochetes induces pathogenic Th1 responses in C3H mice (139,140), but follow-up work using tick transmission demonstrates instead a failure of C3H mice to mount an appropriate Th1 response early in infection (141). Removing proinflammatory IFN-g does not attenuate arthritis in C3H mice (142). In fact, administration of recombinant human IL-11 to C3H mice induces upregulation of IL-12 and iNOS expression and decreases arthritis severity (143). IL-12 depletion with monoclonal antibodies in C3H mice reduces immune control and enhances spirochete expansion *in vivo* (Table 79.2) (144). Nonetheless, this treatment reduces arthritis severity, demonstrating the complexity of cytokine networks and the potential pleiotropic effects of individual cytokines. Anti-IL-11 treatment increases arthritis severity in C3H mice (Table 79.2) (143). The IL-11 receptor and the IL-6 receptors share a subunit (CD130) that is expressed by both immune and somatic cells. Therefore, the same mechanism may underlie the similar findings with anti-IL-11 in C3H mice and the IL-6-deficient C57BL/6 mice. Taken together, the cytokine data suggest an important protective role for Th1 responses, in synergy with the innate immune system; however, this response is ideally balanced with an antiinflammatory response to regulate organ pathogenesis.

CARDITIS

Carditis is a frequent manifestation of *B. burgdorferi* infection in mice. C3H mice that develop severe destructive arthritis also have more severe carditis than C57BL/6 mice (145). $CD4^+$ T cells are not required for pathogenesis, and in fact macrophage infiltrates predominate in the cardiac lesions (146). Macrophage-derived IL-1 and TNF-a recruit Th1 cells to the lesion (147). Although IL-4 deficient BALB/c mice initially develop more severe carditis, resolution occurs with similar kinetics as in control BALB/c mice (148). Carditis is also an inflammatory lesion, but spirochete control seems to be the dominant factor in its resolution rather than conversion to an antiinflammatory Th2 response with antibody production.

VACCINE

Passive transfer of sera from OspA-immunized, immune competent mice to C3H-scid mice or vaccination of immune competent mice with recombinant OspA protects

on subsequent challenge with *B. burgdorferi* (149). Subsequent OspA vaccination does not worsen the disease course in previously infected mice (150). In mice, vaccination protects against tick transmission, but not needle inoculation, of multiple isolates and substrains of *B. burgdorferi* sensu stricto (151,152). In contrast, passive transfer of immune sera from infected, cured mice, which contains many specificities but few anti-OspA antibodies, protects recipients from needle inoculation (153) but not from tick-borne challenge (154). Immunity following natural infection is not cross-protective between different *B. burgdorferi* sensu lato species (113). Anti-OspA antibodies, and to a lesser extent anti-OspE and anti-OspF antibodies, are uniquely able to kill spirochetes *in situ* in the tick midgut (155).

Other recombinant borrelial proteins have been successfully used to immunize mice (156,157); however, the spirochetal lipoproteins are particularly suitable as vaccine targets because of their mitogenic qualities and ability to harness the innate immune system. The lipid moiety of OspA enhances specific T- and B-cell responses (158). Immunity to borrelial lipoproteins can develop in the absence of CD40 ligand, and even in the absence of MHC class II and $CD4^+$ T cells, suggesting that they can act as T-independent antigens (159,160). These results in mice contrast with those in humans, in which specific $CD4^+$ T-cell responses to OspA correlate with antibiotic treatment-resistant Lyme arthritis.

Hamster

Syrian hamsters vaccinated with whole killed *B. burgdorferi* are protected on subsequent infectious challenge (161). Uniquely in this model system, hamsters vaccinated with OspA develop severe destructive arthritis if challenged with cultured *B. burgdorferi* expressing OspA before they have fully developed protective immunity (162,163). Both T cells and macrophages from vaccinated hamsters with severe destructive arthritis can transfer disease in this system (164,165 and 166). Depletion of $CD4^+$ T cells from vaccinated hamsters prevents arthritis induction on infectious challenge (167). This suggests that OspA-specific T cells, amplified by immunization, may home to sproichete-infected joints, where they lead to joint inflammation.

Neuroborreliosis

Neuroborreliosis is more difficult to study in animal models because this manifestation does not occur in the mouse. Infection with *B. burgdorferi* in the rat model results in increased permeability of the blood–brain barrier within 24 hours but no clinical manifestations (168). The rhesus monkey develops neuritis, measured 3 months after infection, characterized by B-cell and macrophage infiltrates (169). Especially in tick-infected monkeys, inflammation resolves and axons regenerate even without antibiotic therapy (169).

SUMMARY

B. burgdorferi infection initiates an inflammatory immune response that has both protective and potentially pathogenic elements. Macrophages are activated by *B. burgdorferi* lipoproteins and possibly by the interaction of host integrins with other *B. burgdorferi* surface receptors to upregulate NF-kB and produce inflammatory cytokines. In the mouse model, innate immune responses are the primary determinant of arthritis susceptibility or resistance, whereas antigen-specific immunity is important in controlling spirochete expansion. Both innate and T-cell-mediated immune responses are primarily proinflammatory, ideally with an antiinflammatory component to limit organ damage. Uniquely in some human patients infected with *B. burgdorferi* sensu stricto, genetic susceptibility and ongoing active infection can lead to proinflammatory autoimmune responses to human LFA-1a, which contains a molecular mimic of the immunodominant T-cell epitope of OspA. In these patients, the autoimmune response is thought to prolong episodes of arthritis, even after eradication of the spirochete from the joint with appropriate antibiotic therapy.

ACKNOWLEDGMENT *We thank Dr. Sam Telford and Dr. Jenifer Coburn for helpful discussions and background information. 80 PARASITIC DISEASES

Frederick P. Heinzel, M.D., and Thomas B. Nutman, M.D.

Parasitic diseases are historically defined as infectious illnesses caused by unicellular protozoa or multicellular helminths as distinct from viral, bacterial, or fungal etiologic agents. They are the special health care problem of developing countries, where the extreme prevalence of malaria, filariasis, schistosomiasis, leishmaniasis, and trypanosomiasis imposes major medical and economic burdens. These diseases afflict hundreds of millions of people worldwide and are responsible for a million or more deaths every year. The importance of parasitic illness has received recent additional emphasis in both developed and developing nations by the emergence of toxoplasma and cryptosporidium as opportunistic pathogens in patients with acquired immunodeficiency syndrome (AIDS).

Control of parasitic illness remains an unfulfilled goal. Attempts at chemotherapy have been foiled by the length of treatment needed in some instances and by the emergence of drug-resistant parasites, exemplified by chloroquine-resistant malaria (1). Vector control has been similarly ineffective because of insecticide resistance and social, logistic, and economic obstacles. The hope that protective immunization against the major parasitic illnesses would circumvent the need for mass chemotherapy and vector control is now tempered by a realization that parasites have achieved a unique evolutionary arrangement with mammalian immune systems that defeats simple vaccine strategies that were previously successful against viral and bacterial targets. The immunology of parasitic disease is therefore relevant both to the development of new vaccine approaches and to the study of normal immunologic functions that may be uniquely understood by the elucidation of parasite subversive mechanisms.

SPECTRUM OF PARASITE–HOST INTERACTIONS

The inclusion of both protozoan and helminth infections in the category of parasitic disease is partially historical and embraces a heterogenous group of organisms with extremely diverse biologies. Protozoa are usually a few micrometers in size, whereas worms are typically centimeters to meters in length. Tissue-dwelling protozoa are often intracellular parasites at some stage of infection, whereas helminths, which are larger than most tissue cells, are almost always extracellular pathogens; the significant exception is encystation of *Trichinella spiralis* within mammalian muscle cells. Protozoa usually replicate during infection of a single host; helminths do not reproduce without the assistance of intermediate hosts or passage through soil or water.

Nevertheless, other aspects of the epidemiology, biology, pathogenesis, and immunology of these illnesses provide some thematic unity to justify this otherwise arbitrary grouping of diverse genera. First, both protozoan and helminth pathogens have characteristically complex life cycles with two or more developmental stages present during infection (2). For example, *Leishmania* promastigotes are introduced into mammalian hosts by biting sandflies; there they invade tissue macrophages and convert to the obligate intracellular amastigote form that replicates asexually and causes disease. In contrast, the plasmodial agent of malaria initiates a more complex biology in mammalian hosts when introduced by mosquito bite as free-living sporozoites that invade liver cells. Following this hepatocyte stage, the organism reemerges as a blood-stage parasite with alternating extracellular merozoite and intraerythrocytic trophozoite forms. Subsequently, some blood-stage parasites evolve into nonreplicating, extracellular gametocytic (sexual) forms.

Helminth life cycles can be similarly complex; in the course of a single infection, the host may be repeatedly exposed to larval, adult, or egg-stage antigens. Free-swimming cercariae of the trematode *Schistosoma mansoni* penetrate the skin of humans immersed in infested water and evolve into tissue-stage schistosomula that migrate to the liver and mesenteric veins for further differentiation into sexually dimorphic adult worms. Eggs are laid that migrate through tissues into the lumen of bowel or bladder for environmental release. Filarial infection similarly involves repeated exposure to arthropod-borne infective larva and chronic parasitization by long-lived adult worms that continuously release microfilariae that circulate in the bloodstream or migrate through subcutaneous tissues.

Because each stage of parasite development may be antigenically distinct, protozoan or helminth infections are often characterized by a series of discrete immune responses that evolve at different times during the course of disease. Protective immunity directed against a single stage may be circumvented by parasite differentiation, assisting in the survival of the pathogen and posing a significant challenge to vaccine development. Each stage of parasite development also may entail a change in tissue tropism, introducing a compartmental feature to immune responses. For example, numerous distinct cutaneous, pulmonary, and intestinal inflammatory or hypereosinophilic syndromes are associated with different stages of *Ascaris* and *Strongyloides* species as they migrate through the skin and lung before reaching adulthood in the gastrointestinal tract (3). This temporal evolution of antigenic complexity and tissue tropism is unique to parasite immunology and further distinguishes this field from that of viral or bacterial immunology.

Because complex parasitic life cycles can be maintained only by sequential passage through a sometimes inflexible choice of intermediate and definitive hosts, parasites have adapted to optimize transmission by prolonging infection. This is critical if passage through a series of intermediate hosts depends on infrequent events, such as ingestion of excreted eggs and larvae or uptake by the occasional biting insect. Perhaps because of this evolutionary pressure, chronicity and latency are hallmarks of both protozoan and helminth infections. For example, adult *Schistosoma* and *Filaria* species can survive in host tissues for as long as 30 years, producing eggs and larval stages all the time. *Plasmodia malariae* remains dormant in the liver for decades. *Leishmania* can recrudesce years after infection to cause post-kala azar dermal leishmaniasis or mucocutaneous disease; the former process may provide an important reservoir for vector-mediated transmission of disease to other humans (4). Chronicity may also reflect pressure for “balanced pathogenicity,” because extreme virulence will disrupt parasite transmission when the host dies before egg-laying or larval release can occur. In response to the evolutionary pressure for chronic infection, a broad range of evasive and suppressive strategies evolved among the parasites to maintain long-term viability in their hosts.

Adaptations for chronicity can be so successful among parasites that naturally acquired protective immunity may not be observed in areas endemic for that disease. Specifically, schistosomiasis results in an incomplete form of protection where reinfection is limited, but adult worms are tolerated for years (concomitant immunity) (5). Antimalarial immunity in highly endemic areas of the world is slow to develop and is usually nonsterilizing. Instead, clinical resistance typically manifests as a well-tolerated, limited parasitemia. Similarly, the presence of a subpopulation of hosts that are genetically susceptibile to dysfunctional immunity and prolonged infection with specific parasites may be essential for sustaining endemicity of the disease. For example, although *Leishmania donovani* often results in subclinical disease that heals with long-lasting immunity, half or more of seroconverting children in Brazil develop progressive visceral leishmaniasis and require drug therapy for cure (6). An active role of the parasite in maintaining this susceptible state is evident by the fact that curing visceral leishmaniasis by chemotherapy generates long-lasting immunity. Similar heterogeneities in host immune responsiveness may help maintain the parasite in animal reservoirs. Filarial infection similarly manifests as a range of clinical manifestations determined by divergent host immune responses. In this case, prolonged microfilaremia reflects apparent immunologic hyporesponsiveness to the parasite, whereas other hosts mount vigorous inflammatory responses that limit transmission but cause pathology (7).

MECHANISMS OF EVASION AND IMMUNOLOGIC SUPPRESSION BY PARASITIC ORGANISMS

Mechanisms of Evasion

Among the mechanisms used by parasites to avoid immune rejection are those of evasion—the use of sequestration, camouflage, and antigenic variation–and suppression or blockade of immune effector pathways.

SEQUESTRATION

Pathogens become sequestered when they enter into intracellular or extracellular compartments that are not accessible to all components of the immune response. *Echinococcus* species, *Taenia solium*, and *Trichinella spiralis* sequester themselves in mammalian tissue primarily by encystation. Whereas it was initially believed that encapsulated organisms were immunologically inert, studies have since demonstrated that macromolecules, including parasite antigens and host antibodies, can traverse cyst membranes (8). This, together with the observation that parasite death, whether spontaneous or in response to chemotherapy, provokes intense local inflammation even in the brain (9), suggests that the cyst membrane may regulate rather than prevent the transport of parasite and host molecules as a means of attenuating the host immune response.

Similarly, adult *Onchocerca volvulus* are surrounded by a relatively avascular, acellular fibrotic capsule that serves as a barrier to the host response and yet permits transport of eggs into the adjacent tissue (10). Tropism for immunologically relatively protected environments (e.g., the eye in *Onchocerca volvulus* infection and *Toxoplasma gondii* and the intestinal lumen for intestinal nematodes and protozoa) also serves to sequester the parasite physically from the host effector systems. Intracellular invasion is a common strategy used by protozoa that removes them from potentially lethal phagocytic cells and humoral factors such as complement and antibody. In the case of malaria, intraerythrocytic *Plasmodia* species may avoid immune or nonspecific destruction during splenic transit by expressing a variety of endothelial adhesion molecules on the surface of the infected red cell, thereby sequestering parasitized cells in the peripheral circulation (11).

MOLECULAR MIMICRY AND CAMOUFLAGE

Molecular mimicry and camouflage are two mechanisms that parasites use as defense strategies against the host response, the result of which is to appear “not foreign” (*self*) to the immune system. Schistosomes adsorb onto their tegument a variety of host serum and cellular proteins, including blood group factors (12), the Fc portion of immunoglobulin (13,14), and major histocompatibility complex (MHC) molecules (15). A related form of camouflage occurs when the parasite synthesizes proteins that share epitopes with host tissues; such molecular mimicry may exploit host immune tolerance against self-determinants. The ribosomal P0 proteins of both humans and *Trypanosoma cruzi* share cross-reactive epitopes for antibodies (16). Similarly, the *T. cruzi* surface antigen FI-160 exhibits an antibody binding site found on human neural tissue (17). There have also been described as antigens of *O. volvulus* that have cross-reactivity with retinal proteins (18,19).

Molecular mimicry may have other consequences. Although the host may be unable to generate protective T-cell and B-cell responses to these epitopes because of developmentally induced nonresponsiveness, autoimmunity may occur if immune tolerance is overridden. The generation of anti-FI-160 antibodies in human patients infected with *T. cruzi* has been suggested as a contributory autoimmune factor in the neural plexus destruction that occurs in chronic Chagas disease (17). Similarly, the finding of antibodies in patients with onchocerciasis that bind to retinal tissue has been suggested as a possible cause for the chorioretinitis seen in this disease (18,19).

ANTIGENIC VARIATION

Trypanosoma brucei, the cause of African trypanosomiasis, survives host immune destruction through periodic switching of the major surface protein (20). Unlike infections associated with other closely related protozoa, such as *T. cruzi* and *Leishmania* spp., *T. brucei* has no intracellular stage during human infection and is therefore vulnerable to cytolytic humoral immune responses. The variant surface glycoprotein (VSG) molecules comprise the major component of the cell surface and are encoded by several hundred VSG genes; each is antigenically distinct, and only one is expressed at a time. Periodic and sequential switches in VSG expression allow isolated clones of cells to survive despite cytocidal antibody responses to preexisting VSG epitopes. Each gene switch results in another cycle of trypanosomal growth and immune-mediated decimation, giving rise to the characteristic fluctuating parasitemia of this disease.

Antigenic heterogeneity due to strain diversity within a single species of parasite can also diminish the effectiveness of immune responses. The failure of humans to efficiently develop resistance against malaria may be related to the extreme antigenic polymorphism present among local strains of *Plasmodia* in endemic areas (21). A highly diverse family of immunogenic adhesion proteins, the var complex, also can contribute to the antigenic complexity of falciparum malaria (22). In addition to strain-related diversity, true antigenic variation within single clonal lineages also occurs because of a high mutation rate in the relevant genes, further complicating the acquisition of protective immunity (21). It has been estimated that immunologically recognizable variation in the erythrocytic phase of malaria occurs at a rate of about 2% per generation. Similar strain heterogeneity occurs in *Giardia lamblia* (23).

SHEDDING OF SURFACE ANTIGEN AND BOUND ANTIBODIES

Parasites that shed antigen on recognition by host antibody also can enhance their survival. This phenomenon has been described with *E. histolytica* (24), *T. cruzi* (25), and *S. mansoni* (26,27) parasites. Tissue- and intestinal-dwelling nematodes also periodically release portions of their outer glycocalyx coat (28), although the role this plays in avoiding immune recognition is not established. Discarded or secreted antigens also conceivably can serve as decoys to misdirect host responses.

Mechanisms of Suppression and Blockade of the Host Effector System

PARASITE-DERIVED FACTORS

Intracellular and extracellular parasites have clearly developed methods of inactivating humoral immune responses. Parasites possess surface-associated or secreted proteases that degrade host antibody molecules. Factors from cyst fluid from *Taeniae* infections have been shown to be able to activate complement (29); similarly, such factors have also been found in hydatid cyst fluid (30) and in soluble extracts of adult *S. mansoni* worms (31).

Unlike helminths that have a thick cuticle, protozoa are more susceptible to lysis following formation of the C5b-C9 membrane attack complex of complement. Several mechanisms have been defined that defeat cytocidal complement formation mediated by both alternative and classical pathways (32). The extracellular trypomastigote form of *T. cruzi* disrupts the function of C3 convertase through the expression of a protein analogous to decay accelerating factor (DAF). *T. gondii* has evolved a surface structure that is a poor substrate for activation of the alternate pathway; however, binding of specific antibody triggers fatal complement formation via the classical pathway. Activation of complement on the surface of *Leishmania* species is rendered noncytocidal because of the ability of the lipophosphoglycan coat to prevent insertion of the C5b-C9 complex (33). Similar mechanisms may operate in *Schistosoma* species (34).

Parasite-derived factors also have been isolated that interfere with T-cell function. For example, the secretion of immunodominant molecules, such as the hapten phosphorylcholine, may act as an inhibitor of T-cell reactivity (35,36,37 and 38) and secondarily as a molecule that diverts the attention of the host immune system (28). Molecules with similar effects on T-cell function have been described in schistosomes as well (31). Other molecules with similar inhibitory functions include the *Achanthocheilonema viteae* excretory-secretory (ES) antigen Av17, a cysteine protease inhibitor that accounts for much of the suppressive activity of filarial ES products on T-cell proliferation in murine studies (39), and the oligosaccharide lacto-*N*-fucopentose III, which downregulates the type 1 response in murine schistosomiasis (40).

Although their role in immunoregulation is unproven, cytokine-like molecules of parasite origin, including homologs of transforming growth factor (TGF-b (41), macrophage migration inhibitory factor (MIF) (42), and interferon-g (IFN-g) (43) also were identified in several helminth species. In the case of the IFN-g homolog of *Trichuris muris*, receptor binding and biologic activity also have been demonstrated *in vitro* (43).

Acute infection with *T. cruzi* is associated with suppressed T-lymphocyte proliferation and lymphokine production, apparently in response to soluble parasite products (44). Of interest, parasites such as *Brugia malayi* (one of the causative agents of lymphatic filariasis) and *Taenia* both utilize endogenous and exogenous arachidonic acid to produce and release prostanoids [prostaglandin E_2 (PGE_2) and prostacyclin] molecules capable of inhibiting T-cell proliferation (45,46 and 47). In another instance, parasite-derived cytocidal activities of *Entamoeba histolytica* contribute to the virulence of this protozoan parasite during invasive infection by lysing host effector cells, including neutrophils and T-lymphocytes (48).

Parasites can modulate the ability of the host to present soluble antigen to the immune system. Schistosome infection appears to render antigen-presenting cells less competent (49). The release of parasite-derived protease inhibitors, such as filarial cystatin (50) or aspartic protease inhibitor from *Ascaris lumbricoides* (51), may block efficient antigen processing dependent on proteolytic lysosomal enzymes. Accessory cell functions also may be disrupted when these cells are themselves the target of parasitization. *Leishmania* species are obligate intramacrophage parasites that can block presentation of parasite antigen by infected cells and that disrupt signal transduction pathways essential for IFN-g-mediated upregulation of MHC II and monokine synthesis (52). Leishmania lipophosphoglycan (LPG) can interrupt signal transduction pathways necessary to interleukin-12 (IL-12) production and inducible nitric oxide synthase (iNOS) expression (53). Infection also induces the release of T-cell-suppressive cytokines from infected macrophages (54).

Other parasite products have antioxidant properties that limit the destructive potential of activated granulocytes or macrophages in the local extracellular milieu. Helminths susceptible to oxidant-mediated killing express both secreted and membrane-associated enzymes, such as superoxide dismutase (55), glutathione-S-transferase (56,57), and glutathione peroxidase (58), molecules thought to play a significant biologic role in assisting parasite survival in inflamed tissues. Protozoa that invade macrophages have evolved similar strategies. Again, the lipophosphoglycan surface molecule of *Leishmania* organisms has antioxidant properties

that may assist in intramacrophage survival (33). *T. gondii* generates glutathione peroxidase and catalase that permit survival in parasitized macrophages (59).

HOST-RELATED FACTORS

The inability to clear parasitic infection often is related to inefficient or counterprotective host responses elicited by helminths or protozoa. These pathogens may elicit cytokines, such as TGF-b, IL-4, IL-13, or IL-10, that antagonize microbicidal cellular immune responses. In some cases, parasitic infection may cause genetically persons to mount cellular immune responses that effectively misdirect host energies toward nonprotective responses. Thus, susceptible hosts may constitute a large enough population to sustain the local prevalence and transmission of disease. Although the suppression of protective immunity is host related, parasitic products actively shape these responses. For example, nonhealing leishmaniasis (including visceral disease) (60), the microfilaremic form of lymphatic filariasis (61,62,63 and 64), and generalized onchocerciasis (65,66,67,68 and 69) and schistosomiasis (70,71 and 72) all are associated with a defective immune response that can be restored when the parasitic burden is diminished by drug therapy (72,73,74 and 75). Infection with *T. cruzi* triggers generalized T-cell immunosuppression mediated by increased synthesis of IL-10 and TGF-b (76,77). Similarly, schistosome egg antigens elicit increased production of the cytokine IL-10 in infected tissue that consequently downregulates Th1-type $CD4^+$ T-lymphocyte responses necessary for the elimination of eggs or adult worms (78).

In addition to suppressing cellular responses, host-related factors may assist in parasite survival by providing a biologic signal necessary for parasite development. Specifically, *S. mansoni* ovulation is delayed in hosts that are unable to mount cell-mediated immune responses; however, reconstitution with proinflammatory molecules, possibly TNF-a, promotes earlier fecundity in some studies (79), although other factors may be necessary (80).

Parasite-induced perturbations of the specific antibody isotype generated during infection may additionally diminish the effects of a given immune response. Helminth infections, particularly lymphatic filariasis and schistosomiasis, result in the production of high levels of immunoglobulin E (IgE) and IgG4. The expression of antibodies of distinct isotypes directed against the same antigens may be beneficial to the host when IgG4 blocks IgE-mediated allergic responses (81); however, the increased magnitude of IgG4 and IgE responses commonly seen in schistosomiasis (82) and filariasis also may diminish the protective response mediated by other antibody isotypes directed against the parasite. Similarly, antibodies of the IgM and IgG2 isotypes also have been able to block antibody-dependent killing of schistosomula (83). Finally, the presence of these blocking antibodies has been associated with susceptibility to reinfection with schistosomiasis following chemotherapy (84).

VECTOR-RELATED FACTORS

Insect bites that convey infectious parasites may contribute to infectivity through biochemical manipulation of the local host environment. Sand fly saliva contains proteins with potent vasodilatory and macrophage-deactivating effects that may increase the availability of macrophage targets permissive for infection with *Leishmania* organisms and that enhance the infectivity of *Leishmania braziliensis* in normally resistant experimental hosts (85,86).

PATHOLOGY ASSOCIATED WITH IMMUNE RESPONSES IN PARASITIC INFECTION

Although the pathologic findings associated with each of the parasitic infections are different and most commonly relate to the presence of the parasites in the host tissue, there are pathologic reactions that stem directly from the host immune response. Although it is not the purpose of this chapter to review the pathologic and immunopathologic aspects of the parasitic diseases, the nature of some of the most common immunopathogenic mechanisms are described.

Immune Complexes

Immune complexes, potent mediators of localized inflammatory processes, form in many parasitic infections, most likely because of the chronic low-dose antigen release seen in these infections. The best-characterized example is the glomerulonephritis associated with *Plasmodium malariae* infection, in which parasite antigen has been demonstrated in the kidneys of patients with this manifestation of infection (1). Circulating immune complexes have clearly been identified in both experimental (87) and human filarial (39) and schistosomal (88) infections. These complexes have been shown to induce lymphatic inflammation and vasculitis in at least one filarial infection as a result of their deposition (89). Furthermore, observations of immune-complex glomerulonephritis have been made in patients with hepatosplenic schistosomiasis (90), loiasis (91), and onchocerciasis (92). Notably, the clinical syndrome of acute schistosomiasis also has been attributed to the presence of immune complexes (88).

Antoantibodies

Autoantibodies have been implicated as causing disease both in protozoal and in helminth infections, presumably reflecting a polyclonal B-cell activation that often accompanies these infections. Whereas this immunopathologic mechanism has been proposed to contribute to the central nervous system (CNS) and cardiac lesions of African trypanosomiasis, the cardiac and neural lesions seen in Chagas disease, and the anemia and nephropathy seen in malaria, the evidence for its existence in helminth infection is less well founded, despite being implicated in filariasis (93,94 and 95), schistosomiasis (96), and hookworm infection (97). Nevertheless, autoantibodies against nuclear material were found in a vast majority of patients with chronic schistosomiasis and much more frequently than in patients with diseases such as systemic lupus erythematosus (SLE) (98). In addition, calreticulin (antibodies to which are found in SLE) (99) have partial (64%) structural identity with the *Onchocercus volvulus* antigen RAL-1, a 42-kd antigen expressed in infective-stage larvae and adults (100). Furthermore, patients with onchocerciasis have antibodies that cross-react with calreticulin, suggesting that autoimmunity may play a role in the pathologic responses in onchocerciasis.

Autoimmune reactions have been considered to underlie some of the pathology seen in filarial infections, most notably in the chorioretinitis seen in onchocerciasis. Evidence was initially provided that demonstrated the presence of antibodies specific for human retinal antigens in *O. volvulus*-infected patients with chorioretinitis (101). Antibodies to several antigens of the inner retina also have been described, but the relationship between chorioretinitis and the presence of these antibodies could not be established (18,102). More recently, an antigen has been found in *O. volvulus* (22 kd) that induces antibody that cross-reacts with a 44-kd antigen component of bovine retinal pigment epithelial cells (19).

T-Cell-Dependent Pathology

Granulomatous reactions can be seen in many protozoal and helminth infections. Parasitic granulomata have been best studied in *S. mansoni* infections, where T-cell regulation of size and development has been well documented (103). Whereas such granulomas presumably act normally to isolate and help eradicate infectious or irritative challenges, these foci of intense immunologic activity often damage normal tissue. This damage may be essential for completing the life cycle of schistosomiasis by allowing eggs to escape through tissue barriers into the intestinal or urinary tract and their subsequent dispersal into the environment; however, granulomatous responses also contribute to the pathology of this disease. For example, scarring of the hepatic portal tracts resulting from fibrosis associated with granuloma formation around schistosome eggs can lead to cirrhosis and portal hypertension. Lymphatic filariasis is associated with similar fibrotic reactions where adult parasites reside in the lymphatic channels and lymph nodes (104); this “scarring” is believed to be partially responsible for the lymphedema, elephantiasis, hydrocele formation, and chyluria found in this condition. The mutilating facial lesions of mucocutaneous leishmaniasis occur in the setting of exuberant delayed-type hypersensitivity and aggressive granulomata formation emerging years after the primary cutaneous infection (usually caused by *L. braziliensis* species) has healed (105). This process is thought to represent attempted immune destruction of small numbers of parasites that persist within the nasal and oral tissues.

The blood stage of malaria is associated with the neuropathologic crisis of cerebral malaria that is partially dependent on T-cell-regulated cytokine responses. Cytoadherence of parasitized erythrocytes within the capillaries of the CNS causes seizures, coma, and death when they obstruct blood flow (106). Because many of the vascular receptors for parasite ligands are upregulated by circulating TNF and other cytokines, the presence of these factors in the blood may predispose to this crisis. TNF may be produced in a nonspecific fashion; schizont rupture directly induces the synthesis of monokines by nonimmune blood mononuclear cells, and serum levels of TNF are associated with the severity of cerebral disease (107). As a consequence, proinflammatory T-lymphocytic responses against malaria that normally contribute to killing of parasite (see later) also can contribute to host mortality. Similarly, $CD4^+$ T cells that produce inflammatory cytokines contribute to the pathology of *Toxoplasma* encephalitis, although they are also important for containment of the dormant parasite (108).

Immediate Hypersensitivity Responses

Many of the immediate hypersensitivity responses are modulated as helminth infections become chronic; during the early and acute phase of infections with invasive helminth parasites, such as ascaris, hookworm, schistosomes, or filariae, patients may manifest symptoms suggestive of allergic reactivity, such as wheezing or urticaria (109). Furthermore, in the clinical syndromes associated with *Loa loa* infection (with its angioedematous Calabar swellings) (110), with tropical pulmonary eosinophilia (3,111), and with larvae currens in strongyloidiasis (112), IgE-mediated reactions are believed to reflect the underlying mechanism of these signs and symptoms.

Eosinophil-associated pathology, unlike IgE-mediated hypersensitivity, is found even more frequently in response to helminth infection. Evidence has been accumulating in parasitic diseases associated with profound or extreme hypereosinophilia, as in endomyocardial fibrosis associated with loiasis in expatriates (110,113)

or in the tropical (filarial) pulmonary eosinophilia syndrome (3), that the major cause of the tissue destruction appears to be the eosinophil and its toxic molecules. In contrast, eosinophilic responses during protozoan infection are rarely observed.

HOST RESPONSES AGAINST PARASITES

Helminth Infections

Although the number of pathogenic helminth infections for humans is large and the biology of each is diverse, helminth infections frequently are accompanied by immune responses with all the features of immediate-type hypersensitivity reactions. These reactions are characterized by IgE antibody production, tissue and peripheral blood eosinophilia, and the participation of inflammatory mediator-rich basophils and mast cells. Whereas in the atopic state these immediate hypersensitivity responses have clearly been implicated in the pathogenesis of allergic diseases, in parasitic helminth infection—although these types of responses can certainly induce pathologic reactions–they also have been implicated in functioning to provide a degree of immunologic protection from the helminth parasites.

A major advance in understanding the regulation of these types of responses was in the identification of functionally distinct populations of $CD4^+$ T cells designated T-helper cells type 1 (Th1) and type 2 (Th2). Th1 cells produce IL-2 and IFN-g in response to antigen or mitogen, whereas Th2 cells produce IL-4, IL-5, IL-6, and IL-10 (114). Th1 and Th2 cells develop from uncommmitted precursor $CD4^+$ cells with less distinctive cytokine profiles. Naive $CD45RA^+$ precursor cells develop into Th0 cells with multipotent or intermediate secretory profiles and further differentiate into Th1 or Th2 cells following repeated antigenic stimulation. A generally stable relationship between Th1 and Th2 $CD4^+$ populations occurs in part through the production of cross-regulatory cytokines (e.g., IL-10 and IFN-g) that suppress function and growth of the opposite cellular subset. This achieves significance when helminth infections bias Th1/Th2 development toward a Th2 type of cytokine production that may be causally linked to the immediate hypersensitivity responses associated with these infections.

IGE RESPONSES

Although IgE antibody responses are regulated both quantitatively and qualitatively in most persons, infection with helminths perturbs these regulatory mechanisms and consistently allows high levels of IgE to be produced *in vivo* (109). Most of the IgE produced is not antigen specific, perhaps representing nonspecific potentiation or deregulation of a normally well-controlled immune response (115,116 and 117). This potentiating effect seems to be selective for the IgE (and perhaps the IgG4) isotype (118). This was demonstrated most definitively in studies in which animals previously sensitized to a nonparasite antigen (e.g, ovalbumin) subsequently were infected with a helminth parasite; they produced IgE antibodies directed not only against the parasite but also against the nonparasite antigen (116).

Elevated total serum IgE levels in parasitized patients have been documented in many studies (119,120). Characteristically, individuals with invasive helminth infections have serum IgE levels approaching 100 times normal values (109). The factors responsible for this degree of elevation are not well defined, although it most likely reflects a clonal expansion of IgE-producing B cells related to an imbalance of T cells producing either IL-4 or IFN-g (7). There seem to be, however, not only quantitative differences but also qualitative ones. In contrast to atopic individuals whose IgE tends to be directed toward only a few antigens, patients with invasive helminth infection produce IgE antibodies with specificity against an incredibly broad range of parasite antigens (121). It has been proposed that such potentiated polyclonal responses lead to the production of irrelevant IgE that saturates the mast cells' high-affinity FceR, rendering it refractory to triggering by parasite antigen.

EOSINOPHIL RESPONSES

Blood and tissue eosinophilia are also characteristic responses in helminth infection and probably are mediated by increased production of IL-5, possibly in synergy with IL-3 and granulocyte macrophage colony-stimulating factor (GM-CSF). Eosinophil-associated pathology can be found in helminth infections and may be caused by eosinophil cationic proteins that are toxic to various normal tissues and cells both *in vitro* and *in vivo* (122,123). Release of proinflammatory eicosanoids, most notably LTC4 and PAF-acether (124), has been implicated in the localized pathology found in tissues with invading helminth infections. Evidence has been accumulating in helminth infections associated with hypereosinophilia, such as onchocerciasis, endomyocardial fibrosis associated with loiasis in expatriates (110,125), or in the tropical (filarial) pulmonary eosinophilia syndrome (111), that the major source for the tissue destruction appears to be the eosinophil and its toxic molecules. Nevertheless, these same molecules can clearly mediate larval killing of many helminths. Chemokines, including MIP-1a, eotaxin-1, eotaxin-2, and regulated on activation normal T cell expressed and secreted (RANTES) (among others) all have been implicated in providing the signals necessary to recruit eosinophils specifically to the sites where helminths or helminth antigens are present (reviewed in 126).

MAST CELL AND BASOPHIL RESPONSES

Mast cells also can contribute to inflammatory reactions directed against invasive helminth parasites. These cells express high-affinity Fce receptors that are sensitized with specific antiparasite IgE and that can be triggered by parasite antigen. Thus, the presence of the mast cell may represent an evolutionary adaptation to infection with parasitic helminths in that they confer a biological advantage to the human host (127,128,129 and 130). Indeed, it has been postulated that mediators specifically released by sensitized mast cells contribute to (a) the recruitment and activation of effector eosinophils; (b) increased local concentrations of antibody and complement; and (c) mucus hypersecretion and increased peristalsis in the gastrointestinal tract that could interfere with the attachment process of certain parasites that would be necessary for chronic infection (reviewed in 128). Despite such apparent benefit, these same effector molecules may also mediate gastrointestinal pathology associated with intestinal parasites.

Basophils are a major source of the T-cell polarizing cytokines IL-4 and IL-13 and produce it in response to either FcÎR crosslinking or to antigen itself (131,132,133 and 134). This suggests that circulating helminth antigens or those helminth parasites that are bloodborne, by inducing basophil-derived IL-4/IL-13, can provide a constant source of those cytokines influencing T-cell subset development and B-cell isotype switching. This may explain how IgE and type 2 T-cell elevations are maintained chronically in helminth infections.

HYPERGAMMAGLOBULINEMIA AND POLYCLONAL ACTIVATION

Hypergammaglobulinemia with elevated levels of parasite-specific antibodies of most (if not all) isotypes has been recognized in many helminth infections, particularly in filarial infections (104). Indeed, in a study of patients with tropical (filarial) pulmonary eosinophilia (111) and one on individuals acquiring loiasis (110), hypergammaglobulinemia was a common finding. Although presumably reflecting a polyclonal expansion of B cells, the mechanism for this polyclonal activation is not well defined. Work examining the interaction between parasite antigen and B-cell responses *in vitro* indicated that polyclonal immunoglobulin responses occur as a result of this interaction almost without exception (135); further, this polyclonal activation occurs among a broad range of helminth parasite infections. In addition, several investigators have isolated antigens from various helminths that appear to have mitogenic activity. These mitogenic factors, however, seem to act indirectly on B cells in that their primary effect is directed at the T-cell arm, which then mediates helper function (136).

SUSCEPTIBILITY TO HELMINTH INFECTION

Because of their tissue-invasive properties, direct chemical and physical damage to the host tissue can initiate inflammatory responses that are not dependent on specific immune interactions. The components mediating this inflammatory response include complement components, a variety of soluble mediators, granulocytes, and T-lymphocytes; the end result is an alteration in the local environment acting to limit the movement and differentiation of the parasite. These inflammatory reactions can clearly encapsulate the worms; but, in many cases, the parasites escape from these inflammatory reactions.

Rapid progress has been made, largely by the use of inbred strains of mice, in defining the genetic basis of susceptibility to protozoal infection, but relatively less work has been done in infections with helminth parasites. Nevertheless, interest in this particular area has been growing because epidemiologic studies in areas where these helminth parasitic diseases are endemic have revealed differential susceptibilities to infection both within the entire population and within families studied (137). Thus, genetic predisposition to innate resistance to parasitic helminth infection must be assumed.

Although the cause of differential susceptibility to clinical expression of helminth infections has been addressed in only a few human studies, the data have implicated, in part, the MHC (138,139). Several large-scale studies attempted to make more compelling the argument of an underlying genetic susceptibility for disease outcome in both filarial and schistosome infection (140,141,142,143,144,145 and 146). For schistosomiasis at least, a genetic locus for susceptibility and resistance has been physically mapped (145).

PROTECTIVE IMMUNITY AGAINST HELMINTHS

Although acquired immunity is difficult to demonstrate definitively in many helminth infections, three important lines of evidence for the presence of acquired, immunologically mediated resistance exist. First, on epidemiologic grounds, there is evidence in schistosomiasis (147,148 and 149) and in each of the filarial infections (150,151) that resistance occurs and that it is acquired with increasing age. Whereas some age-related changes in parasite-specific antibody levels or isotypes have

been reported (82,152,153), the mechanism underlying this age-related acquisition of immunity is not well understood. Second, concomitant immunity, a concept suggesting that despite chronic (and patent) infections, hosts are protected from reinfection by newly invading larvae, also has supporting evidence. Originally described in experimental infections with schistosomes (5,154), other nematodes (155), and *Taenia* organisms (156) in animal models, there is reasonably compelling evidence for its existence in human helminth infection. Finally, genetic predisposition to mounting a specific and effective immune response must be considered and certainly has been demonstrated in several human helminth infections, including intestinal helminths (157,158 and 159) and schistosomes (84,142).

Cytokines and Protective Immune Responses

The characteristic features of helminth infection (eosinophilia, elevated serum IgE, and mastocytosis) are controlled primarily by the type 2 cytokines IL-4, IL-13, and IL-5. In animal models of intestinal helminth infection, $CD4^+$ (but not $CD8^+$) cells are necessary for worm expulsion (160,161), and this expulsion is associated with a dominant Th2-type cytokine response (162,163, reviewed in 164). Abrogation of the type 2 response by administration of soluble IL-4 receptor, anti-IL-4 antibodies, recombinant IFN-g, or IL-12 leads to delayed worm expulsion and a delayed IgE response to infection in these models (165,166,167 and 168). The effect of IL-12 on protective immunity is dependent on IFN-g production and is markedly diminished if treatment is initiated 6 to 8 days after primary infection or, in secondary infection, once a type 2 cytokine response has already been established (167). These data suggest that it is the skewing of the immune response away from a type 2 response rather than a direct effect of IFN-g that is responsible for the decrease in protection in this model.

Although $CD4^+$ cells also play an important role in immunity to tissue-invasive helminth infection, the precise roles of $CD4^+$ helper subsets are not as clear in immunity to these helminths (e.g., filaria, schistosomes, *Strongyloides* species) and may depend on the particular cytokine, life-cycle stage, parasite species, and host studied. Increased adult worm (but not egg) antigen-induced production of IL-5 and IL-4 by $CD4^+$ cells has been correlated with resistance to reinfection in human schistosomiasis (169,170). Multiply vaccinated mice also develop a Th2-type response that can be passively transferred by immune serum (171). In contrast, singly vaccinated immune mice and mice with prepatent infection develop an immune response characterized by Th1-type responses directed primarily at the infective stage (schistosomula), and interference with this response (i.e., by administration of antibodies to IFN-g) has been shown to abolish protective immunity to challenge infection (172,173). Studies examining antigen-induced cytokine production by lymphocytes isolated from strains of mice resistant or susceptible to *Trichinella* infection also demonstrated skewing toward Th1 cytokine production in resistant mice (174).

In murine models of protective immunity to filarial infection, spleen cells from mice immunized with radiation-attenuated *Brugia* L3 larvae proliferate and secrete high levels of IL-4 and IL-5 (but little IFN-g) in response to parasite antigens (175). Both immunity and parasite-induced Th2 cytokine secretion are reduced in mice treated with anti-CD4 antibody (176). A similar correlation between parasite burden and Th2 cytokine production by $CD4^+$ cells was demonstrated in mice infected with *Litomosoides sigmodontis*, a filarial parasite of rodents (177). Long-term residents of filaria-endemic areas without clinical or laboratory evidence of filarial infection (putatively immune) also exhibit heightened lymphocyte proliferation to parasite antigens (69), although the correlation between immune status and parasite-specific Th2 cytokine production remains somewhat controversial (178,179).

Despite these complexities, it appears that Th2-type responses play a significant role in immunity to both intestinal and tissue-invasive helminths, but the data are more compelling for the intestinal helminths.

Antibodies and Protective Responses

Antibodies appear to play a minor role in mediating protection to helminth infection. Indeed, in both B-cell-deficient animals or those with FcR deletions, infections proceed without differences from their immunologically competent wild-type control animals (126,180). Nevertheless, the IgE isotype bears particular mention because IgE has been implicated in mediating some protection in both human and animal studies. In schistosomiasis, studies of *S. haematobium* in Gambia showed that persons with high serum levels of parasite-specific IgE after antischistosomal chemotherapy were less likely to become reinfected or have lighter reinfections compared with those with lower IgE levels (82). Additionally, it was observed that there was an associated increase in serum levels of parasitic-specific IgE with increasing age, which was closely correlated with development of acquired resistance. Similar studies of *S. mansoni* in Brazil pointed to the same conclusion of an association between elevated levels of anti-schistosomal IgE and acquired immunity (181). In support of these findings in humans are animal studies suggesting a protective role for IgE in rats (182) infected with filarial parasites (182), *T. spiralis* (183), or *S. mansoni* (184), filarial-infected cats (185), or baboons infected with *S. mansoni* (186). In contrast, however, are findings in human trichuriasis in which gastrointestinal pathology was associated with the presence of degranulated surface IgE^+ mast cells capable of releasing histamine in the presence of parasite antigen (187). In addition, mice incapable of making IgE (by anti-IL-4 monoclonal antibody therapy) can clearly be vaccinated to *S. mansoni*, suggesting that IgE alone is not mediating protection to schistosome infection (188).

Eosinophils and Protective Immunity

The role of the eosinophil in mediating protection to helminth infection is also under scrutiny. In studies of resistance to reinfection with *S. mansoni* and *S. hematobium*, eosinophilia has been correlated with resistance to reinfection (189,190). There has been conflicting evidence (188,191) on the protective efficacy of eosinophils in animals depleted of eosinophils and subsequently challenged with *S. mansoni* or the enteral parasite *Heligmosomoides polygyrus* (192); in *T. spiralis* (183) and *S. venezuelensis* (193), however, eosinophils were capable of mediating resistance to migrating larvae. Overall, the discrepancy seen in the study of the role of eosinophils in protective immunity in these different animal models of parasite infections may result either from a redundancy of effector immune responses or from the basic differences in animal models and mouse strains.

Epidemiologic studies in humans and animal models demonstrated correlations between eosinophilia and resistance to helminth infection (189,194). Eosinophils (or purified eosinophil granule proteins) are able to kill many different species of tissue invasive helminth larvae *in vitro* in the presence of antibodies and complement (195,196,197,198 and 199). The mechanism of eosinophil-mediated larval killing is incompletely understood but may involve eosinophil peroxidase-mediated formation of active oxygen species, as has been reported in eosinophils from granulomas isolated from the livers of mice infected with *S. mansoni* (200), complement, and antibodies (201).

Results of *in vivo* studies are conflicting with respect to the role of eosinophils in resistance to helminth infection. Mice depleted of peripheral eosinophils using antieosinophil antibodies show increased susceptibility to infection with a variety of helminths (202,203), whereas mice treated with anti-IL-5 antibodies have no decrease in immunity to these same helminths despite a lack of blood or tissue eosinophilia (204,205 and 206). Furthermore, IL-5 transgenic mice, which have increased levels of eosinophilia, are more (rather than less) susceptible to schistosomiasis and show delayed clearance of primary *Trichinella* infection compared with normal mice (207,208).

The most conclusive *in vivo* evidence for the role of eosinophils in helminth killing comes from experiments with diffusion chambers containing infective helminth larvae implanted in the subcutaneous tissue of mice. Not only were eosinophils the only cells that accumulated in the chamber concomitant with larval killing (209), but such killing could be prevented by inhibition of eosinophil migration into the chamber or treatment of the mice with anti-IL-5 antibody (209,210 and 211).

Mast Cells and Protective Immunity

Although the accumulation of mast cells in parasitized tissues has been used as an argument in favor of a role for mast cells in protective immunity, it is not at all certain that these cells serve a protective function in parasite infection. Nevertheless, animal models of immunity to challenge infection provided some experimental evidence for a salutary role of the mast cell. These types of secondary challenge studies provided evidence that mast cells are responsible for the prevention of reinfection (212) in gastrointestinal parasites and for the cytotoxicity against early schistosomula in the epidermis of previously vaccinated primates (213). Further, depletion of mast cells has been shown to abrogate the cytotoxic responses against schistosomula (214). *In vitro*, mast cells, in concert with peroxidase and iodide, also have been shown to be capable of mediating cytotoxicity to schistosomula (215).

Expulsion of intestinal parasites is temporally associated with an increase in the number of mast cells in the intestine and secretion of mast cell proteases and leukotrienes into the tissues and serum (216,217,218 and 219). This mastocytosis is dependent on both T-cell-derived cytokines (IL-3, IL-4, IL-9, and IL-10) (220,221) and T-cell-independent factors [stem cell factor (SCF)] (222). The mechanism by which mast cells are activated by helminth parasites remains unclear, but the high-affinity IgE receptor does not appear to be essential to the process (220,221).

Despite the strong association between mastocytosis and intestinal helminth infection, mast cell-deficient mice (W/Wv mice genetically deficient in the SCF ligand, *c-kit*, or mice treated with antibodies to *c-kit* or SCF itself) exhibit variable responses depending on the infecting species. Administration of monoclonal antibodies to SCF completely abrogates the intestinal mastocytosis (and eosinophilia) seen in murine *Trichinella* infection and results in delayed expulsion of adult parasites (223). In contrast, *Nippostrongylus* adult worms are expelled at a similar rate by wild-type mice, mast cell-deficient W/Wv mice (224) and mice treated *in vivo* with antibodies to IL-3 and IL-4, which have an 85% reduction in the number of mast cells in the gut compared with wild-type mice (225).

The mechanisms by which mast cells might cause worm expulsion remain uncertain. Changes in intestinal muscle contractility and fluid dynamics in response to mast cell release of leukotrienes and prostaglandins have been implicated in some studies (see review by Finkelman et al., 1997 [164]), although expulsion of worms does

occur, albeit in a delayed fashion, in the absence of these alterations in gastointestinal physiology in mast cell-deficient and SCID mice treated with a long-acting preparation of IL-4 (164,226).

Protozoan Infection

Important protozoan causes of human disease include invasive organisms with distinct intracellular and extracellular forms as well as others that cause infections restricted to the gastrointestinal lumen and epithelium. The resulting character of host immunity is greatly influenced by these factors. Generally, extracellular parasites are susceptible to killing mediated by neutralizing or opsonizing antibody, whereas intracellular parasites are controlled by T-lymphocyte responses that activate microbicidal mechanisms in phagocytic and nonphagocytic cells. However, this is an oversimplification of real events. Most intracellular protozoa have brief, obligatory extracellular phases, and some intestinal parasites, such as *Entamoeba histolytica*, are also invasive at times and can cause visceral disease. Furthermore, host responses can be innately heterogeneous, working to the benefit of the parasite if some proportion of the infected population is genetically incapable of mounting protective immune responses. Notably, activation of Th2 $CD4^+$ T cells may promote B-cell and antibody responses to the detriment of protective Th1 $CD4^+$ T-cell responses that are required for control of intracellular parasites (227).

CELL BIOLOGY OF INTRACELLULAR PARASITIZATION

Organisms that invade host cells are provided with some sanctuary against complement-mediated lysis and ingestion by polymorphonuclear phagocytes. An intracellular location may fulfill metabolic and developmental requirements, such as access to hemoglobin for the nutritional use of blood-stage malaria. Whatever the adaptive advantages for intracellular parasitization, it is a common theme of protozoan infection and poses a challenge to host defense strategies distinct from that of extracellular infection. Specifically, T-cell-mediated immunity becomes increasingly important in the control of these organisms, as is clinically apparent by the increased incidence and severity of *Toxoplasma*, *Trypanosoma cruzi*, *Leishmania*, and *Babesia* in immunocompromised AIDS and transplant patients (228,229).

Intracellular parasitism requires that the invasive protozoa attach to specific target cells and cross the plasma membrane. Many parasites accomplish both these goals by binding to cellular receptors that mediate phagocytosis when engaged. *Leishmania* organisms can attach to multiple macrophage receptors via their surface gp63 and lipophosphoglycan molecules; partial activation of complement on the surface of the parasite contributes additional ligands for macrophage complement receptors (230). In other protozoan infections, cellular entry is actively mediated by the parasite without the use of normal host cell phagocytic mechanisms. For instance, *Toxoplasma* organisms enter by an unusual form of induced phagocytosis that actively excludes host membrane proteins from the parasitophorous vacuole that forms, although the identity of the cellular receptor is unclear (231). Uptake may be enhanced by coating with serum-derived fibronectin and engagement of the appropriate integrins on host cells. Both *Toxoplasma* and *Plasmodia* species possess a secretory organelle, called the *rhoptry*, that plays a key role in cellular adherence and invasion. Although mechanistic details are unclear, it is probable that amphipathic proteins and lytic enzymes released by rhoptries help to destabilize the host cell plasma membrane and favorably condition the subsequent parasitophorous vacuole (232,233).

It is surprising that tissue macrophages are the preferred target of several protozoa, including *Leishmania*, *Trypanosoma*, and *Toxoplasma*, considering the ability of these phagocytes to generate microbicidal oxygen and nitrogen products during phagocytosis of opsonized particles. Protozoa avoid these potent nonspecific responses by infecting resident tissue macrophages with diminished oxidative and nitric oxide synthetic functions and by selectively engaging receptors that mediate uptake without triggering these antimicrobial defenses (32,230). *Leishmania* species induce their uptake by engagement of CR1 and CR3 complement receptors that do not activate the oxidative burst. The entry of *Toxoplasma* and *T. cruzi* into macrophages also circumvents activation of cytocidal responses, although the exact nature of the ligands engaged is not known; however, there are limits to the extent that macrophages can be safely invaded. Prior opsonization of protozoa by specific IgG can lead to uptake by Fc receptors that efficiently trigger a microbicidal oxidative burst (32). At least one species of *Leishmania*, however, has adapted this method of cellular entry to facilitate infection by amastigotes that become coated with IgG during intracellular transfer (234); only macrophages with relatively deactivated microbial responses are permissive for intracellular parasitization. Activation of macrophages by exposure to IFN-g or TNF generated as a result of antigen-specific T-lymphocytic responses induces microbicidal functions that can control infection. Although nonmacrophage cell types such as fibroblasts and hepatocytes do not have oxidative burst capability, they can be activated by cytokines to generate nitric oxide capable of killing intracellular *Plasmodia* and *Toxoplasma* organisms (235,236). As a consequence, cell-mediated immunity is usually the critical component of the host response that leads to control of infection and subsequent immunity against reinfection.

Once internalized, parasites must be able to avoid or tolerate the acidic, proteolytic lysosomal environment if phagocytosis is used as means of entry (32). *Toxoplasma* organisms accomplish this by modification of the phagocytic vacuole to prevent acidification and lysosomal fusion (232). *T. cruzi* and *Theileria parva* pass through the phagosomal membrane and replicate within the cytoplasm of the host cell. *T. cruzi* accomplishes this exit by secreting an acid-active hemolysin (Tc-TOX) that disrupts the phagosome membrane; another secreted enzyme with neuraminidase activity may facilitate release by desialating the vacuole interior surface (237). This hemolysin is antigenically similar to human pore-forming complement protein, C9 (238). In contrast, *Leishmania* species are metabolically adapted for survival and replication within the acidic phagolysosome (239). Further protection may be provided by a dense lipophosphoglycan surface coat that can scavenge reactive oxidative products and that suppresses activation of potentially microbicidal responses (33). Products of the C3 complement protein on the surface of *Leishmania* organisms also seem to enhance survival of the parasite within the phagolysosome, although the mechanism involved is not understood (240).

Whatever the mechanism of intracellular survival, the compartmentalization of parasite antigen in the lysosome or cytoplasm may influence how antigen is processed and whether MHC I- or MHC II-restricted activation of $CD4^+$ or $CD8^+$ T-lymphocytic responses dominates cellular immunity (241). Not surprisingly, a greater role for $CD8^+$ T cells in protective immunity against cytoplasmic *T. cruzi* and *T. gondii* is evident in comparison to the obligate phagolysosomal parasite, *Leishmania*.

NONSPECIFIC HOST DEFENSES AGAINST PROTOZOAN INFECTION

Infectious threats, whether intracellular or extracellular, are countered by an orchestrated cascade of nonspecific (*innate*) and antigen-specific (*adaptive*) host defenses. In some cases, however, resistance is mediated by genetic traits of the host that uniquely prevent intracellular entry or survival of parasites. This has been well characterized in areas endemic for malaria, where the frequent appearance of abnormal hemoglobin genes, such as sickle cell trait, results in erythrocytes less able to support parasite replication (242). The loss of the Duffy antigen from the erythrocytes of Africans similarly prevents *P. vivax* infection by removal of the ligand required for red cell invasion (242). As another example, Cape buffalo are protected against infection with *T. brucei*, which causes fatal disease in all other bovine species. In contrast to other bovines, Cape buffalo are capable of markedly downregulating serum levels of catalase during systemic inflammation, an usual response that permits xanthine oxidase-derived oxidative products to accumulate in the bloodstream and kill trypanosomes (243).

Other nonspecific host defenses are part of the innate humoral immune response, which includes the alternative pathway of complement, pattern-recognition molecules, neutrophil responses, and proinflammatory cytokines (244,245,246 and 247). These are rapidly activated in the critical period of infection prior to recruitment of antigen-specific immunity. Serum carbohydrate binding proteins (collectins) and complement are central to the innate humoral immune response; however, as described earlier, pathogenic protozoa may have the ability to evade, inhibit, or subvert the activation or function of the alternative complement pathway. As a result, these parasites are poorly opsonized and are relatively resistant to phagocytosis by polymorphonuclear cells. Microbes that invade host cells further limit their exposure to extracellular complement and professional phagocytes.

In contrast, the innate cellular immune response is centrally directed by macrophages and dendritic cells during infection. Both cell types utilize a wide range of receptor molecules—such as the mannose receptor, advanced glycosylation end-product receptor, toll receptors, and integrins—that bind highly glycosylated fungal and protozoan surfaces and that subsequently mediate cellular responses. These responses include phagocytosis or endocytosis of offending particles identified as microbial by pattern-recognition receptors (246,248). Phagocytosis by macrophages is sufficient to kill most microbes, a process assisted by production of microbicidal-reactive oxygen intermediates and nitric oxide induced during phagocytosis or surface receptor ligation. Because dendritic cells and macrophages also serve as efficient antigen-presenting cells, the scavenging and ingestion of microbial glycoproteins serve an important immune surveillance function for priming antigen-specific immunity in addition to mediating an early nonimmune defense.

The same pattern-recognition molecules that activate phagocytosis also critically stimulate secretion of proinflammatory cytokines, including IL-12, TNF, IL-6, IL-1, and chemokines. These factors may incite fever, which can help limit parasite expansion during infection with *T. cruzi* and malaria (249), direct leukocyte immigration into areas of infection, or elicit production of IFN-g. Although innate cellular cytokine responses are best described in bacterial infection (247), protozoan products with intrinsic inflammatory properties (adjuvant-like effects) can also directly elicit cytokines, although the involvement of Toll receptors in the process is not yet defined. For instance, the erythrocytic phase of malaria is associated with elevated serum TNF levels triggered in response to plasmodial molecules and the by-products of massive hemolysis (107,250). TNF synthesis under these conditions probably benefits the host by activating phagocytic cells in the spleen to ingest and lyse infected blood cells; however, TNF produced in excess is detrimental to the host. At the extreme, it may help precipitate the immunopathologic crisis of cerebral malaria discussed earlier. *T. gondii* also contains glycolipids that strongly activate IL-12 production and systemic inflammation by host dendritic cells (251).

Although usually thought of as a product of mature T-cell immunity, IFN-g can be acutely and nonspecifically secreted by T lymphocytes and NK cells in response to microbial challenges (252). This cytokine response is dependent on the prior production of IL-12 and IL-18 by accessory cells and is antagonized by TGF-b or IL-10 (253). In combination with TNF, IFN-g activates nitric oxide in a wide range of infected cells, with additional stimulatory effects on the oxidative burst and phagocytic functions of phagocytic cells. In the setting of toxoplasmosis, which induces strong innate IL-12 synthesis, IFN-g responses can be rapid, T-cell independent, and

capable of sharply limiting early parasite load (254,255).

ANTIGEN-SPECIFIC IMMUNITY AGAINST PROTOZOAN INFECTION

Although innate immune responses may ameliorate the early stages of parasitic infection, cure of intracellular infection typically is associated with the onset of antigen-specific $CD4^+$ and $CD8^+$ T-lymphocytic responses (reviewed in 227). In the case of parasites that are predominately intracellular, such as *Leishmania* or *T. gondii*, cellular responses may be the only effective type of immunity available to the host, with antibodies providing little protective effect against sequestered protozoa (60). Where both extracellular and intracellular forms of parasite coexist during infection, such as during malaria, humoral and cellular responses may have comparable importance in the control of infection.

As described for antihelminthic responses, functionally distinct subsets of $CD4^+$ and $CD8^+$ T cells variously mediate cure, susceptibility, or tissue pathology in the cellular immune response to protozoa. Whether $CD4^+$ or $CD8^+$ cells predominate in response to intracellular parasitism may depend on the location of the pathogen in infected cells, with lysosomal sites more conducive to MHC II expression of parasite antigen and cytosolic sites more likely to provide antigenic peptides for loading of MHC I complexes (241). Infection of cell types such as fibroblasts and hepatocytes that express little or no MHC II may also account for the dominance of $CD8^+$ T-cell responses against *T. cruzi* and liver-stage *Plasmodia* organisms.

The Th1 and Th2 $CD4^+$ T cell subsets have important roles in the control or progression of intracellular infection (227). As described earlier, Th1 and Th2 cells are defined by mutually exclusive functional properties, notably cytokine release. They derive from precursor cells with less distinctive cytokine phenotypes. The antagonistic roles of Th1 and Th2 cells in the control of intracellular infection has been appreciated using a mouse model of leishmaniasis (60). Strains of inbred mice experimentally infected with *L. major* reproduce a spectrum of disease similar to that seen in humans infected with *L. donovani*, providing a convenient model for the examination of protective and exacerbating host responses. Resistant C57BL/6 and C3H mice heal local infection, develop delayed-type hypersensitivity to leishmania antigens, and exhibit long-lasting immunity against reinfection. BALB/c mice develop progressive infection and die of visceral dissemination that resembles human visceral leishmaniasis. Cure or progression of infection is mediated by Th1-type or Th2-type responses, respectively. The roles of IFN-g and TNF in healing were established by the exacerbating effect of anti-IFN-g and TNF monoclonal antibodies when administered during infection of resistant mice (249,256). Similarly, recombinant human IFN-g has been used clinically to treat drug-resistant visceral leishmaniasis (257). In contrast, the IL-4 product of Th2-type cells proved necessary to progressive infection: Anti-IL-4 cured normally susceptible mice (258). The IL-4-like cytokine IL-13 provides redundant inhibitory effects on leishmania immunity due to signaling through a shared IL-4/IL-13 receptor complex (259).

Cytokine effects on the outcome of infection are twofold. First, Th1 and Th2 cell products have opposing effects on macrophage activation requisite to the efficient killing of leishmania in infected tissues. IFN-g and TNFb activate nitric oxide and reactive oxygen intermediate synthesis, whereas the Th2 product IL-4 blocks these microbicidal functions (260,261). Second, IFN-g and IL-4 are required in the first week of infection to permit subsequent differentiation and amplification of Th1 and Th2 cells, respectively (262,263). The immunologically important cellular source of these cytokines in infected tissue appears to be $CD4^+$ T cells (264). Although NK cells generate IFN-g early in infection, they are not required for the development of protective adaptive immunity (265). A similar involvement of IFN-g and IL-4 in the spectral expression of disease in humans infected with *Leishmania donovani* has been suggested, although murine models of *L. donovani* infection suggest that increased TGF-b activity is necessary and sufficient for progressive infection (266). To summarize, distinct forms of progressive leishmaniasis rely on activation of different suppressive cytokines that antagonize IFN-g-dependent immunity as a common feature.

In contrast to the dominant immunoregulatory role of $CD4^+$ T cells in leishmaniasis, other protozoan infections elicit mixed $CD4^+$ and $CD8^+$ T-cell responses active in cure and prevention of disease. This has been well established for *T. cruzi*, the cause of Chagas disease, which afflicts millions of persons living in Central and South America (228). Extracellular trypomastigote forms enter macrophages, muscle cells, and fibroblasts, where they reproduce as intracellular amastigotes. Acute parasitemia in murine and human hosts resolves in association with the appearance of antigen-specific antibody and T-cell responses. Extracellular trypomastigotes actively inhibit C3 convertase assembly, but specific antibodies may allow parasiticidal opsonophagocytosis and antibody-dependent cellular cytotoxicity. The appearance of amastigotes in the blood during some infections may allow persistence of the parasite despite effective antitrypomastigote defenses because amastigotes are resistant to killing by the C5b-C9 complement attack complex (32). A role for MHC I-restricted parasite killing was demonstrated by the appearance of fatal parasitemia in b_2-microglobulin-deficient mice that do not possess mature $CD8^+$ T cells (267). $CD8^+$ T cells also were involved in the pathogenesis of acute myocarditis; however, both $CD4^+$ and $CD8^+$ T-cell responses are required for optimal killing of the parasite (268). The protective effects of T cells is dependent on production of IFN-b to activate macrophage parasite killing (269,270).

Despite the potential effectiveness of humoral and cellular immunity in control of acute American trypanosomiasis, infection usually persists for the lifetime of the host and can result in chronic pathology. Latency of *T. cruzi* also was demonstrated by the recrudescence of disease following immunosuppression (228). The failure to clear infection totally may be linked to nonspecific immunosuppression of both B- and T-cell function that appears after several weeks of infection. This appears to be caused by activation-induced cell death of responding lymphocytes (271) and is directly linked to the production of IL-10 and TGF-b, which downregulate the synthesis and protective action of IFN-g (76,77).

Antibodies directed against *T. cruzi* also can cross-react with human proteins, reflecting the presence in both protozoa and humans of proteins with conserved sequences, such as the ribosomal P0 protein (16) and the heat shock protein HSP70 (272). Other cross-reactivities are shared by functionally nonhomologous proteins, such as the sharing of an epitope between a *T. cruzi* 160-kd protein and a mammalian neural 48-kd protein (17); however, the role of these cross-reactive immune responses in the mediation of chronic intestinal or cardiac pathology is uncertain because parasites are detectable in these same tissues well into the chronic phase and might be the important target of immune destruction (273).

Toxoplasma gondii is an obligate intracellular parasite that causes asymptomatic infection in 40% to 90% of humans in developed countries. The importance of latent infection, especially contained within dormant cysts in the brain, has been well appreciated as a result of disastrous reactivation following immunosuppression associated with organ transplantation, leukemia chemotherapy, and AIDS. *T. gondii* has a broad range of tissue preferences, with macrophages a frequent target for invasion. As discussed earlier, survival is facilitated by entry without triggering an oxidative burst or fusion of the parasitophorous vacuole with lysosomes (232). Both $CD4^+$ and $CD8^+$ T cells are involved in protective immunity (274). $CD4^+$ T-lymphocytes contribute both to the control of acute infection and to continued dormancy of encysted *T. gondii* because human immunodeficiency virus (HIV)-related $CD4^+$ T-cell depletion in humans and anti-CD4 antibody therapy in infected mice results in recrudescent brain infection (275). $CD8^+$ T cells may be equally important in the generation of native and vaccine-mediated immunity, perhaps through the cytolysis of infected cells (276,277). Regardless of the type of T cell necessary for cure, IFN-g is a central requirement for killing *T. gondii* in macrophages, endothelial cells, and fibroblasts. Recent findings suggest that the mechanisms are not strictly dependent on nitric oxide or superoxide production (278). Other IFN-g-inducible microbicidal responses have been identified that might also contribute to toxoplasma clearance (279).

HOST RESPONSES TO EXTRACELLULAR PROTOZOAN INFECTION

All invasive protozoan parasites have an extracellular stage at some time. This stage may be transient, as in the case of intracellular parasites that briefly enter the extracellular space at intervals when spreading to adjacent target cells. Usually these short forays do not result in appreciable damage to the parasite mediated by humoral immunity. In contrast, the protozoan cause of African sleeping sickness, *T. brucei*, does not have an intracellular stage and is always in contact with serum during infection. Consequently, the generation of antibody can result in clearance of parasitemia through Fc receptor-mediated phagocytosis or by activation of complement; however, as discussed earlier, *T. brucei* uses antigenic variation to escape protective humoral surveillance. Although T-helper cells are required for the generation of cytocidal antitrypanosomal antibodies, IFN-g is also critical for cure of trypanosomiasis and indicates a dual role for $CD4^+$ T cells in recovery (280).

Malaria generates a protozoan infection with a complex series of developmental stages that can be either predominately extracellular or intracellular. Sporozoites introduced into vertebrate hosts by mosquito bite circulate briefly in the bloodstream and then invade hepatocytes. After a variable incubation period of days to years, merozoite forms emerge, invade red blood cells, and engage in multiple cycles of asexual replication in the bloodstream. Symptoms of disease usually occur at this time as a result of the repeated lysis of erythrocytes and margination of parasitized cells within capillaries. Extracellular gametocyte forms develop sporadically to perpetuate the life cycle when subsequently ingested by mosquitoes. Four species of malaria—*Plasmodia falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*, cause human disease. Of these, *P. falciparum* poses the greatest clinical threat because of its worldwide distribution, the often fatal intensity of parasitemia that develops during infection, and its acquisition of chloroquine and mefloquine resistance. At least a million deaths a year are attributed to this single species of parasite.

Acquired immunity against falciparum malaria develops in the inhabitants of highly endemic regions, but such resistance is incomplete in that it takes years to develop, serves to reduce rather than prevent parasitemia, and does not persist following emigration out of endemic areas (281). The delay in acquisition of immunity likely reflects the considerable antigenic polymorphism and variation within the local population of *P. falciparum*. Sporozoite-specific antibodies have been intensively studied because of their production by malaria-immune individuals and because immunization with irradiated sporozoites is beneficial (282,283). Antibodies are directed against tandem peptide repeats in the central portion of the circumsporozoite (CS) protein. Regions of the CS protein that flank these tandem repeats contain the ligand for recognition and invasion of hepatocytes (284). Although antibodies directed against the heptaocyte ligand prevent liver-stage infection, this region is poorly immunogenic in intact sporozoites. One suggestion has been that the intensely immunogenic nature of the tandem repeats, which probably activate B cells in a T-cell-independent fashion, may misdirect the immune response away from more protective epitopes. Although antisporozoite antibodies may activate cytocidal

complement and facilitate Fc receptor-mediated killing of parasites by splenic macrophages, clinical trials of sporozoite vaccine studies have been disappointing (285).

Sporozoites also elicit $CD8^+$ cytotoxic T cells that act to limit hepatic sequestration. Mice immunized against *P. falciparum* require $CD8^+$ T cells and IFN-g for disease resistance (reviewed in 286). IFN-g activates nitric oxide synthesis in infected hepatocytes and kills intracellular plasmodia (235). Possession of the human leukocyte antigen (HLA)B53 MHC background was associated with acquired immunity against *P. falciparum* in endemic regions and permitted immune recognition of a unique peptide derived from the liver stage-specific antigen, LSA-1. This antigen is not expressed by sporozoites and directs specific cytotoxic T-lymphocyte (CTL) responses that can limit hepatic infection (287).

Both humoral and T-cell immunity against blood-stage malaria have been documented. Antibodies directed against antigens of the extracellular merozoite stage may help to limit disease, as suggested by high titers of these immunoglobulins in malaria-resistant humans living in highly endemic areas and by the protective effect of passive immunization with sera from immune donors (288). These effects may be mediated by neutralization of parasite cytoadhesion receptors (289). Several of the parasite-encoded molecules on the surface of parasitized erythrocyte are ligands for the vascular adhesion molecules CD36, thromobospondin, intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), and endothelial leukocyte adhesion molecule-1 (ELAM-1) and may assist parasite survival by preventing circulation of infected red blood cells through the spleen, where deformed or opsonized cells would be removed (21,290). Consequently, antibodies that neutralize adherence of parasitized cells to the peripheral vasculature would be expected to assist in the clearance of blood-stage infection. Multiple ligand–receptor interactions with redundant functions may have evolved in response to immune pressure, suggesting that heterogenous antibody responses are needed for protection. Much of this variability can be ascribed to the antigenically diverse family of var cytoadherence proteins (22).

T-cell immunity against blood-stage *P. falciparum* is easily demonstrated and appears to be important, but the particulars are not well defined (289). Primate and mouse models of malaria clearly demonstrate a requisite role for $CD4^+$-mediated immunity. Intraerythrocytic death of malaria, termed *crisis*, may be causally linked with release of lymphokines and monokines dependent on T-cell activation. Activation of splenic macrophages by IFN-g, a Th1 product, would be expected to help clear parasites and infected red blood cells; however, $CD4^+$ depletion as a result of AIDS has not yet caused recognizable exacerbation of falciparum malaria in endemic areas (291).

In summary, immunity against malaria represents the sum of complex, overlapping cellular and humoral responses to distinct stages of the parasite. Although specific immune protection against homologous strains of parasite can be demonstrated in defined experimental systems, cross-reactivity in the field is profoundly limited by strain heterogeneity and the ability of the parasite to vary critical antigenic targets over time. Naturally acquired immunity is consequently a state of relative disease tolerance and limited parasitemia without evidence of sterilizing immunity.

PROTOZOAN INFECTION OF THE GASTROINTESTINAL TRACT

A variety of pathogenic and nonpathogenic protozoa live within the mammalian gastrointestinal tract. *G. lamblia*, *Entamoeba histolytica*, and *Cryptosporidium parvum* are the most clinically important of these parasites. Of these, *E. histolytica* has the additional ability to invade through the mucosal surface and cause hepatic abscess. Protective immunity against luminal parasitism is restricted in choice of immune mechanisms compared with those available in tissues. There is little evidence that macrophages or polymorphonuclear cells perform a major defensive role on the gastrointestinal epithelia. Although $CD8^+$, ab^+ intraepithelial lymphocytes that can mediate cytocidal and delayed-type hypersensitivity responses are present in the human intestinal epithelium, a role for these cells in protective immunity against parasites has not been defined. T cells present in the deeper lamina propria and Peyer patches have all the characteristics of Th2 cells and support IgA production but probably are inefficient mediators of proinflammatory cellular immune responses. Indeed, the ability to secrete large quantities of dimeric IgA is the best-defined immunologic feature of the gastrointestinal mucosa that may regulate luminal parasitization and that is amenable to study (292).

The role of IgA in neutralizing intestinal protozoan infection is supported by studies of giardiasis (293). In humans, IgA deficiency and other hypogammaglobulinemias have been repeatedly associated with inability to clear intestinal giardiasis, whereas patients with cellular immunodeficiencies are not similarly predisposed. Infection with *Giardia* organisms, which are not known to cross the intestinal epithelium, nevertheless triggers production of *Giardia*-specific IgM, IgG, and IgA in the serum. This likely represents transport of antigen across the mucosal surface to Peyer patch lymphatic tissue by M cells. Oral treatment of experimentally infected mice with anti-*Giardia* IgA preparations has a protective effect. Although $CD8^+$ T-lymphocyte depletion in infected mice does not affect recovery, anti-CD4 antibodies do, but this may be due to inhibition of T-cell-dependent help required to generate IgA (294). Because IgA is not cytolytic and because IgA receptor-positive phagocytes are not a prominent feature of intestinal mucosal immunity, it seems most likely that IgA is disrupting attachment of parasite to epithelial receptors. Further research into clinical effective anti-*Giardia* vaccines may need to address possible antigenic variation in different isolates of this protozoa.

During most of its life cycle in humans, *Cryptosporidium parva* is covered with a thin layer of epithelial cell membrane where it attaches to the gut wall, although actual invasion of the cytoplasm does not occur (295). Replication requires exit into the lumen of the gut as oocysts and as free-dwelling sporozoites that attach to the gut wall. A major role for cellular immunity has been suggested by the increased severity and chronicity of this illness in patients with AIDS (296). A mouse model confirmed that $CD4^+$ T cells and IFN-g are required for protection (297). The importance of gut IgA is less certain, although anecdotal evidence suggests some benefit from specific IgA contained in colostrum.

The enteroinvasive parasites *Entamoeba histolytica* cause a spectrum of disease ranging from asymptomatic colonization to erosive colitis to hepatic abscess (48). Both attachment and lytic factors are central to the pathogenicity of *E. histolytica*. Antibodies that prevent engagement of colonic mucosal cells by the parasite's 260-kd galactose-specific lectin are thought to mediate some degree of protection against intestinal infection (298,299); however, strong amebicidal cell-mediated immunity has been correlated with recovery from colitis and amebic abscess (300). Antigen-specific T-cell responses produce IFN-g, which promotes killing of ameba by activated macrophages *in vitro* (301). *In vivo* studies have been compromised by an inability to recreate the full range of human pathology in experimental animals, although T cell–dependent and nitric oxide–dependent protection against hepatic abscess formation in rodents has been described (302,303).

VACCINE DEVELOPMENT AGAINST PARASITES

Despite the considerable progress achieved in understanding the molecular biology of parasitic infection and the nature of antiparasitic immunity, few clearly effective vaccines have been fielded for prophylaxis against the major parasite threats of the world; however, there is a more comprehensive appreciation of the components of protective or deleterious immune responses necessary for the pursuit of this goal. Specifically, the way in which immunodominant antigens are presented during immunization may critically affect the type of immune response that results. Indeed, single antigen epitopes may elicit either protective or exacerbating immunity against *Leishmania* in different hosts (304). To summarize, the development of effective parasitic vaccines will require the use of (a) carrier molecules or adjuvants (305) that will overcome the innate heterogeneity of immune responses in human populations and specifically induce protective immunity against parasitic infection; (b) cross-reactive, nonpolymorphic antigens where strain heterogeneity is a problem; and (c) multicomponent vaccines to target each of several parasite forms when disease is caused by more than one stage of a parasite life cycle. Efforts to develop an effective malaria vaccine have been particularly intense, and the following discussion focuses on these efforts as a generic model for vaccine design against other protozoan or helminth pathogens (reviewed in 180).

Because many parasites are not easily cultured for large-scale production of immunogenic antigen and because the generation of stable, attenuated parasite strains safe for human use does not seem to be imminent, recombinant proteins will continue to be a key component of parasite vaccine design; however, special delivery systems may be required to minimize the expense of production and to increase tolerance to heat and humidity prevalent in parts of the world where parasitic illnesses are most damaging. Furthermore, recombinant antigens may be highly dependent on the use of adjuvants to generate clinically significant immune responses, as demonstrated during human efficacy studies of a recombinant *P. falciparum* sporozoite vaccine (306). In this regard, the advent of recombinant viral vaccines, either attenuated poxvirus (307) or the comparatively safer fowlpox virus (308), may allow for mass vaccinations without requiring extensive purification of antigen beforehand. Self-limited viral infection promotes specific immunity because it generates antigen at the site of vaccination and because it triggers local inflammatory responses that can substitute for adjuvants in enhancing T-cell and antibody production. Furthermore, because proteins encoded by the virus are produced in cytoplasm and targeted for MHC I coexpression, recombinant viral vaccines are of special interest for those diseases where $CD8^+$ T-cell immunity is protective.

Another approach may be to use recombinant bacille Calmette-Guérin (BCG) (309). Considerable effort has suggested the feasibility of this approach, although clinical information is not yet available on human efficacy and safety. Because BCG may provide a strong adjuvant effect, particularly in support of proinflammatory $CD4^+$ and $CD8^+$ T-cell responses, the development of this vaccine system may overcome the predisposition of some recipients to develop Th2-type immune responses. The use of BCG combined with *Leishmania* antigens as immunotherapy for nonhealing cutaneous leishmaniasis supports the feasibility of this approach (310). A similar technique applied in animal models has been the use of nonpathogenic *Salmonella*-expressing parasite antigen (311). These, too, may generate antigens for stimulation of both $CD4^+$ and $CD8^+$ T-cell immunity, although humoral responses are often poor.

Regardless of the delivery system used, monocomponent vaccines are unlikely to be of use in the setting of multistage parasitic disease and in the face of antigenic heterogeneity. This has been a major obstacle for antimalarial vaccine design, and current efforts are focused on the inclusion of nonpolymorphic sporozoite, merozoite, and gametocyte-stage antigens to limit infection at several sites as well as to provide “altruistic immunity” in the form of transmission-blocking antibody responses (312). Multimeric peptide complexes using a variety of conserved sequences have been explored for their ability to stimulate antiparasitic immunity. B-cell and T-cell epitopes are chemically combined to maximize cognate interactions required for strong humoral and cellular immunity (313); however, despite early reports

of success, a *P. falciparum* synthetic vaccine (SPf66) that uses a “cocktail” of blood-stage antigenic peptides (314) was ineffective where local parasite strains were not antigenically related to the peptides used in SPf66 (315).

Ultimately, many of these objectives might be best met through use of DNA vaccines, which can incorporate multiple antigen genes under the control of strong viral promoters and which have demonstrated long-lasting protection in animal models (316). Expression of plasmid-encoded antigen within the host cell assures strong $CD8^+$ T-cell responses necessary for prevention of intracellular infection, although strong $CD4^+$ T-cell and humoral responses are also observed. The ability to combine different plasmids in a single vaccine is especially well suited for malaria prevention, where a mix of stage specificities is important (317). Furthermore, DNA vaccines provide self-adjuvant properties through the presence of CpG motifs that induce accessory cell function and immunoregulatory cytokine synthesis (318,319). Phase I studies of influenza- and malaria-specific DNA vaccines in humans have already commenced (320,321), potentially inaugurating a new class of vaccines that can be adapted for protection against the wide range of parasitic infections that bedevil humankind.
