Gingivostomatitis is characteristic of HSV type 1. **Herpangina** is an enteroviral infection with sudden onset of high fever, vomiting, headache, malaise, myalgia, poor intake, drooling, sore throat, and dysphagia. The oral lesions of herpangina may be nonspecific, but classically there are one or more small, tender, papular, or pinpoint vesicular lesions on an erythematous base scattered over the soft palate, uvula, and tongue. These vesicles enlarge from 1 to 4 mm over 3-4 days, rupture, and produce small, punched-out ulcers that persist for several days. Similar lesions may have been seen in hand, foot, and mouth disease caused by coxsackieviruses.

Laboratory Evaluation

The principal challenge is to distinguish pharyngitis caused by group A streptococcus from pharyngitis caused by viral organisms. A rapid streptococcal antigen test, a throat culture, or both should be performed to improve diagnostic precision and to identify children most likely to benefit from antibiotic therapy. Antigen-based rapid diagnostic tests for streptococcal pharyngitis have excellent specificity of 95-99%. However, the sensitivity of these rapid tests varies, and negative rapid tests should be confirmed by a throat culture. Throat culture or polymerase chain reaction (PCR) are the definitive diagnostic tests to establish the presence of streptococcal pharyngitis. However, as many as 20% of positive cultures in children during winter months represent chronic **streptococcal carriage** and not acute pharyngitis.

The predictive values of white blood cell count, erythrocyte sedimentation rate, and C-reactive protein are not sufficient to distinguish streptococcal from nonstreptococcal pharyngitis, and these tests are not routinely recommended. The white blood cell count in patients with infectious mononucleosis usually shows a predominance of atypical lymphocytes.

Differential Diagnosis

Decision-Making Algorithm

Lymphadenopathy

The differential diagnosis of infectious pharyngitis includes other local infections of the oral cavity, retropharyngeal abscesses (*S. aureus*, streptococci, anaerobes), diphtheria (if unimmunized), peritonsillar abscesses (streptococci, anaerobes, or, rarely, *S. aureus*), and epiglottitis. In addition, neutropenic mucositis (leukemia, aplastic anemia), thrush (candidiasis secondary to T-cell immune deficiency), autoimmune ulceration (systemic lupus erythematosus, Behçet disease), and Kawasaki disease may cause pharyngitis. Pharyngitis can be a feature of the acute retrovirus syndrome associated with primary HIV infection (see [Chapter 125](#)).

Vincent angina or **trench mouth** refers to a virulent form of anaerobic gingivitis and pharyngitis; gray pseudomembranes are found on the tonsils. **Lemierre syndrome** is acute pharyngitis complicated by thrombosis of the internal jugular vein and septic pulmonary emboli. It primarily occurs in adolescents and is caused by *Fusobacterium necrophorum*. **Ludwig angina** is a mixed anaerobic bacterial cellulitis of the submandibular and sublingual regions. It is typically due to spreading from an abscess of the second or third mandibular molar. It also has been associated with tongue piercing. A propensity for rapid spread, glottic and lingual swelling, and consequent airway obstruction makes prompt intervention imperative.

A syndrome of **periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis (PFAPA)** is a rare cause of recurrent fever in children. The fevers begin at a young age (usually <5 years). Episodes last approximately 5 days, with a mean of 28 days between episodes. Episodes are shorter with oral prednisone and do not respond to nonsteroidal antiinflammatory drugs or antibiotics. Long-term sequelae do not develop.

Treatment

Even if untreated, most episodes of streptococcal pharyngitis resolve uneventfully over a few days. Early antimicrobial therapy accelerates clinical recovery by 24-48 hours. The major benefit of antimicrobial therapy is the prevention of acute rheumatic fever (see [Chapter 146](#)). Because the latent

(incubation) period of **acute rheumatic fever** is relatively long (1-3 weeks), treatment instituted within 9 days of illness onset is virtually 100% successful in preventing rheumatic fever. Treatment begun after this period, although less than 100% successful, has some preventive value. Therefore antibiotic therapy should be started promptly in children with a positive rapid test or throat culture (or PCR) for group A streptococcus or a diagnosis of scarlet fever. In addition, a child who has symptomatic pharyngitis and a history of rheumatic fever, or a recent family history of rheumatic fever, or whose sibling has documented streptococcal infection should be treated.

A variety of antimicrobial agents can be used to treat streptococcal pharyngitis (Table 103.2). Penicillin or amoxicillin remain first-line therapy. Ten days of treatment is recommended to prevent rheumatic fever. Intramuscular penicillin G can be used for children who cannot tolerate oral therapy. Cephalosporins have superior pharyngeal bacterial eradication rates compared to penicillin; however, they are only recommended as an alternative option. Five days of azithromycin is also an alternate treatment option for group A streptococcal pharyngitis, although rates of resistance to azithromycin are higher than those to penicillins. Test of cure for patients who respond clinically to treatment is not required. Children with recurrent episodes of group A streptococcal pharyngitis pose a particular problem. True treatment failure is rare. Recurrent infection may represent nonadherence, chronic streptococcal carriage in the setting of a viral pharyngitis, or reinfection. A second course of treatment can be administered. Amoxicillin-clavulanate or clindamycin can be effective for eliminating streptococcal carriage.

TABLE 103.2

Antimicrobial Treatment of Group A Streptococcal Pharyngitis

Oral penicillin V (2-3 times daily for 10 days) 250-500 mg/dose
Intramuscular benzathine penicillin G (single dose)—For children ≤ 27 kg: 600,000 U; For larger children and adults: 1.2 million U
<i>For persons allergic to penicillin</i>
Cephalexin 25 mg/kg/dose BID, maximum dose 500 mg/dose \times 10 days
Clindamycin 7 mg/kg/dose TID, maximum dose 300 mg/dose \times 10 days
<i>For persons allergic to β-lactams</i>
Azithromycin, children: 12 mg/kg (maximum: 500 mg/dose) on day 1 followed by 6 mg/kg/dose (maximum: 250 mg/dose) OD on days 2 through 5

BID, Twice daily; *OD*, once daily; *TID*, three times daily.

Specific antiviral therapy is unavailable for most cases of viral pharyngitis. Patients with primary herpetic gingivostomatitis benefit from early treatment with oral acyclovir.

Complications and Prognosis

Pharyngitis caused by streptococci or respiratory viruses usually resolves completely. The complications of group A streptococcal pharyngitis include local suppurative complications, such as parapharyngeal abscess and other infections of the deep fascial spaces of the neck, and nonsuppurative complications, such as acute rheumatic fever and acute postinfectious glomerulonephritis. Viral upper respiratory tract infections, including infections caused by influenza A, adenoviruses, parainfluenza type 3, and rhinoviruses, may predispose the patient to bacterial middle ear infections.

Prevention

Antimicrobial prophylaxis with daily oral penicillin V prevents recurrent streptococcal infections and is recommended to prevent recurrences of rheumatic fever in at-risk patients.

CHAPTER 104

Sinusitis

Etiology

Sinusitis is a suppurative infection of the paranasal sinuses and most commonly occurs as a complication of an upper respiratory tract infection (URI). Only the maxillary and ethmoid sinuses are present at birth, whereas the sphenoid sinuses are present by 5 years of age. Frontal sinuses begin to develop at 7 years of age and are not completely developed until adolescence. The ostia draining the sinuses are narrow (1-3 mm) and drain into the middle meatus in the **ostiomeatal complex**. The mucociliary system maintains the sinuses as normally sterile. Indwelling nasogastric and nasotracheal tubes predispose to nosocomial

sinusitis.

Obstruction to mucociliary flow, such as mucosal edema resulting from a URI, impedes sinus drainage and predisposes to bacterial proliferation. The bacterial causes of most cases of acute sinusitis are *Streptococcus pneumoniae*, nontypable *Haemophilus influenzae*, and *Moraxella catarrhalis*. *Staphylococcus aureus* and anaerobes emerge as important pathogens in subacute and chronic sinusitis.

Epidemiology

The true incidence of sinusitis is unknown. In addition to predisposing URI, other risk factors include allergic rhinitis, cystic fibrosis, immunodeficiency, human immunodeficiency virus (HIV) infection, nasogastric or nasotracheal intubation, primary ciliary dyskinesia, nasal polyps, and nasal foreign body.

Clinical Manifestations

Decision-Making Algorithms

Rhinorrhea

Cough

Vomiting

Headaches

The most common presentation of acute bacterial sinusitis is persistent rhinorrhea, nasal congestion, and cough, especially at night. Symptoms should be persistent and not improving for >10 days to distinguish sinusitis from a URI. Less common symptoms include a nasal quality to the voice, halitosis, headache, and facial swelling and tenderness. Alternate presentations of acute bacterial sinusitis include high fever and purulent nasal discharge for at least 3 days or a biphasic illness where a patient has typical URI symptoms for up to a week but then worsens with increasing respiratory symptoms and new or recurrent fever.

Chronic sinusitis includes upper respiratory symptoms for >30 days, often accompanied by sore throat and/or headache. Fever is rare.

Laboratory and Imaging Studies

Culture of the nasal mucosa is not useful. Sinus aspirate culture is the most accurate method of determining etiology but is not practical or necessary in immunocompetent patients.

Routine imaging is not recommended in uncomplicated infections. Plain x-ray, computed tomography (CT), and magnetic resonance imaging (MRI) may reveal sinus clouding, mucosal thickening, or air-fluid levels in the sinuses. However, abnormal radiographic findings do not differentiate infection from allergic disease and often show abnormalities in the sinuses of children with a simple viral URI. Conversely, normal imaging can have a high negative predictive value for bacterial sinusitis. Bony erosion may be seen on imaging studies in immunocompromised hosts.

Treatment

Amoxicillin for 10-14 days can be used as first-line therapy of uncomplicated sinusitis in children. Broadening therapy to amoxicillin-clavulanate is appropriate if there is no clinical response to amoxicillin within 2-3 days, if risk factors for resistant organisms are present (antibiotic treatment in the preceding 1-3 months, day care attendance, age <2 years), if there is chronic sinusitis, or if any amount of eye swelling is present.

Complications and Prognosis

Complications of bacterial sinusitis include orbital cellulitis, epidural or subdural empyema, brain abscess, dural sinus thrombosis, osteomyelitis of the frontal sinus (**Pott puffy tumor**), and meningitis. These all should be managed with sinus drainage and broad-spectrum parenteral antibiotics. Sinusitis also may exacerbate bronchoconstriction in patients with asthma.

Orbital (postseptal) cellulitis is a serious complication of sinusitis that follows bacterial spread into the orbit through the wall of the infected sinus. It typically begins as ethmoid sinusitis and spreads through the **lamina papyracea**, a thin, bony plate that separates the medial orbit and the ethmoid sinus. Orbital involvement can lead to subperiosteal abscess, cavernous sinus thrombosis, and vision loss. Clinical manifestations of orbital cellulitis include a swollen edematous eye, eye pain, proptosis, chemosis, and limitations in extraocular muscle motion, diplopia, and reduced visual acuity. Infection of the orbit must be

differentiated from that of the preseptal (anterior to the palpebral fascia) or periorbital space. **Preseptal (periorbital) cellulitis** is most common in young children; these patients do not have proptosis or ophthalmoplegia. Preseptal cellulitis may be associated with a skin lesion or trauma and usually is caused by *S. aureus* or group A streptococcus.

The diagnosis of orbital cellulitis is confirmed by a CT scan of the orbit, which helps determine the extent of orbital infection and the need for surgical drainage. Therapy for orbital cellulitis involves broad-spectrum parenteral antibiotics, such as vancomycin and ceftriaxone.

Prevention

The best means of prevention are good handwashing to minimize acquisition of URIs and management of allergic rhinitis.

CHAPTER 105

Otitis Media

Etiology

Otitis media (OM) is a suppurative infection of the middle ear cavity. Bacteria gain access to the middle ear when the normal patency of the eustachian tube is blocked by upper airway infection or hypertrophied adenoids. Air trapped in the middle ear is resorbed, creating negative pressure in this cavity and facilitating reflux of nasopharyngeal bacteria.

Bacteria are the most common pathogens in OM, most frequently as a co-infection with viruses. Viruses can be the sole pathogen in OM, but this is less common (<20%). The common bacterial pathogens are *Streptococcus pneumoniae*, nontypable *Haemophilus influenzae*, *Moraxella catarrhalis*, and, less frequently, group A streptococcus. *S. pneumoniae* that is **relatively resistant** to penicillin (minimal inhibitory concentration 2-8 µg/mL) or **highly resistant** to penicillin (minimal inhibitory concentration ≥8 µg/mL) is isolated with increasing frequency from young children, particularly those who attend day care or have recently received antibiotics.

Epidemiology

Diseases of the middle ear account for approximately one third of office visits to pediatricians. The peak incidence of acute otitis media (AOM) is between 6 and 15 months of life. By the second birthday, 90% of children will have experienced at least one episode of symptomatic or asymptomatic OM. OM is more common in younger children, children exposed to young children, and those with a positive family history. In most of the United States, OM is a seasonal disease with a distinct peak in late winter/early spring, which corresponds to the rhinovirus, respiratory syncytial virus, and influenza seasons.

Approximately 10% of children in the general population have **recurrent OM**, as defined by the presence of three or more AOM episodes in the preceding 6 months or four or more episodes in the preceding 12 months, with at least one episode in the past 6 months, and would be considered **otitis prone**. Craniofacial anomalies (cleft palate) and immunodeficiencies often are associated with recurrent OM, although most children with recurrent AOM are otherwise healthy.

Clinical Manifestations

Decision-Making Algorithms

- Ear Pain
- Strabismus
- Abnormal Eye Movements
- Diarrhea
- Hearing Loss
- Fever without a Source

In infants, the most frequent symptoms of AOM are nonspecific and include fever, irritability, and poor feeding. In older children and adolescents, AOM usually is associated with fever and **otalgia** (acute ear pain). AOM also may present with **otorrhea** (ear drainage) after spontaneous rupture of the tympanic membrane. Signs of a common cold, which predisposes to AOM, are often present (see [Chapter 102](#)). A bulging tympanic membrane, air fluid level, or

visualization of purulent material by otoscopy are reliable signs of infection (Table 105.1).

TABLE 105.1

Definition of Acute Otitis Media

<p>A diagnosis of acute otitis media (AOM) requires:</p> <p>History of acute onset of signs and symptoms</p> <p>Presence of middle ear effusion</p> <p>Signs and symptoms of middle ear inflammation</p> <p>The definition of AOM includes all of the following:</p> <p>Recent, usually abrupt, onset of signs and symptoms of middle ear inflammation and middle ear effusion</p> <p>The presence of middle ear effusion that is indicated by any of the following:</p> <p>Bulging of the tympanic membrane</p> <p>Limited or absent mobility of the tympanic membrane</p> <p>Air-fluid level behind the tympanic membrane</p> <p>Otorrhea</p> <p>Signs or symptoms of middle ear inflammation as indicated by either:</p> <p>Distinct erythema of the tympanic membrane</p> <p>Distinct otalgia (discomfort clearly referable to the ear that results in interference with or precludes normal activity or sleep)</p>

Examination of the ears is essential for diagnosis and should be part of the physical examination of any child with fever. The hallmark of OM is the presence of effusion in the middle ear cavity (see Table 105.1). The presence of an effusion does not confirm the presence of a bacterial OM, but it does define the need for appropriate diagnosis and therapy.

Pneumatic otoscopy, using an attachment to an otoscope, allows evaluation of ventilation of the middle ear and is a standard for clinical diagnosis. The tympanic membrane of the normal, air-filled middle ear has much greater compliance than if the middle ear is fluid-filled. With AOM, the tympanic membrane is often characterized by **hyperemia**, or red color rather than the normal pearly gray color, but may appear pink, white, or yellow depending on the degree of bulging (Fig. 105.1). The light reflex is lost, and the middle ear structures are obscured and difficult to distinguish. There should be poor or absent mobility to negative and positive pressure; this is a necessary finding for the diagnosis of OM. A hole in the tympanic membrane or purulent drainage confirms perforation. Occasionally bullae are present on the lateral aspect of the

tympanic membrane, which characteristically are associated with severe ear pain.

FIGURE 105.1 Appearance of tympanic membrane in acute otitis media. **(A)** Erythematous, opaque, bulging tympanic membrane. The light reflex is reduced, and the landmarks are partially obscured. Mobility markedly reduced. **(B)** Presence of air and fluid forming bubbles separated by grayish-yellow menisci. **(C)** Injection at the periphery. Yellow purulent effusion causing the inferior portion to bulge outward. Mobility markedly reduced. (From Yellon RF, Chi DH. Otolaryngology. In: Zitelli BJ, McIntire SC, Nowalk AJ, eds. *Atlas of Pediatric Physical Diagnosis*. 6th ed. Philadelphia: Saunders; 2012:923. Fig. 23–24.)

Laboratory and Imaging Studies

Routine laboratory studies, including complete blood count and erythrocyte sedimentation rate, are not useful in the evaluation of OM. **Tympanometry** provides objective acoustic measurements of the tympanic membrane–middle ear system by reflection or absorption of sound energy from the external ear duct as pressure in the duct is varied. Measurements of the resulting **tympanogram** correlate well with the presence or absence of middle ear effusion.

Instruments using **acoustic reflectometry** are available for office use. Use of reflectometry as a screening test for AOM should be followed by examination with pneumatic otoscopy when abnormal reflectometry is identified.

Bacteria recovered from the nasopharynx do not correlate with bacteria isolated by tympanocentesis. Tympanocentesis and middle ear exudate culture are not always necessary, but they are required for accurate identification of bacterial pathogens and may be useful in neonates, immunocompromised patients, and patients not responding to therapy.

Differential Diagnosis

The major difficulty is differentiation of AOM from **OM with effusion (OME)**, which also is referred to as **chronic OM**. AOM is accompanied by signs of acute illness, such as fever, pain, and upper respiratory tract inflammation. OME is the presence of effusion without any of the other signs and symptoms. OME may occur either as the sequel of AOM or eustachian tube dysfunction secondary to an upper respiratory tract infection. It may also predispose to the development of AOM. Because OME is not an acute infectious process, it is important to be able to differentiate between OME and AOM accurately to prevent overprescribing of antibiotics.

Treatment

Recommendations for treatment are based on age, certainty of diagnosis, and severity of illness (Table 105.2). The recommended first-line therapy for most children meeting criteria for antibiotic therapy is amoxicillin (80-90 mg/kg/day in two divided doses). Some children with mild illness or uncertain diagnosis may be observed if appropriate follow-up within 48-72 hours can be arranged with initiation of antibiotic therapy if symptoms do not self-resolve (Table 105.2). The failure of initial therapy with amoxicillin at 3 days suggests infection with β -lactamase-producing *H. influenza*, *M. catarrhalis*, or resistant *S. pneumoniae*. Recommended next-step treatments include high-dose amoxicillin-clavulanate (amoxicillin 80-90 mg/kg/day), cefdinir, or ceftriaxone (50 mg/kg intramuscularly in daily doses for 3 days). Intramuscular ceftriaxone is especially appropriate for children with vomiting that precludes oral treatment. Tympanocentesis may be required for patients who are difficult to treat or who do not respond to therapy. Acetaminophen and ibuprofen are recommended for fever. Decongestants or antihistamines are not effective.

TABLE 105.2

Recommendations for Initial Management of Confirmed Acute Otitis Media*

AGE	AOM WITH OTORRHEA	AOM WITH SEVERE SYMPTOMS [†]	BILATERAL AOM WITHOUT OTORRHEA	UNILATERAL AOM WITHOUT OTORRHEA
6 months to 2 years	Antibiotics	Antibiotics	Antibiotics	Antibiotics or additional observation [‡]
≥2 years	Antibiotics	Antibiotics	Antibiotics or additional	Antibiotics or additional

		observation	observation
--	--	-------------	-------------

*Applies only to children with well-documented AOM with high certainty of diagnosis.

†A toxic-appearing child, persistent otalgia for >48 hours, temperature $\geq 39^{\circ}\text{C}$ (102.2°F) in the past 48 hours, or if there is uncertain follow-up.

‡Requires shared decision making with parents and close follow-up within 48-72 hours.

Reproduced with permission from Lieberthal AS, Carroll AE, Chonmaitree T, et al. American academy of pediatrics clinical practice guideline: the diagnosis and management of acute otitis media. *Pediatrics*. 2013;131:e964–e999. Copyright 2013 by the AAP.

Complications and Prognosis

Decision-Making Algorithms

Ear Pain

Strabismus

Hearing Loss

The complications of OM are tympanic membrane perforation, chronic effusion, chronic otorrhea, hearing loss, cholesteatoma (mass-like keratinized epithelial growth), petrositis, intracranial extension (brain abscess, subdural empyema, or venous thrombosis), and mastoiditis. **Acute mastoiditis** is a suppurative complication of OM with inflammation and potential destruction of the mastoid air spaces. The disease progresses from a periostitis to an osteitis with mastoid abscess formation. Posterior auricular tenderness, swelling, and erythema, in addition to the signs of OM, are present. The pinna is displaced downward and outward. Computed tomography scan of the mastoid reveals clouding of the air cells, demineralization, or bone destruction. Treatment includes systemic antibiotics and drainage if the disease has progressed to abscess formation.

OME is the most frequent sequela of AOM and occurs most frequently in the first 2 years of life (up to 30-50% of children with AOM). **Persistent middle ear effusion** may last for many weeks or months in some children but usually resolves by 3 months following infection. Evaluating young children for this condition is an important part of all well-child examinations because, although not an infectious process, it is associated with hearing loss.

Conductive hearing loss should be assumed to be present with persistent middle ear effusion; the loss is mild to moderate and often is transient or fluctuating. In children at developmental risk or with frequent episodes of recurrent AOM, 3 months of persistent effusion with significant bilateral hearing loss is a reasonable indicator of need for intervention with insertion of pressure equalization tubes.

Prevention

Parents should be encouraged to continue exclusive breast feeding as long as possible and should be cautioned about the risks of *bottle-propping* and of children taking a bottle to bed. The home should be a smoke-free environment, and pacifier use should be limited.

The conjugate *S. pneumoniae* vaccine reduces pneumococcal OM caused by vaccine serotypes by 50%, all pneumococcal OM by 33%, and all OM by 6-10%. Annual immunization against influenza virus may be helpful in high-risk children.

CHAPTER 106

Otitis Externa

Etiology

Otitis externa, also known as **swimmer's ear**, is defined by inflammation and exudate in the external auditory canal in the absence of other disorders, such as otitis media or mastoiditis. The most common bacterial pathogens are *Pseudomonas aeruginosa*, especially in association with swimming in pools or lakes, and *Staphylococcus aureus*. Otitis externa develops in approximately 20% of children with **tyimpanostomy tubes**, associated with *S. aureus*, *Streptococcus pneumoniae*, *Moraxella catarrhalis*, *Proteus*, *Klebsiella*, and occasionally anaerobes. Coagulase-negative staphylococci and *Corynebacterium* are isolated frequently from cultures of the external canal but represent normal flora. **Malignant otitis externa** is caused by *P. aeruginosa* in immunocompromised persons and adults with diabetes.

Epidemiology

Otitis externa cases peak in summer, in contrast to otitis media, which occurs primarily in colder seasons in association with viral upper respiratory tract infections. Cleaning of the auditory canal, swimming, and, in particular, diving disrupt the integrity of the cutaneous lining of the ear canal and local defenses, such as cerumen, predisposing to otitis externa.

Clinical Manifestations

Decision-Making Algorithm

Ear Pain

Pain, tenderness, and aural discharge are the characteristic clinical findings of otitis externa. Fever is notably absent, and hearing is unaffected. Tenderness with movement of the pinna, especially the tragus, and with chewing is particularly characteristic, which are symptoms notably absent in otitis media. Inspection usually reveals that the lining of the auditory canal is inflamed with mild to severe erythema and edema. Scant to copious discharge from the auditory canal may obscure the tympanic membrane. The most common symptoms of **malignant otitis externa** are similar, but facial nerve palsy occasionally occurs. The most common physical findings are swelling and granulation tissue in the canal, usually with a discharge from the external auditory canal.

Laboratory and Imaging Studies

The diagnosis of uncomplicated otitis externa usually is established solely on the basis of the clinical symptoms and physical examination findings without the need for additional laboratory or microbiologic evaluation. Cultures are required to identify the etiological agent, which is usually *P. aeruginosa*, and the antimicrobial susceptibility.

Differential Diagnosis

Otitis media with tympanic perforation and discharge into the auditory canal may be confused with otitis externa. Pain on movement of the pinnae or tragus, typical of otitis externa, is absent. Local and systemic signs of mastoiditis indicate a process more extensive than otitis externa. **Malignancies** or cholesteatoma presenting in the auditory canal are rare in children but may present with discharge, unusual pain, or hearing loss.

Treatment

Topical antimicrobial/corticosteroid otic preparations (such as ofloxacin, ciprofloxacin with hydrocortisone or dexamethasone, and polymyxin B-neosporin-hydrocortisone) are sufficient in most cases of otitis externa. These preparations are equally effective and are active against *S. aureus* and most gram-negative bacteria, including *P. aeruginosa*. None of these antibiotics has any antifungal activity. Use of aminoglycosides such as neomycin should be avoided in cases of tympanic membrane rupture due to their ototoxicity. **Tympanostomy tube otorrhea** is best treated with quinolone otic drugs, which are considered less likely to be ototoxic.

Treatment with topical otic analgesics and ceruminolytics is usually unnecessary. It is important with any topical therapy to remove purulent discharge from the external auditory canal with a swab or with suction to permit instillation of the solution. Excess water should be removed after bathing and the ear canal dried using a hairdryer. The predisposing activity, such as swimming or diving, should be avoided until the inflammation has resolved.

Fungi such as *Aspergillus*, *Candida*, and dermatophytes are occasionally isolated from the external ear. It may be difficult to determine whether they represent normal flora or are the cause of inflammation. In most cases, local therapy and restoration of normal pH as recommended for bacterial otitis externa are sufficient.

Malignant otitis externa is treated by parenteral antimicrobials with activity against *P. aeruginosa*, such as an extended-spectrum penicillin (piperacillin-tazobactam), a cephalosporin with activity against *P. aeruginosa* (ceftazidime, cefepime), or a fluoroquinolone (ciprofloxacin).

Complications and Prognosis

Acute otitis externa usually resolves promptly without complications within 1-2

days of initiating treatment. Persistent pain, especially if severe or if accompanied by other symptoms (e.g., fever) should prompt re-evaluation for other conditions.

Complications of malignant otitis externa include invasion of the bones at the base of the skull, which may cause cranial nerve palsies. A mortality of 15-20% occurs in adults with malignant otitis media. Relapses within the first year after treatment are common.

Prevention

Overly vigorous cleaning of an asymptomatic auditory canal should be avoided. Drying the auditory canals with acetic acid (2%), Burow solution, or diluted isopropyl alcohol (rubbing alcohol) after swimming may be used prophylactically to help prevent the maceration that facilitates bacterial invasion. There is no role for prophylactic otic antibiotics.

CHAPTER 107

Croup (Laryngotracheobronchitis)

Etiology and Epidemiology

Croup, or laryngotracheobronchitis, is the most common infection of the middle respiratory tract. The most common causes of croup are parainfluenza viruses (types 1, 2, 3, and 4) and respiratory syncytial virus (RSV). Laryngotracheal airway inflammation disproportionately affects children because a small decrease in diameter secondary to mucosal edema and inflammation exponentially increases airway resistance and the work of breathing. During inspiration, the walls of the subglottic space are drawn together, aggravating the obstruction and producing the **stridor** characteristic of croup. Croup is most common in children 6 months to 3 years of age, with a peak in fall and early winter. It typically follows a common cold. Symptomatic reinfection is common, yet reinfections are usually mild. In adolescents, it manifests as laryngitis.

Clinical Manifestations

Decision-Making Algorithms

Cough
Hoarseness
Stridor
Apnea

The manifestations of croup are a harsh cough described as **barking** or **brassy**, hoarseness, inspiratory stridor, low-grade fever, and respiratory distress that may develop slowly or quickly. **Stridor** is a harsh, high-pitched respiratory sound produced by turbulent airflow. It is usually inspiratory, but it may be biphasic and is a sign of upper airway obstruction. Signs of upper airway obstruction, such as labored breathing, cyanosis, and marked suprasternal, intercostal, and subcostal retractions, may be evident on examination (see [Chapter 135](#)). Wheezing may be present if there is associated lower airway involvement.

Laboratory and Imaging Studies

Anteroposterior radiographs of the neck often show the diagnostic subglottic narrowing of croup known as the **steeple sign** ([Fig. 107.1](#)). Routine laboratory studies are not useful in establishing the diagnosis. Leukocytosis is uncommon and suggests epiglottitis or bacterial tracheitis. Many rapid tests (using polymerase chain reaction [PCR]) are available for parainfluenza viruses, RSV, and other less common viral causes of croup, such as influenza and adenoviruses.

FIGURE 107.1 Croup (laryngotracheobronchitis). Radiograph of the airway and chest of a patient with croup, demonstrating the typical subglottic narrowing (“steeple sign”). (From Roosevelt GE. Acute inflammatory upper airway obstruction [croup, epiglottitis, laryngitis, and bacterial tracheitis]. In: Kliegman RM, Stanton BF, St. Geme III JW, Schor NF, eds. *Nelson Textbook of Pediatrics*. 20th ed. Philadelphia: Elsevier; 2016. Fig. 385-1.)

Differential Diagnosis

The diagnosis of croup is usually established by clinical manifestations. The infectious differential diagnosis includes epiglottitis, bacterial tracheitis, and parapharyngeal abscess. Noninfectious causes of stridor include mechanical and anatomical causes (foreign body aspiration, laryngomalacia, subglottic stenosis, hemangioma, vascular ring, vocal cord paralysis). Stridor in infants younger than 4 months of age, positional stridor, or persistence of symptoms for longer than 1 week indicates an increased probability of another lesion and the need for imaging and direct laryngoscopy (see [Chapter 135](#)).

Epiglottitis is a medical emergency because of the risk of sudden airway obstruction. This illness is now rare and usually caused by group A streptococcus or *Staphylococcus aureus* or *Haemophilus influenzae* type b in unimmunized patients. Patients typically prefer sitting, often with the head held forward, the mouth open, and the jaw thrust forward (**sniffing position**), and may appear distressed and toxic. Lateral radiograph reveals thickened and bulging epiglottis (**thumb sign**) and swelling of the aryepiglottic folds. The

diagnosis is confirmed by direct observation of the inflamed and swollen supraglottic structures and swollen, cherry red epiglottitis. Direct observation of the larynx should only be performed in the operating room with an anesthesiologist and a competent surgeon prepared to place an endotracheal tube or perform a tracheostomy if needed. Epiglottitis requires antibiotic therapy and endotracheal intubation to maintain the airway. Both onset and clinical recovery are rapid, and most children can be extubated safely within 48-72 hours.

Bacterial tracheitis is a rare but serious superinfection of the trachea that may follow viral croup and is most commonly caused by *S. aureus*. Patients may be toxic appearing, and intubation may be required. **Spasmodic croup** describes sudden onset of croup symptoms, usually at night, but without a significant upper respiratory tract prodrome. These episodes may be recurrent and severe but usually are of short duration. Spasmodic croup has a milder course than viral croup and responds to relatively simple therapies, such as exposure to cool or humidified air. The etiology is not well understood and may be allergic.

Treatment

Oral or intramuscular dexamethasone for children with croup reduces symptoms and the need for hospitalization, and shortens hospital stays. Dexamethasone (0.6-1 mg/kg) may be given once intramuscularly or orally. Alternatively, prednisolone (2 mg/kg/day) may be given orally in two to three divided doses. For significant airway compromise, administration of aerosolized racemic (D- and L-)epinephrine reduces subglottic edema by adrenergic vasoconstriction, temporarily producing marked clinical improvement. The peak effect is within 10-30 minutes and fades within 60-90 minutes. A rebound effect may occur, with worsening of symptoms as the effect of the drug dissipates. Aerosol treatment may need to be repeated every 20 minutes (for no more than 1-2 hours) in severe cases.

Children should be kept as calm as possible to minimize forceful inspiration. One useful calming method is for a child with croup to sit on the parent's lap. Sedatives should be used cautiously and in the intensive care unit only. Cool mist administered by face mask may help prevent drying of the secretions around the larynx.

Hospitalization is often required for children with cyanosis, or stridor at rest. Children receiving aerosol treatment should be hospitalized or observed for at least 2-3 hours because of the risk of rebound airway obstruction. Decreased

symptoms may indicate improvement or fatigue, and impending respiratory failure.

Complications and Prognosis

The most common complication of croup is viral pneumonia, which occurs in 1-2% of children. Parainfluenza virus pneumonia and secondary bacterial pneumonia are more common in immunocompromised patients. Bacterial tracheitis may also be a complication of croup.

The prognosis for croup is excellent. Illness usually lasts approximately 5 days. As children grow, they become less susceptible to the airway effects of viral infections of the middle respiratory tract.

Prevention

There are no licensed vaccines for parainfluenza or RSV.

CHAPTER 108

Pertussis

Etiology

Classic pertussis (**whooping cough**) is caused by *Bordetella pertussis*, a gram-negative pleomorphic bacillus with fastidious growth requirements. *B. pertussis* infects only humans and is transmitted person to person by coughing.

Epidemiology

The typical incubation period is 7-10 days but can range between 5 and 21 days. Patients are most contagious during the first 2 weeks of cough. The annual rate of pertussis was approximately 100-200 cases per 100,000 population in the prevaccination era; worldwide there continue to be an estimated 15 million cases of pertussis and 200,000 childhood deaths annually. In the United States the incidence of pertussis decreased after the introduction of vaccine, but it has

increased steadily since the 1980s, with more than 18,000 cases reported in 2015. Pertussis incidence peaks among those less than 6 months of age—infants too young to be completely immunized and most likely to have severe complications—at approximately 150 cases per 100,000 population. Rates of infection in late childhood and adolescence have also been rising, likely due to a combination of waning immunity from previous vaccines, underimmunization, and improved diagnostics. Epidemics can occur in fully immunized patients because vaccine-induced immunity wanes.

Clinical Manifestations

Decision-Making Algorithms

Cough
Cyanosis
Apnea

Classic pertussis is seen in children between 1 and 10 years old. The progression of the disease is divided into catarrhal, paroxysmal, and convalescent stages. The **catarrhal stage** is marked by nonspecific signs (increased nasal secretions and low-grade fever) lasting 1-2 weeks. The **paroxysmal stage** is the most distinctive stage of pertussis and lasts 2-4 weeks. Coughing occurs in **paroxysms** during expiration, causing young children to lose their breath. This pattern of coughing is needed to dislodge plugs of necrotic bronchial epithelial tissues and thick mucus. The forceful inhalation against a narrowed glottis that follows this paroxysm of cough produces the characteristic **whoop**. Posttussive emesis is common. The **convalescent stage** is marked by gradual resolution of symptoms over 1-2 weeks. Coughing becomes less severe, and the paroxysms and whoops slowly disappear. Although the disease typically lasts 6-8 weeks, residual cough may persist for months, especially with physical stress or respiratory irritants.

Infants may not display the classic findings, and the first sign in the neonate may be apnea. Young infants are unlikely to have the classic whoop, more likely to have central nervous system damage as a result of hypoxia, and more likely to have secondary bacterial pneumonia. Adolescents and adults with pertussis

usually present with a prolonged bronchitic illness with persistent, nonproductive cough that often begins as a nonspecific upper respiratory tract infection. In general, adolescents and adults do not have a whoop with the cough, although they may have severe paroxysms.

Laboratory and Imaging Studies

The diagnosis depends on isolation of *B. pertussis* or detection of its nucleic acids. Culture on specialized media is usually performed during the early phases of illness on specimens from nasopharyngeal swabs or aspirates, but this can be difficult to accomplish given the organism's fastidious nature. Polymerase chain reaction is available in many clinical laboratories. False-positive results can occur. Direct fluorescent antibody staining is not recommended. Serological tests are not useful for diagnosing acute infection but can be confirmatory in the convalescent phase of illness, though there are no commercial kits approved by the U.S. Food and Drug Administration.

Lymphocytosis is present in 75-85% of infants and young children but is not diagnostic. The white blood cell count may increase from 20,000/mm³ to more than 50,000/mm³, consisting primarily of mature lymphocytes. Physical examination and radiographic signs of segmental lung atelectasis may develop during pertussis, especially during the paroxysmal stage. Perihilar infiltrates are common and are similar to those seen in viral pneumonia.

Differential Diagnosis

For a young child with classic pertussis, the diagnosis based on the pattern of illness is quite accurate. The paroxysmal stage is the most distinctive part of the syndrome. Other causes of pertussis-like prolonged cough illnesses include *Bordetella parapertussis* and *Bordetella holmesii*—which cause a similar but milder illness and are not prevented by *B. pertussis* vaccination—*Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, adenoviruses, and respiratory syncytial virus.

Treatment

Macrolide antibiotics (azithromycin, clarithromycin, or erythromycin) are recommended for treatment. Azithromycin is preferred in neonates due to the

association between erythromycin treatment and the development of pyloric stenosis. Treatment during the catarrhal phase eradicates nasopharyngeal carriage of organisms within 3-4 days and may lessen symptom severity. Treatment in the paroxysmal stage does not alter the course of illness but decreases the potential for spread to others. Trimethoprim-sulfamethoxazole is an alternative therapy among children older than 2 months, although studies of its use for this indication are limited.

Complications and Prognosis

Major complications are most common among infants and young children and include hypoxia, apnea, pneumonia, seizures, encephalopathy, malnutrition, and death. The most frequent complication is pneumonia caused by *B. pertussis* itself or resulting from secondary bacterial infection with *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus aureus*. Atelectasis may develop secondary to mucous plugs. The force of the paroxysm may produce pneumomediastinum, pneumothorax, or interstitial or subcutaneous emphysema; epistaxis; hernias; and retinal and subconjunctival hemorrhages. Otitis media and sinusitis may occur.

Most children recover normal pulmonary function with complete healing of the respiratory epithelium. Most permanent disability is a result of encephalopathy.

Prevention

Active immunity is induced with acellular pertussis components given as a vaccine in combination with the tetanus and diphtheria toxoids (DTaP). The acellular pertussis vaccines contain two to five antigens of *B. pertussis*, including pertussis toxin, pertactin, filamentous hemagglutinin, and fimbrial agglutinogens FIM-2 and FIM-3. DTaP vaccine is recommended at 2, 4, 6, and 15-18 months, with a booster at 4-6 years, and has an efficacy of 70-90%. A single booster dose of Tdap vaccine is recommended at 11-12 years or once for all adults. A booster dose of Tdap vaccine is recommended for pregnant women with each pregnancy, preferably in the third trimester, to provide higher levels of antibodies to the infant via transplacental transfer.

Macrolides are effective in preventing secondary cases in contacts exposed to pertussis. Underimmunized close contacts under 7 years of age should receive a

booster dose of DTaP (unless a booster dose has been given within the preceding 3 years), whereas those 7-10 years of age should receive Tdap. All close contacts should receive prophylactic antibiotics for 5 days (azithromycin) or 7-14 days (clarithromycin or erythromycin, duration based on age).

CHAPTER 109

Bronchiolitis

Etiology

Bronchiolitis is a disease of small bronchioles with increased mucus production and occasional bronchospasm, sometimes leading to airway obstruction. It is most commonly caused by a viral lower respiratory tract infection. Bronchiolitis is most commonly seen in infants and young children, with most severe cases occurring among infants. Bronchiolitis is potentially life-threatening.

Respiratory syncytial virus (RSV) is a primary cause of bronchiolitis, followed in frequency by human metapneumovirus, parainfluenza viruses, influenza viruses, adenoviruses, rhinoviruses, coronaviruses, and, infrequently, *Mycoplasma pneumoniae*. Viral bronchiolitis is extremely contagious and is spread by contact with infected respiratory secretions. Although coughing produces aerosols, hand carriage of contaminated secretions is the most frequent mode of transmission.

Epidemiology

Bronchiolitis is a leading cause of hospitalization of infants. Bronchiolitis occurs almost exclusively during the first 2 years of life, with a peak age at 2-6 months. Many healthy children with bronchiolitis can be managed as outpatients; however, premature infants and children with chronic lung disease of prematurity, hemodynamically significant congenital heart disease, neuromuscular weakness, or immunodeficiency are at increased risk of severe, potentially fatal disease. Children acquire infection after exposure to infected family members, who typically have symptoms of an upper respiratory tract infection, or from infected children in day care. In the United States, annual

peaks are usually in the late winter months from December through March.

Clinical Manifestations

Decision-Making Algorithms

Wheezing
Apnea

Bronchiolitis caused by RSV typically has an incubation period of 4-6 days. Bronchiolitis classically presents as a progressive respiratory illness similar to the common cold in its early phase, with cough and rhinorrhea. It progresses over 3-7 days to noisy, raspy breathing and audible wheezing. There is usually a low-grade fever accompanied by irritability, which may reflect the increased work of breathing. In contrast to the classic progression of disease, young infants infected with RSV may not have a prodrome and may have apnea as the first sign of infection.

Physical signs of bronchiolar obstruction include prolongation of the expiratory phase of breathing, nasal flaring, intercostal retractions, suprasternal retractions, and air trapping with hyperexpansion of the lungs. During the wheezing phase, percussion of the chest usually reveals only hyperresonance, but auscultation usually reveals diffuse wheezes and crackles throughout the breathing cycle. With more severe disease, grunting and cyanosis may be present.

Laboratory and Imaging Studies

Routine laboratory tests are not required to confirm the diagnosis. It is important to assess oxygenation in severe cases of bronchiolitis. **Pulse oximetry** is adequate for monitoring oxygen saturation. Frequent, regular assessments and cardiorespiratory monitoring of infants are necessary because respiratory failure may develop precipitously in very tired infants even though blood gas values taken before rapid decompensation are reassuring.

Rapid viral diagnosis of nasopharyngeal secretions performed by polymerase chain reactions for RSV, parainfluenza viruses, influenza viruses, and

adenoviruses are sensitive tests to confirm the infection. Identifying the viral agent is helpful for cohorting children with the same infection but is not necessary to make the diagnosis of bronchiolitis.

Chest radiographs are not always necessary but frequently show signs of lung hyperinflation, including increased lung lucency and flattened or depressed diaphragms. Areas of increased density may represent either viral pneumonia or localized atelectasis.

Differential Diagnosis

The major difficulty in the diagnosis of bronchiolitis is to differentiate other diseases associated with wheezing. It may be difficult to differentiate asthma from bronchiolitis by physical examination, but age of presentation, presence of fever, and absence of personal or family history of asthma are the major differential factors. Bronchiolitis occurs primarily in the first year of life and is accompanied by fever, whereas asthma usually presents in older children with previous wheezing episodes typically unaccompanied by fever unless a respiratory tract infection is the trigger for the asthma exacerbation.

Wheezing may also be due to an airway foreign body, congenital airway obstructive lesion, cystic fibrosis, exacerbation of chronic lung disease, viral or bacterial pneumonia, and other lower respiratory tract diseases (see [Chapter 78](#)). **Cardiogenic asthma**, which can be confused with bronchiolitis in infants, is wheezing associated with pulmonary congestion secondary to left-sided heart failure. Wheezing associated with gastroesophageal reflux is likely to be chronic or recurrent, and the patient may have a history of frequent emesis. Cystic fibrosis is associated with poor growth, chronic diarrhea, and a positive family history. A focal area on radiography that remains inflated despite changes in position suggests **foreign body aspiration**.

Treatment

Bronchiolitis treatment consists of supportive therapy, including respiratory monitoring, control of fever, hydration, upper airway suctioning, and, if needed, oxygen administration. Indications for hospitalization include moderate to marked respiratory distress, hypoxemia, apnea, inability to tolerate oral feeding, and lack of appropriate care available at home. Hospitalization of high-risk children with bronchiolitis should be considered. Among hospitalized infants,

supplemental oxygen by nasal cannula is often necessary, but intubation and ventilatory assistance for respiratory failure or apnea are required in <10% of these infants. Bronchodilators, corticosteroids, chest physiotherapy, and hypertonic saline are seldom effective and are not generally recommended. Likewise, antibiotics should be avoided unless there is strong suspicion for concomitant bacterial infection.

Complications and Prognosis

Most hospitalized children show marked improvement in 2-5 days with supportive treatment alone. The course of the wheezing phase varies, however. Tachypnea and hypoxia may progress to respiratory failure requiring assisted ventilation. Apnea is a major concern for very young infants with bronchiolitis.

Most cases of bronchiolitis resolve completely, although minor abnormalities of pulmonary function and bronchial hyperreactivity may persist for several years. Recurrence is common but tends to be mild and should be assessed and treated similarly to the first episode. The incidence of asthma seems to be higher in children hospitalized for bronchiolitis as infants, but it is unclear whether this is causal or whether children prone to asthma are more likely to be hospitalized with bronchiolitis. There is a 1-2% mortality rate, highest among infants with preexisting cardiopulmonary or immunological impairment.

Prevention

Monthly injections of **palivizumab**, an RSV-specific monoclonal antibody, initiated just before the onset of the RSV season confers some protection from severe RSV disease. Palivizumab is indicated for some infants with prematurity (born before 29 weeks, 0 days' gestation), chronic lung disease of prematurity, and those with hemodynamically significant cyanotic and acyanotic congenital heart disease in the first year of life, and rarely in the second year of life. Immunization with influenza vaccine is recommended for all children older than 6 months and may prevent influenza-associated disease.

CHAPTER 110

Pneumonia

Etiology

Pneumonia is an infection of the lower respiratory tract that involves the airways and parenchyma, with consolidation of the alveolar spaces. The term **lower respiratory tract infection** is often used to encompass bronchitis, bronchiolitis (see [Chapter 109](#)), pneumonia, or any combination of the three. **Pneumonitis** is a general term for lung inflammation that may or may not be associated with consolidation. **Lobar pneumonia** describes pneumonia localized to one or more lobes of the lung. **Atypical pneumonia** describes patterns typically more diffuse or interstitial than lobar pneumonia. **Bronchopneumonia** refers to inflammation of the lung that is centered in the bronchioles and leads to the production of a mucopurulent exudate that obstructs some of these small airways and causes patchy consolidation of the adjacent lobules. **Interstitial pneumonitis** refers to inflammation of the interstitium, which is composed of the walls of the alveoli, the alveolar sacs and ducts, and the bronchioles. Interstitial pneumonitis is characteristic of acute viral infections but may also be a chronic inflammatory or fibrosing process.

Defects in host defenses increase the risk of pneumonia. Lower airways and secretions are sterile as a result of a multifactorial system. Airway contaminants are caught in the mucus secreted by the goblet cells. Cilia on epithelial surfaces, composing the ciliary elevator system, beat synchronously to move particles upward toward central airways and into the throat, where they are swallowed or expectorated. Polymorphonuclear neutrophils from the blood and tissue macrophages ingest and kill microorganisms. IgA secreted into the upper airway fluid protects against invasive infections and facilitates viral neutralization.

Infectious agents that commonly cause community-acquired pneumonia vary by age ([Table 110.1](#)). *Streptococcus pneumoniae* is the most common bacterial cause of pneumonia (particularly **lobar pneumonia**) and occurs in children of any age outside the neonatal period. Other common causes include respiratory syncytial virus (RSV) in infants (see [Chapter 109](#)), other respiratory viruses (parainfluenza viruses, influenza viruses, human metapneumovirus, adenoviruses) in children younger than 5 years old, and *Mycoplasma pneumoniae* in children older than age 5 years. *M. pneumoniae* and *Chlamydomphila pneumoniae* are principal causes of **atypical pneumonia**.

TABLE 110.1

Etiological Agents and Empirical Antimicrobial Therapy for Pneumonia in Pa History of Recent Antibiotic Therapy

AGE GROUP	COMMON PATHOGENS* (IN APPROXIMATE ORDER OF FREQUENCY)*	LESS COMMON PATHOGENS	OUTPATIENTS (7-10 DAYS TOTAL DURATION OF TREATMENT) [†]	PATIENTS REQUIRING HOSPITALIZATION (10-14 DAYS TOTAL DURATION OF TREATMENT) [‡]
Neonates (up to 1 mo of age)	Group B streptococcus, <i>Escherichia coli</i> , other gram-negative bacilli, <i>Streptococcus pneumoniae</i>	Cytomegalovirus, Herpes simplex virus, <i>Listeria monocytogenes</i> , <i>Treponema pallidum</i> , <i>Haemophilus influenzae</i> (type b, [§] nontypable)	Outpatient management not recommended	Ampicillin <i>plus</i> cefotaxime or an aminoglycoside <i>plus</i> an antistaphylococcal agent if <i>Staphylococcus aureus</i> is suspected
1-3 mo				
Febrile pneumonia	Respiratory syncytial virus, other respiratory viruses (parainfluenza viruses, influenza viruses, adenoviruses), <i>S. pneumoniae</i> , <i>H. influenzae</i> (type b, [§] nontypable)		Initial outpatient management not recommended	Amoxicillin or ampicillin if fully immunized for age <i>S. pneumoniae</i> and <i>H. influenzae</i> type b. Alternatives: cefotaxime or ceftriaxone if not fully immunized or local <i>S. pneumoniae</i> penicillin resistance is significant, with clindamycin if MRS suspected
Afebrile pneumonia	<i>Chlamydia trachomatis</i> , <i>Mycoplasma hominis</i> , <i>Ureaplasma urealyticum</i> , cytomegalovirus, <i>Bordetella pertussis</i>		Erythromycin, azithromycin, or clarithromycin with close follow-up	Erythromycin, azithromycin, clarithromycin
3 mo to 5 yr	Respiratory syncytial virus, other respiratory viruses (parainfluenza viruses, influenza viruses, human metapneumovirus adenoviruses), <i>S. pneumoniae</i> , <i>H. influenzae</i> (type b, [§] nontypable)	<i>C. trachomatis</i> , <i>Mycoplasma pneumoniae</i> , <i>Chlamydia pneumoniae</i> , group A streptococcus, <i>S. aureus</i> , <i>Mycobacterium tuberculosis</i>	Amoxicillin <i>plus</i> erythromycin, azithromycin, or clarithromycin if atypical pneumonia suspected	Ampicillin Alternatives: cefotaxime or ceftriaxone if not fully immunized or local <i>S. pneumoniae</i> penicillin resistance is significant, with clindamycin if MRSA suspected; Add erythromycin, azithromycin, or clarithromycin if atypical

				pneumonia suspected
5-18 yr	<i>M. pneumoniae</i> , <i>S. pneumoniae</i> , <i>C. pneumoniae</i>	<i>H. influenzae</i> (type b, [§] nontypable), influenza viruses, adenoviruses, other respiratory viruses	Amoxicillin <i>plus</i> erythromycin, azithromycin, or clarithromycin if atypical pneumonia suspected	Ampicillin <i>plus</i> erythromycin, azithromycin, or clarithromycin if atypical pneumonia suspected
≥18 yr [§]	<i>M. pneumoniae</i> , <i>S. pneumoniae</i> , <i>C. pneumoniae</i> , <i>H. influenzae</i> (type b, [§] nontypable), influenza viruses, adenoviruses	<i>Legionella pneumophila</i> , <i>M. tuberculosis</i>	Amoxicillin, or erythromycin, azithromycin, clarithromycin, doxycycline, moxifloxacin, gatifloxacin, levofloxacin, or gemifloxacin [¶] if atypical pneumonia suspected	Ampicillin <i>plus</i> erythromycin, azithromycin, or clarithromycin if atypical pneumonia suspected <i>or</i> moxifloxacin, gatifloxacin, levofloxacin, or gemifloxacin

*Severe pneumonia, from *Streptococcus pneumoniae*, *Staphylococcus aureus*, group A streptococcus, *Haemophilus influenzae*, or *Mycoplasma pneumoniae* requiring admission to an intensive care unit. Antipseudomonal agents should be added if *Pseudomonas* is suspected.

†Oral administration.

‡Intravenous administration for inpatients except for the macrolides (erythromycin, azithromycin, and clarithromycin), which are given orally.

§*Haemophilus influenzae* type b infection is uncommon with universal *H. influenzae* type b immunization.

¶Fluoroquinolones are contraindicated for children younger than 18 years of age and pregnant or lactating women. Tetracyclines are not recommended for children younger than 9 years.

MRSA, Methicillin-resistant *Staphylococcus aureus*.

Chlamydia trachomatis and less commonly *Mycoplasma hominis*, *Ureaplasma urealyticum*, and cytomegalovirus (CMV) cause a similar respiratory syndrome in infants 2 weeks to 3 months of age, with subacute onset of an **afebrile pneumonia**; cough and hyperinflation are the predominant signs. These infections are difficult to diagnose and distinguish from each other. In adults these organisms are carried primarily as part of the genital mucosal flora. Women who harbor these agents may transmit them perinatally to newborns.

Additional agents occasionally cause pneumonia. **Severe acute respiratory syndrome (SARS)** is due to SARS-associated coronavirus (SARS-CoV). **Avian influenza (bird flu)** is a highly contagious viral disease of poultry and other birds caused by **influenza A (H5N1)**. There were outbreaks among humans in

Southeast Asia in 1997 and 2003-2004, with high mortality rates. A novel influenza A (H1N1) of swine origin began circulating in 2009. Other etiological agents to consider, based on specific exposure history, include *Staphylococcus aureus* and *Streptococcus pyogenes* (especially after influenza infection), *Mycobacterium tuberculosis*, *Francisella tularensis*, *Brucella* spp., *Coxiella burnetii*, *Chlamydomphila psittaci*, *Legionella pneumophila*, hantavirus, *Histoplasma capsulatum*, *Coccidioides immitis*, *Blastomyces dermatitidis*, and oral flora or gram-negative bacilli (after aspiration).

Causes of pneumonia in immunocompromised persons include gram-negative enteric bacteria, mycobacteria (*M. avium* complex), fungi (aspergillosis), viruses (CMV), and *Pneumocystis jirovecii* (formerly *carinii*). Pneumonia in patients with cystic fibrosis is usually caused by *S. aureus* in infancy and *Pseudomonas aeruginosa* or *Burkholderia cepacia* in older patients.

Epidemiology

Immunizations have markedly reduced the incidence of pneumonia caused by pertussis, diphtheria, measles, *Haemophilus influenzae* type b, and *S. pneumoniae*. Where used, bacille Calmette-Guérin (BCG) immunization for tuberculosis has also had some impact. Pneumonia is the single largest contributor of childhood mortality worldwide, killing an estimated 1 million children under 5 years of age annually. Risk factors for lower respiratory tract infections include gastroesophageal reflux, neurological impairment (aspiration), immunocompromised states, anatomical abnormalities of the respiratory tract, residence in residential care facilities, and hospitalization, especially in an intensive care unit.

Clinical Manifestations

Decision-Making Algorithms

- Cough
- Wheezing
- Hemoptysis
- Chest Pain
- Abdominal Pain
- Failure to Thrive

Acidemia

Age is a determinant in the clinical manifestations of pneumonia. Neonates may have fever or hypoxia only, with subtle or absent physical examination findings (see [Chapter 65](#)). With a young infant, apnea may be the first sign of pneumonia. Fever, chills, tachypnea, cough, malaise, pleuritic chest pain, retractions, and apprehension—because of difficulty breathing or shortness of breath—are common in older infants and children. Physical examination findings cannot reliably distinguish viral and bacterial pneumonias, but complete physical examination may help identify other foci of disease or associated findings to suggest an etiology.

Viral pneumonias are generally associated more often with cough, wheezing, or stridor; fever is less prominent than with bacterial pneumonia. Mucosal congestion and upper airway inflammation suggest a viral infection. Bacterial pneumonias are typically associated with higher fever, chills, cough, dyspnea, and auscultatory findings of lung consolidation. Atypical pneumonia in young infants is characterized by tachypnea, cough, and crackles on auscultation. Concomitant conjunctivitis may be present in infants with chlamydial pneumonia. Other signs of respiratory distress include nasal flaring, intercostal and subcostal retractions, and grunting.

Asymmetry or shallow breathing may be due to splinting from pain. Hyperexpansion, common in asthma but also frequently accompanying viral lower respiratory infections, may cause a low diaphragm seen on a chest x-ray. Poor diaphragmatic excursion may indicate hyperexpanded lungs or an inability for expansion due to a large consolidation or effusion. Dullness to percussion may be due to lobar or segmental infiltrates or pleural fluid. Auscultation may be normal in early or very focal pneumonia, but the presence of localized crackles, rhonchi, and wheezes may help one detect and locate pneumonia. Distant breath sounds may indicate a large, poorly ventilated area of consolidation or pleural fluid.

Laboratory and Imaging Studies

Bacterial flora of the upper respiratory tract do not accurately reflect flora present in lower respiratory tract infections, and high-quality sputum is rarely obtainable from children. In otherwise healthy children without life-threatening

disease, invasive procedures to obtain lower respiratory tissue or secretions are seldom indicated. Serological tests are not useful for the most common causes of bacterial pneumonia.

The white blood cell (WBC) count with viral pneumonias is often normal or mildly elevated, with a predominance of lymphocytes, whereas with bacterial pneumonias the WBC count is elevated ($>15\text{-}20,000/\text{mm}^3$), with a predominance of neutrophils. Mild eosinophilia is characteristic of infant *C. trachomatis* pneumonia. Blood cultures should be performed on ill, hospitalized children to attempt to diagnose a bacterial cause of pneumonia. Blood cultures identify a bacterial respiratory pathogen in 5-10% of children hospitalized for pneumonia (and 10-20% of those with pneumonia with empyema or large effusion). Urinary antigen tests are especially useful for *L. pneumophila* (Legionnaires disease).

Viral respiratory pathogens can be diagnosed using polymerase chain reaction (PCR) or rapid viral antigen detection, but neither can rule out concomitant bacterial pneumonia. *M. pneumoniae* can be confirmed by *Mycoplasma* PCR. CMV pneumonitis can be diagnosed with PCR from bronchoalveolar lavage fluid. The diagnosis of *M. tuberculosis* is established by the tuberculin skin test, serum interferon-gamma release assay, or analysis of sputum or gastric aspirates by culture, antigen detection, or PCR.

The need to establish an etiological diagnosis of pneumonia is greater in immunocompromised patients, patients with recurrent pneumonia, or those with pneumonia unresponsive to empirical therapy. For these patients, bronchoscopy with bronchoalveolar lavage and brush mucosal biopsy, needle aspiration of the lung, and open lung biopsy are methods of obtaining material for microbiologic diagnosis.

When there is a pleural **effusion or empyema**, a thoracentesis to obtain pleural fluid can be diagnostic and therapeutic. Evaluation differentiates between empyema and a sterile parapneumonic effusion caused by irritation of the pleura contiguous with the pneumonia. Gram stain, bacterial culture, or broad-range bacterial PCR may lead to microbiologic diagnosis. The pleural fluid can also be cultured for mycobacteria and fungi. Removal of grossly purulent pleural fluid reduces the patient's toxicity and associated discomfort and may facilitate more rapid recovery. Drainage of large pleural accumulations also improves pulmonary mechanics and gas exchange by increasing the ability of the lung to expand.

Frontal and lateral radiographs are required to localize disease and adequately visualize retrocardiac infiltrates; they are recommended for diagnosis among

hospitalized children but are not necessary to confirm the diagnosis in well-appearing outpatients. Although there are characteristic radiographic findings of pneumonia, radiography alone cannot provide a definitive microbiologic diagnosis. Bacterial pneumonia characteristically shows lobar consolidation or a round pneumonia, with pleural effusion in 10-30% of cases (Fig. 110.1). Viral pneumonia characteristically shows diffuse, streaky infiltrates of bronchopneumonia (Fig. 110.2) and hyperinflation. Atypical pneumonia, as with *M. pneumoniae* and *C. pneumoniae*, shows increased interstitial markings or bronchopneumonia. Chest radiographs may be normal in early pneumonia, with infiltrates appearing during treatment as hydration is restored. Hilar lymphadenopathy is uncommon with bacterial pneumonia but may be a sign of tuberculosis, endemic mycoses, autoimmune conditions, or an underlying malignant neoplasm. Decubitus views or ultrasound should be used to assess the size of pleural effusions and whether they are freely mobile. Computed tomography (CT) is used to evaluate serious disease, lung abscesses, bronchiectasis, and effusion characteristics. Unusual etiologies or recurrent pneumonias require special considerations (Table 110.2). Lung abscesses, pneumatoceles, and empyema may require surgical management.

FIGURE 110.1 Acute lobar pneumonia of the right lower lobe in a 14-year-old boy with fever and cough. **(A)** Posteroanterior and **(B)** lateral chest radiographs demonstrate right-lower-lobe airspace consolidation, which obliterates the silhouette of the right heart border. (From Kelly MS, Sandora TJ. Community-acquired pneumonia. In: Kliegman RM, Stanton BF, St. Geme III JW, Schor NF, eds. *Nelson Textbook of Pediatrics*. 20th ed. Philadelphia: Elsevier; 2016. Aspiration (oropharyngeal incoordination)

NONINFECTIOUS MIMICS OF PNEUMONIA

Autoimmune diseases (e.g., granulomatosis with polyangiitis)

Hypersensitivity pneumonitis

Differential Diagnosis

Pneumonia must be differentiated from other acute pulmonary diseases, including allergic pneumonitis, asthma, and cystic fibrosis; cardiac diseases, such as pulmonary edema caused by heart failure; and autoimmune diseases, such as certain vasculitides and systemic lupus erythematosus. Radiographically pneumonia must be differentiated from lung trauma and contusion, hemorrhage, foreign body aspiration, and sympathetic effusion due to subdiaphragmatic inflammation.

Treatment

Decision-Making Algorithm

Fever Without a Source

Therapy for pneumonia includes supportive and specific treatment and depends on the degree of illness, complications, and knowledge of the infectious agent likely causing the pneumonia. Most cases of pneumonia in healthy children can be managed on an outpatient basis. However, children with hypoxemia, inability to maintain adequate hydration, or moderate to severe respiratory distress should be hospitalized. Hospitalization should be considered in infants under 6 months with suspected bacterial pneumonia, those in whom

there is a concern for a pathogen with increased virulence (e.g., methicillin-resistant *S. aureus*), or when concern exists about a family's ability to care for the child and to assess symptom progression.

Because viruses cause many community-acquired pneumonias in young children, not all children require empiric antibiotic treatment for pneumonia. Recommended therapies in those without recent antibiotic exposure are listed in [Table 110.1](#). Exceptional situations include lack of response to empiric therapy, unusually severe presentations, nosocomial pneumonia, and immunocompromised children susceptible to infections with opportunistic pathogens ([Table 110.3](#)). Presumed pneumococcal pneumonia can be treated with high-dose ampicillin therapy even with high-level penicillin resistance. Ceftriaxone and/or vancomycin can be used if the isolate shows high-level resistance and the patient is severely ill. For infants 2-18 weeks old with afebrile pneumonia most likely caused by *C. trachomatis*, a macrolide is the recommended treatment. Oseltamivir or zanamivir should be used if influenza is identified or suspected, ideally within 48 hours of symptom onset.

TABLE 110.3

Antimicrobial Therapy for Pneumonia Caused by Specific Pathogens*

PATHOGEN	RECOMMENDED TREATMENT	ALTERNATIVE TREATMENT
<i>Streptococcus pneumoniae</i> with MIC for penicillin ≤ 2.0 $\mu\text{g/mL}$	Ampicillin or penicillin IV; amoxicillin PO	Ceftriaxone, cefotaxime, clindamycin, or vancomycin IV; Cefuroxime, cefpodoxime, levofloxacin, [†] or linezolid PO
<i>S. pneumoniae</i> with MIC for penicillin ≥ 4.0 $\mu\text{g/mL}$	Ceftriaxone IV; levofloxacin [†] or linezolid PO	Ampicillin, levofloxacin, [†] clindamycin, or vancomycin IV; clindamycin PO
Group A streptococcus	Penicillin or ampicillin IV; amoxicillin or penicillin PO	Ceftriaxone, cefotaxime, clindamycin, or vancomycin IV; clindamycin PO
Group B streptococcus	Penicillin or ampicillin IV; amoxicillin or penicillin PO	Ceftriaxone, cefotaxime, clindamycin, or vancomycin IV; clindamycin PO
<i>Haemophilus influenzae</i>	Ampicillin IV or amoxicillin PO if β -lactamase negative; ceftriaxone or cefotaxime IV or amoxicillin-clavulanate PO if β -lactamase positive	Ciprofloxacin [†] or levofloxacin [†] IV; cefdinir, cefixime, or cefpodoxime PO
<i>Mycoplasma pneumoniae</i> , <i>Chlamydia pneumoniae</i> , or <i>Chlamydia trachomatis</i>	Azithromycin IV or PO	Erythromycin or levofloxacin IV; clarithromycin, erythromycin, doxycycline, [†] or a fluoroquinolone [†] PO
<i>Staphylococcus aureus</i> ,	Cefazolin, oxacillin, or nafcillin IV; cephalexin	Clindamycin or vancomycin IV;

methicillin susceptible (MSSA)	PO	clindamycin PO
<i>S. aureus</i> , methicillin resistant (MRSA)	Clindamycin or vancomycin IV; clindamycin PO	TMP-SMX or Linezolid IV or PO
Gram-negative aerobic bacilli (except <i>P. aeruginosa</i>)	Cefotaxime or ceftriaxone with or without an aminoglycoside IV; amoxicillin-clavulanate, cefdinir, or cefixime PO	Piperacillin-tazobactam plus an aminoglycoside [‡] ; fluoroquinolone [†] PO
<i>P. aeruginosa</i>	Ceftazidime IV with or without an aminoglycoside [‡] ; ciprofloxacin [†] if susceptible PO	Piperacillin-tazobactam IV with or without an aminoglycoside [‡]
Herpes simplex virus	Acyclovir IV	

*Oral outpatient therapy may be used for mild illness. Intravenous inpatient therapy should be used for moderate to severe illness.

†Appropriate respiratory fluoroquinolones include moxifloxacin, gatifloxacin, levofloxacin, and gemifloxacin. Fluoroquinolones are contraindicated for children younger than 18 years of age and pregnant or lactating women. Tetracyclines are not recommended for children younger than 9 years.

‡Aminoglycoside dosing should be guided by serum antibiotic concentrations after a steady state has been reached.

IV, Intravenous; MIC, minimum inhibitory concentration; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin susceptible *Staphylococcus aureus*; PO, per os (orally); TMP-SMX, trimethoprim-sulfamethoxazole.

Complications and Prognosis

Bacterial pneumonias frequently cause inflammatory fluid to collect in the adjacent pleural space, causing a **parapneumonic effusion** or, if grossly purulent, an **empyema**. Small effusions may not require any special therapy. Large effusions may restrict breathing and require drainage. Air dissection within lung tissue results in a **pneumatocele**. Scarring of the airways and lung tissue may leave dilated bronchi, resulting in **bronchiectasis** and increased risk for recurrent infection.

Pneumonia that causes necrosis of lung tissue may evolve into a **lung abscess**. Lung abscess is an uncommon problem in children and is usually caused by aspiration, infection behind an obstructed bronchus, or certain virulent organisms. Anaerobic bacteria usually predominate, along with various streptococci, *Escherichia coli*, *Klebsiella pneumoniae*, *P. aeruginosa*, and *S. aureus*. Chest radiograph or CT scan reveals a cavitary lesion, often with an air-fluid level, surrounded by parenchymal inflammation. If the cavity communicates with the bronchi, organisms may be isolated from sputum. Diagnostic bronchoscopy may be indicated to exclude a foreign body and obtain

microbiologic specimens. Lung abscesses usually respond to appropriate antimicrobial therapy with clindamycin, penicillin G, or ampicillin-sulbactam.

Most children recover from pneumonia rapidly and completely, although radiographic abnormalities may persist for 6-8 weeks. In a few children, symptoms may last longer than 1 month or may be recurrent. In such cases, the possibility of underlying disease must be investigated further, such as with the tuberculin skin test, sweat chloride determination for cystic fibrosis, serum immunoglobulin and IgG subclass determinations, bronchoscopy to identify anatomical abnormalities or foreign body, and barium swallow for gastroesophageal reflux.

Severe adenovirus pneumonia may result in **bronchiolitis obliterans**, a subacute inflammatory process in which the small airways are replaced by scar tissue, resulting in a reduction in lung volume and lung compliance. **Unilateral hyperlucent lung**, or **Swyer-James syndrome**, is a focal sequela of severe necrotizing pneumonia in which all or part of a lung has increased translucency radiographically; it has been linked to adenovirus type 21.

Prevention

Annual influenza vaccine is recommended for all children over 6 months of age (see [Chapter 94](#)). Trivalent or quadrivalent, inactivated influenza vaccines are licensed for use beginning at 6 months of age; live-attenuated vaccine can be used for persons 2-49 years of age. Universal childhood vaccination with conjugate vaccines for *H. influenzae* type b and *S. pneumoniae* has greatly diminished the incidence of these pneumonias. RSV infections can be prevented by use of palivizumab in some high-risk patients (see [Chapter 109](#)).

Reducing the duration of mechanical ventilation and administering antibiotics judiciously reduces the incidence of ventilator-associated pneumonias. The head of the bed should be raised to 30-45 degrees for intubated patients to minimize risk of aspiration, and all suctioning equipment and saline should be sterile. Handwashing before and after every patient contact and use of gloves for invasive procedures are important measures to prevent nosocomial transmission of infections. Hospital staff with respiratory illnesses or who are carriers of certain organisms, such as methicillin-resistant *S. aureus*, should comply with infection control policies to prevent transfer of organisms to patients. Treating sources of aerosols, such as air coolers, can prevent *L. pneumoniae*.

CHAPTER 111

Infective Endocarditis

Etiology

Infective endocarditis (IE) is an infection on the endothelial surface of the heart, including the heart valves. The management of infections on the endothelial surfaces of blood vessels (**endovascular infections**) is very similar. Turbulent flow from congenital heart disease or an indwelling central venous catheter can result in endothelial damage. Fibrin and platelets gather at the site, forming a thrombus. In the setting of transient bacteremia, this lesion can become infected and can result in a **vegetation**, which usually occurs on a valve leaflet and is composed of microorganisms trapped in a fibrin mesh that extends into the bloodstream.

Many microorganisms have been reported to cause endocarditis, although there are only a few common causes in children ([Table 111.1](#)). *Streptococcus viridans* is the principal cause in children with congenital heart diseases without previous surgery. *Staphylococcus aureus* and coagulase-negative staphylococci (CONS) are important causes of endocarditis, especially following cardiac surgery and in the presence of prosthetic cardiac and endovascular materials. Gram-negative endocarditis is rare. *Candida* species can cause fungal endocarditis, especially in premature infants with central venous catheters and/or on parenteral nutrition.

TABLE 111.1

Pathogens Causing Infective Endocarditis in Children

BACTERIA

Viridans *Streptococcus* groups: *S. sanguis*, *S. mitis*, *S. mutan*, *S. anginosus*, *S. salivarius*, *S. bovis*

Staphylococcus aureus

Enterococcus

Coagulase-negative staphylococci

Streptococci: groups A, B (in neonates and elderly), *Streptococcus pneumoniae*

Gram-negative enteric bacilli

HACEK organisms (i.e., *Haemophilus aphrophilus*, *Aggregatibacter species*, *Cardiobacterium hominis*, *Eikenella*)

corrodens, and *Kingella kingae*)

Chlamydophila

Coxiella burnetii (Q fever)

FUNGI

Candida species

CULTURE NEGATIVE

Fastidious organisms (*Abiotrophia* or *Granulicatella* species)

Bartonella species

Tropheryma whipplei

Coxiella burnetii (Q fever)

Epidemiology

Rheumatic heart disease used to be a major risk factor for IE but has become much less common. Patients at highest risk for IE include those with prosthetic cardiac valves and children who have cyanotic congenital heart disease, either with or without repair. The risk in these patients is increased after dental and oral procedures, instrumentation, or surgical procedures of the respiratory, genitourinary, or gastrointestinal tracts. Use of central vascular catheters is a significant risk factor for native valve endocarditis. Approximately 8-10% of IE in children occurs without structural heart disease (normal native valve) or other obvious risk factors. *S. aureus* is the most likely infective organism in these cases.

Clinical Manifestations

Decision-Making Algorithms

Heart Murmurs
Fever and Rash

The most common early symptoms of IE are nonspecific and include fever, malaise, and weight loss. Tachycardia and a new or changed heart murmur are common findings. The subtle and nonspecific findings underscore the need to obtain blood cultures if endocarditis is suspected, especially for children with

congenital heart disease and for unexplained illness after dental or surgical procedures. Endocarditis is often a subacute, slowly progressive process, but it can also present acutely with high fevers and a sepsis-like picture. Heart failure, splenomegaly, petechiae, glomerulonephritis, and embolic phenomena (Osler nodes, Roth spots, Janeway lesions, and splinter hemorrhages) may be present. In neonates, the signs and symptoms of IE may be especially subtle and variable, including feeding issues, respiratory distress, and hypotension, in addition to changes in the cardiac exam.

Laboratory Studies and Imaging

The key to diagnosis is confirming continuous bacteremia or fungemia by culturing the blood. Multiple blood cultures should be obtained before initiating antibiotic therapy. For optimal sensitivity, adequate volumes of blood should be obtained, 1-3 mL for infants and young children and at least 5-7 mL for older children. If volumes are not adequate, emphasis should be placed on obtaining aerobic blood cultures, as anaerobic organisms rarely cause IE. If possible, in patients who are not critically ill, empiric antibiotic therapy should be held until at least three sets of blood cultures (from different venipuncture sites) are obtained. Patients who have recently been treated with antibiotics or who are currently receiving antibiotics should have additional serial cultures performed. Despite adequate blood culture techniques, the microbiologic diagnosis is not confirmed in 5-15% of cases, known as **culture-negative endocarditis**.

The agent in culture-negative endocarditis may be identified by antibody testing and examination of the valve tissue (following surgery) by polymerase chain reaction (PCR) for bacterial (16S) or fungal (18S) ribosomal RNA.

Erythrocyte sedimentation rate and C-reactive protein are often elevated. Leukocytosis, anemia, and hematuria are common laboratory findings.

Echocardiography should be performed in all cases where IE is suspected. It can be used to visualize vegetations and assess valvular regurgitation and conduit flow. Transesophageal echocardiography (TEE) is more sensitive than transthoracic echocardiography (TTE) for adolescents and adults and for patients with prosthetic valves, but it is often unnecessary in children.

Differential Diagnosis

IE must be differentiated from other causes of bacteremia and other cardiac

conditions. The modified **Duke criteria** can be used to assist in the diagnosis of IE (Table 111.2). Noninfectious causes of endocardial vegetations must be excluded, such as sterile clots. Prolonged bacteremia can be caused by infectious endothelial foci outside of the heart, often associated with congenital vascular malformations, vascular trauma, an infected venous thrombosis, or previous vascular surgery.

TABLE 111.2

Modified Duke Clinical Criteria for Diagnosis of Infective Endocarditis

<p>DEFINITE INFECTIVE ENDOCARDITIS</p> <p>Histopathological Criteria</p> <p>Microorganisms shown by culture or histopathological examination in a vegetation, emboli, intracardiac abscess. <i>or</i> Active endocardial lesions on pathological examination</p> <p>Clinical Criteria</p> <p>Two major criteria <i>or</i> one major and three minor criteria <i>or</i> five minor criteria</p> <p>Major Criteria</p> <p>Positive blood cultures</p> <p>Two or more separate cultures positive with typical organisms for infective endocarditis</p> <p>Two or more positive cultures of blood drawn more than 12 hr apart or 4 positive blood cultures irrespective of timing of obtaining specimen</p> <p>A positive blood culture for <i>Coxiella burnetii</i> or positive IgG titer >1 : 800</p> <p>Evidence of endocardial involvement</p> <p>Positive findings on echocardiogram (vegetation on valve or supporting structure, abscess, new valvular regurgitation)</p> <p>Minor Criteria</p> <p>Predisposition—predisposing heart condition or injection drug use</p> <p>Fever—temperature >38°C (>100.4°F)</p> <p>Vascular phenomena (major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway lesions)</p> <p>Immunological phenomena (glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor)</p> <p>Microbiologic evidence (positive blood culture result, but not meeting major criteria, or serological evidence of active infection with organism consistent with infective endocarditis)</p> <p>POSSIBLE INFECTIVE ENDOCARDITIS</p> <p>Clinical Criteria</p> <p>One major and one minor criteria or three minor criteria</p> <p>REJECTED</p> <p>Firm alternative diagnosis for manifestations of endocarditis <i>or</i></p> <p>Resolution of manifestations of endocarditis with antibiotic therapy for <4 days <i>or</i></p> <p>No pathological evidence of endocarditis at surgery or autopsy after antibiotic therapy of >4 days <i>or</i> does not meet criteria</p>

Modified from Tissieres P, Gervaix A, Beghetti M, et al. Value and limitations of the van Reyn, Duke, and modified Duke criteria for the diagnosis of infective endocarditis in children. *Pediatrics*. 2003;112:e467–e471.

Treatment

Severely ill patients must be stabilized with supportive therapies for cardiac failure, pulmonary edema, and low cardiac output (see [Chapter 145](#)). Empirical antibiotic therapy may be started for acutely ill patients after blood cultures are obtained. With subacute disease, awaiting results of blood cultures to confirm the diagnosis is recommended to direct therapy according to the susceptibility of the isolate. Because antibiotics must reach the organisms by passive diffusion through the fibrin mesh, high doses of bactericidal antibiotics are required for an extended period of treatment (4-8 weeks). Exact duration of therapy varies depending on the presence of prosthetic material and the causative organism. *Staphylococcus aureus* bacteremia can be persistent, and if associated with an indwelling catheter, requires line removal in most cases. Surgery is indicated if medical treatment is unsuccessful, if bacteremia is persistent, or if the pathogen is unusual or difficult to treat (e.g., fungal endocarditis). Surgical intervention may also be required with the presence of a valve annulus or myocardial abscess, rupture of a valve leaflet, valvular insufficiency with acute or refractory heart failure, recurrent serious embolic complications, or refractory prosthetic valve disease.

Complications and Prognosis

The major complications of IE are direct damage to cardiac tissue and function and distant complications secondary to **septic emboli** from vegetations. Damage to cardiac valves may cause regurgitation, defects in valve leaflets, abscess of the valve ring, or myocardial abscess. Cardiac function can decline, resulting in heart failure. These complications should be monitored by physical examination and echocardiography. Septic emboli can result in pneumonia, osteomyelitis, and abscesses in the brain, kidneys, and spleen.

The prognosis of IE varies depending on causative organism and underlying cardiac condition. Cardiovascular infections with gram-negative bacilli and fungi have the poorest prognosis.

Prevention

Good oral hygiene should be emphasized in all patients at risk for IE. In certain high-risk patients (unrepaired cyanotic heart disease, previous IE, repaired congenital heart disease with residual defects, cardiac transplantation), prophylactic antibiotics may be considered before certain dental and other invasive procedures of the respiratory tract and/or infected skin or muscle.

CHAPTER 112

Acute Gastroenteritis

Etiology and Epidemiology

Acute gastroenteritis refers to a clinical syndrome of diarrhea (>3 stool episodes in 24 hours) with or without vomiting that generally lasts for several days. In general, diarrhea is caused by a variety of infectious or inflammatory processes in the intestine that directly affect enterocyte secretory and absorptive functions. Gastroenteritis or enteritis has many infectious causes, including viruses, bacteria, and parasites (Table 112.1). Based on pathogenesis, diarrhea can be classified as invasive or inflammatory, or it can be classified as secretory, producing either bloody stools with abdominal cramping and fever or large quantities of watery stool without other symptoms (Table 112.2).

TABLE 112.1

Common Pathogenic Organisms Causing Diarrhea and Their Virulence Mechanisms

ORGANISMS	PATHOGENIC MECHANISM(S)
VIRUSES	
Rotaviruses	Damage to microvilli
Caliciviruses (noroviruses)	Mucosal lesion
Astroviruses	Mucosal lesion
Enteric adenoviruses (serotypes 40 and 41)	Mucosal lesion
BACTERIA	
<i>Campylobacter jejuni</i>	Invasion, enterotoxin
<i>Clostridium difficile</i>	Cytotoxin, enterotoxin
<i>Escherichia coli</i>	
Enteropathogenic (EPEC)	Adherence, effacement
Enterotoxigenic (ETEC) (traveler's diarrhea)	Enterotoxins (heat-stable or heat-labile)
Enteroinvasive (EIEC)	Invasion of mucosa
Enterohemorrhagic (EHEC) (includes O157: H7)	Adherence, effacement, cytotoxin

causing HUS)	
Enteroaggregative (EAEC)	Adherence, mucosal damage
<i>Salmonella</i>	Invasion, enterotoxin
<i>Shigella</i>	Invasion, enterotoxin, cytotoxin
<i>Vibrio cholerae</i>	Enterotoxin
<i>Vibrio parahaemolyticus</i>	Invasion, cytotoxin
<i>Yersinia enterocolitica</i>	Invasion, enterotoxin
PARASITES	
<i>Entamoeba histolytica</i>	Invasion, enzyme and cytotoxin production; cyst resistant to physical destruction
<i>Giardia lamblia</i>	Adheres to mucosa; cyst resistant to physical destruction
Spore-forming intestinal protozoa <i>Cryptosporidium parvum</i> <i>Isospora belli</i> <i>Cyclospora cayetanensis</i>	Adherence, inflammation
Microsporidia (<i>Enterocytozoon bieneusi</i> , <i>Encephalitozoon intestinalis</i>)	

HUS, Hemolytic uremic syndrome.

TABLE 112.2

Mechanisms of Infectious Diarrhea

PRIMARY MECHANISM	DEFECT	STOOL EXAMINATION	EXAMPLES	COMMENTS
Secretory	Decreased absorption, increased secretion: electrolyte transport	Watery, normal osmolality	Cholera, toxigenic <i>Escherichia coli</i> (EPEC, ETEC); carcinoid, <i>Clostridium difficile</i> , cryptosporidiosis (in AIDS)	Persists during fasting; bile salt malabsorption also may increase intestinal water secretion; no stool leukocytes
Mucosal invasion	Inflammation, decreased mucosal surface area and/or colonic reabsorption, increased motility	Blood and increased WBCs in stool	Celiac disease, <i>Salmonella</i> infection, shigellosis, amebiasis, yersiniosis, <i>Campylobacter</i> infection	Dysentery (blood, mucus, and WBCs)

WBCs, White blood cells; infection may also contribute to increased motility.

From Wyllie R. Major symptoms and signs of digestive tract disorders. In: Kliegman RM, Behrman RE, Jenson HB, eds. *Nelson Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders; 2007:152. Table 303.7.

Infectious diarrhea is a leading cause of morbidity and mortality in children around the world. Rates of disease and death vary with age and access to health care, clean water, and sanitation. Gastrointestinal infections are generally acquired via fecal-oral transmission or through ingestion of contaminated food or water. The patient's immune status and environmental exposures (i.e., food, water, travel, antibiotics, child care) help guide the differential diagnosis in the presence of acute gastrointestinal symptoms. Traveler's diarrhea occurs frequently, especially within the first 1-2 weeks of arrival. Epidemiology varies with destination, but in general children are at risk for the same illnesses that affect adult travelers.

Viral gastroenteritis is the most common cause of diarrhea in children globally. These illnesses may be associated with vomiting as well as diarrhea, have incubation periods of hours to days, and are usually self-limited illnesses lasting 3-7 days. **Rotavirus** is the most frequent cause of diarrhea in young children during the winter months. Primary infection with rotavirus may cause moderate to severe disease in infancy but is less severe later in life. The rotavirus vaccine has resulted in significant reductions in the incidence of acute gastroenteritis and hospitalizations due to rotavirus. **Norovirus** occurs in people of all ages, year round, and is the most common cause of outbreaks of acute gastroenteritis because it is highly contagious. Other viral causes of acute gastroenteritis include astroviruses, sapovirus, and enteric adenoviruses (serotypes 40 and 41).

Food-borne and water-borne diseases are important causes of acute gastroenteritis both for individual and public health reasons. In the United States, the most common bacterial food-borne causes (in order of frequency) are nontyphoidal *Salmonella*, *Campylobacter*, *Shigella*, *Escherichia coli* O157:H7, *Yersinia*, *Listeria monocytogenes*, and *Vibrio cholerae*. Food-borne diarrhea can also result from ingestion of preformed enterotoxins produced by bacteria, such as *Staphylococcus aureus* and *Bacillus cereus*, which multiply in contaminated foods, and nonbacterial toxins such as from fish, shellfish, and mushrooms. After a short incubation period, vomiting and cramps are prominent symptoms, and diarrhea may or may not be present. Heavy metals that leach into canned food or drinks causing gastric irritation and emetic syndromes may mimic symptoms of acute infectious enteritis.

Nontyphoidal *Salmonella* produces diarrhea by invading the intestinal mucosa. The organisms are transmitted through contact with infected animals (chickens, iguanas, other reptiles, turtles) or from contaminated food products,

such as dairy products, eggs, and poultry. A large inoculum of organisms is required for disease because *Salmonella* is killed by gastric acidity. The incubation period for gastroenteritis ranges from 6 to 72 hours but is usually less than 24 hours.

Shigella dysenteriae may cause disease by producing **Shiga toxin**. The incubation period is 1-7 days. Infected adults may shed organisms for 1 month. Infection is spread by person-to-person contact or by the ingestion of contaminated food with 10-100 organisms. The colon is selectively affected. High fever and febrile seizures may occur in addition to diarrhea.

Only certain strains of *E. coli* produce diarrhea. Strains associated with enteritis are classified by the mechanism of diarrhea: enterotoxigenic (ETEC), enterohemorrhagic (EHEC) or Shiga toxin-producing (STEC), enteroinvasive (EIEC), enteropathogenic (EPEC), or enteroaggregative (EAEC). ETEC strains produce **heat-labile (cholera-like) enterotoxin, heat-stable enterotoxin**, or both. ETEC is a frequent cause of **traveler's diarrhea**. ETEC adhere to the epithelial cells in the upper small intestine and produces disease by liberating toxins that induce intestinal secretion and limit absorption. EHEC or STEC, especially the *E. coli* O157:H7 strain, produces a **Shiga-like toxin** that is responsible for a hemorrhagic colitis and most cases of diarrhea associated with **hemolytic uremic syndrome (HUS)**, which presents with microangiopathic hemolytic anemia, thrombocytopenia, and renal failure (see [Chapter 164](#)). STEC is associated with contaminated food, including unpasteurized fruit juices and especially undercooked beef, and can present with nonbloody diarrhea that then becomes bloody. EIEC invades the colonic mucosa, producing widespread mucosal damage with acute inflammation similar to *Shigella*. EIEC diarrhea is usually watery and is often associated with fever. EPEC causes mild watery diarrhea but can cause severe dehydration in young children in resource-poor countries in sporadic or epidemic patterns.

Campylobacter jejuni is spread by person-to-person contact and by contaminated water and food, especially poultry, raw milk, and cheese. The organism invades the mucosa of the jejunum, ileum, and colon. *Yersinia enterocolitica* is transmitted by pets and contaminated food, especially chitterlings. Infants and young children characteristically have a diarrheal disease, whereas older children usually have acute lesions of the terminal ileum or acute mesenteric lymphadenitis mimicking appendicitis or Crohn disease. Postinfectious arthritis, rash, and spondylopathy may develop.

Clostridium difficile causes diarrhea and/or colitis and is usually associated

with prior antibiotic exposure. The organism produces spores that spread from person to person and also as fomites on surfaces. Infection is generally hospital-acquired, but community acquisition of infection is increasingly reported. Diagnosis is made by detection of toxin in the stool. Infants <12 months of age should not be tested for *C. difficile* as they are frequently asymptotically colonized with the organism in their stool, possibly due to a lack of the receptor required for infection. Of note, patients on antibiotics often experience diarrhea related to alterations in their intestinal flora that are unrelated to *C. difficile* infection.

Important enteric parasites found in North America include *Entamoeba histolytica* (amebiasis), *Giardia lamblia*, and *Cryptosporidium parvum*. **Amebiasis** occurs in warmer climates, whereas giardiasis is endemic throughout the United States and is common among infants in daycare centers. *E. histolytica* infects the colon; amebae may pass through the bowel wall and invade the liver, lung, and brain. Diarrhea is of acute onset, is bloody, and contains leukocytes. **G. lamblia** is transmitted through ingestion of cysts, either from contact with an infected individual or from food or freshwater or well water contaminated with infected feces. The organism adheres to the microvilli of the duodenal and jejunal epithelium. Insidious onset of progressive anorexia, nausea, gaseousness, abdominal distention, watery diarrhea, secondary lactose intolerance, and weight loss is characteristic of giardiasis. **Cryptosporidium** causes mild, watery diarrhea in immunocompetent persons that resolves without treatment. It produces severe, prolonged diarrhea in persons with acquired immunodeficiency syndrome (AIDS; see [Chapter 125](#)).

Clinical Manifestations

Decision-Making Algorithms

Vomiting
Diarrhea
Edema
Eosinophilia

Gastroenteritis may be accompanied by systemic findings, such as fever,

lethargy, myalgias, and abdominal pain. **Viral diarrhea** is characterized by watery stools with no blood or mucus. Vomiting may be present and dehydration may be prominent, especially in infants and younger children. Fever, when present, is low grade.

Dysentery is enteritis involving the colon and rectum, with blood and mucus, possibly foul-smelling stools, and fever. *Shigella* is the prototypical cause of dysentery, which must be differentiated from infection with EIEC, EHEC, *E. histolytica* (**amebic dysentery**), *C. jejuni*, *Y. enterocolitica*, and nontyphoidal *Salmonella*. Gastrointestinal bleeding and blood loss may be significant.

A chief consideration in management of a child with diarrhea is assessing the degree of dehydration as evident from clinical signs and symptoms, ongoing losses, and daily requirements (see [Chapter 33](#)). The degree of dehydration dictates the urgency of the situation and the volume of fluid needed for rehydration. Mild to moderate dehydration can usually be treated with oral rehydration; severe dehydration usually requires intravenous rehydration and may even require admission to an intensive care unit.

Laboratory and Imaging Studies

Initial laboratory evaluation of moderate to severe diarrhea includes electrolytes, blood urea nitrogen, creatinine, and urinalysis for specific gravity as an indicator of hydration. Stool specimens should be examined for mucus, blood, and leukocytes, which indicate colitis in response to bacteria that diffusely invade the colonic mucosa. Patients infected with Shiga toxin–producing *E. coli* and *E. histolytica* generally have minimal fecal leukocytes.

Viral polymerase chain reaction (PCR)—also called the nucleic acid amplification test (NAAT)—assays may be used if the diagnosis will alter management. Bacterial stool cultures are recommended for patients with fever, profuse diarrhea, and dehydration or if HUS or pseudomembranous colitis is suspected. If the stool test result is negative for blood and leukocytes and there is no history to suggest contaminated food ingestion, a viral etiology is most likely. Stool evaluation for parasitic agents should be considered for acute dysenteric illness, especially in returning travelers, and in protracted cases of diarrhea in which no bacterial agent is identified. The diagnosis of *E. histolytica* is based on identification of the organism in the stool. Serological tests are useful for diagnosis of extraintestinal amebiasis, including amebic hepatic abscess. Giardiasis can be diagnosed by identifying trophozoites or cysts in stool, but this

may require three specimens. More specific and sensitive fecal immunoassays and NAATs are the diagnostic tests of choice.

Positive blood cultures are uncommon with bacterial enteritis except for *Salmonella* and *E. coli* enteritis in very young infants. In typhoid fever, blood cultures are positive early in the disease, whereas stool cultures become positive only after the secondary bacteremia.

Differential Diagnosis

Decision-Making Algorithms

Abdominal Pain
Vomiting
Diarrhea
Failure to Thrive

Diarrhea can be caused by infection, toxins, gastrointestinal allergy (including allergy to milk or soy proteins), malabsorption defects, inflammatory bowel disease, celiac disease, or any injury to enterocytes. Acute enteritis may mimic other acute diseases, such as intussusception and acute appendicitis, which are best identified by diagnostic imaging. Many noninfectious causes of diarrhea produce chronic diarrhea, with persistence for more than 14 days. Persistent or chronic symptoms may require tests for malabsorption or invasive studies, including endoscopy and small bowel biopsy.

Treatment

Most infectious causes of diarrhea in children are self-limited. Antibiotics are not generally useful and may be a risk factor in the development of HUS when *E. coli* O157:H7 is present. Management of viral and most bacterial causes of diarrhea is primarily supportive and consists of correcting dehydration and ongoing fluid and electrolyte deficits.

Hyponatremia is common; hypernatremia is less common. Metabolic acidosis results from losses of bicarbonate in stool, lactic acidosis results from shock, and phosphate retention results from transient prerenal-renal insufficiency.

Traditionally therapy for 24 hours with oral rehydration solutions alone is effective for viral diarrhea. Therapy for severe fluid and electrolyte losses involves intravenous hydration. Less severe degrees of dehydration (<10%) in the absence of excessive vomiting or shock may be managed with oral rehydration solutions containing glucose and electrolytes. Ondansetron may be administered to reduce emesis when this is persistent.

Antibiotic therapy may be necessary for high-risk patients or those with severe disease or bacteremia. Antibiotic treatment of *Shigella* may reduce the duration of symptoms and decrease transmission of infection. Azithromycin is first-line oral therapy for children. Many *Shigella sonnei* isolates, the predominant strain affecting children, are resistant to amoxicillin and trimethoprim-sulfamethoxazole. Fluoroquinolone resistance in *Salmonella* and many other gram-negative organisms is increasing in many parts of the world. *Salmonella* is treated with antibiotics in children less than 3 months of age.

Treatment of traveler's diarrhea is generally supportive, although antibiotics can be indicated in instances of bloody diarrhea or a febrile illness, in which case azithromycin is a recommended choice for children. Due to lack of consistent access to health care in many areas, providing a prescription to a family in advance of travel to a high-risk area such as in Asia, Africa, or South America may be considered.

Treatment of *C. difficile* (pseudomembranous colitis) includes discontinuation of the inciting antibiotic and oral metronidazole or vancomycin. *E. histolytica* dysentery is treated with metronidazole followed by a luminal agent, such as iodoquinol. The treatment of *G. lamblia* is metronidazole, tinidazole, or nitazoxanide.

Complications and Prognosis

The major complication of gastroenteritis is dehydration and hypovolemic shock. Seizures may occur with high fever, especially with *Shigella*. Intestinal abscesses can form with *Shigella*, *Yersinia*, and *Salmonella* infections, leading to intestinal perforation, a life-threatening complication. Severe vomiting associated with gastroenteritis can cause esophageal tears or aspiration pneumonia.

Deaths resulting from diarrhea reflect the principal problem of disruption of fluid and electrolyte homeostasis, which can lead to dehydration, electrolyte imbalance, hemodynamic instability, and shock. Diarrheal diseases cause

approximately 10% of childhood deaths worldwide.

Prevention

The most important means of preventing childhood diarrhea is the provision of clean, uncontaminated water and proper hygiene in growing, collecting, and preparing foods. Good hygienic measures, especially appropriate handwashing with soap and water, are the best means of controlling person-to-person spread of most organisms causing gastroenteritis. Poultry products should be considered potentially contaminated with *Salmonella* and should be handled and cooked appropriately. Families should also be aware of the risk of acquiring salmonellosis from household reptile pets. Transmission of *Salmonella* from reptiles can be prevented by thorough handwashing after handling the animals or their cages. Children under 5 years of age and immunocompromised persons should avoid contact with reptiles.

Immunization against rotavirus infection is recommended for all children beginning at 6 weeks of age, with the first dose by 14 weeks 6 days and the last dose by 8 months (see [Chapter 94](#)). Two typhoid vaccines are licensed in the United States: an oral live-attenuated vaccine (Ty21a) for children 6 years of age and older and a capsular polysaccharide vaccine (ViCPS) for intramuscular administration for children 2 years of age and older. These are recommended for travelers to endemic areas of developing countries or for household contacts of *S. typhi* chronic carriers.

The risk for traveler's diarrhea, caused primarily by ETEC, may be minimized by avoiding uncooked food and untreated drinking water. Symptomatic self-treatment for mild diarrhea with an **oral rehydration solution** is recommended for children at least 6 years of age and adults. Self-treatment of moderate diarrhea and fever with a fluoroquinolone is recommended in adults. Similarly, children can receive azithromycin. Prompt medical evaluation is indicated for disease persisting more than 3 days, bloody stools, fever above 102°F (38.9°C) or chills, persistent vomiting, or moderate to severe dehydration.

CHAPTER 113

Viral Hepatitis

Etiology

Acute hepatitis, or liver inflammation, can be the result of a number of infectious and noninfectious etiologies. Among infectious causes of hepatitis, viruses play an important role. The six primary hepatotropic viruses, hepatitis A to G, differ in their virological characteristics, transmission, severity, likelihood of persistence, and subsequent risk of causing hepatocellular carcinoma ([Table 113.1](#)). The cause of 10-15% of cases of acute hepatitis is unknown.

TABLE 113.1

Characteristics of Agents Causing Acute Viral Hepatitis

FEATURE	HAV	HBV	HCV	HDV	HEV	HGV
Viral structure	27-nm ssRNA virus	42-nm dsDNA virus	30- to 60-nm ssRNA virus	36-nm circular ssRNA hybrid particle with HBsAg coat	27- to 34-nm ssRNA virus	50- to 100-nm ssRNA virus
Family	Picornavirus	Hepadnavirus	Flavivirus	Satellite	Flavivirus	Flavivirus
Transmission	Fecal-oral, rarely parenteral	Transfusion, sexual, inoculation, perinatal	Parenteral, transfusion, perinatal	Similar to HBV	Fecal-oral (endemic and epidemic)	Parenteral, transfusion
Incubation period	15-30 days	60-180 days	30-60 days	Coinfection with HBV	35-60 days	Unknown
Serum markers	Anti-HAV	HBsAg, HBcAg, HBeAg, anti-HBs, anti-HBc	Anti-HCV (IgG, IgM), RIBA, PCR assay for HCV RNA	Anti-HDV, RNA	Anti-HEV	RNA by RT-PCR assay
Fulminant liver failure	Rare	<1% unless coinfection with HDV	Uncommon	2-20%	20%	Probably no
Persistent infection	No	5-10% (90% with perinatal infection)	85%	2-70%	No	Persistent infection common; chronic disease rare
Increased risk of hepatocellular carcinoma	No	Yes	Yes	No	No	Unknown

Prophylaxis	Vaccine: immune serum globulin	Vaccine: hepatitis B immunoglobulin (HBIG)			
-------------	---	--	--	--	--

dsDNA, Double-stranded DNA; *HAV*, hepatitis A virus; *HBV*, hepatitis B virus; *HCV*, hepatitis C virus; *HDV*, hepatitis D virus; *HEV*, hepatitis E virus; *HGV*, hepatitis G virus; *PCR*, polymerase chain reaction; *RIBA*, recombinant immunoblot assay; *RT-PCR*, reverse transcriptase–polymerase chain reaction; *ssDNA/ssRNA*, single-stranded DNA/RNA; *TTV*, transfusion-transmitted virus.

Epidemiology

Hepatitis A virus (HAV) is the most common cause of acute viral hepatitis and is spread by fecal-oral transmission. HAV is common in children globally, especially in areas of poor sanitation. Among U.S. children, infection due to HAV was often associated with childcare settings; however, rates have decreased since the introduction of routine vaccination. Hepatitis B virus (HBV), hepatitis C virus (HCV), and hepatitis D virus (HDV) infections can result in chronic hepatitis, or a chronic carrier state, which facilitates spread. HDV, also known as the **delta agent**, is a defective virus that requires HBV for spread and causes either coinfection with HBV or superinfection in chronic carriers of hepatitis B surface antigen (HBsAg). Routine vaccination has also been effective in reducing the rates of HBV infection, especially in children.

The major risk factors for HBV and HCV are injectable drug use, frequent exposure to blood products, and perinatal transmission from maternal infection. Hepatitis E virus (HEV) infection occurs following travel to endemic areas (South Asia) outside of the United States. Hepatitis G virus (HGV) is prevalent in HIV-infected persons. HBV and HCV cause chronic infection, which may lead to cirrhosis and hepatocellular carcinoma and represents a persistent risk of transmission.

Clinical Manifestations

Decision-Making Algorithms

Jaundice
Hepatomegaly
Fever Without a Source

Asymptomatic or mild, nonspecific illness without icterus is common with HAV, HBV, and HCV, especially in young children. When present, symptoms of acute infection are difficult to distinguish between these viruses. Younger children are often asymptomatic when infected with HAV, HBV, and HCV. Fulminant HAV infection is rare, and chronic infection does not occur. In acute HBV infection the likelihood of symptoms increases with age, ranging from 1% of infants <12 months of age to 30-50% of people >5 years. In HBV infection, the **preicteric phase**, which lasts approximately 1 week, is characterized by headache, anorexia, malaise, abdominal discomfort, nausea, and vomiting; it usually precedes the onset of clinically detectable disease. Extrahepatic manifestations such as arthralgia, arthritis, rash, thrombocytopenia, glomerulonephritis, or papular acrodermatitis (**Gianotti-Crosti syndrome**) can occur early in the illness. Jaundice and tender hepatomegaly occur later and characterize the **icteric phase**. Prodromal symptoms, particularly in children, may abate during the icteric phase. Hepatic enzymes may increase 15- to 20-fold. Resolution of the hyperbilirubinemia and normalization of the transaminases may take 6-8 weeks.

Laboratory and Imaging Studies

Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels are elevated and generally reflect the degree of parenchymal inflammation. Alkaline phosphatase and total and direct (conjugated) bilirubin levels indicate the degree of cholestasis, which results from hepatocellular and bile duct damage. The prothrombin time is a good predictor of severe hepatocellular injury and progression to fulminant hepatic failure (see [Chapter 130](#)).

The diagnosis of viral hepatitis is confirmed by serological testing (see [Table 113.1](#) and [Fig. 113.1](#)). The presence of IgM-specific antibody to HAV with low or absent IgG antibody is presumptive evidence of acute HAV infection.

Hepatitis A

Hepatitis B

Hepatitis C

FIGURE 113.1 Clinical course and laboratory findings associated with hepatitis A, hepatitis B, and hepatitis C. *ALT*, Alanine aminotransferase; *HAV*, hepatitis A virus; *anti-HBc*, antibody to hepatitis B core antigen; *HBeAg*, hepatitis B early antigen; *anti-HBe*, antibody to hepatitis B early antigen; *HBsAg*, hepatitis B surface antigen; *anti-HBs*, antibody to hepatitis B surface antigen; *HCV*, hepatitis C virus; *PCR*, polymerase chain reaction.

The presence of HBsAg signifies acute or chronic infection with HBV. Antigenemia appears early in the illness and is usually transient but is characteristic of chronic infection. Maternal HBsAg status should always be determined when HBV infection is diagnosed in children younger than 1 year of age because of the likelihood of vertical transmission. Hepatitis B early antigen (HBeAg) appears in the serum with acute HBV. The continued presence of HBsAg and HBeAg in the absence of antibody to e antigen (anti-HBe) indicates high risk of transmissibility that is associated with ongoing viral replication. Clearance of HBsAg from the serum precedes a variable **window period**, followed by the emergence of the antibody to surface antigen (anti-HBs), which indicates development of lifelong immunity and is also a marker of immunization. Antibody to core antigen (anti-HBc) is a useful marker for recognizing HBV infection during the window phase (when HBsAg has disappeared but before the appearance of anti-HBs). Anti-HBe is useful in predicting a low degree of infectivity during the carrier state.

Seroconversion after HCV infection may occur 6 months after infection. A positive result of HCV enzyme-linked immunosorbent assay (ELISA) should be confirmed with the more specific recombinant immunoblot assay, which detects antibodies to multiple HCV antigens. Detection of HCV RNA by polymerase chain reaction (PCR) is a sensitive marker for active infection, and results may be positive just 3 days after inoculation.

Differential Diagnosis

Many other viruses may cause hepatitis as a component of systemic infection, including Epstein–Barr virus, cytomegalovirus, varicella-zoster virus, herpes simplex virus, and adenoviruses. Bacterial sepsis can also cause hepatic inflammation and dysfunction. Patients with cholecystitis, cholangitis, and choledocholithiasis may present with acute symptoms and jaundice. Other causes of acute liver disease in childhood include drugs (isoniazid, phenytoin, valproic acid, carbamazepine, oral contraceptives, acetaminophen), parenteral

nutrition, toxins (ethanol, poisonous mushroom), Wilson disease, metabolic disease (galactosemia, tyrosinemia, mitochondrial disorders), α_1 -antitrypsin deficiency, tumor, shock, anoxia, autoimmune hepatitis, hemophagocytic syndromes, and graft-versus-host disease (see [Chapter 130](#)).

Treatment

The treatment of acute hepatitis is largely supportive and involves rest, hydration, and adequate nutrition. Hospitalization is indicated for children with severe vomiting and dehydration, a prolonged prothrombin time, or signs of hepatic encephalopathy. When the diagnosis of viral hepatitis is established, attention should be directed toward preventing its spread to close contacts. For HAV, hygienic measures include handwashing and careful disposal of excreta, contaminated diapers or clothing, needles, and other blood-contaminated items.

The treatment of chronic HBV and HCV infections is evolving with the development of new antivirals. The decision to treat is based on the patient's age, viral genotype, and stage of viral infection.

Complications and Prognosis

Most cases of acute viral hepatitis resolve without specific therapy, with less than 0.1% of cases progressing to fulminant hepatic necrosis. HAV and HEV cause acute infection only. HBV, HCV, and HDV may persist as chronic infection, with chronic inflammation, fibrosis, and cirrhosis and the associated risk of hepatocellular carcinoma.

From 5 to 10% of adults with HBV develop persistent infection, defined by persistence of HBsAg in the blood for more than 6 months, compared with 90% of children who acquire HBV by perinatal transmission. Chronic HBsAg carriers are usually HBeAg-negative and have no clinical, biochemical, or serological evidence of active hepatitis unless there is superinfection with HDV. Approximately 10-15% of HBsAg carriers eventually clear HBsAg.

Approximately 85% of persons infected with HCV remain chronically infected, which is characterized by fluctuating transaminase levels (see [Fig. 113.1](#)). There is poor correlation of symptoms with ongoing liver damage. Approximately 20% of persons with chronic infection develop cirrhosis, and approximately 25% of those develop hepatocellular carcinoma. HIV infection and ethanol use increase the risk of HCV progression.

Prevention

Good hygienic practices significantly reduce the risk of fecal–oral transmission of HAV. HAV vaccine is recommended for routine immunization of all children beginning at 12 months. Unvaccinated household and sexual contacts of persons with HAV should receive postexposure prophylaxis as soon as possible and within 2 weeks of the last exposure. A single dose of HAV vaccine at the age-appropriate dose is preferred for persons 12 months to 40 years of age. Immunoglobulin (0.02 mL/kg) given intramuscularly (IGIM) is preferred for children under 12 months of age, persons over 40 years of age, and immunocompromised persons. For preexposure prophylaxis, unvaccinated travelers to endemic regions who are 12 months of age or older should also receive a single dose of HAV vaccine administered at any time before departure. Infants <12 months of age, older adults, immunocompromised people, or those with chronic liver disease or other chronic medical conditions can receive IGIM along with the HAV vaccine dose to optimize protection. This regimen can also be considered for travel <2 weeks in the future.

HBV vaccine is recommended for routine immunization of all infants beginning at birth and for all children and adolescents through 18 years of age who have not been immunized previously (see [Fig. 94.1](#)). It is also recommended as a preexposure vaccination for older children and adults at increased risk of sexual, percutaneous, or mucosal exposure to HBV as well as those with chronic liver disease, human immunodeficiency virus (HIV), and travelers to areas of endemic HBV infection. Routine prenatal screening for HBsAg is recommended for all pregnant women in the United States. Infants born to HBsAg-positive mothers should receive HBV vaccine and hepatitis B immunoglobulin (HBIG; 0.5 mL) within 12 hours of birth, with subsequent vaccine doses at 1 and 6 months of age followed by testing for HBsAg and anti-HBs at 9-15 months of age. Infants born to mothers whose HBsAg status is unknown should receive vaccine within 12 hours of birth. If maternal testing is positive for HBsAg, the infant should receive HBIG as soon as possible (no later than 1 week of age). The combination of HBIG and vaccination is 99% effective in preventing vertical transmission of HBV. Vaccination alone without HBIG may prevent 75% of cases of perinatal HBV transmission and approximately 95% of cases of symptomatic childhood HBV infection.

Postexposure prophylaxis of unvaccinated persons using HBIG and vaccine is recommended following needle-stick injuries with blood from an HBsAg-

positive patient and for sexual or needle-sharing contacts or victims of sexual abuse by an HBsAg-positive person. The screening of blood donors significantly reduces the risk of blood-borne transmission.

CHAPTER 114

Urinary Tract Infection

Etiology

Urinary tract infections (UTIs) include **cystitis** (infection localized to the bladder), **pyelonephritis** (infection of the renal parenchyma, calyces, and renal pelvis), and **renal abscess**, which may be intrarenal or perinephric. The urinary tract and urine are normally sterile. *Escherichia coli*, ascending from bowel (perineum) flora, accounts for 85% of first infections. Other bacteria commonly causing infection include *Klebsiella*, *Proteus*, *Enterococcus*, *Pseudomonas*, and *Enterobacter*. *Staphylococcus saprophyticus* is associated with UTI in some children and accounts for $\geq 15\%$ of UTIs in adolescent girls. *Staphylococcus aureus* is an uncommon cause of UTI and usually represents bacteremic seeding of the urinary tract.

Epidemiology

Approximately 3% of girls and 1% of boys have a UTI during their prepubertal years with the highest incidence in the first year of life. It is only during the first year of life that the incidence of UTIs in males exceeds that in females; during this period uncircumcised boys are at 10-fold greater risk of developing a UTI compared to circumcised boys. After 12 months of age, UTI in healthy children usually is seen in girls.

A short urethra predisposes girls to UTIs. Obstruction to urine flow and urinary stasis is the major risk factor and may result from anatomical abnormalities, nephrolithiasis, renal tumor, indwelling urinary catheter, ureteropelvic junction obstruction, megaureter, extrinsic compression, and pregnancy. Severe vesicoureteral reflux, whether primary or secondary to urinary tract obstruction, predisposes to chronic infection and renal scarring. Scarring

may also develop in the absence of reflux. Constipation or withholding urine also increases the risk of UTI.

Clinical Manifestations

Decision-Making Algorithms

Dysuria
Enuresis
Red Urine and Hematuria

The symptoms and signs of UTI vary markedly with age. Few have high positive predictive value in neonates, with failure to thrive, feeding problems, and fever as the most consistent symptoms. Infants 1 month to 2 years of age may present with feeding problems, failure to thrive, diarrhea, vomiting, or unexplained fever. The symptoms may masquerade as gastrointestinal illness, with colic, irritability, and crying periods. At 2 years of age, children begin to show the classic signs of UTI, such as urgency, dysuria, frequency, and abdominal or back pain. The presence of UTI should be suspected in all infants and young children with unexplained fever and in patients of all ages with fever and congenital anomalies of the urinary tract.

Laboratory and Imaging Studies

The diagnosis of UTI in infants and young children requires the presence of both pyuria and at least 50,000 CFU/mL of a single pathogenic organism. For older children and adolescents, >100,000 CFU/mL indicates infection. It is appropriate to obtain urine cultures by midstream, clean-catch technique for older children and adolescents, whereas suprapubic bladder aspiration or transurethral catheterization is the appropriate method for younger children and infants. Perineal bags for urine collection are prone to contamination and are not recommended for urine collection for culture. If there is uncertainty about diagnosis of UTI in a younger child or infant, urine can be collected by the most convenient method for urinalysis, and if suggestive of infection, collect urine by catheterization prior to starting antibiotics.

Urinalysis showing **pyuria** (leukocyturia of >10 white blood cells [WBCs]/mm³) suggests infection but is also consistent with urethritis, vaginitis, nephrolithiasis, glomerulonephritis, and interstitial nephritis. Other urinalysis findings suggestive of infection include any bacteria per high-powered field in the unstained uncentrifuged urinary sediment, positive urinary leukocyte esterase test, and positive urinary nitrite test. Combined testing for leukocyte esterase, nitrite, and microscopic bacteria has almost 100% sensitivity for detecting UTI by positivity of ≥ 1 of the three tests. The negative predictive value of a urinalysis is about 100% if all three tests are negative and may obviate the need for culture except in neonates, where urinalysis results are less reliable predictors of infection.

Ultrasonography of the bladder and kidneys is recommended for infants and non-toilet trained children with first-time febrile UTIs so as to exclude structural abnormalities or detect hydronephrosis. Voiding cystourethrogram (VCUG) is indicated if the ultrasound is abnormal (hydronephrosis, scarring, or other findings suggesting obstruction or congenital abnormality). Vesicoureteral reflux is the most common abnormality found and is ranked from grade I (ureter only) to grade V (complete gross dilation of the ureter and obliteration of caliceal and pelvic anatomy) (see [Chapter 167](#)). A technetium-99m dimercaptosuccinic acid (DMSA) scan can identify acute pyelonephritis and is most useful to define renal scarring as a late effect of UTI.

Differential Diagnosis

The diagnosis of a UTI is confirmed by a positive urine culture, but this does not distinguish between upper and lower tract infection. Localization of a UTI is important because upper Pyelonephritis is associated more frequently with bacteremia and anatomical abnormalities than is uncomplicated cystitis. The clinical manifestations of UTI do not reliably distinguish the site of infection in neonates, infants, and toddlers. Fever and abdominal pain may occur with either lower or upper UTI, although high fever, vomiting, costovertebral tenderness, leukocytosis on complete blood count (CBC), and bacteremia each suggest upper tract involvement.

The manifestations of UTI overlap with signs of sepsis seen in young children and with enteritis, appendicitis, mesenteric lymphadenitis, and pneumonia in older children. Dysuria may indicate pinworm infection, hypersensitivity to soaps or detergents, vaginitis, or sexual abuse and infection.

Treatment

Decision-Making Algorithm

Fever Without a Source

Empirical therapy should be initiated for symptomatic children and for all children with a urine culture confirming UTI. For infants and children who do not appear ill but have a positive urine culture, oral antibiotic therapy should be initiated. For all young infants and any child with suspected UTI who appears toxic, appears dehydrated, or is unable to retain oral fluids, initial antibiotic therapy should be administered parenterally.

Neonates with UTI are treated for 7-14 days with parenteral antibiotics because UTIs in this age group are assumed to occur from hematogenous spread regardless of blood culture results. If a 7-day course of parental antibiotics is given, 7 additional days of enteral antibiotics are provided to complete a 14-day total course of therapy. Older children with UTI are treated for 7-14 days of enteral antibiotics or a combination of parenteral followed by enteral antibiotic therapy. Initial treatment with parenteral antibiotics in this age group is determined by clinical status. Parenteral antibiotics should be continued until there is clinical improvement (typically 24-48 hours), defined as resolution of fever and improved oral intake. Empiric antibiotic therapy should be guided by the local antimicrobial susceptibility patterns and the results of the patient's prior urine cultures because of increasing problems related to antimicrobial resistance. Definitive antibiotic therapy should be guided by the patient's urine culture results. Commonly used empiric parenteral antibiotics include cefazolin, ceftriaxone, or ampicillin plus gentamicin. Oral regimens include a cephalexin, amoxicillin plus clavulanic acid, or trimethoprim-sulfamethoxazole. Infants and children who do not show the expected clinical response within 2 days of starting antimicrobial therapy should be re-evaluated, have another urine specimen obtained for culture, and undergo imaging promptly to evaluate for renal abscess.

The degree of toxicity, dehydration, and ability to retain oral intake of fluids should be assessed carefully. Restoring or maintaining adequate hydration, including correction of electrolyte abnormalities that are often associated with

vomiting or poor oral intake, is important.

Complications and Prognosis

Bacteremia occurs in approximately 5% of patients with pyelonephritis and is more likely in infants than in older children. Focal renal abscesses are an uncommon complication. Parents should be counseled to follow up for evaluation for subsequent fevers to determine the possibility of a recurrence of UTI. If a recurrent UTI is diagnosed, further imaging studies (VCUG) are indicated, if not already performed, to evaluate the possibility of vesicoureteral reflux (see [Chapter 167](#)).

Prevention

Primary prevention is achieved by promoting good perineal hygiene and managing underlying risk factors for UTI, such as chronic constipation, encopresis, and daytime and nighttime urinary incontinence. There is evidence that antibiotic prophylaxis may prevent more severe symptomatic recurrent infections, although the effect is small and is associated with the development of resistant organisms. The impact of secondary prophylaxis to prevent renal scarring is unknown. Acidification of the urine with cranberry juice is not recommended as the sole means of preventing UTI in children at high risk.

CHAPTER 115

Vulvovaginitis

Etiology

Vulvovaginitis, which is inflammation of the vulva or vagina or both, is the most common gynecological problem in prepubertal girls. Poor hygienic practices, close proximity of the vagina to the rectum, and low levels of estrogen predispose prepubertal girls to vulvovaginal irritation. Low levels of estrogen result in thin, atrophic vaginal epithelium that is susceptible to bacterial invasion. At puberty, estrogen increases, and the pH of the vagina becomes more

acidic. Vulvovaginitis can be due to nonspecific and specific causes. **Nonspecific vaginitis** results from overgrowth of normal aerobic vaginal flora that is associated with poor hygiene. There are several specific causes of vulvovaginitis (Table 115.1), including sexually transmitted infections such as *Trichomonas vaginalis* and herpes simplex virus (see Chapter 116). **Bacterial vaginosis** is the most common cause of vaginitis in postpubertal women and represents disruption of the normal vaginal flora with reduction in *Lactobacillus* and overgrowth of organisms including *Gardnerella vaginalis*, *Bacteroides*, *Mobiluncus*, and *Peptostreptococcus*.

TABLE 115.1

Characteristics of Vulvovaginitis

ETIOLOGY CONDITION/DISORDER	PRESENTATION	DIAGNOSIS	TREATMENT
Physiological vaginal discharge (physiological leukorrhea)	Minimal, clear, thin discharge without pruritus or inflammation; occurs soon after birth and again at 6-12 mo before menarche	No pathogenic organisms on culture	Reassurance
Nonspecific vaginitis	Vaginal discharge, dysuria, pruritus; fecal soiling of underwear	Evidence of poor hygiene; no pathogenic organisms on culture	Improved hygiene, sitz baths 2-3 times/day
Bacterial vaginosis	Often asymptomatic; possible thin vaginal discharge with a “fishy” odor	≥3 of the following criteria: (1) thin, homogeneous vaginal discharge; (2) vaginal pH >4.5; (3) a fishy odor of volatile amines on the addition of a drop of 10% potassium hydroxide to a drop of vaginal discharge (the “whiff test”); and (4) the presence of clue cells on a saline wet mount of vaginal discharge	Metronidazole, clindamycin
Candidiasis	Pruritus, dysuria, white “cottage cheese” vaginal discharge that is usually not malodorous	<i>Candida</i> on KOH preparation of vaginal discharge	Topical antifungal (e.g., butoconazole, clotrimazole, miconazole, nystatin) Single oral dose fluconazole

Enterobiasis (pinworms)	Perineal pruritus (nocturnal); gastrointestinal symptoms; variable vulvovaginal contamination from feces; often recurrent symptoms	Adult worms in stool or eggs on perianal skin ("Scotch tape test")	Mebendazole or albendazole
Molluscum contagiosum	Vulvar lesions, nodules with central umbilication; white core of curd-like material	Clinical appearance; Isolation of poxvirus	Dermal curettage of umbilicated area
<i>Phthirus pubis</i> infection (pediculosis pubis)	Pruritus, excoriation, sky-blue macules; inner thigh or lower abdomen	Nits on hair shafts, lice on skin or clothing	1% permethrin
<i>Sarcoptes scabiei</i> infection (scabies)	Nocturnal pruritus, pruritic vesicles, pustules in runs	Mites; ova, black dots of feces (microscopic)	5% permethrin
<i>Shigella</i> infection	Bloody vaginal discharge; fever, malaise, fecal contamination, diarrhea; blood and mucus in stool, abdominal cramps	Stools: white blood cells and red blood cells, positive for <i>Shigella</i>	Oral third-generation cephalosporin
<i>Staphylococcus</i> , <i>Streptococcus</i> infection	Vaginal discharge, possibly bloody; hyperemic vulvar mucosa; spread from primary lesion	Isolation of causative organism on bacterial culture	First-generation cephalosporin or dicloxacillin; penicillin or amoxicillin for group A streptococcus infection
Foreign body	Foul-smelling vaginal discharge, sometimes bloody	Foreign body on physical examination	Removal of foreign body

KOH, Potassium hydroxide.

Epidemiology

Nonspecific vaginitis is the most common cause of vulvovaginitis in prepubertal girls. *G. vaginalis* is often present as part of the normal vaginal flora in prepubertal girls, and its role as a cause of vaginitis in this age group is uncommon. *Candida* is much less common in prepubertal girls than in women.

Clinical Manifestations

Decision-Making Algorithms

Abnormal Vaginal Bleeding
Vaginal Discharge

The primary symptoms of vulvovaginitis are vaginal discharge, erythema, foul smell, dysuria, and pruritus. Characteristics of specific etiologies are outlined in [Table 115.1](#).

Laboratory and Imaging Studies

Wet mount microscopic examination, prepared by mixing vaginal secretions with normal saline solution, and culture may be used to confirm a specific diagnosis (see [Table 115.1](#)). **Clue cells** are vaginal epithelial cells that are covered with *G. vaginalis* and have a granular appearance ([Fig. 115.1](#)). Vaginal cultures for *G. vaginalis* are not useful. *Candida* may be identified by KOH stain or by culture.

FIGURE 115.1 A film of coccobacilli covers squamous cells in a cervical cytology sample. This aspect is commonly referred to as “clue cells” and is associated with bacterial vaginosis (Papanicolaou stain, $\times 100$). (From Tambouret R. *Gynecologic infections*. In: Kradin RL, ed. *Diagnostic Pathology of Infectious Diseases*. Philadelphia: Elsevier; 2010.)

Differential Diagnosis

Noninfectious causes of vulvovaginitis include physical agents (foreign body, sand), chemical agents (bubble bath, soap, detergent), and vulvar skin disease (atopic dermatitis, seborrhea, psoriasis). Physiological vaginal discharge or **physiological leukorrhea** of desquamated vaginal cells and mucus occurs normally in females soon after birth, with discharge lasting for about 1 week, and appears again at 6-12 months before menarche. The discharge is minimal, clear, and thin without pruritus or inflammation. No treatment is necessary.

Treatment

The treatment of vulvovaginitis depends on the etiology (see [Table 115.1](#)). Treatment of nonspecific vaginitis focuses on improving perineal hygiene. Douching or vaginal irrigation is not beneficial and is not recommended.

Complications and Prognosis

Complications of nonspecific vulvovaginitis are rare, and prognosis is excellent. Bacterial vaginosis is associated with birth complications such as chorioamnionitis and preterm labor, but evidence regarding treatment of bacterial vaginosis to prevent these complications is conflicting.

Prevention

There are no recognized prophylactic measures for bacterial vaginosis or nonspecific vaginitis other than maintaining good perineal hygiene. Douching is not protective and reduces normal vaginal flora, which are protective against pathogenic organisms.

CHAPTER 116

Sexually Transmitted Infections

Decision-Making Algorithms

Dysmenorrhea
 Abnormal Vaginal Bleeding
 Vaginal Discharge

Adolescents have the highest rates of sexually transmitted infections (STIs). Compared with adults, sexually active adolescents are more likely to believe they will not contract an STI, more likely to come into contact with an infected sexual partner, less likely to receive health care when an STI develops, and less likely to be compliant with treatment for an STI.

Although numerous organisms cause STIs, the diseases can be grouped by their characteristic clinical presentations. **Urethritis** and **endocervicitis** (Table 116.1) are characteristic of *Neisseria gonorrhoeae* and *Chlamydia trachomatis* and are the most common STIs. Note that 70% of new genital chlamydial infections occur in adolescents aged 15-24 years and most infections are asymptomatic. **Genital ulcers** (Table 116.2) are characteristic of syphilis (*Treponema pallidum*), genital herpes simplex virus (HSV) infections, chancroid (*Haemophilus ducreyi*), lymphogranuloma venereum (LGV; *C. trachomatis*), and granuloma inguinale, also known as *donovanosis* (*Klebsiella granulomatis*). **Vaginal discharge** (Table 116.3) is a symptom of trichomoniasis (*Trichomonas vaginalis*) and is part of the spectrum of vulvovaginitis (see Chapter 115), which is not always associated with sexual activity. Human papillomavirus (HPV) causes **condylomata acuminata**, or **genital warts** (Table 116.4), and is the major risk factor for cervical, vulvar, and vaginal cancers.

TABLE 116.1

Features of Sexually Transmitted Infections Caused by *Chlamydia trachomatis* and *Neisseria gonorrhoeae**

FEATURE	<i>C. TRACHOMATIS</i>	<i>N. GONORRHOEAE</i>
Incubation period	7-21 days	2-7 days
Possible presentations	Conjunctivitis (including neonatal conjunctivitis), pneumonia, urethritis, cervicitis, proctitis, epididymitis, perihepatitis, lymphogranuloma venereum, reactive arthritis (arthritis, urethritis, and bilateral conjunctivitis)	Pharyngitis, conjunctivitis (including neonatal conjunctivitis), urethritis, cervicitis, proctitis, epididymitis, perihepatitis, disseminated disease (arthritis, dermatitis, endocarditis, meningitis)
SIGNS/SYMPTOMS OF COMMON SYNDROMES		
Urethritis	<i>Female</i> Dysuria, frequency	

	>10 PMNs/hpf <i>Male</i> Penile discharge >10 PMNs/hpf	
Mucopurulent cervicitis	Cervical erythema, friability, with thick creamy discharge	Cervical edema, erythema, or friability with purulent or mucopurulent discharge
	>10 PMNs/hpf	>10 PMNs/hpf
	Mild cervical tenderness	Mild cervical tenderness
	Gram-negative intracellular diplococci	Gram-negative diplococci
Pelvic inflammatory disease	Onset of symptoms within 7 days menstrual cycle	
	Lower abdominal pain	
	Adnexal tenderness, mass (5-50%)	
	Pain on cervical motion (>95%)	
	Fever (35%)	
	Vaginal discharge (55%)	
	Mucopurulent cervical discharge (80%)	
	Menstrual irregularities (variable)	
	Nausea, vomiting (variable)	
	Weakness, syncope, dizziness (variable)	
	Perihepatitis (5%)	
Diagnostic tests	NAAT, culture	NAAT, culture
Treatment	Ceftriaxone <i>plus</i> doxycycline or azithromycin If PID: cefotetan or ceftioxin <i>plus</i> doxycycline	

*Coinfection is common, and clinical presentations have significant overlap.

hpf, High-power field; *NAAT*, nucleic acid amplification test; *PID*, pelvic inflammatory disease; *PMNs*, polymorphonuclear cells.

TABLE 116.2

Features of Sexually Transmitted Infections Characterized by Genital Ulcers

	SYPHILIS	GENITAL HERPES	CHANCROID	GRANULOMA INGUINALE (DONOVANOSIS)
Agent	<i>Treponema pallidum</i>	HSV-1, HSV-2	<i>Haemophilus ducreyi</i>	<i>Klebsiella granulomatis</i>
Incubation	10-90 days	2-14 days	1-10 days	8-80 days
Systemic findings	Primary syphilis: Uncommon Secondary syphilis: Fever, rash, malaise, anorexia,	Headache, fever, malaise, myalgia (40- 70%)	None	Local spread only

	arthralgia, lymphadenopathy			
Inguinal lymphadenopathy	Late, bilateral, nontender, no suppuration	Early, bilateral, tender, no suppuration	Early, rapid, tender, and unilateral; suppuration likely (bubo)	Lymphatic obstruction
Primary lesion	Papule	Vesicle	Papule to pustule	Subcutaneous nodule
ULCER CHARACTERISTICS				
Number	>1	Multiple	<3	>1, may coalesce
Edges	Distinct	Reddened, ragged	Sharply demarcated, serpiginous borders	Rolled, distinct
Depth	Shallow	Shallow	Shallow	Raised
Base	Red, smooth	Red, smooth	Necrotic	Beefy red, clean
Secretion	Serous	Serous	Purulent	None
Induration	Firm	None	None	Firm
Pain	None	Usual	Often	None
Diagnosis				
Serology	MHA-TP or FTA-ABS; VDRL or RPR	Seroconversion (primary infection only)	None	None
Isolation	No in vitro test; rabbit testes inoculation	Culture	Swab of ulcer on selective medium, node aspirates usually sterile	None
Microscopic	Dark-field examination	PCR or fluorescent antibody staining	Gram-negative coccobacilli	Staining of ulcer biopsy material for donovan bodies
Treatment	<i>Early (primary, secondary and early latent):</i> Benzathine penicillin G (2.4 million U IM) once	Acyclovir or famciclovir or valacyclovir	Aspirate or excise fluctuant nodes	Doxycycline or azithromycin
	<i>Late latent (>1 yr duration):</i> Benzathine penicillin G (2.4 million U IM) weekly × 3 doses		Incision and drainage of buboes >5 cm Azithromycin or ceftriaxone or ciprofloxacin or erythromycin	

FTA-ABS, Fluorescent treponemal antibody–absorption; *HSV*, herpes simplex virus; *IM*, intramuscular; *MHA-TP*, microhemagglutination assay-*Treponema pallidum*; *PCR*, polymerase chain reaction; *RPR*, rapid plasma reagin; *VDRL*, Venereal Disease Research Laboratory.

TABLE 116.3

Features of Sexually Transmitted Infections Characterized by Vaginal Discharge

FEATURE	PHYSIOLOGICAL LEUKORRHEA (NORMAL)	TRICHOMONIASIS	BACTERIAL VAGINOSIS
Agent	Normal flora	<i>Trichomonas vaginalis</i>	Reduction in <i>Lactobacillus</i> and overgrowth organisms including <i>Gardnerella vaginalis</i> , <i>Bacteroides</i> , <i>Mobiluncus</i> , and <i>Peptostreptococcus</i>
Incubation	—	5-28 days	Not necessarily sexually transmitted
Predominant Symptoms			
Pruritus	None	Mild to moderate	None to mild
Discharge	Minimal	Moderate to severe	Mild to moderate
Pain	None	Mild	Uncommon
Vulvar inflammation	None	Common	Uncommon
Characteristics of Discharge			
Amount	Small	Profuse	Moderate
Color	Clear, milky	Yellow-green or gray	Gray
Consistency	Flocculent	Frothy	Homogeneous
Viscosity	Thin	Thin	Thin
Foul odor	None	Possible	Yes
Odor with KOH	None	Possible	Characteristic fishy odor (amine)
pH	<4.5	>5.0	>4.5
Diagnosis			
Saline drop	Squamous and few WBCs	WBC; Motile flagellates, slightly larger than WBCs	Squamous cells studded with bacteria (“clue cells”) and WBCs
Gram stain	Gram-positive and gram-negative rods and cocci	<i>Trichomonas</i>	Predominance of gram-negative rods and cocci with paucity of gram-positive rods
Culture	Mixed flora with <i>Lactobacillus</i> predominant	Culture generally not indicated; antibody and nucleic acid tests available	Culture not useful
Treatment	Reassurance	Metronidazole or tinidazole	Metronidazole or clindamycin

KOH, Potassium hydroxide; WBCs, white blood cells.

TABLE 116.4**Features of Sexually Transmitted Infections Characterized by Nonulcerative External Genital Symptoms**

FEATURE	GENITAL WARTS	VULVOVAGINAL CANDIDIASIS	PEDICULOSIS PUBIS (CRABS)
Agent	Human papillomavirus	<i>Candida albicans</i>	<i>Phthirus pubis</i>
Incubation/transmission	Variable	Uncommon sexual transmission	5-10 days for eggs to hatch
Presenting complaints	Genital warts are seen or felt	Vulvar itching or discharge	Pubic itching; live organisms may be seen; sexual partner has “crabs”
Signs	Firm, gray-to-pink, single or multiple, fimbriated, painless excrescences on vulva, introitus, vagina, cervix, penis, perineum, anus	Inflammation of vulva, with thick, white, “cottage cheese” discharge, pH < 4.5; friable mucosa that easily bleeds	Eggs (nits) at base of pubic hairs, lice may be visible; excoriated, red skin secondary to infestation
Clinical associations	Cervical neoplasia, dysplasia	Oral contraceptives, diabetes, antibiotics	—
Diagnosis	Clinical appearance; most infections asymptomatic; acetowhite changes on colposcopy; enlarged cells with perinuclear halo and hyperchromatic nuclei	KOH (10%): pseudohyphae; Gram stain: gram-positive pseudohyphae; Nickerson or Sabouraud medium for culture	History and clinical appearance
Treatment	<i>Patient-applied therapies:</i> podofilox solution or gel or imiquimod cream	<i>Intravaginal agents:</i> butoconazole or clotrimazole or miconazole or nystatin <i>Oral agent:</i> fluconazole	Permethrin 1% cream or pyrethrin with piperonyl butoxide
	<i>Provider-applied therapies:</i> cryotherapy with liquid nitrogen or cryoprobe or topical podophyllin resin or trichloroacetic acid or bichloroacetic acid or surgical removal		

KOH, Potassium hydroxide.

STIs are associated with significant physiological and psychological morbidity. Early diagnosis and treatment are important for preventing medical complications and infertility. All STIs are preventable; primary prevention of

STIs should be a goal of all health care providers for adolescents. Diagnosis of an STI necessitates evaluation or treatment for concomitant STIs and notification and treatment of sexual partners; some STIs are reportable to state health departments.

Many infections that are not traditionally considered STIs are sexually transmissible, including those caused by human immunodeficiency virus (HIV), human T-cell leukemia viruses types I and II, cytomegalovirus, Epstein-Barr virus, human herpes virus (HHV-6, HHV-7), hepatitis B virus, molluscum contagiosum virus, and *Sarcoptes scabiei*. The presence of any STI suggests behavior that increases risk for HIV (see [Chapter 125](#)), and HIV counseling and testing should be provided to all adolescents with STIs. Acquisition of gonorrhea, chlamydia, syphilis, genital HSV, and trichomoniasis in prepubertal children beyond the neonatal period indicates sexual contact and signifies the need to investigate for possible sexual abuse (see [Chapter 22](#)); diagnosis of STIs in infants can represent abuse or perinatal acquisition. The association of sexual abuse with vulvovaginitis and genital HPV infection, which may result from skin or genital HPV types, is less certain.

Pelvic Inflammatory Disease

Direct extension of *N. gonorrhoeae* and/or *C. trachomatis* to the endometrium, fallopian tubes, and peritoneum causes **pelvic inflammatory disease (PID)**. Complications of PID include tubo-ovarian abscess, perihepatitis (**Fitz-Hugh-Curtis syndrome**, an inflammation of the liver capsule), and infertility. The differential diagnosis of PID includes ectopic pregnancy, septic abortion, ovarian cyst torsion or rupture, urinary tract infection, appendicitis, mesenteric lymphadenitis, and inflammatory bowel disease. Pelvic ultrasound may detect thickened adnexal structures and is the imaging study of choice to exclude other possible diagnoses. Minimum clinical criteria for diagnosis of PID are pelvic or lower abdominal tenderness with uterine, adnexal, or cervical motion tenderness. Additional criteria that support the diagnosis are fever, mucopurulent cervical discharge or cervical friability, presence of abundant numbers of white blood cells (WBCs) on saline microscopy of vaginal fluid, elevated inflammatory markers, and documented infection with *N. gonorrhoeae* or *C. trachomatis*. Adolescents should be hospitalized for treatment if there is uncertainty about the diagnosis, pregnancy, no clinical response to oral therapy within 72 hours, inability to adhere to or tolerate oral therapy, a tubo-ovarian abscess, or severe

illness with high fever, nausea, and vomiting. The recommended parenteral treatment for hospitalized patients is cefotetan or cefoxitin plus doxycycline orally. The recommended ambulatory treatment of PID is ceftriaxone (250 mg) in a single intramuscular (IM) dose, plus doxycycline (100 mg) orally twice a day for 14 days, with or without metronidazole (500 mg twice a day) orally for 14 days. Follow-up examination should be performed within 72 hours.

Gonorrhea (*Neisseria gonorrhoeae*)

Neisseria gonorrhoeae, a gram-negative coccus, is often seen microscopically as diplococci. Gonorrhea is a common STI among adolescents. The highest incidence in the United States is in 15- to 24-year-olds, and incidence rates differ by race and gender, with more cases in men than in women. The organism causes infection at the site of acquisition, which commonly results in mucopurulent cervicitis and urethritis (see [Table 116.1](#)), but infection of the rectum and pharynx can also occur. **Disseminated gonococcal infections** can occur with hematogenous spread and results in petechial or pustular acral skin lesions, asymmetric polyarthralgia, tenosynovitis or oligoarticular septic arthritis, and, occasionally, endocarditis or meningitis. Perinatal transmission of maternal infection can lead to neonatal sepsis, meningitis (see [Chapter 65](#)), and ophthalmia neonatorum (see [Chapter 119](#)).

Gonococcal infection is diagnosed by either culture of endocervical (women) or urethral (men) swab specimens or nucleic acid amplification tests (NAATs) of endocervical swabs, vaginal swabs, urethral swabs, throat specimens, and urine. Culture should be performed in cases of possible treatment failure to allow for antimicrobial susceptibility testing. In cases of suspected sexual abuse, culture is the preferred diagnostic method due to concerns regarding NAAT false-positive results from cross reaction with nongonococcal *Neisseria* species.

Treatment regimens should be effective against *N. gonorrhoeae* and *C. trachomatis* because of the high frequency of coinfection. Increasing rates of resistance to fluoroquinolones limit treatment options. A single IM dose of ceftriaxone (250 mg) in combination with a single oral dose of azithromycin (1 g) is recommended for uncomplicated gonococcal infections of the cervix, urethra, and rectum. The addition of azithromycin helps to prevent the emergence of resistance in *N. gonorrhoeae* and also serves as empirical *C. trachomatis* treatment. Hospitalization and treatment with ceftriaxone for 7-28 days, depending on the diagnosis, plus a single dose of azithromycin are

recommended for disseminated gonococcal infections.

Chlamydia (*Chlamydia trachomatis*)

Decision-Making Algorithms

Dysuria
Scrotal Pain
Abnormal Vaginal Bleeding
Vaginal Discharge

Chlamydiae are obligate intracellular bacteria with a biphasic life cycle, existing as relatively inert elementary bodies in their extracellular form and as reticulate bodies when phagocytosed and replicating within a phagosome. Reticulate bodies divide by binary fission and, after 48-72 hours, reorganize into elementary bodies that are released from the cell. Chlamydia infects nonciliated squamocolumnar cells and the transitional epithelial cells that line the mucosa of the urethra, cervix, rectum, and conjunctiva. The incidence of chlamydial infections is highest among persons <25 years of age, and annual screening is recommended for all sexually active women in this age group.

There are at least 18 *C. trachomatis* serovars. Serovars A through C cause trachoma, an ocular infection eventually leading to blindness from extensive local scarring; serovars B and D through K cause urethritis, cervicitis, PID, inclusion conjunctivitis in newborns, and infant pneumonia; serovars L13 cause LGV, an infrequent STI characterized by an ulcerative genital lesion followed by unilateral, painful inguinal lymphadenitis.

Chlamydia is the most frequently diagnosed bacterial STI in adolescents and accounts for most cases of **nongonococcal urethritis and cervicitis** (see [Table 116.1](#)). There is a 2.5:1 female-to-male ratio. Males often have dysuria and mucopurulent discharge, although asymptomatic infection also occurs. Women are more often asymptomatic or may have minimal symptoms, including dysuria, mild abdominal pain, or vaginal discharge. Prepubertal girls may have vaginitis. At least 30% of persons with gonococcal cervicitis, urethritis, proctitis, or epididymitis have *C. trachomatis* coinfection.

Chlamydia infection is usually diagnosed by NAAT detection of vaginal,

cervical, urethral, and early-morning first-voided urine specimens. Amplification tests have supplanted less sensitive culture and enzyme-linked immunosorbent assay (ELISA) tests. NAAT can be used for vaginal and urine specimens from girls in the evaluation of sexual abuse. Culture is still preferred for detection of urogenital infection in boys and to evaluate for extragenital *C. trachomatis* in boys and girls.

Treatment regimens effective against *C. trachomatis* include a single oral dose of azithromycin (1 g) or doxycycline for 7 days. Individuals should be advised to avoid unprotected intercourse until all their sexual partners have been tested and treated. Tests of cure are not recommended unless therapeutic adherence is in question, symptoms persist, or reinfection is suspected.

Syphilis (*Treponema pallidum*)

Decision-Making Algorithms

Vaginal Discharge
Fever and Rash
Lymphadenopathy
Petechiae/Purpura

Syphilis is caused by *T. pallidum*, a long, slender, coiled spirochete. It cannot be cultivated routinely in vitro but can be observed by dark-field microscopy. Untreated infection progresses through several clinical stages (see [Table 116.2](#)). **Primary syphilis** is manifested as a single, painless genital ulcer, or **chancre**, usually on the genitalia, that appears approximately 3 weeks after inoculation and spontaneously heals in a few weeks. **Secondary syphilis** follows 4-8 weeks later and is manifested as fever, generalized lymphadenopathy, and a disseminated maculopapular rash that is also present on the palms and soles. Plaque-like skin lesions, **condylomata lata**, and mucous membrane lesions occur, particularly in moist areas around the vulva and anus, and are infectious. Secondary syphilis resolves spontaneously within 3-12 weeks. **Tertiary syphilis** is a slowly progressive disease involving the cardiovascular, neurological, and musculoskeletal systems that manifests 15-30 years after initial infection. **Latent syphilis** is an asymptomatic infection detected by serological testing. Early

latent syphilis indicates acquisition within the preceding year; all other cases of latent syphilis are designated as either late latent syphilis or latent syphilis of unknown duration. Infection can be passed from pregnant women to infect their infants, resulting in **congenital syphilis** (see [Chapter 66](#)).

The diagnosis of syphilis is based on serological testing. There are different types of serological tests for syphilis, and both are required to make a diagnosis: **nontreponemal antibody tests**: the **Venereal Disease Research Laboratory (VDRL)** test, the **rapid plasma reagin (RPR)** test; specific **treponemal antibody tests**: the **microhemagglutination assay–*T. pallidum*** (MHA-TP), the **fluorescent treponemal antibody-absorption (FTA-ABS)** test, various enzyme immunoassays (EIAs), and chemiluminescence immunoassays. The syphilis screening algorithm starts with a screening-specific treponemal EIA or chemiluminescence immunoassay. Screening with specific treponemal antibody tests will identify persons with active disease but will also be positive in persons who were previously adequately treated for syphilis, those with incompletely treated syphilis, and those with false-positive results. Positive treponemal screening antibody tests should be followed by a nontreponemal test with titer. The titer can help guide management, as it increases with increasing duration of infection and decreases in response to therapy. Negative nontreponemal tests should be confirmed with a different treponemal test to confirm the results of the initial treponemal test. A nonquantitative VDRL test can be performed on cerebrospinal fluid but is insensitive. Rheumatic disease and other infectious diseases may cause false-positive VDRL results. Dark-field examination of chancres, mucous membranes, or cutaneous lesions may reveal motile organisms.

The treatment of choice for all stages of syphilis is parenteral penicillin G. Primary syphilis, secondary syphilis, and early latent syphilis are treated with a single IM dose of benzathine penicillin G. Tertiary, late latent, and latent syphilis of unknown duration are treated with three doses at 1-week intervals. Neurosyphilis is treated with intravenous aqueous crystalline penicillin G for 10–14 days. A systemic, febrile **Jarisch-Herxheimer reaction** can occur within the first 24 hours of penicillin initiation in patients being treated for syphilis.

Herpes Simplex Virus Infection

Decision-Making Algorithms

Sore Throat
Dysuria
Vaginal Discharge
Vesicles and Bullae
Fever and Rash
Lymphadenopathy

HSV-1 and HSV-2 are large, double-stranded DNA viruses of the herpesvirus family with a linear genome contained within an icosahedral capsid. There is significant DNA homology between types 1 and 2. The virus initially infects mucosal surfaces and enters cutaneous neurons, where it migrates along the axons to sensory ganglia. As viral replication occurs in the ganglia, infectious virus moves along the axon to infect and destroy epithelial cells. Infection may disseminate to other organs in immunocompromised patients. Virus latency is maintained in the ganglia where it undergoes periodic reactivation and replication triggered by undefined events. Although either virus can be found in any site, HSV-1 more commonly occurs in the central nervous system, eyes, and mouth, whereas HSV-2 more commonly involves the genitalia. Reinfection can occur with exposure to the other type or even a second strain of the same type.

Primary genital herpes is characterized by multiple painful, grouped vesicles or ulcerative and crusted external genital lesions on an erythematous base (see [Table 116.2](#)). In females the cervix may also be involved. Symptoms may include fever, regional lymphadenopathy, discharge, and dysuria. Primary illness lasts 10-20 days. Asymptomatic primary infection may also occur. **Secondary, recurrent, or reactivation eruptions** are not as dramatic and are not associated with systemic symptoms. In primary infection, viral shedding lasts an average of 11 days, and the entire course from vesicle and ulcer onset resolves over 20 days. In recurrent disease, virus shedding lasts for an average of 4 days, and the course resolves over 9-10 days. Many persons experience 4-6 recurrences per year. Some primary and many recurrent episodes are asymptomatic.

Viral cultures and polymerase chain reaction (PCR) are the preferred methods of diagnosis; culture typically shows cytopathic effect in 1-3 days and seldom takes longer than 5 days. PCR assays have increased sensitivity over culture. Viral shedding is intermittent after primary infection, so both culture and PCR can fail to detect latent infection. Serological testing is useful for primary infection only (to show seroconversion between acute and convalescent sera),

and positive serologies persist lifelong. Titers are not helpful in guiding management of recurrences.

Oral famciclovir and valacyclovir are effective treatments in reducing the severity and duration of symptoms in primary cases and may reduce recurrences. Once-daily suppressive therapy reduces the frequency of genital herpes recurrences by >75%, and lesions tend to be mild when they do occur. Local hygiene and sitz baths may relieve discomfort. The use of condoms provides some protection against sexual transmission of HSV.

Trichomoniasis (*Trichomonas vaginalis*)

Decision-Making Algorithms

Abnormal Vaginal Bleeding
Vaginal Discharge

Trichomoniasis is caused by the protozoan *T. vaginalis* and often is associated with other STIs, such as gonorrhea and *Chlamydia*. Infection is asymptomatic in as many as 70-85% of infected persons. Symptomatic males can have urethritis. Symptomatic females have vaginitis, with thin, malodorous, frothy yellow-green discharge, vulvar irritation, and cervical “strawberry hemorrhages” (see [Table 116.3](#)). Diagnosis is based on visualization of motile, flagellated protozoans in the urine or in a saline wet mount, which has a sensitivity of only 60-70% among symptomatic women. *T. vaginalis*-specific NAAT is available for testing vaginal, endocervical, and urine samples and is highly sensitive (95-100%) and specific (95-100%). Rapid point-of-care testing has become available in recent years, with a turnaround time of approximately 10 minutes. Treatment of sexual partners with oral metronidazole or tinidazole in a single dose is recommended.

Genital Warts (Human Papillomaviruses)

Decision-Making Algorithms

Hoarseness
Vaginal Discharge

HPV, the cause of genital warts (**condylomata acuminata**), is the most common STI in the United States, with the highest prevalence rates among 15- to 24-year-olds. Most HPV infections are asymptomatic or subclinical (90%) and self-resolve within 2 years. HPV types 6 and 11 cause 90% of genital warts and are nononcogenic. HPV types 16 and 18 are associated with 70% of cases of cervical cancer. HPV types 31, 33, 45, 52, and 58 are also oncogenic.

Genital warts can occur on the squamous epithelium or mucous membranes of the genital and perineal structures of females and males (see [Table 116.4](#)). Genital warts are usually multiple, firm, gray-to-pink excrescences. Untreated genital warts may remain unchanged, increase in size or number, or resolve spontaneously. Warts can become tender if macerated or secondarily infected. The diagnosis is usually established by appearance without biopsy. The differential diagnosis includes condylomata lata (secondary syphilis) and tumors.

The goal of treatment is removal of symptomatic warts to induce wart-free periods. Treatment modalities involve destruction of infected epithelium; patient-applied therapies include podofilox, sinecatechins, or imiquimod; and provider-applied therapies include cryotherapy with liquid nitrogen or cryoprobe and trichloroacetic acid or bichloroacetic acid. An alternative is surgical removal. Intralesional interferon and laser surgery have also been effective. Factors that may influence selection of treatment include wart number, size, anatomical sites, wart morphology, patient preference, treatment cost, convenience, adverse effects, and provider experience. Recurrences after treatment are common and are frequently asymptomatic.

Pubic Lice (*Phthirus pubis*)

Pubic lice, or pediculosis pubis, are caused by infestation with *Phthirus pubis*, the **pubic crab louse**. The louse is predominantly sexually transmitted and lives out its life cycle on pubic hair, where it causes characteristic, intense pruritus (see [Table 116.4](#)). Diagnosis can be made clinically; lice are visible to the naked eye. Erythematous papules and **egg cases (nits)** are not seen before puberty. Treatment consists of education regarding personal and environmental hygiene and the application of an appropriate pediculicide, such as permethrin 1% cream or pyrethrins with piperonyl butoxide. Bedding and clothing should be decontaminated (machine-washed and machine-dried using the heat cycle or dry

cleaned) or removed from body contact for at least 72 hours. Fumigation of living areas is not necessary.

CHAPTER 117

Osteomyelitis

Etiology

Acute hematogenous osteomyelitis is the most common manifestation of osteomyelitis in children and evolves secondary to bacteremia. **Subacute osteomyelitis** may also follow local inoculation by penetrating trauma and is not associated with systemic symptoms; **chronic osteomyelitis** results from an untreated or inadequately treated (usually subacute) osteomyelitis.

In children beyond the newborn period and without hemoglobinopathies, bone infections occur almost exclusively in the metaphyses of long bones due to sluggish blood flow through tortuous vascular loops unique to this site. Preceding nonpenetrating trauma is often reported and may lead to local bone injury that predisposes to infection. Bone infections in children with sickle cell disease occur in the diaphyseal portion of the long bones, probably as a consequence of antecedent focal infarction. In children younger than 12-18 months of age, capillaries perforate the epiphyseal growth plate, permitting spread of infection across the epiphysis and leading to suppurative arthritis, whereas in older children, infection is contained in the metaphysis because these vessels no longer cross the epiphyseal plate ([Fig. 117.1A and B](#)).

FIGURE 117.1 (A) Major structures of the bone of an infant before maturation of the epiphyseal growth plate. Note the transphyseal vessel, which connects the vascular supply of the epiphysis and metaphysis, facilitating spread of infection between these two areas. (B) Major structures of the bone of a child. Joint capsule A inserts below the epiphyseal growth plate, as in the hip, elbow, ankle, and shoulder. Rupture of a metaphyseal abscess in these bones is likely to produce pyarthrosis. Joint capsule B inserts at the epiphyseal growth plate, as in other tubular bones. Rupture of a metaphyseal abscess in these bones is likely to lead to a subperiosteal abscess but seldom to an associated pyarthrosis. (From Gutman LT. Acute, subacute, and chronic osteomyelitis and pyogenic arthritis in children. *Curr Probl Pediatr.* 1985;15:1–72.)

Staphylococcus aureus is responsible for more than 80% of acute skeletal infections. Other common causes include group A streptococcus and *Streptococcus pneumoniae*. *Neisseria meningitidis*, *Mycobacterium tuberculosis*, *Bartonella henselae*, *Actinomyces* spp., and anaerobes are less common causes. Group B streptococcus and enteric gram-negatives are other major causes in neonates. Sickle cell disease and other hemoglobinopathies predispose to osteomyelitis caused by *Salmonella* and *S. aureus*. *Pasteurella multocida* osteomyelitis may follow cat or dog bites. The use of polymerase chain reaction (PCR) testing reveals that a significant proportion of **culture-negative osteomyelitis** is due to *Kingella kingae*, particularly in children under 5 years of age. Conjugate vaccine has greatly reduced the incidence of *Haemophilus influenzae* type b infections.

Subacute focal bone infections caused by *Pseudomonas aeruginosa* and *S. aureus* usually occur in ambulatory persons who sustain **puncture wounds** of the foot. *Pseudomonas chondritis* is strongly associated with puncture wounds through sneakers, which harbor *Pseudomonas* in the foam insole. *S. aureus* is the most common cause of chronic osteomyelitis. **Chronic recurrent multifocal osteomyelitis** is an autoinflammatory noninfectious syndrome characterized by

recurrent episodes of fever, bone pain, and radiographic findings of osteomyelitis. Bones uncommonly involved in acute hematogenous osteomyelitis—such as the clavicle, scapula, or small bones of the hands or feet—are often affected. Pathogens are not identified on culture and histopathology demonstrates plasmacytic infiltrates.

Epidemiology

Osteomyelitis may occur at any age but is most common in children 3-12 years of age; it affects boys twice as frequently as girls. Osteomyelitis from penetrating trauma or peripheral vascular disease is more common in adults.

Clinical Manifestations

Decision-Making Algorithms

- Limp
- Knee Pain
- Extremity Pain
- Stiff or Painful Neck
- Fever Without a Source
- Fever of Unknown Origin

The most common presenting complaints are focal pain, exquisite point tenderness over the bone, warmth, erythema, and swelling. Fever, anorexia, irritability, and lethargy may accompany the focal findings. Weight bearing and active and passive motion of the affected extremity are decreased, mimicking paralysis (**pseudoparalysis**). Muscle spasm may make the extremity difficult to examine. The adjacent joint space may be involved in young children, suggested by pain with minimal joint range of motion (see [Chapter 118](#)).

Usually only one bone is involved. The femur, tibia, or humerus is affected in approximately two thirds of patients. Approximately 15% of cases involve the bones of the hands or feet, and 10% involve the pelvis. Vertebral osteomyelitis is notable for an insidious onset, vague symptoms, backache, occasional spinal cord compression, and usually little associated fever or systemic toxicity.

Patients with osteomyelitis of the pelvis may present with fever, limp, and vague abdominal, hip, groin, or thigh pain. **Pyomyositis** of pelvic muscles may mimic osteomyelitis.

Laboratory and Imaging Studies

The presence of leukocytosis is inconsistent. Blood cultures are important but are negative in many cases. Elevated acute-phase reactants, erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP) are sensitive but nonspecific findings. Serial determinations of ESR and CRP are helpful in monitoring the course of the illness and response to treatment. Direct subperiosteal or metaphyseal needle aspiration can definitively establish the diagnosis. Identification of bacteria in aspirated material by Gram stain can establish the diagnosis within hours of clinical presentation.

Plain radiographs can demonstrate soft tissue swelling such as the **loss of the periosteal fat line** within the first 3 days of symptoms, but bony lesions such as **periosteal elevation** and **bone destruction** are absent until after 10-14 days of symptoms. **Brodie abscess** is a subacute intraosseous abscess that does not drain into the subperiosteal space and is classically located in the distal tibia. **Sequestra**, portions of avascular bone that have separated from adjacent bone, frequently are covered with a thickened sheath, or **involucrum**, both of which are hallmarks of chronic osteomyelitis.

Radionuclide scanning for osteomyelitis has largely been supplanted by magnetic resonance imaging, which is sensitive to the inflammatory marrow changes even during the earliest stages of osteomyelitis (Fig. 117.2). Technetium-99m bone scans are useful for identifying multifocal disease.

FIGURE 117.2 Acute osteomyelitis of the distal femur in a 5-year-old boy. **(A)** T2-weighted fat-saturated axial magnetic resonance imaging (MRI) shows a large subperiosteal abscess (*arrows*) at the posterior femur. Increased signal is seen within the bone, along with adjacent soft-tissue edema. **(B)** T1-weighted fat-saturated postgadolinium sagittal MRI demonstrates the longitudinal extent of the same subperiosteal abscess and its enhancing wall (*arrows*). (From Kan JH, Azouz EM. Musculoskeletal infections. In: Coley BD, ed. *Caffey's Pediatric Diagnostic Imaging*. 12th ed. Philadelphia: Saunders; 2013. Fig. 138.13.)

Differential Diagnosis

Osteomyelitis must be differentiated from infectious arthritis (see [Chapter 118](#)), cellulitis, pyomyositis, fasciitis, diskitis, trauma, juvenile idiopathic arthritis, bone cysts, histiocytosis, and malignancy.

Treatment

Decision-Making Algorithm

Fever Without a Source

Initial antibiotic therapy for osteomyelitis is based on the likely organism for the age of the child, Gram stain of bone aspirate, and associated diseases ([Table 117.1](#)). Initial therapy includes an antibiotic that targets *S. aureus* and *Kingella*, such as cefazolin or nafcillin. Clindamycin or vancomycin should be used if

methicillin-resistant *S. aureus* is suspected based on patient factors or local *S. aureus* epidemiology. For patients with sickle cell disease, initial therapy should include an antibiotic with activity against *Salmonella* and *S. pneumoniae*.

TABLE 117.1

Recommended Antibiotic Therapy for Osteomyelitis in Children

COMMON PATHOGEN	RECOMMENDED TREATMENT*
ACUTE HEMATOGENOUS OSTEOMYELITIS	
<i>Staphylococcus aureus</i>	
Methicillin-sensitive	Nafcillin (or oxacillin) or cefazolin
Methicillin-resistant	Clindamycin or vancomycin or linezolid
<i>Streptococcus pyogenes</i> (group A streptococci)	Ampicillin/amoxicillin
<i>Streptococcus pneumoniae</i>	Ampicillin/amoxicillin or ceftriaxone/cefotaxime or vancomycin
SUBACUTE FOCAL OSTEOMYELITIS	
<i>Pseudomonas aeruginosa</i>	Ceftazidime or piperacillin-tazobactam or ciprofloxacin
<i>Kingella kingae</i>	Ampicillin/amoxicillin or cefotaxime

*Optimal specific therapy is based on susceptibilities of the organism that is isolated.

Response to intravenous (IV) antibiotics usually occurs within 48 hours. Lack of improvement after 48 hours indicates that surgical drainage may be necessary or that an unusual pathogen may be present. Surgical drainage may be indicated for presence of extensive, severe, chronic, or atypical disease; presence of abscess; hip joint involvement; or **sequestrum** or spinal cord compression. Antibiotics are administered for a minimum of 4-6 weeks. After initial inpatient treatment and adequate clinical response, including decreases in CRP or ESR, transition to home therapy with oral or IV antibiotics may be considered if adherence is ensured. Home IV antibiotics are associated with increased adverse event rates and need for unscheduled medical visits.

Complications and Prognosis

Complications of acute osteomyelitis are uncommon and usually arise because of inadequate or delayed therapy or concomitant bacteremia. Vascular insufficiency, which affects delivery of antibiotics, and trauma are associated with higher rates of complications.

Hematogenous osteomyelitis has an excellent prognosis if treated promptly

and if surgical drainage is performed when appropriate. The poorest outcomes are in neonates and in infants with involvement of the hip or shoulder joints (see [Chapter 118](#)). Approximately 2-4% of acute infections recur despite adequate therapy, and approximately 25% of these fail to respond to extensive surgical debridement and prolonged antimicrobial therapy, ultimately resulting in bone loss, sinus tract formation, or amputation (although rare). Sequelae related to skeletal growth disturbance are most common with neonatal osteomyelitis.

Prevention

There are no effective means of preventing hematogenous *S. aureus* osteomyelitis. Universal immunization of infants with conjugate *H. influenzae* type b vaccine has practically eliminated serious bacterial infections from this organism, including bone and joint infections.

Children with puncture wounds to the foot should receive prompt irrigation, cleansing, debridement, removal of any visible foreign body or debris, and tetanus prophylaxis. The value of oral prophylactic antibiotics for preventing osteomyelitis after penetrating injury is uncertain.

CHAPTER 118

Infectious Arthritis

Etiology

Infectious arthritis (**suppurative** or **septic arthritis**) is a serious bacterial infection of the joint space resulting from hematogenous bacterial dissemination. Infectious arthritis less often results from contiguous spread of infection from surrounding soft tissues or direct inoculation into the joint (penetrating trauma). Spread of osteomyelitis into the joint space is more common in children under 18 months of age and occurs via organisms passing through transphyseal vessels to the epiphysis (see [Fig. 117.1A](#)). The bacteria causing infectious arthritis are similar to those causing osteomyelitis ([Table 118.1](#)). Lyme disease may also cause arthritis (see [Chapter 122](#)).

TABLE 118.1**Pathogenic Organisms Causing Arthritis in Children**

COMMON	UNCOMMON
YOUNG INFANT (<2 MO)	
Group B streptococci	<i>Neisseria gonorrhoeae</i>
<i>Staphylococcus aureus</i>	<i>Candida</i>
<i>Escherichia coli</i>	
<i>Klebsiella pneumoniae</i>	
OLDER INFANTS AND CHILDREN (2 MO TO MATURITY)	
<i>S. aureus</i>	Anaerobic bacteria
<i>Streptococcus pneumoniae</i>	<i>Pseudomonas aeruginosa</i>
Group A streptococci	<i>Enterobacteriaceae</i>
<i>Kingella kingae</i>	<i>Haemophilus influenzae</i> type b*
<i>N. gonorrhoeae</i>	<i>Mycobacterium tuberculosis</i>
<i>Borrelia burgdorferi</i> (Lyme disease)	
REACTIVE ARTHRITIS	
<i>Yersinia enterocolitica</i>	
<i>Campylobacter jejuni</i>	
<i>Shigella flexneri</i>	
<i>Chlamydia trachomatis</i>	
Salmonella	
Group A streptococci	
<i>Neisseria meningitidis</i>	
<i>Coccidioides immitis</i>	
Rubella virus	

*The incidence of invasive infections caused by *Haemophilus influenzae* type b has diminished greatly with universal childhood Hib vaccination.

The arthritis of **disseminated gonococcal infections** includes both reactive and suppurative forms in early and late gonococcal disease, respectively. With untreated genital infection, gonococcemia may occur with fever and a polyarticular, symmetric arthritis and rash, known as the **arthritis-dermatitis syndrome**. Bacterial cultures of the synovium are sterile at this stage, despite a relatively high prevalence of bacteremia. Monarticular arthritis of large, weight-bearing joints develops days to weeks later. Cultures of affected synovial fluid at this stage often yield the pathogen.

Reactive arthritis is immune-mediated synovial inflammation that follows a bacterial or viral infection, especially with *Chlamydia trachomatis*, *Yersinia*, and other enteric infections. Reactive arthritis of the hip joints in children 3-6 years of age is known as **toxic** or **transient synovitis** (see [Chapter 200](#)).

Epidemiology

Infectious arthritis occurs most commonly in children younger than 5 years of age and adolescents.

Clinical Manifestations

Decision-Making Algorithms

Limp
Arthritis
Knee Pain
Extremity Pain

The typical features of suppurative arthritis include monarticular involvement with erythema, warmth, swelling, and tenderness over the affected joint with a palpable effusion and markedly decreased range of movement secondary to pain. The onset may be sudden or insidious with symptoms noted when the joint is moved only, such as during a diaper change, or if parents become aware of decreased voluntary movement of a joint or limb. Toddlers may exhibit a limp or refuse to walk. In septic arthritis of the hip, the lower limb may be preferentially held in external rotation and flexion to minimize pain from pressure on the joint capsule. Similarly, the knee and elbow joints are usually held in flexion. The joints of the lower extremity are most often involved: knees (40%), hips (20%), and ankles (14%). Small joints, such as those of the hand, are usually involved after penetrating trauma or closed fist injuries.

Minor genital tract symptoms that have been ignored may precede development of the early arthritis–dermatitis syndrome associated with disseminated gonococcal infection. A history of febrile illness antedating the development of monarticular arthritis characterizes late gonococcal arthritis.

Reactive arthritis is typically symmetric and polyarticular, and it usually involves the large joints, especially the hips. Patients may have had a preceding episode of gastroenteritis or urethritis. Urethritis may appear with the arthritis.

Laboratory and Imaging Studies

Leukocytosis and an elevated erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are common. Arthrocentesis is important to distinguish among the causes of arthritis (Table 118.2). Adolescents with acute infectious arthritis should have urethral, cervical, rectal, and pharyngeal examinations and cultures or nucleic acid amplification tests performed for *Neisseria gonorrhoeae*.

TABLE 118.2

Synovial Fluid Findings in Various Joint Diseases

CONDITION	APPEARANCE	WBC COUNT (mm ³ /L)	PMNs (%)	MUCIN CLOT	SYNOVIAL FLUID– BLOOD GLUCOSE DIFFERENCE (mg/dL)	COMM
Normal	Clear, yellow	0-200 (200)*	<10	Good	No difference	—
Trauma	Clear, turbid, or hemorrhagic	50-4,000 (600)	<30	Good	No difference	Common in hemoph
Systemic lupus erythematosus	Clear or slightly turbid	0-9,000 (3,000)	<20	Good to fair	No difference	LE cell posi complemen decrease
Juvenile idiopathic arthritis, reactive arthritis, inflammatory bowel disease	Turbid	250-80,000 (19,000)	>70	Poor	30	Decreased complemen
Infectious pyogenic infection	Turbid	10,000- 250,000 (80,000)	>90	Poor	50-90	Positive cult result, p Gram stain
Tuberculosis	Turbid	2,500- 100,000 (20,000)	>60	Poor	40-70	Positive resu culture, interferon gamma assay tes and acid stain

Lyme arthritis	Turbid	500-100,000 (20,000)	>60	Poor	70	History of tick or erythema migrans appropriate travel risk factors
----------------	--------	----------------------	-----	------	----	---

*Average in parentheses.

LE, Lupus erythematosus; PMN, polymorphonuclear cell; PPD, purified protein derivative; WBC, white blood cell.

Blood or joint cultures are positive in approximately 50% of cases. Joint fluid that exhibits the characteristics of pyogenic infection may not reveal bacterial pathogens, even in the absence of preceding antibiotic therapy, because of the bacteriostatic effects of synovial fluid. Gram stain should be performed and is often informative even if the cultures are negative. PCR testing for *Kingella* is essential in all culture-negative samples.

Ultrasound is especially useful for identifying joint effusions and is the initial diagnostic procedure of choice for evaluating suppurative infections of the hip. Plain radiographs typically add little information to the physical findings. Radiographs may show joint capsule swelling, a widened joint space, and displacement of adjacent normal fat lines. Radionuclide scans are of limited use, although magnetic resonance imaging may be helpful to exclude concurrent bone infection or deep abscesses.

Differential Diagnosis

The differential diagnosis of infectious arthritis in infants, children, and adolescents includes other infectious diseases, autoimmune disorders, rheumatic fever, malignancy, and trauma.

Suppurative arthritis must be distinguished from Lyme disease, osteomyelitis, suppurative bursitis, fasciitis, myositis, cellulitis, and soft tissue abscesses. Psoas muscle abscess often presents with fever and pain on hip flexion and rotation. Juvenile idiopathic arthritis, Kawasaki syndrome, Henoch–Schönlein purpura, other rheumatic disorders, and Crohn disease must be differentiated from infectious arthritis. In most of these diseases, the presence of symmetric or multiple joint involvement often excludes infectious arthritis. **Suppurative bursitis** with *Staphylococcus aureus* occurs most often in older boys and men and is usually a consequence of trauma or, less commonly, a complication of bacteremia.

Treatment

Initial antibiotic therapy for infectious arthritis is based on the likely organism for the age of the child and the Gram stain of joint fluid. Suppurative arthritis of the hip joint, especially, or shoulder joint necessitates prompt surgical drainage. With insertion of the joint capsule below the epiphysis in these ball-and-socket joints, increased pressure in the joint space can adversely affect the vascular supply to the head of the femur or humerus, leading to avascular necrosis. Infections of the knee may be treated with repeated arthrocenteses in addition to appropriate parenteral antibiotics.

Several antimicrobial agents provide adequate antibiotic levels in joint spaces (Table 118.3). Initial therapy for neonates should include antibiotics such as nafcillin and cefotaxime with activity against *S. aureus*, group B streptococcus, and aerobic gram-negative rods. Initial therapy for children 3 months to 5 years old should include antibiotics with activity against *S. aureus*. Addition of appropriate antibiotics should be considered if the child is unimmunized against *Haemophilus influenzae* type b (Hib). Confirmed methicillin-susceptible *S. aureus* infections are best treated with nafcillin, oxacillin, or cefazolin initially; methicillin-resistant *S. aureus* infections are best treated with clindamycin if susceptible or vancomycin otherwise.

TABLE 118.3

Recommended Antibiotic Therapy for Infectious Arthritis in Children

AGE GROUP	COMMON PATHOGENS	RECOMMENDED TREATMENT*
Infants (younger than 2 mo of age)	Group B streptococci	Ampicillin <i>plus</i> aminoglycoside
	<i>Escherichia coli</i>	Cefotaxime <i>with or without</i> aminoglycoside
	<i>Klebsiella pneumoniae</i>	Cefotaxime <i>with or without</i> aminoglycoside
Older infants and children	<i>Staphylococcus aureus</i>	Nafcillin (<i>or</i> oxacillin <i>or</i> cefazolin), <i>or</i> clindamycin <i>or</i> vancomycin
	<i>S. aureus</i>	Nafcillin (<i>or</i> oxacillin <i>or</i> cefazolin), <i>or</i> clindamycin <i>or</i> vancomycin
	<i>Streptococcus pneumoniae</i>	Ampicillin <i>or</i> cefotaxime (<i>or</i> ceftriaxone) <i>or</i> vancomycin
	Group A streptococci	Penicillin G
	<i>Kingella kingae</i>	Amoxicillin, ampicillin, <i>or</i> cefotaxime

	<i>Haemophilus influenzae</i> type b [†]	Ampicillin or cefotaxime or ceftriaxone
	<i>Neisseria gonorrhoeae</i> : disseminated gonococcal infection	Ceftriaxone

^{*}Use the narrowest-spectrum agent available based on organism's susceptibilities.

[†]The incidence of invasive infections caused by *Haemophilus influenzae* type b has diminished greatly with universal childhood *Haemophilus influenzae* type b vaccination.

The duration of therapy depends on clinical resolution of fever and pain and decline of the ESR and CRP. Infection with virulent organisms, such as *S. aureus*, usually necessitates treatment for at least 21 days, although shorter courses of 10-14 days have been used in some circumstances. Treatment may be transitioned to oral antibiotics if adherence can be ensured. Oral agents with excellent activity against *S. aureus* that are often used to complete therapy include cephalexin, clindamycin, amoxicillin-clavulanate, dicloxacillin, and ciprofloxacin, though due to concerns about ciprofloxacin's side effects it should not be first-line.

Complications and Prognosis

The prognosis for the common forms of infectious arthritis encountered in infants and children is excellent. The major complications of neonatal, childhood, and gonococcal arthritis are loss of joint function resulting from damage to the articular surface. The highest incidence of these complications occurs with hip and shoulder infections, presumably resulting from avascular necrosis. The high incidence of concurrent suppurative arthritis with adjacent osteomyelitis in neonates places the epiphyseal growth plate at high risk for growth abnormalities. Neonates with osteomyelitis have an approximately 40-50% likelihood of growth disturbances with loss of longitudinal bone growth and ultimate limb shortening.

Prevention

There are no effective means of preventing hematogenous *S. aureus* arthritis. Universal immunization of infants with conjugate Hib vaccine has practically eliminated serious bacterial infections from this organism, including bone and joint infections.

CHAPTER 119

Ocular Infections

Etiology

Acute conjunctivitis is usually a viral or bacterial infection of the eye characterized by a rapid onset of symptoms that persist for a few days. Nontypable *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Moraxella catarrhalis* account for approximately two thirds of bacterial causes (Table 119.1). Other causes include *Neisseria gonorrhoeae* and *Pseudomonas aeruginosa*; the latter is associated with extended-wear soft contact lenses. *Bartonella henselae* can cause a granulomatous conjunctivitis associated with preauricular lymphadenopathy or **Parinaud oculoglandular syndrome**. Viral conjunctivitis most commonly is caused by adenoviruses, which cause **epidemic keratoconjunctivitis**, and less frequently by coxsackieviruses and other enteroviruses. **Keratitis**, or inflammation of the cornea, is not commonly associated with conjunctivitis but occurs with *N. gonorrhoeae*, herpes simplex virus (HSV), and adenovirus infections.

TABLE 119.1

Manifestations of Acute Conjunctivitis in Children

FEATURE	CLINICAL CHARACTERISTICS	
	BACTERIAL	VIRAL
Common pathogens	<i>Haemophilus influenzae</i> (usually nontypable)	Adenoviruses types 8, 19
	<i>Streptococcus pneumoniae</i>	Enteroviruses
	<i>Moraxella catarrhalis</i>	Herpes simplex virus
Incubation	24-72 hr	1-14 days
SYMPTOMS		
Photophobia	Mild	Moderate to severe
Blurred vision	Common with discharge	If keratitis is present
Foreign body sensation	Unusual	Yes

SIGNS		
Discharge	Purulent discharge	Mucoid/serous discharge
Palpebral reaction	Papillary response	Follicular response
Preauricular lymph node	Unusual for acute (<10%)	More common (20%)
Chemosis	Moderate	Mild
Hemorrhagic conjunctivae	Occasionally with pneumococcus or <i>Haemophilus species</i>	Frequent with enteroviruses
Treatment (topical)	Polymyxin B-trimethoprim or sulfacetamide 5% or erythromycin	Adenovirus: self-limited Herpes simplex virus: trifluridine 1% solution or ganciclovir 0.15% gel or acyclovir; ophthalmologic consultation
End of contagious period	24 hr after start of effective treatment	7 days after onset of symptoms

Neonatal conjunctivitis, or **ophthalmia neonatorum**, is purulent conjunctivitis during the first month of life, usually acquired during birth. The common causes of neonatal conjunctivitis, in order of decreasing prevalence, are chemical conjunctivitis secondary to silver nitrate gonococcal prophylaxis, *Chlamydia trachomatis*, common bacterial causes of conjunctivitis, *Escherichia coli*, other gram-negative enteric bacilli, HSV, and *N. gonorrhoeae*.

Epidemiology

Conjunctivitis is common in young children, especially if they come in contact with other children with conjunctivitis. Predisposing factors for bacterial infection include nasolacrimal duct obstruction, sinus disease, ear infection, and allergic disease when children rub their eyes frequently. Conjunctivitis occurs in 1-12% of neonates. Approximately 50% of infants born vaginally to infected mothers have neonatal acquisition of *C. trachomatis*, with which the risk of chlamydial conjunctivitis (**inclusion conjunctivitis**) is 25-50%.

Clinical Manifestations

Decision-Making Algorithm

Red Eye

Symptoms of ocular infection include redness, discharge, matted eyelids, and mild photophobia. Physical examination findings include chemosis, injection of the conjunctiva, and edema of the eyelids. Corneal involvement suggests gonococcal or herpetic infection. Herpetic corneal lesions appear as dendritic or ameboid ulcers or, more commonly, in recurrent infection, as a deep keratitis. Unilateral conjunctivitis with ipsilateral otitis media is often caused by nontypable *H. influenzae*.

The timing and manifestations of neonatal conjunctivitis are helpful in identifying the cause (Table 119.2). *N. gonorrhoeae* causes severe conjunctivitis with profuse purulent discharge. Chlamydial conjunctivitis usually occurs in the second week of life but may appear 3 days to 6 weeks after delivery. There is mild to moderate inflammation with purulent discharge issuing from one or both eyes.

TABLE 119.2

Clinical Manifestations and Treatment of Neonatal Conjunctivitis

ETIOLOGICAL AGENT	CASES (%)	DISCHARGE AND EXTERNAL EXAMINATION	TYPICAL AGE AT ONSET	DIAGNOSIS	ASSOCIATED MANIFESTATIONS
Chemical: silver nitrate	Variable (1%), depending on use of silver nitrate	Watery discharge	1-3 days	No organisms on smear or culture	None
<i>Chlamydia trachomatis</i> (inclusion conjunctivitis)	2-40	Scant discharge; mild swelling; hyperemia; follicular response; late corneal staining	4-19 days	Test of discharge with a DIF test or PCR assay	May presage C pneumoniae of age)
Bacterial: <i>Staphylococcus</i> , <i>Streptococcus</i> , <i>Pseudomonas</i> , <i>E. coli</i>	30-50	Purulent moderate discharge; mild lid and conjunctival swelling; corneal involvement with risk for perforation	2-7 days	Gram stain; culture on blood agar	
<i>Neisseria gonorrhoeae</i>	<1	Copious, purulent discharge; swelling of lids and conjunctivae; corneal involvement common; risk for perforation and	1-7 days	Gram stain (gram-negative intracellular diplococci); culture on chocolate agar. Culture other	May be associated disseminated infection

		corneal scar		sites including blood and CSF	
HSV	<1	Clear or serosanguineous discharge; lid swelling; keratitis with cloudy cornea; dendrite formation	3 days-3 wk	Viral culture; DIF test, PCR assay	May be associated with disseminated HSV infection

CSF, Cerebrospinal fluid; DIF, direct immunofluorescence; HSV, herpes simplex virus; PCR, polymerase chain reaction.

Laboratory and Imaging Studies

Cultures are not routinely obtained because bacterial conjunctivitis is usually self-limited or responds quickly to topical antibiotic treatment. If gonococcal conjunctivitis is suspected, especially in neonates, Gram stain and culture must be obtained. In these infants, blood and other sites of infection (such as cerebrospinal fluid) should also be cultured. Additional testing for *Chlamydia*, human immunodeficiency virus (HIV), and syphilis should be performed on the mother and infant as necessary.

Differential Diagnosis

Distinguishing bacterial from viral conjunctivitis by presentation and appearance is difficult (see [Table 119.1](#)). Vesicular lid lesions, if present, suggest HSV. **Hyperpurulent conjunctivitis** characterized by reaccumulation of purulent discharge within minutes is characteristic of *N. gonorrhoeae* infection. The differential diagnosis is delineated in [Table 119.3](#).

TABLE 119.3

Differential Diagnosis of Ocular Infections

CONDITION	ETIOLOGICAL AGENTS	SIGNS AND SYMPTOMS	TREATMENT
Bacterial conjunctivitis	<i>Haemophilus influenzae</i> , <i>Haemophilus aegyptius</i> , <i>Streptococcus pneumoniae</i> , <i>Neisseria gonorrhoeae</i>	Mucopurulent unilateral or bilateral discharge, normal vision, photophobia, conjunctival injection and edema (chemosis); gritty sensation	Topical antibiotics, parenteral ceftriaxone for gonococcus
Viral conjunctivitis	Adenovirus, echovirus, coxsackievirus	Same as for bacterial infection; may be hemorrhagic, unilateral	Self-limited

Neonatal conjunctivitis	<i>Chlamydia trachomatis</i> , gonococcus, chemical (silver nitrate), <i>Staphylococcus aureus</i>	Palpebral conjunctival follicle or papillae; same as for bacterial infection	Ceftriaxone for gonococcus and oral erythromycin for <i>C. trachomatis</i>
Allergic conjunctivitis	Seasonal pollens or allergen exposure	Itching, incidence of bilateral chemosis (edema) greater than that of erythema, tarsal papillae	Antihistamines, steroids, cromolyn
Keratitis	Herpes simplex, adenovirus, <i>S. pneumoniae</i> , <i>S. aureus</i> , <i>Pseudomonas</i> , <i>Acanthamoeba</i> , chemicals	Severe pain, corneal swelling, clouding, limbus erythema, hypopyon, cataracts; contact lens history with amebic infection	Specific antibiotics for bacterial/fungal infections; keratoplasty, acyclovir for herpes
Endophthalmitis	<i>S. aureus</i> , <i>S. pneumoniae</i> , <i>Candida albicans</i> , associated surgery or trauma	Acute onset, pain, loss of vision, swelling, chemosis, redness; hypopyon and vitreous haze	Specific antibiotics for bacterial/fungal infections
Anterior uveitis (iritis)	JIA, reactive arthritis, sarcoidosis, Behçet disease, inflammatory bowel disease	Unilateral/bilateral; erythema, ciliary flush, irregular pupil, iris adhesions; pain, photophobia, small pupil, poor vision	Topical steroids, plus therapy for primary disease
Posterior uveitis (choroiditis)	Toxoplasmosis, histoplasmosis, <i>Toxocara canis</i>	No signs of erythema, decreased vision	Specific therapy for pathogen
Episcleritis/scleritis	Idiopathic autoimmune disease (e.g., SLE, Henoch-Schönlein purpura)	Localized pain, intense erythema, unilateral; blood vessels bigger than in conjunctivitis; scleritis may cause globe perforation	Episcleritis is self-limiting; topical steroids for fast relief
Foreign body	Occupational or other exposure	Unilateral, red, gritty feeling; visible or microscopic size	Irrigation, removal; check for ulceration
Blepharitis	<i>S. aureus</i> , <i>Staphylococcus epidermidis</i> , seborrheic, blocked lacrimal duct; rarely molluscum contagiosum, <i>Phthirus pubis</i> , <i>Pediculus capitis</i>	Bilateral, irritation, itching, hyperemia, crusting, affecting lid margins	Topical antibiotics, warm compresses
Dacryocystitis	Obstructed lacrimal sac: <i>S. aureus</i> , <i>H. influenzae</i> , <i>S. pneumoniae</i>	Pain, tenderness, erythema and exudate in areas of lacrimal sac (inferomedial to inner canthus); tearing (epiphora); possible orbital cellulitis	Systemic, topical antibiotics; surgical drainage
Dacryoadenitis	<i>S. aureus</i> , <i>S. pneumoniae</i> , CMV, measles, EBV, enteroviruses; trauma, sarcoidosis, leukemia	Pain, tenderness, edema, erythema over gland area (upper temporal lid); fever, leukocytosis	Systemic antibiotics; drainage of orbital abscesses
Orbital cellulitis (postseptal cellulitis)	Paranasal sinusitis: <i>H. influenzae</i> , <i>S. aureus</i> , <i>S. pneumoniae</i> , other streptococci Trauma: <i>S. aureus</i> Fungi: <i>Aspergillus</i> , <i>Mucor</i> if	Rhinorrhea, chemosis, vision loss, painful extraocular motion, proptosis, ophthalmoplegia, fever, lid edema, leukocytosis	Systemic antibiotics; drainage of orbital abscesses

	immunodeficient		
Periorbital cellulitis (preseptal cellulitis)	Trauma: <i>S. aureus</i> , other streptococci Bacteremia: pneumococcus, streptococci, <i>H. influenzae</i>	Cutaneous erythema, warmth, normal vision, minimal involvement of orbit; fever, leukocytosis, toxic appearance	Systemic antibiotics

CMV, Cytomegalovirus; EBV, Epstein-Barr virus; JIA, juvenile idiopathic arthritis; SLE, systemic lupus erythematosus.

Blepharitis is associated with staphylococcal infections, seborrhea, and meibomian gland dysfunction. The child complains of photophobia, burning, irritation, and a foreign body sensation that causes the child to rub the eyes. Eyelid hygiene with an **eyelid scrub** routine is the initial step in treatment.

Hordeola are acute suppurative nodular inflammatory lesions of the eyelids associated with pain and redness. **External hordeola** or **styes** occur on the anterior eyelid, in the Zeis glands, or in the lash follicles and usually are caused by staphylococci. **Internal hordeola** occur in the meibomian glands and may be infected with staphylococci or may be sterile. If the meibomian gland becomes obstructed, the gland secretions accumulate, and a **chalazion** develops. Hordeola usually respond spontaneously to local treatment measures, but may recur.

Dacryocystitis is an infection or inflammation of the lacrimal sac, which is usually obstructed, and is most commonly caused by *Staphylococcus aureus* or coagulase-negative staphylococci. A mucopurulent discharge can be expressed with gentle pressure on the nasolacrimal sac. Treatment usually requires probing of the nasolacrimal system to establish communication.

Endophthalmitis is an emergent, sight-threatening infection that usually follows trauma, surgery, or hematogenous spread from a distant focus. Causative organisms include coagulase-negative staphylococci, *S. aureus*, *S. pneumoniae*, *Bacillus cereus*, and *Candida albicans*. Examination is difficult because of severe blepharospasm and extreme photophobia. A **hypopyon** and haze in the anterior chamber may be visible on examination.

Treatment

The lids should be treated as needed with warm compresses to remove accumulated discharge. Acute bacterial conjunctivitis is frequently self-limited, but topical antibiotics hasten resolution. Antibiotics are instilled between the eyelids four times a day until the discharge and chemosis subside. Recommended treatment includes topical trimethoprim-polymyxin B solution, sulfacetamide 5% solution, or erythromycin ointment. Ciprofloxacin solution

should be restricted to corneal infections and resistant gram-negative infections in hospitalized patients. Gonococcal conjunctivitis in adults is treated with a single intramuscular (IM) dose of ceftriaxone (1 g) plus azithromycin (1 g in a single dose, to treat possible concomitant chlamydial infection and cover for the possibility of antimicrobial resistance to ceftriaxone).

The treatment of **ophthalmia neonatorum** depends on the cause (see [Table 119.2](#)). Gonococcal ophthalmia neonatorum is treated with a single dose of ceftriaxone (25-50 mg/kg intravenous [IV] or IM; maximum dose 125 mg). These infants should be hospitalized. Antibiotic treatment also is recommended for infants born to mothers with untreated gonorrhea. Chlamydial conjunctivitis is treated with oral erythromycin for 14 days, partly to reduce the risk of subsequent chlamydial pneumonia.

Complications and Prognosis

The prognosis for bacterial and viral conjunctivitis is excellent. The major complication is keratitis, which can lead to ulcerations and perforation, and is uncommon except with *N. gonorrhoeae* and HSV infections. Chlamydial conjunctivitis may progress in infants to chlamydial pneumonia, which typically develops from 2-18 weeks of age (see [Chapter 110](#)).

Prevention

Careful hand washing is important to prevent spread of conjunctivitis. Bacterial conjunctivitis is considered contagious for 24 hours after initiating effective treatment. Children may return to school, but treatment measures must be continued until there is complete clinical resolution.

All newborns, whether delivered vaginally or by cesarean section, should receive prophylaxis for gonococcal ophthalmia neonatorum as soon as possible after delivery. A single application of erythromycin 0.5% ointment is used most often. Alternative methods include tetracycline 1% ointment and silver nitrate 1% solution. These are equally effective in preventing gonococcal ophthalmia, but silver nitrate usually causes a chemical conjunctivitis. Neither silver nitrate solution nor tetracycline ophthalmic ointment is manufactured in the United States currently. Erythromycin ointment does not prevent chlamydial ophthalmia.

CHAPTER 120

Infection in the Immunocompromised Person

Etiology

Many diseases or their treatments adversely affect the immune system, including primary immunodeficiencies, human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS), cancer, stem cell and organ transplantation, and immunosuppressive drugs used to treat cancer, autoimmune diseases, and transplant patients. These patients are at significant risk of life-threatening infections from invasive bacterial or fungal flora of the oropharynx, skin, and gastrointestinal tract; acquisition of exogenous infection from infected persons or the environment; and reactivation of latent infections until their immune function recovers (Table 120.1).

TABLE 120.1

Immunodeficiencies and Associated Prevalent Pathogens

DEFECT	PATHOGEN
Granulocytopenia	GRAM-POSITIVE COCCI
	<i>Staphylococcus aureus</i>
	Coagulase-negative staphylococci (<i>S. epidermidis</i> , <i>S. haemolyticus</i> , <i>S. hominis</i>)
	Viridans group streptococci (<i>S. mitis</i> , <i>S. oralis</i>)
	<i>Granulicatella</i> and <i>Abiotrophia</i> spp. (formerly nutritionally variant streptococci)
	Enterococci (<i>E. faecalis</i> , <i>E. faecium</i>)

	<i>Escherichia coli</i>
	<i>Pseudomonas aeruginosa</i>
	<i>Klebsiella pneumoniae</i>
<i>Enterobacter</i> and <i>Citrobacter</i> spp.	
Damaged integument	

Skin and central venous catheter related	Coagulase-negative staphylococci (<i>S. epidermidis</i> , <i>S. haemolyticus</i> , <i>S. hominis</i>)
	<i>Staphylococcus aureus</i>
	<i>Stenotrophomonas maltophilia</i>
	<i>Pseudomonas aeruginosa</i>
	<i>Acinetobacter</i> spp.
	Corynebacteria
	<i>Candida</i> spp. (<i>C. albicans</i> , <i>C. parapsilosis</i>)
	<i>Rhizopus</i> spp.
Oral mucositis	Viridans group streptococci (<i>S. mitis</i> , <i>S. oralis</i>)
	<i>Abiotrophia</i> and <i>Granulicatella</i> species (nutritionally variant streptococci)
	<i>Capnocytophaga</i> spp.
	<i>Fusobacterium</i> spp.
	<i>Rothia mucilaginosa</i>
	<i>Candida</i> spp. (<i>C. albicans</i> , <i>C. tropicalis</i> , <i>C. glabrata</i>)
	Herpes simplex virus
Gut mucosal barrier injury	<i>Escherichia coli</i>
	<i>Pseudomonas aeruginosa</i>
	Coagulase-negative staphylococci
	Enterococci (<i>E. faecalis</i> , <i>E. faecium</i>)
	<i>Candida</i> spp.
Neutropenic enterocolitis	<i>Clostridium</i> spp. (<i>C. septicum</i> , <i>C. tertium</i>)
	<i>Staphylococcus aureus</i>
	<i>Pseudomonas aeruginosa</i>
Impaired cellular immunity	Herpesviruses
	Cytomegalovirus
	Respiratory viruses
	<i>Listeria monocytogenes</i>
	<i>Nocardia</i> spp.
	<i>Mycobacterium tuberculosis</i>
	Nontuberculous mycobacteria
	<i>Pneumocystis jirovecii</i>
	<i>Aspergillus</i> spp.
	<i>Cryptococcus</i> spp.
	<i>Histoplasma capsulatum</i>
	<i>Coccidioides</i> spp.
	<i>Penicillium marneffeii</i>
<i>Toxoplasma gondii</i>	

Impaired humoral immunity	<i>Streptococcus pneumoniae</i>
	<i>Haemophilus influenzae</i>
COMPROMISED ORGAN FUNCTION	
Splenectomy	<i>Streptococcus pneumoniae</i>
	<i>Haemophilus influenzae</i>
	<i>Neisseria meningitidis</i>
Deferoxamine for iron overload	<i>Rhizopus</i> spp.
	<i>Yersinia enterocolitica</i>

From JP Donnelly. Infections in the immunocompromised host: general principles. In: Mandell GL, Bennett JE, Dolin R, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*. 7th ed. Philadelphia: Elsevier; 2010:3782.

The infections seen in immunocompromised persons can often be predicted by which component of the immune system is abnormal. Episodes of fever and **neutropenia**, defined as an **absolute neutrophil count (ANC)** of less than 500/mm³, are especially common in cancer and transplant patients and increase risk for bacterial and fungal infections. The use of **corticosteroids** and potent immunosuppressive drugs that impair the activation of T lymphocytes increases the risk for pathogens normally controlled by T cell-mediated responses, such as *Pneumocystis jirovecii* and *Toxoplasma gondii*, as well as intracellular pathogens, such as *Salmonella*, *Listeria*, and *Mycobacterium*. Lymphopenia also increases the risk of viral infections, either due to primary acquisition or reactivation of latent infection.

Immunocompromised patients also have increased risk for bacterial infection due to the presence of central indwelling catheters. Organisms most commonly isolated in this case include coagulase-negative staphylococci, *S. aureus*, gram-negative bacteria, *Enterococcus*, and *Candida* (see [Chapter 121](#)).

Fungal pathogens account for approximately 10% of all infections associated with childhood cancer. *Candida* species are the most common cause of all fungal infections, with *Aspergillus* being the second most common pathogen. Other risk factors for fungal infections include oropharyngeal and gastrointestinal mucositis facilitating systemic fungal invasion, presence of long-term indwelling intravascular catheters, parenteral nutrition, hyperglycemia, extreme prematurity, and broad-spectrum antibacterial therapy that promotes fungal colonization as a precursor to infection.

Infection with *T. gondii* represents reactivation of quiescent infection facilitated by cancer-associated or therapy-associated cellular immunodeficiency. *P. jirovecii* primarily causes pneumonitis in patients with leukemia, lymphoma,

HIV, or those on long-term corticosteroids and can occasionally cause extrapulmonary disease (sinusitis, otitis media).

Viral opportunistic infections in patients with cancer usually represent symptomatic reactivation from latency facilitated by cancer or therapy-associated cellular immunodeficiency. Herpes simplex virus (HSV) can cause severe and prolonged mucocutaneous infection or disseminated disease. Cytomegalovirus (CMV) can also cause focal or systemic disease in immunocompromised persons, especially in transplant patients. Manifestations of CMV disease include retinitis, hepatitis, pneumonitis, esophagitis, encephalitis, and colitis. Reactivation of Epstein-Barr virus (EBV) is associated with **posttransplant lymphoproliferative disorder (PTLD)**. Varicella-zoster virus (VZV) can cause serious primary infection in susceptible persons, sometimes with accompanying encephalitis, hepatitis, or pneumonitis. VZV can also reactivate as shingles during chemotherapy and may cause disseminated infection.

Epidemiology

Chemotherapeutic agents target rapidly dividing cells, especially myeloproliferative cells, which causes myelosuppression. Children receiving allogeneic transplants are at greater risk for infection than children receiving autologous transplants. Prolonged time to hematological engraftment is a significant risk factor for infection in these patients ([Fig. 120.1](#)). Foreign bodies (shunts, central venous catheters) and mucositis interfere with cutaneous barriers against infection and, together with neutropenia and/or lymphopenia, increase the risk of bacterial or fungal infections. Multiple antimicrobial exposures put these patients at risk for resistant bacterial, fungal, and viral infections.

FIGURE 120.1 Infectious phases after transplant. The infectious complications that occur most commonly are set against the phases before and after an allogeneic hematopoietic stem cell transplant. Note the time scale progresses from days to weeks, then to months. The fluctuations in the different components of the immune system are represented at the bottom of the figure and show when severe deficiency coincides with the time of engraftment and begins to recover thereafter. The various classes of microorganism change during the different phases, but note that viruses and fungi can cause infections throughout the entire period. *CMV*, Cytomegalovirus; *HHV-6*, human herpesvirus 6; *HSV*, herpes simplex virus; *NK*, natural killer; *RSV*, respiratory syncytial virus; *VZV*, varicella-zoster virus. (From Donnelly JP, Blijlevens NMA, van der Velden WJFM. Infections in the immunocompromised host: general principles. In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*. 8th ed. Philadelphia: Elsevier; 2015. Fig 309.6.)

The relative rate of some infection in patients with cancer is 10-15%. The most frequently infected sites, in descending order, are the respiratory tract (lung, sinuses), the bloodstream, surgical wounds, and the urinary tract.

Clinical Manifestations

Decision-Making Algorithms

Neutropenia

Pancytopenia
Fever Without a Source
Recurrent Infections

Fever is the most common, and sometimes the only, presenting symptom of serious infection in cancer and transplant patients. The presence of fever with neutropenia, even in the absence of other signs or symptoms, demands prompt evaluation and empiric antimicrobial therapy because of the potential for life-threatening infection. All symptoms and signs should be evaluated thoroughly. However, some symptoms may be absent based on the underlying immunodeficiency. In the absence of neutrophils to induce localized signs of inflammation, determination of the source of infection by physical examination is often difficult. For example, chest findings may be absent, despite pneumonia, and revealed only by chest radiograph at presentation or when the neutrophil count recovers.

Laboratory Tests and Imaging

Evaluation of fever and neutropenia in immunocompromised persons requires blood cultures for bacterial and fungal pathogens obtained by peripheral venipuncture and from all lumens of any indwelling vascular catheters (Table 120.2). A complete blood count with manual differential, C-reactive protein, complete chemistry panel, culture of urine, and Gram staining/culture of potential sites of specific infection found during history and physical should be performed. Chest radiographs are important to assess for the presence of pulmonary infiltrates. Specialized imaging studies, such as computed tomography (CT) or magnetic resonance imaging (MRI), can be useful in selected cases, such as with suspected sinusitis or intraabdominal infection, or to further delineate the location and extent of abnormalities seen on plain radiographs. Sinus infection with bacteria, *Aspergillus*, or *Zygomycetes* is common in neutropenic hosts and may be detected only on the CT scan. Viruses can be detected in blood, respiratory samples, cerebrospinal fluid, and skin lesions by polymerase chain reaction (PCR).

TABLE 120.2

Initial Diagnostic Evaluation of Children With Fever and Neutropenia

Initial Diagnostic Evaluation of Children with Fever and Neutropenia

- Careful medical history
- Physical examination with attention to the skin, perirectal area, and other mucosal sites (which should be repeated at least daily in febrile neutropenic patients)
- Specimens for culture
 - Blood: peripheral venipuncture and specimens from every lumen or access port of intravascular catheters
 - Urine
 - Respiratory secretions: for bacteria and viruses if symptoms are present
 - Any site with clinical signs of infection, including *Clostridium difficile* toxin assay if diarrhea present and cerebral spinal fluid if headache, meningismus, or mental status change
- Chest radiograph
- Other imaging studies or diagnostic procedures as clinically indicated
 - Sinus radiograph or computed tomography
 - Abdominal ultrasonography or computed tomography
 - Head CT or MRI with contrast

Modified from Koh AY, Pizzo PA. Fever and Granulocytopenia. In: Long SS, ed. *Principles and Practice of Pediatric Infectious Diseases*. 4th ed. Philadelphia: Elsevier; 2012.

Differential Diagnosis

Initially the patient should have a complete physical examination, including careful scrutiny of the oropharynx, nares, external auditory canals, skin and axilla, groin, perineum, and rectal area. The exit site and subcutaneous tunnel of any indwelling vascular catheter should be examined closely for erythema and palpated for tenderness and expression of purulent material. Perirectal abscess is a potentially serious infection in neutropenic hosts, with tenderness being the only clue on examination. Any presumptive infection identified during the evaluation should direct appropriate cultures and tailor anti-infective therapy.

Treatment

Treatment should be provided as appropriate for focal infections identified by physical examination or diagnostic imaging. Select *low-risk* patients may be managed as outpatients. Empirical treatment of fever and neutropenia without an identified source should include an extended-spectrum penicillin or cephalosporin with activity against gram-negative bacilli, including *P. aeruginosa*. If the patient has an indwelling vascular catheter, vancomycin may be added because of the increasing prevalence of methicillin-resistant *S. aureus* (MRSA) but can be discontinued if *S. aureus* is not cultured after 48-72 hours. Specific antibiotic regimens should be guided by local antibiotic resistance patterns at each institution.

If no microbiologic cause is isolated, empirical broad-spectrum antibiotics are

continued as long as the patient remains neutropenic, regardless of whether the fever resolves. Antibiotic therapy should be modified as indicated by new findings or if the patient's clinical status deteriorates. Further investigation for fungal infection and empirical treatment with antifungal agents is instituted in patients who have neutropenia and persistent fever without a focus, despite broad-spectrum antibacterial therapy for approximately 5 days.

Prevention

Current guidelines discourage the use of broad-spectrum prophylactic antibiotics to prevent fever and neutropenia because of lack of efficacy and concerns about development of antibiotic resistance. Administration of trimethoprim-sulfamethoxazole to prevent *P. jiroveci* infection is routine for patients undergoing intensive chemotherapy or immunosuppression for transplantation. Prophylaxis against *P. jiroveci* generally starts with initiation of chemotherapy and continued until 6 months after it has been completed. In select populations, such as patients undergoing hematopoietic stem cell transplantation, prophylactic antifungals such as fluconazole or voriconazole are beneficial. Patients at risk for viral reactivation with HSV, VZV, and/or CMV may be placed on antiviral prophylaxis with acyclovir or ganciclovir.

Immunocompromised susceptible persons exposed to chickenpox within 2 days before the onset of rash until 5 days after the onset of rash in the index case should receive varicella-zoster immune globulin (VZIG). Modified infection after VZIG may not result in protective immunity, and persons who receive VZIG prophylaxis should be considered still at risk with any subsequent exposures.

CHAPTER 121

Infections Associated With Medical Devices

Infections are a common and important complication of indwelling medical devices and are a major part of **health care–associated infections** (formerly

known as **nosocomial infections**).

Vascular Device Infections

Vascular catheters are inserted in most inpatients and used in many outpatients. The use of catheters for long-term access to the bloodstream has been an important advance for the care of persons who require parenteral nutrition, chemotherapy, or extended parenteral antibiotic therapy. The major complication of such catheters is infection. Short, peripheral intravenous (IV) catheters used for short-term access in stable patients are associated with a low rate of infection, especially in children. **Peripherally inserted central catheters (PICC)** are commonly used for medium-term venous access. **Central venous catheters** are commonly placed for extended vascular access, such as for chemotherapy, using tunneled silicone elastomer catheters (**Broviac** or **Hickman catheters**) that are surgically inserted into a central vein, passed through a subcutaneous tunnel before exiting the skin, and anchored by a subcutaneous cuff. Contamination of the catheter hub or any connection of the IV tubing is common and is a major predisposition to catheter-associated infection. Totally implanted venous access systems (Port-a-Cath, Infuse-a-Port) have a silicone elastomer catheter tunneled beneath the skin to a reservoir implanted in a subcutaneous pocket. Implanted catheters or ports decrease, but do not eliminate, the opportunity for microbial entry at the skin site.

Catheter-related thrombosis and catheter-related infection can develop separately or together. Ultrasound can identify thrombi, but infection can be identified by culture only. **Thrombophlebitis** is inflammation with thrombosis in a blood vessel. **Septic thrombophlebitis** is thrombosis with organisms embedded in the clot. **Central line associated bloodstream infection (CLABSI)** implies isolation of the same organism from a catheter and from peripheral blood of a patient with clinical symptoms of bacteremia and no other apparent source of infection. Confirmation requires quantitative colony counts of both samples, which is not routinely performed. Possible sources of the bacteremia include the infusate, contamination via tubing and catheter connections, or transient bacteremia seeding the catheter, which may or may not be clinically apparent. Infection may be associated with an **exit site infection** limited to the insertion site or may extend along the catheter tunnel of buried catheters to cause a **tunnel infection**. Given the proximity of central venous catheters to cardiac valves, persistent central infections can also be complicated

by endocarditis. An echocardiogram should be considered in patients with persistent bacteremia related to a central line (see [Chapter 111](#)).

Many microorganisms cause catheter-related infections ([Table 121.1](#)). Gram-positive cocci, primarily staphylococci, cause more than 50% of CLABSIs and exit site infections. Other skin flora, such as coagulase-negative staphylococci, diphtheroids, and *Bacillus* are often involved. Gram-negative organisms also commonly cause infection. Polymicrobial infections of central venous catheters are common. Fungal catheter infections, usually *Candida* species, are most common among persons receiving broad-spectrum antibiotics or parenteral nutrition.

TABLE 121.1

Organisms Causing Catheter-Related Infections

CLASSIFICATION OF PATHOGEN	COMMON	UNCOMMON
Gram-positive organisms	Coagulase-negative staphylococci, <i>Staphylococcus aureus</i> , <i>Enterococcus</i>	Diphtheroids, <i>Bacillus</i> , <i>Micrococcus</i>
Gram-negative organisms	<i>Escherichia coli</i> , <i>Klebsiella</i> , <i>Pseudomonas aeruginosa</i>	<i>Acinetobacter</i> , <i>Enterobacter</i> , <i>Neisseria</i>
Fungi	<i>Candida</i> species	<i>Malassezia furfur</i>
Miscellaneous		Nontuberculous mycobacteria, <i>Lactobacillus</i>

Risk factors for CLABSI include prematurity, burns and skin disorders that adversely affect the skin integrity, neutropenia, and other immunodeficiencies (see [Chapter 120](#)). Infection rates are lower for tunneled and implanted catheters. Catheters inserted in emergency settings are more likely to be infected than catheters placed electively.

Clinical signs of catheter-associated bacteremia or fungemia range from mild fever to overwhelming sepsis. Infection at the site of the central catheter entrance is manifested as a localized cellulitis with warmth, tenderness, swelling, erythema, and discharge. Tunnel infection is manifested by similar findings along the tunnel route. Thrombophlebitis is classically manifested as a warm, erythematous, tender palpable cord originating at the IV catheter site but may be subclinical or manifested only by persistent fever without signs of local inflammation.

Decision-Making Algorithm

Fever and Rash

The treatment of catheter-related infection depends on the site of the infection and the pathogen involved. CLABSI is optimally treated with catheter removal; however, in a stable patient or with certain organisms, antibiotic therapy alone may suffice. Infection with organisms of low virulence may be manifested by fever alone, and removal of the catheter frequently is followed by prompt defervescence and complete resolution of infection. Nonetheless many patients are dependent on the catheter and removal may be difficult. Empirical initial therapy for suspected infection should include antibiotics active against gram-negative organisms such as a broad-spectrum cephalosporin and against *S. aureus* and coagulase-negative staphylococci with vancomycin. Subsequently, antibiotic regimens should be tailored to the specific organism identified. If the patient is not critically ill and the pathogen is likely to be susceptible to antibiotic therapy, a trial of antibiotics is given through the infected catheter. The total duration of therapy depends on the pathogen and the duration of positive cultures and is usually 10-14 days after sterilization of the bloodstream. Catheter removal is indicated with sepsis, septic thrombophlebitis, clinical deterioration (despite appropriate therapy), persistently positive blood culture results after 48-72 hours of appropriate antimicrobial therapy, embolic lesions, or fungal infection because of poor response to antifungal therapy alone. Catheter removal is also recommended for infection with *Staphylococcus aureus* and *Pseudomonas aeruginosa*. Infection of the pocket around an implanted port is unlikely to respond to antibiotics alone, and removal of the foreign body is usually necessary.

Antibiotic-lock therapy is a method of sterilizing intravascular catheters by using high concentrations of antibiotics or ethanol infused into the portion of the catheter between the hub and the vessel entry. The solution is allowed to dwell within the catheter segment for several hours. It may be useful for treatment of catheter-associated infections in which line salvage is desired and/or for prevention of infection in patients at high risk.

Aseptic technique is essential during catheter insertion. Catheters that are placed during emergency situations should be replaced as soon as medically feasible. Care of indwelling catheters involves meticulous attention to sterile

technique whenever the system is entered. Care of the catheter entry site commonly involves a topical antibiotic or disinfectant. Catheters that are no longer necessary should be removed.

Ventilator-Associated Pneumonia

Intubation of the airway provides direct access to the lungs and bypasses normal host defenses. Organisms enter the lungs directly through the lumen of the tube or by descending around the tube, which may result in **ventilator-associated pneumonia**. Contaminated respiratory equipment, humidification systems, or condensate introduces bacteria directly into lower airways. The continuously open upper airway increases the risk of aspiration of oropharyngeal flora and reflux of gastric contents and interferes with clearance of the airway because an effective cough requires a closed glottis.

Urinary Catheters

The most important risk factors for urinary tract infections (UTIs) are the presence of catheters, instrumentation, and anatomical abnormalities (see [Chapter 114](#)). Organisms enter the bladder through the catheter by instillation of contaminated irrigation fluids, backflow of contaminated urine from the drainage bag, or ascent of bacteria around the meatus along the outside of the catheter. Indwelling catheters facilitate direct access to the bladder and should have a closed drainage system. After simple, straight catheterization, the incidence of UTI is 1-2%. Organisms that cause catheter-associated UTIs include fecal flora, such as gram-negative enteric bacilli, most commonly *Escherichia coli* and *Enterococcus*. With concomitant antibiotic treatment, resistant organisms predominate, and fungi may emerge as pathogens.

The most important aspect of prevention is to minimize the duration and use of catheterization. Intermittent catheterization is preferred over indwelling catheter drainage whenever feasible. Insertion of catheters must be performed with aseptic technique, and the drainage system must remain closed at all times, with sterile technique used whenever the system is entered. Drainage bags always should be dependent to avoid backflow of urine into the bladder.

Peritoneal Dialysis–Associated Infections

Indwelling catheters used for peritoneal dialysis may develop exit site infections, tunnel infections, or lead to peritonitis. The usual route of infection is from the skin surface along the tunnel and into the peritoneum. The most common pathogens are skin flora, including *Staphylococcus* species; organisms that contaminate water, such as *Pseudomonas* and *Acinetobacter*; enteric flora, such as *E. coli* and *Klebsiella*; and fungi, such as *C. albicans*. Peritonitis may present with fever, vague abdominal pain, and cloudy dialysate. The diagnosis is established on clinical manifestations and confirmed by culture of the dialysate. Prevention of infection requires careful planning of the location of the exit site to minimize contamination, aseptic insertion of the catheter, meticulous care of the catheter site, securing of the catheter to avoid tension and motion, and aseptic technique during dialysis.

Central Nervous System Shunts

Important risk factors of health care–associated central nervous system (CNS) infections are surgery, presence of a ventriculoperitoneal shunt (VPS), and cerebrospinal fluid (CSF) leaks. Infection of a VPS results from contamination of the system at the time of placement, breakdown of overlying skin, or from hematogenous seeding. Externalized ventricular drains and subdural bolts allow direct access of skin flora to the CSF. For these devices, the rates of infection increase with the duration of catheterization, especially beyond 5 days. Device-related CNS infections can be diagnosed in the same way as other types of meningitis or ventriculitis with assessment of the CSF for pleocytosis, protein, glucose, and gram stain and culture.

The most common pathogens causing shunt infections are coagulase-negative staphylococci and *S. aureus*. After skull fracture or cranial surgery, a CSF leak may facilitate ascending infection from the nasopharynx, especially with *Streptococcus pneumoniae*, which frequently colonizes the nasopharynx. Patients with shunt infections may present with only fever and headache or may present with typical signs and symptoms of meningitis (see [Chapter 100](#)). Infections caused by coagulase-negative staphylococci or *Propionibacterium acnes* typically present with insidious onset of fever, malaise, headache, and vomiting. Empirical therapy is with vancomycin, with additional antibiotics if gram-negative bacteria are suspected.

Antibiotics frequently are used perioperatively during placement of shunts and other neurosurgical procedures. It is not clear that antibiotics decrease infection

rates in these clean procedures, especially beyond one dose. External ventricular drains should be maintained as closed systems with aseptic technique and removed as soon as possible. Drainage bags always should be dependent to avoid backflow.

CHAPTER 122

Zoonoses and Vector Borne Infections

Zoonoses are classically defined as infections that are transmitted in nature between vertebrate animals and humans. Many zoonotic pathogens are maintained in nature by means of an **enzootic cycle**, in which mammalian hosts and arthropod vectors reinfect each other. Humans frequently are only incidentally infected. Of the more than 150 different human zoonotic diseases that have been described (Table 122.1), Lyme disease (*Borrelia burgdorferi*) is the most common tick-borne infection in the United States. Other common pathogens include *Rickettsia rickettsii* (Rocky Mountain spotted fever [RMSF]), ehrlichiosis (*Ehrlichia chaffeensis*), West Nile virus, and anaplasmosis (*Anaplasma phagocytophilum*). The epidemiology of zoonoses is related to the geographic distribution of the hosts and, if vector-borne, the distribution and seasonal life cycle of the vector.

TABLE 122.1

Major Zoonotic Infections*

DISEASE	CAUSATIVE AGENT	COMMON ANIMAL RESERVOIRS	VECTORS/MODES OF TRANSMISSION	GEOGRAPHIC DISTRIBUTION
BACTERIAL DISEASES				
Anthrax	<i>Bacillus anthracis</i>	Cattle, goats, sheep	Aerosol inhalation of spores in hides and other animal by-products, direct contact with infected animals or their carcasses	Worldwide; rare in United States
Brucellosis	<i>Brucella</i>	Cattle, sheep, goats, swine, elk, bison, deer, dogs	Aerosol inhalation, direct contact, ingestion of contaminated goat cheese	Worldwide

			and milk	
Campylobacteriosis	<i>Campylobacter jejuni</i>	Poultry, dogs (puppies), kittens, hamsters	Direct contact, ingestion of contaminated food or water	Worldwide
<i>Capnocytophaga canimorsus</i>		Dogs, cats (rare)	Bites, scratches	Worldwide
Cat-scratch disease	<i>Bartonella henselae</i>	Cats, dogs (rare)	Bites and scratches	Worldwide
Erysipeloid	<i>Erysipelothrix rhusiopathiae</i>	Sheep, swine, cattle, horses, birds, fish	Direct contact	Worldwide
Listeriosis	<i>Listeria monocytogenes</i>	Cattle, fowl, goats, sheep	Ingestion of contaminated food, unpasteurized cheese and dairy products	Worldwide
<i>Pasteurella multocida</i>		Cats, dogs	Bites, scratches, licks	Worldwide
Plague	<i>Yersinia pestis</i>	Wild and domestic rodents, cats, prairie dogs	Direct contact, flea bite	New Mexico, Arizona, Utah, Colorado, California
Psittacosis	<i>Chlamydia psittaci</i>	Pet birds, poultry	Aerosol inhalation	
Rat-bite fever (streptobacillary or Haverhill fever)	<i>Streptobacillus moniliformis</i>	Rodents (especially rats), cats, gerbils	Bites, ingestion of contaminated food or water	Japan, Asia; rare in United States
Salmonellosis	Nontyphoidal <i>Salmonella</i>	Poultry, dogs, cats, reptiles, amphibians	Direct contact, ingestion of contaminated food or water	Worldwide
Tularemia	<i>Francisella tularensis</i>	Rabbits, sheep, cattle, cats	Aerosol inhalation, direct contact, ingestion of contaminated meat, tick bite, deerfly bite	California, Utah, Arkansas, Oklahoma
Yersiniosis	<i>Yersinia enterocolitica</i> , <i>Yersinia pseudotuberculosis</i>	Rodents, cattle, goats, sheep, swine, birds, horses	Direct contact, ingestion of contaminated food or water	Worldwide

MYCOBACTERIAL DISEASES

Mycobacteriosis	<i>Mycobacterium marinum</i> , <i>Mycobacterium fortuitum</i> , <i>Mycobacterium kansasii</i>	Fish, aquarium	Direct contact, scratches	Worldwide
-----------------	---	----------------	---------------------------	-----------

SPIROCHETAL DISEASES

--	--	--	--	--

Leptospirosis	<i>Leptospira</i> species	Dogs, rodents, livestock	Direct contact, contact with water or soil contaminated by urine of infected animals	Worldwide
Lyme disease	<i>Borrelia burgdorferi</i>	Rodents	Tick bite (<i>Ixodes scapularis</i> , <i>Ixodes pacificus</i>)	Northeast and Midwestern United States, California
Rat-bite fever	<i>Spirillum minus</i> (Asia); <i>Streptobacillus moniliformis</i> (U.S.)	Mice, rats, hamsters	Bites, ingestion of contaminated food or water	Japan, Asia; United States
Relapsing fever	<i>Borrelia</i> (e.g., <i>Borrelia hermsii</i>)	Rodents	Soft tick bite	Western and southern United States
Southern tick-associated rash illness	Unknown	Deer, rodents	Tick bite	Southeastern and southern central U.S.
RICKETTSIAL DISEASES				
Spotted Fever Group				
Rocky Mountain spotted fever	<i>Rickettsia rickettsii</i>	Dogs, rodents	Tick bite	Western hemisphere
Mediterranean spotted fever (Boutonneuse fever)	<i>Rickettsia conorii</i>	Dogs, rodents	Tick bite	Africa, Mediterranean region, India, Middle East
African tick-bite fever	<i>Rickettsia africae</i>	Cattle, possibly goats	Tick bite	Sub-Saharan Africa, Caribbean
Rickettsialpox	<i>Rickettsia akari</i>	Mice	Mite bite	North America, Russia, Ukraine, Adriatic region, Korea, South Africa
Murine typhus–like illness	<i>Rickettsia felis</i>	Opossums, cats	Flea bite	Western hemisphere, Europe
Typhus Group				
Typhus, flea-borne endemic	<i>Rickettsia typhi</i>	Rats, cats	Rat flea or cat flea feces	Worldwide
Typhus, louse-borne endemic	<i>Rickettsia prowazekii</i>	Flying squirrels	Lice or fleas of flying squirrel, person-to-person via body louse	United States
Scrub Typhus				
Scrub typhus	<i>Orientia tsutsugamushi</i>	Rodents	Chigger bite	Southern Asia, Japan, Indonesia, Australia, Korea, Asiatic Russia, India, China
Ehrlichiosis and Anaplasmosis				
Human monocytic ehrlichiosis	<i>Ehrlichia chaffeensis</i>	Deer, dogs	Tick bite	United States, Europe, Africa

Anaplasmosis (human granulocytic ehrlichiosis)	<i>Anaplasma phagocytophilum</i>	Rodents, deer, ruminants	Tick bite	United States, Euro
Ehrlichiosis ewingii	<i>Ehrlichia ewingii</i>	Dogs	Tick bite	United States
Sennetsu ehrlichiosis	<i>Neorickettsia sennetsu</i>	Unknown	Unknown; possibly ingestion of raw fish	Japan, Malaysia
Q Fever				
Q fever	<i>Coxiella burnetii</i>	Cattle, sheep, goats, cats, wild rodents	Inhalation of infected aerosols, ingestion of contaminated dairy products, direct contact with excreta	Worldwide
VIRAL DISEASES				
Colorado tick fever	Colorado tick fever virus	Rodents	Tick bite	Rocky Mountains, Pacific northwest, western Canada
Hantavirus cardiopulmonary syndrome	Hantavirus	Rodents, mice	Aerosol inhalation of infected excreta	Southwestern United States
Herpesvirus B infection	Herpesvirus B	Macaque monkeys	Animal bite	Africa, Asia (and primate centers worldwide)
Lymphocytic choriomeningitis	Lymphocytic choriomeningitis virus	Rodents, hamsters, mice	Aerosol inhalation, direct contact, bite	Worldwide
Monkeypox	Monkeypox virus	Prairie dogs, African rodents	Direct contact, bite, scratch	Central and west Africa
Orf	Orf virus	Sheep, goats	Direct contact with infected saliva	Worldwide
Rabies	Rabies virus	Skunks, bats, raccoons, foxes, cats, dogs	Bites and scratches	Worldwide
Vesicular stomatitis	Vesicular stomatitis virus	Horses, cattle, swine	Direct contact	Americas
PROTOZOAN DISEASES				
African Trypanosomiasis				
East African sleeping sickness	<i>Trypanosoma brucei rhodesiense</i>	Wild animals (antelope, bush buck, and hartebeest), rarely cattle	Insect bite (tsetse fly)	East Africa
West African sleeping sickness	<i>Trypanosoma brucei gambiense</i>	Humans are main reservoir, wild and domestic animals	Insect bite (tsetse fly)	West Africa
American trypanosomiasis	<i>Trypanosoma cruzi</i>	Raccoons, opossums, rodents, dogs	Insect bite (reduviid bug); contact with fecal	South America, Central America, south

(Chagas disease)			material of reduviid bug	Texas
Babesiosis	<i>Babesia</i>	White-footed mouse	Tick bite, blood transfusion	Worldwide
Leishmaniasis, mucocutaneous and cutaneous	<i>Leishmania</i>	Rodents, dogs	Sandfly bite	Tropics
Leishmaniasis, visceral	<i>Leishmania donovani</i> complex	Rodents, dogs	Sandfly bite	Tropics
Toxoplasmosis	<i>Toxoplasma gondii</i>	Cats, livestock	Ingestion of oocysts in fecally contaminated material or ingestion of tissue cysts in undercooked meat	Worldwide

*Many helminths are also zoonotic (see [Tables 123.4](#) and 123.5).

†In addition to fever.

RLQ, Right lower quadrant.

From Kimberlin DW, Brady MT, Jackson MA, et al. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:1015–1022. Copyright 2015 American Academy of Pediatrics. Reproduced with permission.

Many zoonoses are spread by ticks, including Lyme disease, RMSF, ehrlichiosis, tularemia, tick typhus, and babesiosis. Preventive measures to avoid tick-borne diseases include using insect repellents that contain **DEET** (*N,N*-diethyl-*m*-toluamide) on skin and insect repellents that contain **permethrin** on clothing; avoiding tick-infested habitats (thick scrub oak, briar, poison ivy sites); avoiding excretory products of wild animals; wearing appropriate protective clothing (closed-toe shoes, long pants); and promptly removing ticks.

Ticks are best removed using blunt forceps or tweezers to grasp the tick as close to the skin as possible to pull the tick steadily outward. Squeezing, twisting, or crushing the tick should be avoided because the tick's bloated abdomen can act like a syringe if squeezed. Transmission of infection seems to be most efficient after 24-48 hours of nymphal tick attachment for human granulocytic ehrlichiosis, after 36 hours for *B. burgdorferi*, and after 36-48 hours for *Babesia*. Prophylactic antimicrobial therapy after a tick bite or exposure is not recommended.

Lyme Disease (*Borrelia burgdorferi*)

Etiology

Lyme disease is a tick-borne infection caused by the spirochete, *B. burgdorferi*. The vector in the eastern and midwestern United States is *Ixodes scapularis*, the **black-legged tick** that is commonly known as the **deer tick**. The vector on the Pacific coast is *Ixodes pacificus*, the **western black-legged tick**. Ticks usually become infected by feeding on the white-footed mouse (*Peromyscus leucopus*), which is a natural reservoir for *B. burgdorferi*. The larvae are dormant over winter and emerge the following spring in the nymphal stage, the stage of the tick that is most likely to transmit the infection to humans.

Epidemiology

Over 20,000 cases are reported annually in the United States, with >90% of cases reported from New England and the eastern parts of the middle Atlantic states (Fig. 122.1). In Europe most cases occur in Scandinavian countries and central Europe. Because exposure to ticks is more common in warm months, Lyme disease is noted predominantly in spring and summer. The incidence is highest among children 5-9 years old, at almost twice the incidence among adolescents and adults.

Reported Cases of Lyme Disease in the United States, 2014.

1 dot placed randomly within county
of residence for each confirmed case

FIGURE 122.1 The geographic distribution of 25,359 confirmed cases of Lyme disease in the United States in 2014. The risk for acquiring Lyme disease varies by the distribution of *Ixodes scapularis* and *Ixodes pacificus*, the proportion of infected ticks for each species at each stage of the tick's life cycle, and the presence of grassy or wooded locations favored by white-tailed deer. (From Centers for Disease Control and Prevention: Lyme Disease—United States, 2014. Available from the CDC website: http://www.cdc.gov/lyme/resources/reportedcasesoflymedisease_2014.pdf.)

Clinical Manifestations

Decision-Making Algorithms

Arthritis
Fever and Rash

The clinical manifestations are divided into early and late stages. Early infection may be localized or disseminated. **Early localized disease** develops 7-14 days after a tick bite as the site forms an erythematous papule that expands to form a red, raised border, often with central clearing (Fig. 122.2). The lesion, **erythema migrans**, is pruritic or painful, harbors *B. burgdorferi*, and, without treatment, may expand to as much as 15 cm in diameter. Systemic manifestations may include malaise, lethargy, fever, headache, arthralgias, stiff neck, myalgias, and lymphadenopathy. The skin lesions and early manifestations resolve without treatment over 2-4 weeks. Not all patients with Lyme disease recall a tick bite or develop erythema migrans.

FIGURE 122.2 Expanding annular lesion of erythema migrans at the site of a tick bite. (Courtesy Dr. Jay Capra, Abilene, Texas.)

Approximately 25% of children with Lyme disease are initially diagnosed with **early disseminated disease**, which is a consequence of bacteremic dissemination of *B. burgdorferi* to multiple sites. Early disseminated disease is characterized by multiple secondary skin lesions, aseptic meningitis, pseudotumor, papilledema, neuropathies including Bell palsy, polyradiculitis, peripheral neuropathy, mononeuritis multiplex, or transverse myelitis. Carditis with various degrees of heart block rarely may develop during this stage. Neurological manifestations usually resolve by 3 months but may recur or become chronic.

Late disease begins weeks to months after infection and is diagnosed in approximately 7% of children at initial presentation. Arthritis is the usual manifestation and may develop in 50-60% of untreated patients. The knee is involved in greater than 90% of cases, but any joint may be affected. Symptoms may resolve over 1-2 weeks but often recur in other joints. **Neuroborreliosis**, the late manifestations of Lyme disease involving the central nervous system (CNS), is rarely reported in children.

Laboratory and Imaging Studies

Antibody tests during early, localized Lyme disease may be negative and are not

useful. Additionally, patients appropriately treated for their early, localized Lyme disease may not develop a positive antibody test. The diagnosis of late disease is confirmed by serological tests specific for *B. burgdorferi*. The sensitivity and specificity of serological tests for Lyme disease vary substantially. A positive enzyme-linked immunosorbent assay or immunofluorescence assay result must be confirmed by immunoblot showing antibodies against at least either two to three (for IgM) or five (for IgG) proteins of *B. burgdorferi* (at least one of which is one of the more specific, low molecular weight, outer-surface proteins).

In late disease, the erythrocyte sedimentation rate is elevated and complement may be reduced. The joint fluid shows an inflammatory response with total white blood cell count of 25,000-125,000 cells/mm³, often with a polymorphonuclear predominance (see [Table 118.2](#)). The rheumatoid factor and antinuclear antibody are negative, but the Venereal Disease Research Laboratory test may be falsely positive. With CNS involvement, the cerebrospinal fluid shows a lymphocytic pleocytosis with normal glucose and slightly elevated protein.

Differential Diagnosis

A history of a tick bite and the classic rash is helpful but is not always present. Erythema migrans of early, localized disease may be confused with nummular eczema, tinea corporis, granuloma annulare, an insect bite, or cellulitis. **Southern tick-associated rash illness (STARI)**, which is similar to erythema migrans but not associated with any of the disseminated complications of Lyme disease, occurs in southeastern and south-central states and is associated with the bite of *Amblyomma americanum*, the lone star tick, which is abundant in the southern states and incapable of transmitting *B. burgdorferi*.

During early, disseminated Lyme disease, multiple lesions may appear as erythema multiforme or urticaria. The aseptic meningitis is similar to viral meningitis, and the seventh nerve palsy is indistinguishable from herpetic or idiopathic Bell palsy. Lyme carditis is similar to viral myocarditis. Monarticular or pauciarticular arthritis of late Lyme disease may mimic suppurative arthritis, juvenile idiopathic arthritis, or rheumatic fever (see [Chapter 89](#)). The differential diagnosis of neuroborreliosis includes degenerative neurological illness, encephalitis, and depression.

Treatment

Early localized disease and early disseminated disease, including facial nerve palsy (or other cranial nerve palsy) and carditis with first-degree or second-degree heart block, is treated with doxycycline or amoxicillin for 14-21 days. Early disseminated disease with carditis with third-degree heart block or meningitis and late neurological disease are treated with intravenous or intramuscular ceftriaxone or intravenous penicillin G for 14-28 days. Arthritis is treated with doxycycline (for children ≥ 8 years of age) or amoxicillin for 28 days. If there is recurrence, treatment should be with a repeated oral regimen or with the regimen for late neurological disease.

Complications and Prognosis

Carditis, especially conduction disturbances, and arthritis are the major complications of Lyme disease. Even untreated, most cases eventually resolve without sequelae. Lyme disease is readily treatable and curable. The long-term prognosis is excellent for treated early and late disease. Early treatment of erythema migrans almost always prevents progression to later stages. Recurrences of arthritis after treatment occur in 5-10% of patients. The most common reason patients “recur” or do not respond to treatment is that the initial diagnosis was incorrect.

Prevention

Measures to minimize exposure to tick-borne diseases are the most reasonable means of preventing Lyme disease. Postexposure prophylaxis is not routinely recommended because the overall risk of acquiring Lyme disease after a tick bite is only 1-3% even in endemic areas, and treatment of the infection, if it develops, is highly effective. Nymphal stage ticks must feed for >36 hours before the risk of transmission of *B. burgdorferi* from infected ticks becomes substantial. In hyperendemic regions, prophylaxis of adults with doxycycline, 200 mg as a single dose, within 72 hours of a nymphal tick bite is effective in preventing Lyme disease.

Rocky Mountain Spotted Fever (*Rickettsia rickettsii*)

Etiology

The cause of RMSF is *R. rickettsii*, gram-negative coccobacillary organisms that resemble bacteria but have incomplete cell walls and require an intracellular site for replication. The organism invades and proliferates within the endothelial cells of blood vessels of all major organs and tissues, causing vasculitis and resulting in increased vascular permeability, edema, and, eventually, decreased vascular volume, altered tissue perfusion, and widespread organ failure. Many tick species are capable of transmitting *R. rickettsii*. The principal ticks are the **American dog tick** (*Dermacentor variabilis*) in the eastern United States and Canada, the **wood tick** (*Dermacentor andersoni*) in the western United States and Canada, the **brown dog tick** (*Rhipicephalus sanguineus*) in Mexico and southwestern United States, and *Amblyomma cajennense* in Central and South America.

Epidemiology

RMSF is the most common rickettsial illness in the United States, occurring primarily in the eastern coastal, southeastern, and south-central states. Most cases occur from April to September after outdoor activity in wooded areas. RMSF occurs more commonly in adults, but the case fatality rate is highest in children 5-9 years of age. In approximately 50% of pediatric cases of RMSF there is no recall of a tick bite.

Clinical Manifestations

Decision-Making Algorithms

- Hepatomegaly
- Fever and Rash
- Petechiae/Purpura
- Fever Without a Source

The incubation period of RMSF is 2-14 days, with an average of 7 days. The onset is nonspecific with headache, malaise, and fever. A pale, rose-red macular or maculopapular rash appears in 90% of cases usually 2-5 days after fever onset. The early rash blanches on pressure and is accentuated by warmth. It

progresses over hours or days to a petechial and purpuric eruption that appears first on the feet and ankles, then the wrists and hands, and progresses centripetally to the trunk and head. A hallmark feature is the involvement of the palms and soles (Fig. 122.3). Myalgias, especially of the lower extremities, and intractable headaches are common. Severe cases progress with splenomegaly, myocarditis, renal impairment, pneumonitis, and shock.

FIGURE 122.3 Petechial and purpuric rash of Rocky Mountain Spotted Fever. (From McQuiston JH, Regan JJ, Paddock CD. *Rickettsia rickettsii* [Rocky Mountain Spotted Fever]. In: Long SS, Pickering LK, Prober CG, eds. *Principles and Practice of Pediatric Infectious Diseases*. 4th ed. Philadelphia: Churchill Livingstone; 2012. Fig. 178.4B.)

Laboratory and Imaging Studies

Thrombocytopenia, anemia, hyponatremia, hypoalbuminemia, and elevated hepatic transaminase levels are common laboratory findings. Organisms can be detected in skin biopsy specimens by fluorescent antibodies or polymerase chain reaction, although this test is not widely available. Serological testing is used to confirm the diagnosis. Approximately 50% of patients will not have detectable antibody until the second week of illness, and treatment should not be withheld pending confirmation.

Differential Diagnosis

The differential diagnosis includes meningococemia, bacterial sepsis, toxic

shock syndrome, leptospirosis, ehrlichiosis, measles, enteroviruses, infectious mononucleosis, collagen vascular diseases, Henoch-Schönlein purpura, and idiopathic thrombocytopenic purpura. The diagnosis of RMSF should be suspected with fever and petechial rash, especially with a history of a tick bite or outdoor activities during spring and summer in endemic regions. Delayed diagnosis and late treatment usually result from atypical initial symptoms and late appearance of the rash.

Treatment

Therapy for suspected RMSF should not be postponed pending results of diagnostic tests. Doxycycline is the drug of choice, even for young children, despite the theoretical risk of dental staining in children younger than 8 years of age.

Complications and Prognosis

In severe infections, capillary leakage results in noncardiogenic pulmonary edema (acute respiratory distress syndrome), hypotension, disseminated intravascular coagulation, circulatory collapse, and multiple organ failure, including encephalitis, myocarditis, hepatitis, and renal failure.

Untreated illness may persist for 3 weeks and progress to multisystem involvement. The mortality rate is 20-80% without treatment, which is reduced to 1-3% with treatment. Permanent sequelae are common after severe disease.

Prevention

Preventive measures to avoid tick-borne infections and careful removal of ticks are recommended.

Ehrlichiosis (*Ehrlichia chaffeensis*) and Anaplasmosis (*Anaplasma phagocytophilum*)

Etiology

The term **ehrlichiosis** often is used to refer to all forms of infection with *Ehrlichia*. **Human monocytic ehrlichiosis** is caused by *E. chaffeensis*, which infects predominantly monocyte cells and is transmitted by the tick *A.*

americanum (lone star tick). Disease may also be caused by *Ehrlichia ewingii* (granulocytes) and *Ehrlichia muris*-like agent (unknown, suspected monocytes). **Human anaplasmosis** is caused by *A. phagocytophilum* and is transmitted by the tick *I. scapularis* (black-legged tick) or *I. pacificus* (western black-legged tick).

Epidemiology

Human monocytic ehrlichiosis occurs in broad areas across the southeastern, south-central, and mid-Atlantic United States in a distribution that parallels that of RMSF. Anaplasmosis is found mostly in the northeastern and upper midwestern United States, but infections have been identified in northern California, the mid-Atlantic states, and broadly across Europe. Ehrlichiosis due to *E. muris*-like agents have been reported only from Wisconsin and Minnesota.

Clinical Manifestations

Human monocytic ehrlichiosis, anaplasmosis, and *Ehrlichiosis ewingii* cause similar acute febrile illnesses characterized by fever, malaise, headache, myalgias, anorexia, and nausea. Rash occurs more commonly in ehrlichiosis than anaplasmosis but even so is uncommon in adults. In contrast to adult patients, nearly two thirds of children with human monocytic ehrlichiosis present with a macular or maculopapular rash, although petechial lesions may occur. Symptoms usually last for 1-2 weeks.

Laboratory and Imaging Studies

Characteristic laboratory findings include leukopenia, lymphocytopenia, thrombocytopenia, anemia, and elevated hepatic transaminases. Morulae are found infrequently in circulating monocytes of persons with human monocytic ehrlichiosis, but are found in 20-60% of persons with anaplasmosis (Fig. 122.4). Seroconversion or fourfold rise in antibody titer confirms the diagnosis; this requires acute and convalescent samples and is not helpful during the acute illness. Polymerase chain reaction (PCR) tests for both ehrlichiosis and anaplasmosis are available and can confirm diagnosis during the acute illness.

FIGURE 122.4 Intracellular inclusion within a neutrophil of a patient with human granulocytic anaplasmosis (arrows). *Ehrlichia chaffeensis* and *Anaplasma phagocytophilum* have similar morphologies but are serologically and genetically distinct. (Wright stain, original magnification $\times 1,000$.) (From Dumler JS, Walker DH. *Ehrlichia chaffeensis* [human monocytotropic ehrlichiosis], *Anaplasma phagocytophilum* [human granulocytotropic anaplasmosis], and other Anaplasmatidae. In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*. 8th ed. Philadelphia: Elsevier; 2015. Fig. 194.2.)

Differential Diagnosis

Ehrlichiosis is clinically similar to other arthropod-borne infections, including RMSF, tularemia, babesiosis, early Lyme disease, murine typhus, relapsing fever, and Colorado tick fever. The differential diagnosis also includes infectious mononucleosis, Kawasaki disease, endocarditis, viral infections, hepatitis, leptospirosis, Q fever, collagen vascular diseases, and leukemia.

Treatment

As with RMSF, therapy for suspected ehrlichiosis should not be postponed pending results of diagnostic tests. Ehrlichiosis and anaplasmosis are treated with doxycycline.

Complications and Prognosis

Severe pulmonary involvement with acute respiratory distress syndrome has

been reported in several cases. Other reported severe complications include meningoencephalitis and myocarditis. Most patients improve within 48 hours. Failure to respond to doxycycline within 3 days suggests either misdiagnosis or co-infection with another organism.

Prevention

Preventive measures to avoid tick-borne infections and careful removal of ticks are recommended.

West Nile Virus (see Chapter 101)

Dengue Fever

There are four dengue fever virus types (flaviviruses) transmitted to humans predominantly by the *A. aegypti* mosquito vector. Enzootic transmission via monkeys may occur, but person (viremic) to mosquito to person is the most frequent mechanism of viral infection. Dengue virus is most prevalent in the tropics, and endogenous infections have been reported in Florida and Texas.

Infected patients may have subclinical disease or a self-limited febrile illness. Dengue hemorrhagic fever, the most severe manifestation of the illness, occurs in patients who have had a previous Dengue virus infection (different serotype) and who manifest an exaggerated immunological response to the new Dengue virus serotype.

Dengue viremia usually precedes the influenza-like illness characterized by fever, myalgias, musculoskeletal pain (**break bone fever**), headaches, macular rash, elevated liver enzymes, acute respiratory distress syndrome, and peripheral cytopenias. Shock may occur with third space fluid losses, which may be associated with an increasing hematocrit. Epistaxis, hemoptysis, gastrointestinal, and uterine bleeding may occur.

Diagnosis is based on the geographic epidemiology, clinical presentation, and detection of dengue virus by PCR. Therapy requires good supportive care with fluid and blood replacement as needed.

Ebola Virus

Ebola virus is a filovirus producing a severe and often lethal hemorrhagic fever syndrome. It is transmitted by direct person-to-person contact, particularly body fluids; the fruit bat may be the animal reservoir for ebola and the related marburg virus. Ebola is most often seen in central Africa, although imported cases have been reported in persons traveling from endemic or epidemic regions.

Clinical manifestations may begin with a sudden onset of fever, myalgias, diarrhea, and malaise, but are then followed by significant hemorrhagic manifestations. Leukopenia, lymphopenia, thrombocytopenia, elevated liver enzymes, and prolonged clotting times are common. The diagnosis is confirmed by the presence of IgM and IgG antibodies to the virus. Treatment is supportive, including replacement of blood and fluid losses.

Chikungunya Virus

Chikungunya virus (CHIK) is an alphavirus in the togavirus family and is transmitted by most *Aedes* species of mosquitos in Africa and Latin America. Nonhuman primates may be the animal reservoir.

CHIK fever is characterized by a sudden illness with high fever, rash, and severe arthralgias. Fever may abate but return in the “saddleback” pattern. Polyarthralgias involve the small joints, which are exquisitely tender, and may persist for several weeks. The rash appears as facial flushing but evolves to a maculopapular occasionally pruritic eruption on the trunk, extremities, soles, and palms. Children may have CNS symptoms (irritability, seizures). Leukopenia, lymphocytosis, and an elevated erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) are common.

The diagnosis is confirmed by PCR or antibody responses. Treatment is supportive, particularly for the incapacitating joint manifestations. Tumor necrosis factor (TNF)-blocking agents may be beneficial for severe and persistent arthritis.

Zika Virus

Zika virus, a member of the flavivirus group, is transmitted by many *Aedes* mosquito species and is prevalent in equatorial regions of South America and Asia. Monkeys may be the animal reservoir. Zika virus infection is manifest with fever, rash, arthralgia, nonpurulent conjunctivitis, and headache. Infection in children and adults is usually self-limited; the greatest concern is infection during pregnancy resulting in transplacental transmission to the fetus with subsequent severe microcephaly and other congenital malformation.

Diagnosis is confirmed by Zika virus antibody titers or PCR.

CHAPTER 123

Parasitic Diseases

Protozoal Diseases

Protozoa are the simplest organisms of the animal kingdom. They are unicellular. Most are free-living, but some have a commensal or parasitic existence. Protozoal diseases include malaria, toxoplasmosis, babesiosis, and the intestinal protozoal diseases, amebiasis, cryptosporidiosis, and giardiasis.

Malaria

Etiology

Malaria is caused by obligate intracellular protozoa of the genus *Plasmodium*, including *P. falciparum*, *P. malariae*, *P. ovale*, *P. vivax*, and *P. knowlesi*. *Plasmodium* has a complex life cycle that enables survival in different cellular environments in the human host and in the mosquito vector. There are two major phases in the life cycle, an **asexual phase (schizogony)** in humans and a **sexual phase (sporogony)** in mosquitoes. The **erythrocytic phase** of *Plasmodium* asexual development begins when the merozoites released from exoerythrocytic schizonts in the liver penetrate erythrocytes. When inside the erythrocyte, the parasite transforms into the **ring form**, which enlarges to become a **trophozoite**. These latter two forms can be identified with Giemsa stain on blood smear, which is the primary means of confirming the diagnosis of malaria.

The parasites usually are transmitted to humans by female *Anopheles* mosquitoes. Malaria also can be transmitted through blood transfusion, via contaminated needles, and transplacentally to a fetus.

Epidemiology

Malaria is a worldwide problem with transmission in more than 100 countries with a combined population of more than 3.2 billion people. Malaria is an important cause of fever and morbidity in the tropical world. The principal areas of transmission are sub-Saharan Africa, southern Asia, Southeast Asia, and Central and South America. Approximately 1,500-2,000 imported cases are recognized annually in the United States, with most cases occurring among infected foreign civilians from endemic areas who travel to the United States and among U.S. citizens who travel to endemic areas without appropriate chemoprophylaxis.

Clinical Manifestations

Decision-Making Algorithm

Fever of Unknown Origin

The clinical manifestations of malaria range from asymptomatic infection to fulminant illness and death, depending on the virulence of the infecting malaria species and the host immune response. The incubation period ranges from 7-30 days, depending on the *Plasmodium* species (Table 123.1). The most characteristic clinical feature of malaria, which is seldom noted with other infectious diseases, is **febrile paroxysms** alternating with periods of fatigue but otherwise relative wellness. The classic symptoms of the febrile paroxysms of malaria include high fever, rigors, sweats, and headache. Paroxysms coincide with the ruptures of schizonts that occur every 48 hours with *P. vivax* and *P. ovale* (**tertian periodicity**), every 72 hours with *P. malariae* (**quartan periodicity**), and every 24 hours with *P. knowlesi*. Periodicity can be tertian with *P. falciparum* infections but is often irregular.

TABLE 123.1

Characteristics of *Plasmodium* Species Causing Malaria

CHARACTERISTIC	<i>P. FALCIPARUM</i>	<i>P. VIVAX</i>	<i>P. OVALE</i>	<i>P. MALARIAE</i>	<i>P. KNOWL</i>
Exoerythrocytic cycle	5.5-7 days	6-8 days	12 days	9 days	16 days
Erythrocytic cycle	43-52 hr	48 hr	48 hr	72 hr	24 hr
Usual incubation period (range)	13-14 days	13-14 days	13-14 days	35 days	Unknown
Erythrocyte preference	Can infect all	Reticulocytes	Older erythrocytes	Reticulocytes	Can infect a
Usual parasite load (% erythrocytes infected)	High	Low	Low	Low	May be high
Secondary exoerythrocytic cycle (hypnozoites) and relapses	Absent	Present	Present	Absent	Absent
Severity of primary attack	Can be severe	Mild to severe	Mild	Mild—severe disease in a patient suspected of having <i>P. malariae</i> should raise	Mild to severe

				the suspicion of <i>P. knowlesi</i>	
Usual periodicity of febrile attacks	None	48 hr	48 hr	72 hr	24 hr

Modified from Taylor T, Agbenyega T. Malaria. In: Magill AJ, Edward R, Tom S, David H, eds. *Hunter's Tropical Medicine and Emerging Infectious Disease*. 9th ed. Philadelphia: Saunders; 2013:700.

Short-term relapse describes the recurrence of symptoms after a primary attack that is due to the survival of erythrocyte forms in the bloodstream. **Long-term relapse** describes the renewal of symptoms long after the primary attack, usually due to the release of merozoites from an exoerythrocytic source in the liver. Long-term relapse occurs with *P. vivax* and *P. ovale* because of persistence in the liver (Fig. 123.1).

FIGURE 123.1 The *Plasmodium* life cycle and disease patterns of recrudescence and relapse. Anopheline mosquitoes transmit malaria by injecting sporozoites into the human host. The sporozoites then invade hepatocytes, in which they develop into schizonts. Each infected hepatocyte ruptures to liberate 10,000-30,000 merozoites that invade circulating erythrocytes. Growth and development of the parasites in red cells result in subsequent waves of merozoite invasion. This asexual blood cycle repeats every 24 (*Plasmodium knowlesi*), 48 (*Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*), or 72 (*Plasmodium malariae*) hours, leading to amplification of parasite density; paroxysms of chills, fevers, and sweats; and other manifestations of disease. Malaria symptoms are typically experienced 2-4 weeks after the mosquito bite. If the parasites are not cleared (e.g., patient receives partially effective therapy), recrudescence of parasitemia and malaria symptoms can occur. Eradicating parasites with an effective drug regimen cures malaria. Some *P. vivax* and *P. ovale* parasites can postpone their development in the liver,

persisting as latent forms called hypnozoites. Hypnozoites are not eradicated by standard therapy (e.g., chloroquine) directed against blood stages. Resumption of hypnozoite development months to years after initial infection can lead to malaria relapse that requires an additional round of drug therapy to treat recurrent symptoms and eradicate blood-stage parasites. A course of primaquine can prevent relapses of malaria, but this treatment may not always be successful because of inadequate patient compliance, interindividual variations of drug metabolism, or variable parasite responses to low or high drug doses. (From Fairhurst RM, Wellem TE. Malaria [*Plasmodium* species]. In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*. 8th ed. Philadelphia: Elsevier; 2015. Fig. 276.2.)

Laboratory and Imaging Studies

The diagnosis of malaria is established by the identification of organisms on stained smears of peripheral blood. In nonimmune persons, symptoms typically occur 1-2 days before parasites are detectable on blood smear. Although *P. falciparum* is most likely to be identified from blood during a febrile paroxysm, the timing of the smears is less important than obtaining smears several times each day over 3 successive days. Both thick and thin blood smears should be examined. The concentration of erythrocytes on a **thick smear** is approximately 20-40 times greater than that on a **thin smear**. Thick smears are used to scan large numbers of erythrocytes quickly. Thin smears allow for positive identification of the malaria species and determination of the percentage of infected erythrocytes, called parasitemia, which also is useful in following the response to therapy. **Rapid diagnostic tests** are available as point-of-care tests. Such tests provide results in 15-20 minutes and are particularly useful in areas where reliable microscopic diagnosis is not available. The rapid tests are able to detect *P. falciparum* but are unable to differentiate between *P. vivax*, *P. ovale*, and *P. malariae*. Sensitivity is low for non-*falciparum* species and in patients with low-level parasitemia. For these reasons as well as to guide management decisions, all rapid tests should be followed by microscopic examination regardless of the results.

Differential Diagnosis

The most important aspect of diagnosing malaria in children is to consider the possibility of malaria in any child who has fever, chills, splenomegaly, anemia, or decreased level of consciousness with a history of recent travel or residence in an endemic area, regardless of the use of chemoprophylaxis. The differential

diagnosis is broad and includes many infectious diseases, such as typhoid fever, tuberculosis, brucellosis, relapsing fever, infective endocarditis, influenza, poliomyelitis, yellow fever, trypanosomiasis, kala-azar, and amebic liver abscess.

Treatment

Oral chloroquine is the recommended treatment except for chloroquine-resistant *P. falciparum*. Either atovaquone-proguanil, mefloquine, or artemether-lumefantrine is an appropriate first-line therapy for malaria acquired in areas of chloroquine resistance. Specific treatment should be guided by where the patient acquired the infection and the local resistance patterns. Patients with malaria usually require hospitalization and may require intensive care unit admission. Quinidine gluconate is the only drug available in the United States that is used for parenteral treatment. Artesunate is available from the Centers for Disease Control and Prevention as an investigational new drug.

Complications and Prognosis

Cerebral malaria is a complication of *P. falciparum* infection and a frequent cause of death (10-40% of cases), especially among children and nonimmune adults. Similar to other complications, cerebral malaria is more likely to occur among patients with intense parasitemia (>5% of erythrocytes on a blood smear). Other complications include splenic rupture, renal failure, severe hemolysis (**blackwater fever**), pulmonary edema, hypoglycemia, thrombocytopenia, and **algid malaria** (sepsis syndrome with vascular collapse).

Death may occur with any of the malarial species but is most frequent with complicated *P. falciparum* malaria. The likelihood of death is increased in children with pre-existing health problems, such as measles, intestinal parasites, schistosomiasis, anemia, and malnutrition. Death is much more common in developing countries.

Prevention

There are two components of malaria prevention: reduction of exposure to infected mosquitoes and chemoprophylaxis. Mosquito protection is necessary because no prophylactic regimen can guarantee protection in every instance due to the widespread development of resistant organisms.

Chemoprophylaxis is necessary for all visitors to, and residents of, the

tropics who have not lived there since infancy. Children of nonimmune women should have chemoprophylaxis from birth. Children of women from endemic areas have passive immunity until 3-6 months of age, after which they are increasingly likely to acquire malaria. Specific chemoprophylaxis should be guided by the distribution of resistance pattern and determined before making specific recommendations (http://www.cdc.gov/malaria/travelers/country_table/a.html). Mefloquine, doxycycline, chloroquine, and atovaquone-proguanil are commonly prescribed medications.

Toxoplasmosis

Decision-Making Algorithms

Splenomegaly
Lymphadenopathy
Petechiae/Purpura
Fever of Unknown Origin

Toxoplasmosis is a zoonosis caused by *Toxoplasma gondii*, an intracellular protozoan parasite. Infection is acquired by infectious oocysts, such as those excreted by newly infected cats, which play an important role in amplifying the organism in nature, or from ingesting cysts in contaminated, undercooked meat. Less commonly, transmission occurs transplacentally during acute infection of pregnant women. In the United States, the incidence of congenital infection is 1-10 per 10,000 live births.

Acquired toxoplasmosis is usually asymptomatic. Symptomatic infection is typically a heterophile-negative mononucleosis syndrome that includes lymphadenopathy, fever, and hepatosplenomegaly. Disseminated infection, including myocarditis, pneumonia, and central nervous system (CNS) toxoplasmosis, is more common among immunocompromised persons, especially persons with acquired immunodeficiency syndrome (AIDS). Among women infected during pregnancy, 50-60% give birth to an infected infant. The later in pregnancy that infection occurs, the more likely it is that the fetus will be infected, but the less severe the illness (see [Chapter 66](#)). Serological diagnosis

can be established by a fourfold increase in antibody titer or seroconversion, a positive IgM antibody titer, or positive polymerase chain reaction for *T. gondii* in peripheral white blood cells, cerebrospinal fluid (CSF), serum, or amniotic fluid.

Treatment includes pyrimethamine and sulfadiazine, which act synergistically against *Toxoplasma*. Because these compounds are folic acid inhibitors, they are used in conjunction with folinic acid. Spiramycin, which is not licensed in the United States but can be obtained from the manufacturer at no cost as an investigational new drug, is also used in therapy of pregnant women with toxoplasmosis. Corticosteroids are reserved for patients with acute CNS or ocular infection.

Ingesting only well-cooked meat and avoiding cats or soil in areas where cats defecate are prudent measures for pregnant or immunocompromised persons. Administration of spiramycin to infected pregnant women has been associated with lower risks of congenital infection in their offspring.

Helminthiases

Helminths are divided into three groups: roundworms, or nematodes, and two groups of flatworms, the trematodes (flukes) and the cestodes (tapeworms).

Hookworm Infections

Hookworm infection is caused by several species of hookworms, with *Ancylostoma duodenale* and *Necator americanus* being the most important (Table 123.2). There are more than 600 million humans worldwide infected with hookworms. *Ancylostoma duodenale* is the predominant species in the Mediterranean region, northern Asia, and certain areas of South America. *N. americanus* predominates in the Western hemisphere, sub-Saharan Africa, and Southeast Asia. Optimal soil conditions and fecal contamination are found in many agrarian tropical countries and in the southeastern United States. Infection typically occurs in young children, especially during the first decade of life. The larvae are found in warm, damp soil and infect humans by penetrating the skin. They migrate to the lungs, ascend the trachea, are swallowed, and reside in the intestine. The worms mature and attach to the intestinal wall, where they suck blood and shed eggs.

TABLE 123.2

Major Pediatric Syndromes Caused by Parasitic Nematodes

SYNDROME	ETIOLOGICAL AGENT	TRANSMISSION	TREATMENT
Hookworm iron deficiency	<i>Ancylostoma duodenale</i>	Larval ingestion and penetration	Albendazole <i>or</i> mebendazole <i>or</i> pyrantel pamoate
	<i>Necator americanus</i>	Larval penetration	
Cutaneous larva migrans	<i>Ancylostoma braziliense</i> (a zoonotic hookworm)	Larval penetration (and failure to migrate)	Generally self-limited; albendazole <i>or</i> ivermectin
<i>Trichuris</i> dysentery or colitis	<i>Trichuris trichiura</i>	Egg ingestion	Mebendazole <i>or</i> albendazole <i>or</i> ivermectin
Intestinal ascariasis	<i>Ascaris lumbricoides</i>	Ingestion of <i>Ascaris</i> eggs	Albendazole <i>or</i> mebendazole <i>or</i> ivermectin
Visceral larva migrans	<i>Toxocara canis</i> <i>Toxocara cati</i> <i>Baylisascaris procyonis</i>	Egg ingestion	Albendazole <i>or</i> mebendazole <i>or</i> ivermectin
Ocular larva migrans	<i>Toxocara canis</i> <i>Toxocara cati</i> <i>Baylisascaris procyonis</i>	Egg ingestion	Albendazole <i>or</i> mebendazole <i>or</i> ivermectin
Diarrhea, malabsorption (celiac-like)	<i>Strongyloides stercoralis</i>	Larval penetration	Ivermectin
Pinworm	<i>Enterobius vermicularis</i>	Egg ingestion	Albendazole <i>or</i> mebendazole <i>or</i> pyrantel pamoate
Trichinellosis	<i>Trichinella spiralis</i>	Ingestion of infected undercooked meat	Albendazole <i>or</i> mebendazole <i>plus</i> corticosteroids for severe symptoms
Abdominal angiostrongyliasis	<i>Angiostrongylus costaricensis</i>	Ingestion of contaminated food	Albendazole <i>or</i> mebendazole
Eosinophilic meningitis	<i>Angiostrongylus cantonensis</i> (rat lungworm)	Ingestion of undercooked contaminated seafood	Albendazole

Infections are usually asymptomatic. Intense pruritus (*ground itch*) occurs at the site of larval penetration, usually the soles of the feet or between the toes, and may include papules and vesicles. Migration of larvae through the lungs usually is asymptomatic. Symptoms of abdominal pain, anorexia, indigestion, fullness, and diarrhea occur with hookworm infestation. The major manifestation of infection is anemia. Examination of fresh stool for hookworm eggs is diagnostic. Therapy includes anthelmintic treatment with albendazole, mebendazole, or pyrantel pamoate and treatment for anemia. Eradication depends on sanitation of the patient's environment and treatment with antiparasitics.

Ascariasis

Ascariasis is caused by *Ascaris lumbricoides*, a large nematode. It is the most prevalent helminthiasis, affecting more than 800 million people (see [Table 123.2](#)). After humans ingest the eggs, larvae are released and penetrate the intestine, migrate to the lungs, ascend the trachea, and are swallowed. On entering the intestines again, they mature and produce eggs that are excreted in the stool and are deposited in the soil, where they survive for prolonged periods.

Manifestations may be the result of migration of the larvae to other sites of the body or the presence of adult worms in the intestine. **Pulmonary ascariasis** occurs as the larvae migrate through the lung, producing cough, blood-stained sputum, eosinophilia, and transient infiltrates on chest x-ray films. Adult larvae in the small intestine may cause abdominal pain and distention. Intestinal obstruction from adult worms can occur, particularly in children due to the small diameter of their intestinal lumens and their propensity to acquire large worm burdens. Migration of worms into the bile duct may rarely cause acute biliary obstruction. Examination of fresh stool for characteristic eggs is diagnostic. Effective control depends on adequate sanitary treatment and disposal of infected human feces.

Visceral Larva Migrans

Visceral larva migrans is a systemic nematodiasis caused by ingestion of the eggs of the dog tapeworm, *Toxocara canis*, or, less commonly, the cat tapeworm, *Toxocara cati*, or the raccoon tapeworm, *Baylisascaris procyonis* (see [Table 123.2](#)). These organisms also cause **ocular larva migrans**.

Visceral larva migrans is most common in young children with pica who have dogs or cats as pets. Ocular toxocariasis occurs in older children. The eggs of these roundworms are produced by adult worms residing in the dog and cat intestine. Ingested eggs hatch into larvae that penetrate the gastrointestinal tract and migrate to the liver, lung, eye, CNS, and heart, where they die and calcify.

Symptoms of visceral larva migrans are the result of the number of migrating larvae and the associated immune response. Light infections are often asymptomatic. Symptoms include fever, cough, wheezing, and seizures. Physical findings may include hepatomegaly, crackles, rash, and lymphadenopathy. Visual symptoms may include decreased acuity, strabismus, periorbital edema, or blindness. Eye examination may reveal granulomatous lesions near the

macula or disc. Ocular larva migrans is generally characterized by isolated, unilateral ocular disease and no systemic findings.

Eosinophilia and hypergammaglobulinemia associated with elevated isohemagglutinin levels suggest the diagnosis, which is confirmed by serology (enzyme-linked immunosorbent assay) or, less commonly, by biopsy. This is usually a self-limited illness. In severe disease, albendazole or mebendazole is used. Deworming puppies and kittens, major excretors of eggs, decreases the risk of infection.

Enterobiasis (Pinworm)

Decision-Making Algorithms

Dysuria
Vaginal Discharge

Pinworm is caused by *Enterobius vermicularis*, a nematode that is distributed worldwide. Enterobiasis affects individuals at all socioeconomic levels, especially children. Crowded living conditions predispose to infection. Humans ingest the eggs carried on hands, present in house dust or on bedclothes. The eggs hatch in the stomach, and the larvae migrate to the cecum and mature. At night the females migrate to the perianal area to lay their eggs (up to 10,000 eggs), which remain infective in the indoor environment for 2-3 weeks.

The most common symptoms are nocturnal anal pruritus (**pruritus ani**) and sleeplessness, presumably resulting from the migratory female worms. Vaginitis and salpingitis may develop secondary to aberrant worm migration. The eggs are detected by microscopically examining adhesive cellophane tape pressed against the anus in the morning to collect eggs. Less commonly, a worm may be seen in the perianal region. Treatment is with albendazole or pyrantel pamoate each given as a single oral dose and repeated in 2 weeks.

Schistosomiasis

Decision-Making Algorithm

Eosinophilia

Schistosomiasis (bilharziasis) is caused by flukes that parasitize the bloodstream, including *Schistosoma haematobium*, *S. mansoni*, *S. japonicum*, and, rarely, *S. intercalatum* and *S. mekongi* (Table 123.3). Schistosomiasis affects more than 190 million people. Humans are infected by cercariae in contaminated water that emerge in an infectious form from snails and penetrate intact skin. Each adult worm migrates to specific sites: *S. haematobium* to the **bladder plexus** and *S. mansoni* and *S. japonicum* to the **mesenteric vessels**. The eggs are deposited by the adult flukes in urine (*S. haematobium*) or stool (*S. mansoni* and *S. japonicum*). *S. haematobium* is prevalent in Africa and the Middle East; *S. mansoni* in Africa, the Middle East, the Caribbean, and South America; *S. japonicum* in China, the Philippines, and Indonesia; *S. mekongi* in Cambodia and Laos; and *S. intercalatum* in West and Central Africa.

TABLE 123.3

Major Pediatric Syndromes Caused by Parasitic Trematodes

SYNDROME	ETIOLOGICAL AGENT	TRANSMISSION	TREATMENT
Schistosomiasis		Freshwater contact with penetration through the skin	
Intestinal or hepatic schistosomiasis	<i>Schistosoma mansoni</i> <i>Schistosoma japonicum</i> <i>Schistosoma mekongi</i>		Praziquantel or oxamniquine
Urinary schistosomiasis	<i>Schistosoma haematobium</i>		
Parasitoses due to other trematodes		Ingestion of raw or inadequately cooked foods	
Clonorchiasis	<i>Clonorchis sinensis</i> (Chinese liver fluke)		Praziquantel or albendazole
Fascioliasis	<i>Fasciola hepatica</i> (sheep liver fluke)		Triclabendazole
Fasciolopsiasis	<i>Fasciolopsis buski</i>		Praziquantel
Heterophyiasis	<i>Heterophyes heterophyes</i>		Praziquantel
Metagonimiasis	<i>Metagonimus yokogawai</i>		Praziquantel
Metorchiasis	<i>Metorchis conjunctus</i> (North American liver fluke)		Praziquantel
Nanophyetiasis	<i>Nanophyetus salmincola</i> (salmon fluke)		Praziquantel

Opisthorchiasis	<i>Opisthorchis viverrini</i> (Southeast Asian liver fluke)		Praziquantel or albendazole
Paragonimiasis	<i>Paragonimus westermani</i> , <i>P. kellicotti</i> , <i>P. uterobilateralis</i> , <i>P. skjabini</i> , <i>P. heterotremus</i> , <i>P. africanus</i> (lung flukes)		Praziquantel or triclabendazole

The manifestations of schistosomiasis result from eggs that are trapped at the site of deposition or at metastatic locations. Within 4-8 weeks of infection, while the worms are maturing, a syndrome of fever, malaise, cough, abdominal pain, hepatosplenomegaly, eosinophilia, and rash can occur (**Katayama fever**). This syndrome is followed by a resultant inflammatory response that leads to further symptoms. Eggs may be found in the urine (*S. haematobium*) or stool (*S. mansoni* and *S. japonicum*) of infected individuals. Sanitary measures, molluscicides, and therapy for infected individuals may help control the illness.

Echinococcosis

Echinococcosis includes **hydatid or unilocular cyst disease**, caused by *Echinococcus granulosus* (the **minute dog tapeworm**), polycystic disease, caused by *Echinococcus vogeli*, and **alveolar cyst disease**, caused by *Echinococcus multilocularis* (Table 123.4). Dogs become infected with tapeworms by eating infected sheep or cattle viscera and excrete eggs in their stools. Humans acquire echinococcosis by ingesting eggs and become an intermediate host. The eggs hatch in the intestinal tract, and the larva (**oncospheres**) penetrate the mucosa and enter the circulation to pass to the liver and other visceral organs, forming cysts.

TABLE 123.4

Major Pediatric Syndromes Caused by Parasitic Cestodes

SYNDROME	ETIOLOGICAL AGENT	TRANSMISSION	TREATMENT
Echinococcosis		Ingestion of <i>Echinococcus</i> eggs	
Unilocular	<i>E. granulosus</i>		Surgical resection <i>plus</i> albendazole
Alveolar echinococcosis	<i>E. multilocularis</i>		Surgical resection is only reliable means of treatment; some reports suggest adjunct use of albendazole or mebendazole
Neurocysticercosis	Larval stage of <i>Taenia solium</i> (cysticerci)	Ingestion of eggs through direct fecal-oral contact or	Albendazole <i>or</i> praziquantel

		ingestion of fecally contaminated foods	
Adult tapeworm infections	<i>T. solium</i> (pork tapeworm)	Ingestion of contaminated raw/undercooked pork	Praziquantel
	<i>Hymenolepis diminuta</i>	Ingestion of infected insect	Praziquantel
	<i>Hymenolepis nana</i>	Fecal-oral	Praziquantel

E. granulosus has a worldwide distribution and is endemic in sheep-raising and cattle-raising areas of Australia, South America, South Africa, the former Soviet Union, and the Mediterranean region. The prevalence is highest in children. Symptoms caused by *E. granulosus* result from space-occupying cysts. Pulmonary cysts may cause hemoptysis, cough, dyspnea, and respiratory distress. Brain cysts appear as tumors; liver cysts cause problems as they compress and obstruct blood flow. Ultrasonography identifies cystic lesions, and the diagnosis is confirmed by serological testing. Large or asymptomatic granulosa cysts are removed surgically. Treatment with albendazole has shown some benefit.

Neurocysticercosis

Neurocysticercosis is caused by infection with the embryonated eggs of the **pork tapeworm**, *Taenia solium*, and is the most frequent helminthic infection of the CNS (see [Table 123.4](#)). Humans are infected after consuming cysticerci in raw or undercooked larva-containing pork. Infected humans then pass *T. solium* eggs in their feces. Fecal-oral transmission of eggs, either to the originally infected host or other individuals, then results in cysticerci development in organs; in particular, subcutaneous tissues, brain, and eyes. *T. solium* is endemic in Asia, Africa, and Central and South America.

Cysts typically enlarge slowly, causing no or minimal symptoms for years or decades until the organism begins to die. The cyst then begins to swell, and leakage of antigen incites an inflammatory response, resulting in the presenting signs of focal or generalized seizures and calcified cerebral cysts identified by computed tomography or magnetic resonance imaging. The CSF shows lymphocytic or eosinophilic pleocytosis. The diagnosis is confirmed by serological testing. Neurocysticercosis is treated with albendazole or praziquantel, corticosteroids for concomitant cerebral inflammation from cyst death, and anticonvulsant drugs.

Tuberculosis

Etiology

Mycobacterium tuberculosis bacilli are pleomorphic, weakly gram-positive curved rods that are **acid fast**, which is the capacity to form stable mycolate complexes with arylmethane dyes. *M tuberculosis* grows slowly; culture from clinical specimens on solid synthetic media usually takes 3-6 weeks. Drug-susceptibility testing requires an additional 4 weeks. Growth can be detected in 1-3 weeks in selective liquid media using radiolabeled nutrients. Polymerase chain reaction (PCR) of clinical specimens allows rapid diagnosis in many laboratories.

Epidemiology

It is estimated that one third of the world's population is infected with tuberculosis (TB). Most of these are latent infections. Without treatment, tuberculosis *disease* develops in 5-10% of immunologically normal adults with tuberculosis *infection* at some time during their lives; the risk is higher in infants, those who are immunocompromised, and especially HIV-positive individuals. An estimated 9 million new cases of tuberculosis occur each year worldwide, including 1 million children. One to 2 million deaths are attributed to the disease annually. Almost 10,000 TB cases were reported in the United States in 2014.

Transmission of *M. tuberculosis* is from person to person, usually by respiratory droplets that become airborne when a symptomatic individual coughs, sneezes, laughs, or even breathes. Infected droplets dry and become droplet nuclei, which may remain suspended in the air for hours, long after the infectious person has left the environment.

Several patient-related factors are associated with an increased chance of transmission. Of these, a positive acid-fast smear of the sputum most closely correlates with infectivity. Children with primary pulmonary tuberculosis disease rarely, if ever, infect others because tubercle bacilli are relatively sparse in the endobronchial secretions of children with pulmonary tuberculosis. In addition,

when young children cough, they rarely produce sputum, lacking the tussive force necessary to project and suspend infectious particles of the requisite size. Hospitalized patients with suspected pulmonary tuberculosis should be placed initially in airborne isolation. Most infectious patients become noninfectious within 2 weeks of starting effective treatment. Cavitory disease, nonadherence to treatment, and resistant infection increase the risk of transmission.

In North America, tuberculosis rates are highest in foreign-born persons from high-prevalence countries, residents of prisons, residents of nursing homes, homeless persons, users of illegal drugs, persons who are poor and without health care, health care workers, and children exposed to adults in high-risk groups. Most children are infected with *M. tuberculosis* from household contacts, but outbreaks of childhood tuberculosis centered in schools, daycares, churches, school buses, and stores still occur. A high-risk adult working in the area has been the source of the outbreak in most cases. Immunodeficiency, especially from HIV infection or from immunosuppressive drugs, is an important risk factor. Certain biological response modifiers (anti-tumor necrosis factor [TNF] antibodies), often used for inflammatory conditions, can increase risk of development of tuberculosis disease.

Clinical Manifestations

Decision-Making Algorithms

Cough
Hemoptysis
Back Pain
Fever and Rash
Lymphadenopathy
Fever of Unknown Origin

Latent tuberculosis describes the asymptomatic stage of infection with *M. tuberculosis*. The tuberculin skin test (TST) or interferon-gamma release assay (IGRA) is positive, but the chest radiograph is normal or shows healed infection (calcification). **Tuberculosis disease** occurs when there are clinical signs and symptoms and/or an abnormal chest radiograph or other extrapulmonary

manifestation. The interval between latent tuberculosis and the onset of disease may be several weeks in children or many decades in adults. In young children, tuberculosis usually develops as an immediate complication of the primary infection, and the distinction between infection and disease may be less obvious.

Primary tuberculosis in children is often an asymptomatic infection. Often the disease is manifested by a positive TST or IGRA with mild abnormalities on the chest radiograph, such as atelectasis or an infiltrate accompanied by hilar or other adenopathy (**Ghon complex**). Malaise, low-grade fever, erythema nodosum, or symptoms resulting from lymph node enlargement may occur after the development of delayed hypersensitivity. **Progressive primary disease** is characterized by a primary pneumonia that develops shortly after initial infection. Progression to disseminated miliary disease or central nervous system (CNS) infection occurs most commonly in the first year of life. Cavitation is rare in children but more typical with reactivation pulmonary TB in adolescents and adults.

Tuberculous pleural effusion, which may accompany primary infection, generally represents the immune response to the organisms and most commonly occurs in older children or adolescents. Pleurocentesis reveals lymphocytes and an increased protein level, but the pleural fluid usually does not contain bacilli.

Reactivation pulmonary tuberculosis, common in adolescents and typical in adults, usually is confined to apical segments of upper lobes or superior segments of lower lobes. There is usually little lymphadenopathy and no extrathoracic infection. This is a manifestation of a secondary expansion of infection at a site seeded years previously during primary infection. Advanced disease is associated with cavitation and endobronchial spread of bacilli. Symptoms include fever, night sweats, malaise, and weight loss. A productive cough and hemoptysis often herald cavitation and bronchial erosion.

Miliary tuberculosis refers to widespread hematogenous dissemination to multiple organs. The lesions are of roughly the same size as a millet seed, from which the name *miliary* is derived. Miliary tuberculosis is characterized by fever, general malaise, weight loss, lymphadenopathy, night sweats, and hepatosplenomegaly. Diffuse bilateral pneumonitis is common, and meningitis may be present. The chest radiograph reveals bilateral miliary infiltrates, showing overwhelming infection. The TST may be nonreactive as a result of **anergy**. Liver or bone marrow biopsy may be useful for diagnosis.

Tuberculous meningitis most commonly occurs in children <5 years of age or immunocompromised patients and often within 6 months of primary

infection. Tubercle bacilli that seed the meninges during the primary infection replicate, triggering an inflammatory response. This condition may have an insidious onset, initially characterized by low-grade fever, headache, and subtle personality change. Progression of the infection results in basilar meningitis with impingement of the cranial nerves and is manifested by meningeal irritation and, eventually, increased intracranial pressure, deterioration of mental status, and coma. Computed tomography (CT) scans show hydrocephalus, edema, periventricular lucencies, and infarctions. Cerebrospinal fluid (CSF) analysis reveals pleocytosis (50-500 leukocytes/mm³), which early in the course of disease may be either lymphocytes or polymorphonuclear leukocytes. Glucose is low, and protein is significantly elevated. Acid-fast bacilli are not detected frequently in the CSF by either routine or fluorescent staining procedures. Although culture is the standard for diagnosis, PCR for *M. tuberculosis* may be useful to confirm meningitis, but lacks sensitivity.

Skeletal tuberculosis results from either hematogenous seeding or direct extension from a caseous lymph node. This is usually a chronic disease with an insidious onset that may be mistaken for chronic osteomyelitis. Radiographs reveal cortical destruction. Biopsy and culture are essential for proper diagnosis. Tuberculosis of the spine, **Pott disease**, is the most common skeletal site.

Other forms of tuberculosis include **abdominal tuberculosis** that occurs from swallowing infected material. This is a relatively uncommon complication in developed nations where dairy herds are inspected for bovine tuberculosis. Gastrointestinal TB can present with signs and symptoms similar to inflammatory bowel disease. **Tuberculous peritonitis** is associated with abdominal tuberculosis and presents as fever, anorexia, ascites, and abdominal pain. **Urogenital tuberculosis** is a late reactivation complication and is rare in children. Symptomatic illness presents as dysuria, frequency, urgency, hematuria, and *sterile* pyuria. Tuberculosis may also result in extrathoracic lymphadenitis in the cervical, supraclavicular, and submandibular areas (**scrofula**).

Congenital tuberculosis can mimic neonatal sepsis or present at days to weeks of age with hepatosplenomegaly and respiratory disease.

Laboratory and Imaging Studies

Two types of tests are used to detect the immune response to *M. tuberculosis* and are used to screen patients for latent tuberculosis and investigation of active

tuberculosis. The TST response to tuberculin antigen is a manifestation of a T cell-mediated delayed hypersensitivity. The **Mantoux test**, an intradermal injection of 5 TU (tuberculin units) of **purified protein derivative standard (PPD-S)**, usually on the volar surface of the forearm, is the standard TST. It is usually positive 2-6 weeks after onset of infection (up to 3 months) and at the time of symptomatic illness. This test is preferred in children less than 5 years of age ([Table 124.1](#)). False-negative responses may occur early in the illness, with overwhelming TB infection, with concomitant viral infection, or as a result of immunosuppression (secondary to underlying illness, HIV, or malnutrition). Tests with questionable results should be repeated after several weeks. All internationally adopted children with an initially negative TST should have a repeat TST after 3 months in the United States. The TST is interpreted based on the host status and size of induration ([Table 124.2](#)). In general, interpretation of TST in people who have had previous **bacille Calmette-Guérin (BCG)** vaccine can be difficult, given the cross reaction of TST with antigens present in the vaccine. However, in situations when a tuberculosis exposure has occurred, the TST should be read and interpreted as if no vaccine had been given.

TABLE 124.1

Tuberculin Skin Test Recommendations for Infants, Children, and Adolescents*

CHILDREN FOR WHOM IMMEDIATE TST OR IGRA IS INDICATED[†]:
<ul style="list-style-type: none"> • Contacts of people with confirmed or suspected contagious tuberculosis (contact investigation) • Children with radiographic or clinical findings suggesting tuberculosis disease • Children immigrating from countries with endemic infection (e.g., Asia, Middle East, Africa, Latin America, countries of the former Soviet Union), including international adoptees • Children with travel histories to countries with endemic infection and substantial contact with indigenous people from such countries
CHILDREN WHO SHOULD HAVE ANNUAL TST OR IGRA[‡]:
<ul style="list-style-type: none"> • Children infected with HIV infection (TST only)
CHILDREN AT INCREASED RISK OF PROGRESSION OF LTBI TO TUBERCULOSIS DISEASE:
<ul style="list-style-type: none"> • Children with other medical conditions, including diabetes mellitus, chronic renal failure, malnutrition, and congenital or acquired immunodeficiencies, deserve special consideration. Without recent exposure, these people are not at increased risk of acquiring tuberculosis infection. Underlying immune deficiencies associated with these conditions theoretically would enhance the possibility for progression to severe disease. Initial histories of potential exposure to tuberculosis should be included for all of these patients. If these histories or local epidemiological factors suggest a possibility of exposure, immediate and periodic TST or IGRA should be considered. A TST or IGRA should be performed before initiation of immunosuppressive therapy, including prolonged steroid administration, organ transplantation, use of tumor necrosis factor-alpha antagonists or blockers, or other immunosuppressive therapy in any child requiring these treatments.

Bacille Calmette-Guérin immunization is not a contraindication to a TST.

[†]Beginning as early as 3 months of age.

[‡]If the child is well, the TST or IGRA should be delayed for up to 10 weeks after return.

HIV, Human immunodeficiency virus; *IGRA*, interferon-gamma release assay; *LTBI*, latent tuberculosis infection; *TST*, tuberculin skin test.

From Recommendations from American Academy of Pediatrics. Tuberculosis. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015. Copyright 2015 American Academy of Pediatrics. Reproduced with permission.

TABLE 124.2

Criteria for Positive Tuberculin Skin Test Results in Clinically Defined Pediatric Populations*

POSITIVE RESULT	POPULATION(S)
Induration ≥5 mm	Children in close contact with persons with known or suspected contagious tuberculosis disease
	Children suspected to have tuberculosis disease Findings on chest radiograph consistent with active or previously active tuberculosis Clinical evidence of tuberculosis disease [†]
	Children receiving immunosuppressive therapy [‡] or with immunosuppressive conditions, including HIV infection
Induration ≥10 mm	Children at increased risk for disseminated disease
	Children <4 yr of age Children with other medical conditions, including Hodgkin disease, lymphoma, diabetes mellitus, chronic renal failure, and malnutrition
	Children with increased exposure to tuberculosis disease Children born, or whose parents were born, in high-prevalence regions of the world Children frequently exposed to adults who are HIV-infected, homeless, users of illicit drugs, residents of nursing homes, incarcerated or institutionalized, or migrant farm workers Children who travel to high-prevalence regions of the world
Induration ≥15 mm	Children ≥4 yr of age without any risk factors

These criteria apply regardless of previous BCG immunization. Erythema at tuberculin skin test site does not indicate a positive test result. Tuberculin reactions should be read at 48-72 hours after placement.

[†]Evidence by physical examination or laboratory assessment that would include tuberculosis in the working differential diagnosis (e.g., meningitis).

[‡]Including immunosuppressive doses of corticosteroids.

BCG, Bacille Calmette-Guérin; *HIV*, human immunodeficiency virus.

An **IGRA** is a whole blood test that measures interferon-gamma production by T lymphocytes in response to antigens from the *M. tuberculosis* complex, which includes *M. bovis* but not antigens found in the BCG vaccine. An IGRA is the recommended diagnostic test for persons older than 5 years of age in the United States. It has similar sensitivity to the TST but improved specificity because it is unaffected by prior BCG vaccination. It is also practically easier to obtain, as it requires only one visit to complete. As with the TST, in immunocompromised persons and in active tuberculosis, IGRA findings may be indeterminate.

The ultimate diagnostic confirmation relies on culture of the organism. Sputum is an excellent source for diagnosis in pulmonary disease in adults but is difficult to obtain in young children. Induced sputum or gastric fluid obtained via an indwelling nasogastric tube with samples taken before or immediately on waking contains swallowed sputum and provides alternate samples in young children. Large volumes of fluid (CSF, pericardial fluid) yield a higher rate of recovery of organisms, but slow growth of the mycobacteria makes culture less helpful in acute illness. Even with optimal collection, cultures are positive in less than half of children with tuberculosis. When the organism is grown, drug susceptibilities should be determined because of the increasing incidence of resistant organisms. Utilization of culture and susceptibility results from the source case is often necessary given the difficulty of obtaining timely results.

PCR testing for mycobacteria has expedited diagnosis, especially with CNS disease. However, these assays have limited sensitivity and provide no susceptibility data. Most experts would recommend that young infants <12 months of age with suspected tuberculosis undergo lumbar puncture for evaluation of CNS involvement.

Diagnostic Imaging

Because many cases of pulmonary tuberculosis in children are clinically relatively silent, radiography is a cornerstone for the diagnosis of disease (Figs. 124.1 and 124.2). All lobar segments of the lung are at equal risk of being the focus of the initial infection. In 25% of cases, two or more lobes of the lungs are involved, although disease usually occurs at one site only. Spread of infection to regional lymph nodes occurs early. Hilar lymphadenopathy is inevitably present with childhood tuberculosis. Partial bronchial obstruction caused by external compression from the enlarging nodes can cause air trapping, hyperinflation, and

lobar emphysema. Occasionally children have a picture of lobar pneumonia without impressive hilar lymphadenopathy. If the infection is progressively destructive, liquefaction of the lung parenchyma leads to formation of a thin-walled primary tuberculous cavity. Adolescents with pulmonary tuberculosis may develop segmental lesions with hilar lymphadenopathy or the apical infiltrates, with or without cavitation, that are typical of adult reactivation tuberculosis.

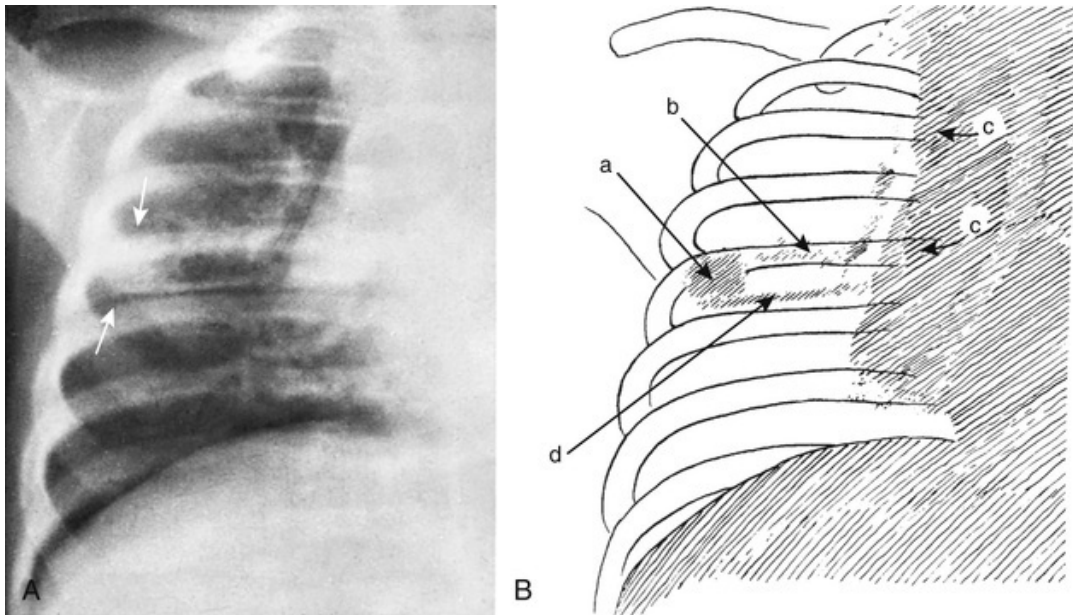

FIGURE 124.1 Fresh primary tuberculous complex in an infant 4 months of age. The pulmonary focus is the small shadow of increased density (*arrows*) in the inferolateral segment of the right upper lobe. **(A)** Roentgenogram. **(B)** Schematic drawing: *a*, primary focus; *b*, lymphangitis; *c*, enlarged hilar and mediastinal nodes; *d*, loculated pleural exudate. (From Silverman FN, Kuhn JP, et al. *Essentials of Caffey's Pediatric X-Ray Diagnosis*. Philadelphia: Saunders; 1990:292. Fig. 11.23.)

FIGURE 124.2 Huge calcifying primary tuberculous focus in the right lower lobe that dwarfs the rest of the complex in an asymptomatic girl 6 years of age. The healing and calcification of this huge necrotic focus without manifest clinical disease at any time demonstrates the often benign clinical aspects of severe structural tuberculous disease. In **(A)**, a frontal projection, the large calcifying focus appears to be perihilar, but in **(B)**, a lateral projection, this focus lies far behind the lung root in a dorsal subsegment of the right lower lobe near the dorsal pleura. (From Silverman FN, Kuhn JP, et al. *Essentials of Caffey's Pediatric X-Ray Diagnosis*. Philadelphia: Saunders; 1990:293. Fig. 11.26.)

Radiographic studies aid greatly in the diagnosis of **extrapulmonary tuberculosis** in children. Plain radiographs, CT, and magnetic resonance imaging (MRI) of the tuberculous spine usually show collapse and destruction of the vertebral body with narrowing of the involved disk spaces. Radiographic findings in bone and joint tuberculosis range from mild joint effusions and small lytic lesions to massive destruction of the bone. CT or MRI of the brains of patients with CNS involvement may be normal during early stages of the infection. As disease progresses, basilar enhancement and communicating hydrocephalus with signs of cerebral edema or early focal ischemia are the most common findings.

Granulomas on pathology of tissue can also help to establish the diagnosis of tuberculosis on samples from lymph nodes and other biopsies.

Differential Diagnosis

The differential diagnosis of tuberculosis includes a multitude of diagnoses because tuberculosis may affect any organ, and in early disease the symptoms and signs may be nonspecific. In pulmonary disease, tuberculosis may appear

similar to bacterial or fungal pneumonia, malignancy, and any systemic disease in which generalized lymphadenopathy occurs. The diagnosis of tuberculosis should be suspected if the TST or IGRA is positive or if there is history of tuberculosis exposure.

The differential diagnosis of tuberculous lymphadenopathy includes infections caused by atypical mycobacteria, *Bartonella*, fungi, viruses, and bacteria, as well as toxoplasmosis, sarcoidosis, drug reactions, and malignancy.

Treatment

Combination therapy is the backbone of therapy for tuberculosis disease to prevent the emergence of resistance. The treatment of tuberculosis is affected by the presence of naturally occurring drug-resistant organisms in large bacterial populations, even before therapy is initiated, and the fact that mycobacteria replicate slowly and can remain dormant in the body for prolonged periods. Patients with latent tuberculosis infection have small bacterial populations, and a single drug, such as **isoniazid (INH)**, can be given for 9 months. Therapy for latent infection is aimed at eradicating organisms sequestered within macrophages and suppressed by normal T-cell activity. Children with primary pulmonary tuberculosis and patients with extrapulmonary tuberculosis have medium-sized populations in which significant numbers of drug-resistant organisms may or may not be present. In general these patients are treated with at least two drugs ([Table 124.3](#)) for a prolonged course, typically 6-9 months, depending on the type of disease. Isoniazid and **rifampin (RIF)** are bactericidal for *M. tuberculosis*. Along with pyrazinamide ± ethambutol, they form the backbone of the antimicrobial treatment of tuberculosis. Other drugs and prolonged regimens are used in special circumstances, such as CNS infection and multidrug-resistant (**MDR**) or extensively drug-resistant (**XDR**) tuberculosis, which are unfortunately increasing in prevalence in some parts of the world, and are associated with increased treatment failure and mortality.

TABLE 124.3

Recommended Treatment Regimens for Drug-Susceptible Tuberculosis in Infants, Children, and Adolescents

INFECTION OR

DISEASE CATEGORY	REGIMEN	COMMENTS
LATENT TUBERCULOSIS INFECTION (POSITIVE TEST RESULT, NO DISEASE)		
Isoniazid-susceptible	9 mo of isoniazid, once a day	If daily therapy is not possible, DOT twice a week can be used for 9 mo.
Isoniazid-resistant	6 mo of rifampin, once a day	
Isoniazid-rifampin-resistant	Consult a tuberculosis specialist	
Pulmonary and extrapulmonary (except meningitis)	2 mo of isoniazid, rifampin, and pyrazinamide daily, followed by 4 mo of isoniazid and rifampin twice weekly under DOT	If possible drug resistance is a concern, another drug (ethambutol or an aminoglycoside) is added to the initial three-drug therapy until drug susceptibilities are determined. DOT is highly desirable.
		If hilar lymphadenopathy only, a 6-mo course of isoniazid and rifampin is sufficient.
		Drugs can be given 2 or 3 times per week under DOT in the initial phase if nonadherence is likely.
Meningitis	2 mo of isoniazid, rifampin, pyrazinamide, and an aminoglycoside or ethionamide, once a day, followed by 7-10 mo of isoniazid and rifampin, once a day or twice a week (9-12 mo total)	A fourth drug, usually an aminoglycoside, is given with initial therapy until drug susceptibility is known.
		For patients who may have acquired tuberculosis in geographic areas where resistance to streptomycin is common, capreomycin, kanamycin, or amikacin may be used instead of streptomycin.

DOT, Directly observed therapy; TST, tuberculin skin test.

From Recommendations from Kimberlin DW, Brady MT, Jackson MA, Long SS, et al. *Red Book: 2015 Report of the Committee on Infectious Diseases*. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015. Copyright 2015 American Academy of Pediatrics. Reproduced with permission.

In the United States, drug-susceptible pulmonary tuberculosis is treated with 2 months of four drugs and then completed with INH and RIF for an additional 4 months. Noncompliance, or nonadherence, is a major problem in tuberculosis control because of the long-term nature of treatment and the sometimes difficult social circumstances of the patients. As treatment regimens become shorter, adherence assumes an even greater importance. Improvement in compliance occurs with **directly observed therapy (DOT)**, which requires a health care worker to witness the administration of medications and is the standard of care in most settings.

Complications and Prognosis

The prognosis of tuberculosis in infants, children, and adolescents is excellent with early recognition and effective chemotherapy. In most children with pulmonary tuberculosis, the disease completely resolves, and ultimately radiographic findings are normal. The prognosis for children with bone and joint tuberculosis and tuberculous meningitis depends directly on the stage of disease at the time antituberculosis medications are started. Tuberculosis of the spine may result in angulation or **gibbus** formation that requires surgical correction after the infection is cured. Most childhood tuberculous meningitis occurs in developing countries, where the prognosis is poor. Resistant organisms are more difficult to treat and worsen prognosis.

Prevention

Tuberculosis control programs work on case finding and treatment, which interrupts secondary transmission of infection from close contacts. Infected close contacts are identified by positive TST or IGRA testing and can be started on appropriate treatment to prevent transmission.

Prevention of transmission in health care settings involves appropriate physical ventilation of the air around the source case. Offices, clinics, and hospital rooms used by adults with possible tuberculosis should have adequate ventilation, with air exhausted to the outside (**negative-pressure ventilation**). Health care providers should have annual screening with a TST or IGRA.

The only available vaccine against tuberculosis is the BCG vaccine. The original vaccine organism was a strain of attenuated *Mycobacterium bovis*. The preferred route of administration is intradermal injection with a syringe and needle because this is the only method that permits accurate measurement of an individual dose. The official recommendation of the World Health Organization is a single dose administered during infancy. This vaccine is not routinely used in the United States. Some studies show BCG provides 80-90% protection from tuberculosis, and other studies show no protective efficacy at all. In general it is thought that vaccination reduces the incidence of miliary disease and TB meningitis in infants. Many who receive BCG vaccine never have a positive TST reaction. When a reaction does occur, the induration size is usually less than 10 mm, and variably wanes after several years. BCG vaccination does not affect results of an IGRA.

Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

Etiology

The cause of acquired immunodeficiency syndrome (AIDS) is the human immunodeficiency virus (HIV), a single-stranded RNA virus of the retrovirus family that produces a reverse transcriptase enabling the viral RNA to act as a template for DNA transcription and integration into the host genome. HIV-1 causes 99% of all human cases. HIV-2, which is less virulent, causes 1-9% of cases in parts of Africa and is very rare in the United States.

HIV infects **helper T cells (CD4 cells)** and cells of monocyte-macrophage lineage via interaction of viral protein gp120 with the CD4 molecule and chemokines (CXCR4 and CCR5) that serve as coreceptors. Interaction with these molecules facilitates membrane fusion and cell entry by the virus. HIV infection directly and indirectly depletes CD4 T cells. Because helper T cells are important for delayed hypersensitivity, T cell–dependent B-cell antibody production, and T cell–mediated lymphokine activation of macrophages, their destruction produces a profound combined (B and T cell) immunodeficiency. A lack of T-cell regulation and unrestrained antigenic stimulation result in polyclonal hypergammaglobulinemia with nonspecific and ineffective globulins. Other cells bearing CD4, such as microglia, astrocytes, oligodendroglia, and placental tissues, also may be infected with HIV.

HIV infection is a continuously progressive process with a variable period of clinical latency before development of AIDS-defining conditions. All untreated patients have evidence of ongoing viral replication and progressive CD4 lymphocyte depletion. There are no overt manifestations of immunodeficiency until CD4 cell numbers decline to critical threshold levels. Quantitation of the viral load (HIV-1 RNA level) has become an important parameter in management.

Horizontal transmission of HIV is by sexual contact (vaginal, anal, or orogenital), percutaneous contact (from contaminated needles or other sharp

objects), or mucous membrane exposure to contaminated blood or body fluid. Transmission by contaminated blood and blood products has been eliminated in developed countries by screening donated blood products, but still occurs in developing countries. **Vertical transmission** of HIV from mother to infant may occur transplacentally in utero, during birth, or via breast feeding. Risk factors for perinatal transmission include prematurity, prolonged rupture of membranes, and high maternal HIV viral load at delivery. In non-breast feeding infants, perinatal transmission can be decreased from approximately 25% to less than 8% with administration of intravenous (IV) zidovudine during labor and postnatal treatment of the infant with oral zidovudine. Maternal treatment during pregnancy with combination antiretroviral therapy (cART) can reduce the risk of transmission to <1%. Breast feeding by HIV-infected mothers increases the risk of vertical transmission. In developing countries where breast feeding is associated with increased survival and decreased morbidity from malnutrition, diarrheal diseases, and other infections, continued administration of either cART for the mother or postnatal prophylactic ART for the infant can reduce transmission risk from breast feeding. In untreated infants, the mean incubation interval for development of an AIDS-defining condition after vertical transmission is 5 months (range, 1-24 months) compared with a longer incubation period after horizontal transmission of 7-10 years.

Epidemiology

Worldwide, as of 2015, approximately 36.7 million persons are living with HIV, and 3.4 million of them are children. There were 2.1 million new infections in 2015 with approximately 150,000 new infections in children. Approximately 70% of all people living with HIV reside in sub-Saharan Africa. Worldwide, 1.1 million people died from HIV-related illnesses in 2015. In 2012 the estimated number of people over the age of 13 years and living with HIV in the United States was 1.2 million, and approximately 2,000 children have perinatally-acquired infection. Vertical transmission is much less common than previously, and approximately 100 infants each year in the United States acquire HIV perinatally. Most pediatric cases in the United States occur in adolescents who engage in unprotected sexual activities. Worldwide the number of deaths related to HIV and the numbers of children infected with HIV have steadily decreased in large part due to treatment with antiretroviral therapy.

Clinical Manifestations

Decision-Making Algorithms

Neck Masses
 Hoarseness
 Diarrhea
 Arthritis
 Fever and Rash
 Lymphadenopathy
 Anemia
 Petechiae/Purpura
 Failure to Thrive

In adolescents and adults, primary infection results in the **acute retroviral syndrome** (resembling mononucleosis) that develops after an incubation period of 2-6 weeks and consists of fever, malaise, weight loss, pharyngitis, lymphadenopathy, and often a maculopapular rash. The risk of opportunistic infections and other AIDS-defining conditions is related to the depletion of CD4 T cells. A combination of CD4 cell count and percentage and clinical manifestations is used to classify HIV infection in children (Tables 125.1 and 125.2).

TABLE 125.1

2014 Human Immunodeficiency Virus Pediatric Classification System: Immu

IMMUNE CATEGORY	LABORATORY CRITERIA				C
	<12 MO		1 TO <6 YR		
	CD4 ⁺ CELLS/MM ³	% TOTAL LYMPHOCYTES	CD4 ⁺ CELLS/MM ³	% TOTAL LYMPHOCYTES	
Category 1 (no suppression)	≥1,500	≥34	≥1,000	≥30	≥
Category 2 (moderate suppression)	750-1,499	26-33	500-999	22-29	20
Category 3 (severe suppression)	<750	<26	<500	<22	<

TABLE 125.2

Human Immunodeficiency Virus–Related Symptoms

MILD HIV-RELATED SYMPTOMS
Children with two or more of the conditions listed but none of the conditions listed in Moderate Symptoms category:
<ul style="list-style-type: none"> • Lymphadenopathy (≥0.5 cm at more than 2 sites; bilateral at 1 site) • Hepatomegaly • Splenomegaly • Dermatitis • Parotitis • Recurrent or persistent upper respiratory tract infection, sinusitis, or otitis media
MODERATE HIV-RELATED SYMPTOMS
<ul style="list-style-type: none"> • Anemia (hemoglobin <8 g/dL), neutropenia (white blood cell count <1,000/μL), and/or thrombocytopenia (platelet count <100 × 10³/μL) persisting for ≥30 mo • Bacterial meningitis, pneumonia, or sepsis (single episode) • Candidiasis, oropharyngeal (thrush), persisting (>2 mo) in children older than age 6 mo • Cardiomyopathy • Cytomegalovirus infection, with onset before 1 mo • Diarrhea, recurrent or chronic • Hepatitis • Herpes simplex virus (HSV) stomatitis, recurrent (>2 episodes within 1 yr) • HSV bronchitis, pneumonitis, or esophagitis with onset before 1 mo • Herpes zoster (shingles) involving at least 2 distinct episodes or more than 1 dermatome • Leiomyosarcoma • Lymphoid interstitial pneumonia or pulmonary lymphoid hyperplasia complex • Nephropathy • Nocardiosis • Persistent fever (lasting >1 mo) • Toxoplasmosis, onset before 1 mo • Varicella, disseminated (complicated chickenpox)
STAGE-3-DEFINING OPPORTUNISTIC ILLNESSES IN HIV INFECTION
<ul style="list-style-type: none"> • Bacterial infections, multiple or recurrent* • Candidiasis of bronchi, trachea, or lungs • Candidiasis of esophagus • Cervical cancer, invasive[†] • Coccidioidomycosis, disseminated or extrapulmonary • Cryptococcosis, extrapulmonary • Cryptosporidiosis, chronic intestinal (>1 mo duration) • Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age >1 mo • Cytomegalovirus retinitis (with loss of vision) • Encephalopathy attributed to HIV • HSV: chronic ulcers (>1 mo duration) or bronchitis, pneumonitis, or esophagitis (onset at age >1 mo) • Histoplasmosis, disseminated or extrapulmonary • Isosporiasis, chronic intestinal (>1 mo duration) • Kaposi sarcoma • Lymphoma, Burkitt (or equivalent term) • Lymphoma, immunoblastic (or equivalent term) • Lymphoma, primary, of brain

- *Mycobacterium avium* complex or *Mycobacterium kansasii*, disseminated or extrapulmonary
- *Mycobacterium tuberculosis* of any site, pulmonary, disseminated, or extrapulmonary
- *Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary
- *Pneumocystis jirovecii* (previously known as *Pneumocystis carinii*) pneumonia
- Pneumonia, recurrent[†]
- Progressive multifocal leukoencephalopathy
- *Salmonella* septicemia, recurrent
- Toxoplasmosis of brain, onset at age >1 mo
- Wasting syndrome attributed to HIV

^{*}Only among children aged <6 years.

[†]Only among adults, adolescents, and children aged ≥6 years.

HIV, Human immunodeficiency virus; *HSV*, herpes simplex virus.

From the Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children. Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection. Available at <http://aidsinfo.nih.gov/contentfiles/lvguidelines/pediatricguidelines.pdf>. [Table 6].

Initial symptoms with vertical transmission vary and may include failure to thrive, neurodevelopmental delay, lymphadenopathy, hepatosplenomegaly, chronic or recurrent diarrhea, interstitial pneumonitis, or oral thrush. These findings may be subtle and remarkable only by their persistence. Manifestations that are more common in children than adults with HIV infection include recurrent bacterial infections, lymphoid hyperplasia, chronic parotid swelling, lymphocytic interstitial pneumonitis, and earlier onset of progressive neurological deterioration. Pulmonary manifestations of HIV infection are common and include *Pneumocystis jirovecii* pneumonia, which can present early in infancy as a primary pneumonia characterized by hypoxia, tachypnea, retractions, elevated serum lactate dehydrogenase, and fever.

In the United States, most pregnant women are screened and, if indicated, treated for HIV infection. Women with high HIV viral loads at delivery will be offered a cesarean section. All infants born to HIV-infected mothers are bathed prior to receiving their newborn hepatitis B vaccine and vitamin K injection, receive antiretroviral prophylaxis, are exclusively formula fed, and are prospectively tested for infection. The diagnosis of HIV infection in most infants born in the United States is confirmed before development of clinical signs of infection.

Laboratory and Imaging Studies

HIV infection can be diagnosed definitively in non–breast fed infants by 1 month of age and in virtually all infected infants by 6 months of age using viral diagnostic assays (RNA polymerase chain reaction [PCR] or DNA PCR).

Maternal antibodies may be detectable until 12-15 months of age, and a positive serological test in the infant is not considered diagnostic until 18 months of age. HIV PCR (RNA or DNA) is the preferred method for diagnosing HIV infection during infancy and identifies ~50% of infected newborns at 48 hours and ~90% at 28 days. Timing of diagnostic viral testing varies depending on specific risk factors but typically involves testing at 1-2 weeks of age, at 1-2 months of age, and at 4-6 months of age. Testing at birth should be considered for infants at high risk for in utero infection (high maternal HIV viral load at delivery). HIV RNA PCR has 25-60% sensitivity during the first weeks of life, increasing to 90-100% by 2-3 months of age.

HIV infection of an exposed infant is confirmed if virological tests are positive on two separate occasions. HIV infection can be reasonably excluded in non-breast fed infants with at least two virological tests performed at older than 1 month of age, with one test being performed after 4 months of age. Loss of HIV antibody combined with negative HIV DNA PCR confirms absence of HIV infection. Persistence of a positive HIV antibody test after 18 months of age indicates HIV infection.

Differential Diagnosis

The differential diagnosis of AIDS in infants includes primary immunodeficiency syndromes and intrauterine infections such as cytomegalovirus (CMV) and syphilis. Prominence of individual symptoms, such as diarrhea, may suggest other etiologies.

Treatment

Management of HIV infection in children and adolescents is evolving and complex. It should be directed by a specialist in the treatment of HIV infection. cART is recommended for all HIV-infected children; however, urgency of cART initiation is based on age, the severity of HIV disease as indicated by AIDS-defining conditions, and the risk of disease progression as indicated by CD4 cell count ([Table 125.3](#)). Initiation of antiretroviral therapy while the patient is still asymptomatic may preserve immune function and prevent clinical progression but incurs the adverse effects of therapy and may facilitate emergence of drug-resistant virus if medication adherence is poor.

TABLE 125.3**Indications for Initiation of Therapy in Antiretroviral Naive Children Infected With Human Immunodeficiency Virus**

AGE	CRITERIA	RECOMMENDATION
<12 mo	Regardless of clinical symptoms, immune status, or viral load	Urgent treatment
1 to <6 yr	CDC Stage 3-defining opportunistic illnesses	Urgent treatment
	CDC Stage 3 immunodeficiency. CD4 <500 cells/mm ³	
	Moderate HIV-related symptoms	Treat within 1-2 wk, including an expedited discussion on adherence
CD4 cell count 500-999 cells/mm ³		
	Asymptomatic or mild symptoms and CD4 cell count ≥1,000 cells/mm ³	Treat*
≥6 yr	CDC Stage 3-defining opportunistic illnesses	Urgent treatment
	CDC Stage 3 immunodeficiency. CD4 <200 cells/mm ³	
	Moderate HIV-related symptoms	Treat within 1-2 wk, including an expedited discussion on adherence
CD4 cell count 200-499 cells/mm ³		
	Asymptomatic or mild symptoms and CD4 cell count ≥500 cells/mm ³	Treat*

*More time can be taken to fully assess and address issues associated with adherence with the caregivers and the child prior to initiating therapy. Patients/caregivers may choose to postpone therapy, and on a case-by-case basis, providers may elect to defer therapy based on clinical and/or psychosocial factors.

From the Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children. Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection. Available at <http://aidsinfo.nih.gov/contentfiles/lvguidelines/pediatricguidelines.pdf>. [page F-2].

Urgent initiation of therapy (see [Table 125.3](#)) is recommended for infants less than 12 months of age regardless of symptoms of HIV disease or HIV RNA level. Urgent initiation of therapy is recommended for all children >1 year of age with AIDS or significant HIV-related symptoms or severe immunosuppression (CD4 below 500 cells/mm³ for children ages 1 to ≤6 years and below 200 cells/mm³ for children >6 years of age), regardless of symptoms or HIV RNA level. For all other children not meeting criteria for urgent cART initiation, more time can be taken to fully assess and address issues associated with adherence prior to initiating therapy.

Effective cART significantly reduces viral loads and leads to the amelioration of clinical symptoms and opportunistic infections. Combination therapy that includes either a non-nucleoside reverse transcriptase inhibitor (NNRTI), a

protease inhibitor (PI), or an integrase inhibitor depending on the child's age plus a dual-nucleoside/nucleotide reverse transcriptase inhibitor (NRTI) backbone is recommended for initial treatment of all HIV infected children. The goal of therapy is to reduce the HIV viral load to below the level of detection and normalize or preserve the patient's immune status. The most recent specific recommendations for treatment regimens (<http://aidsinfo.nih.gov/guidelines/>) should be consulted before initiating therapy for any patient.

The ability of HIV to develop resistance to antiretroviral agents rapidly and the development of cross-resistance to several classes of agents simultaneously are major problems. Determination of HIV viral load, CD4 cell count, and HIV resistance genotype is essential for monitoring and modifying antiretroviral treatment.

Routine immunizations are recommended but may result in suboptimal immune responses. In addition to 13-valent pneumococcal conjugate vaccine, 23-valent pneumococcal polysaccharide vaccine is recommended for HIV-infected children at 2 years of age and adolescents and adults with CD4 counts at or above 200/mm³. Because of the risk of fatal measles in children with AIDS, children without severe immunosuppression should receive their first dose of MMR at 12 months of age and the second dose at 4-6 years of age. Varicella-zoster virus (VZV) vaccine should be given only to asymptomatic, nonimmunosuppressed children beginning at 12 months of age as two doses of vaccine at least 3 months apart. Inactivated split influenza virus vaccine should be administered annually to all HIV-infected children at or after 6 months of age.

Complications

The approach to the numerous opportunistic infections in HIV-infected patients involves treatment and prophylaxis for infections likely to occur as CD4 cells are depleted. With potent antiretroviral therapy and immune reconstitution, routine prophylaxis for common opportunistic infections depends on the child's age and CD4 count. Infants born to HIV-infected mothers receive prophylaxis for *P. jiroveci* pneumonia with trimethoprim-sulfamethoxazole (TMP-SMX) beginning at 4-6 weeks of age and continued for the first year of life or until HIV infection has been excluded. TMP-SMX prophylaxis for *P. jiroveci* pneumonia for older children and adolescents is provided if CD4 cell counts are less than 500 cells/mm³ or CD4 percentage <15% for children 1 to <6 years of age, or less than 200 cells/mm³ or CD4 percentage <15% for children <6 years of age.

Clarithromycin prophylaxis for *Mycobacterium avium* complex infection is provided if CD4 cell counts are below 750 cells/mm³ for children <1 year of age, below 500 cells/mm³ for children 1 to <2 years of age, below 75 cells/mm³ for children 2 to <6 years of age, and below 50 cells/mm³ for children ≥6 years of age.

P. jiroveci pneumonia is treated with high-dose TMP-SMX and corticosteroids. Oral and gastrointestinal candidiasis is common in children and usually responds to fluconazole therapy. VZV infection may be severe and should be treated with acyclovir or other antivirals. Recurrent herpes simplex virus (HSV) infections also may require long-term antiviral prophylaxis. Other common infections in HIV-infected patients include toxoplasmosis, CMV, Epstein-Barr virus infection, salmonellosis, and tuberculosis.

Prognosis

The availability of cART has improved the prognosis for HIV and AIDS dramatically. Risk of death is directly related to the degree of immunosuppression, viral load, and young age. Children less than 1 year of age with very low CD4 percentiles and high viral loads have the poorest prognosis.

Prevention

Identification of HIV-infected women before or during pregnancy is crucial to providing optimal therapy for infected women and their infants and to preventing perinatal transmission. Prenatal HIV counseling and testing with consent should be provided for all pregnant women in the United States.

The rate of vertical transmission is reduced to less than 8% by chemoprophylaxis with a regimen of oral zidovudine to the mother started during pregnancy, continued during delivery with IV zidovudine, and then administered orally to the newborn for the first 6 weeks of life. Administration of maternal cART throughout pregnancy to achieve viral suppression (viral load <1,000 copies/mL) with postnatal antiretroviral prophylaxis to the infant reduces the risk of transmission even further to <1% in non-breast feeding infants. The current recommendations for the United States include a 4- to -6-week prophylactic regimen with zidovudine for the infant in combination with maternal intrapartum therapy. The maternal regimen includes continuation or initiation of antiretroviral therapy. In high-risk situations (e.g., mother's viral

load is >1,000 copies/mL or is unknown, mother did not receive cART during pregnancy), intravenous zidovudine during delivery is administered and additional antiretrovirals may be given to the infant postnatally (http://aidsinfo.nih.gov/contentfiles/lvguidelines/peri_recommendations.pdf).

Scheduled cesarean section at 38 weeks to prevent vertical transmission is recommended for women with HIV RNA levels greater than 1,000 copies/mL, but it is unclear whether cesarean section is beneficial when viral load is less than 1,000 copies/mL or when membranes have already ruptured.

Preventing HIV infection in adults decreases the incidence of infection in children. Adult prevention results from behavior changes such as safe-sex practices, decrease in intravenous drug use, and needle exchange programs. Screening of blood donors has almost eliminated the risk of HIV transmission from blood products. HIV infection almost never is transmitted in a casual or nonsexual household setting.

Pearls for Practitioners

Chapter 93

Infectious Disease Assessment

- A complete infectious diseases history should include environmental exposures, sick contacts, travel, immune status, and immunization history.
- Routine screening tests may include complete blood count with differential, inflammatory markers, transaminases, urinalysis and culture, lumbar puncture, or blood culture.
- A microbiologic diagnosis of infection may be confirmed or suggested by rapid antigen tests, cultures, serological tests, or molecular tests (e.g., polymerase chain reaction).

Chapter 94

Immunization and Prophylaxis

- Purified polysaccharide vaccines are poor immunogens for children <2 years of age. Conjugation of a polysaccharide to a protein carrier creates immunogenic vaccines for *Haemophilus influenzae* type b, *Streptococcus pneumoniae*, and *Neisseria meningitidis* for this age group.
- Contraindications to vaccination include anaphylaxis to prior immunization and immunocompromised patients (live-virus vaccines).
- Administration of blood products and immunoglobulin can diminish response to live-virus vaccines if administered before the recommended interval.

Chapter 95

Antiinfective Therapy

- Obtain relevant cultures prior to initiating empiric antibiotics.
- Use of broad-spectrum empiric therapy is recommended for

critically ill or immunocompromised patients.

- Sites with poor antimicrobial drug penetration may need drainage (abscess, osteomyelitis).
- Use targeted antimicrobial therapy to employ the least toxic, most narrow-spectrum agent effective against the causative pathogen.

Chapter 96

Fever Without a Focus

- Children <1 month of age with fever should have a complete evaluation of blood, urine, and cerebrospinal fluid (CSF) and should receive empiric antibiotics.
- Urinary tract infection is the most common serious bacterial infection in children <6 months of age.
- Children 3-36 months with fever should have a careful history and physical exam. Those without localizing signs or symptoms may need urine and blood cultures.
- Children with sickle cell anemia are at increased risk of bacteremia with encapsulated organisms.
- Children with unexplained fevers >14 days have fever of unknown origin. Among these episodes of fever of unknown origin, infections cause ~40-50%, inflammatory diseases ~20%, and malignancy ~10%.

Chapter 97

Infections Characterized by Fever and Rash

- Common childhood causes of febrile illnesses with rash include measles, rubella, human herpesvirus type 6 (HHV-6), parvovirus B19, and varicella.
- Chickenpox is characterized by fever and a pruritic vesicular

rash that comes in crops; secondary staphylococcal or streptococcal skin infection is a common complication.

- Measles is characterized by cough, coryza, conjunctivitis, fever, rash, and Koplik spots on the buccal mucosa.
- Congenital rubella syndrome is characterized by intrauterine growth restriction, retinitis, blueberry muffin rash, and patent ductus arteriosus.
- Roseola (due to human herpes viruses 6 and 7) is characterized by an abrupt onset of a rash that appears after defervescence.
- Erythema infectiosum (due to parvovirus B19) is characterized by fever, malaise, a slapped cheek rash, and transient aplastic crisis in children with sickle cell anemia.

Chapter 98

Cutaneous Infections

- Many childhood cutaneous infections are caused by *Staphylococcus aureus* or group A streptococci.
- Crusted impetigo is often caused by *S. aureus*.
- Necrotizing fasciitis is a surgical emergency and is suggested by rapid extension of lesions, pain out of proportion to lesions, toxic appearance, or crepitus.
- Common viral causes of superficial skin infections include herpes simplex virus (HSV), human papillomavirus (HPV), and molluscum contagiosum virus.

Chapter 99

Lymphadenopathy

- Cervical lymphadenitis is the most common childhood regional lymphadenitis; common causes include streptococcal pharyngitis, respiratory viruses, Epstein-Barr virus (EBV), and

cytomegalovirus (CMV).

- The differential diagnosis of cervical adenitis should include Kawasaki disease, cat-scratch disease, atypical tuberculosis, mononucleosis, human immunodeficiency virus (HIV), and lymphoma.

Chapter 100

Meningitis

- The organisms that most commonly cause neonatal meningitis are group B streptococcus, *Escherichia coli*, and *Listeria monocytogenes*. Older children are more likely to have *Streptococcus pneumoniae* and *Neisseria meningitidis* as a cause of meningitis.
- Partially treated bacterial meningitis may decrease the ability to grow the organism; polymerase chain reaction (PCR) is useful to detect the pathogen but does not provide antimicrobial pathogen sensitivities.
- Enteroviruses and parechovirus are common causes of viral meningitis.
- Herpes simplex may produce meningoencephalitis and requires treatment with intravenous acyclovir.
- Presumptive therapy for neonatal meningitis includes ampicillin and cefotaxime and for older children should be ceftriaxone and vancomycin.

Chapter 101

Encephalitis

- Viruses are the most common infectious cause of aseptic meningitis and encephalitis. Intravenous (IV) acyclovir should be used empirically if HSV or varicella-zoster virus (VZV) are

suspected.

- Autoimmune encephalitis should be considered in all patients with encephalitis; diagnosis is by detecting brain-specific autoantibodies in blood and CSF.

Chapter 102

Upper Respiratory Tract Infection

- Young children typically have multiple upper respiratory tract infections (URIs) each year, up to 8-12. Antibiotics are not beneficial in treating these episodes and may instead cause harm.
- Complications of a URI include otitis media, sinusitis, and exacerbation of asthma.

Chapter 103

Pharyngitis

- Viruses are the most common cause of pharyngitis. However, if group A streptococcus is isolated by rapid antigen test or culture, it should be treated in order to prevent acute rheumatic fever. Penicillin or amoxicillin are first-line therapies.
- A major reason to treat streptococcal pharyngitis is to prevent rheumatic fever. Streptococcal pharyngitis is relatively uncommon in young children <3 years of age.

Chapter 104

Sinusitis

- The bacterial causes of acute sinusitis mirror those of otitis media and are *Streptococcus pneumoniae*, nontypable *Haemophilus influenzae*, and *Moraxella catarrhalis*.
- Complications of sinusitis include orbital cellulitis, Potts puffy

tumor, and brain abscess.

Chapter 105

Otitis Media

- Poor or absent tympanic membrane mobility to negative and positive pressure using pneumatic otoscopy is a necessary finding for the diagnosis of acute otitis media (AOM).
- Complications of AOM include persistent middle ear effusion, hearing loss, mastoiditis, brain abscess, perforated tympanic membrane, and cholesteatoma.
- Otitis media (OM) with effusion is the most frequent sequela of AOM and may result in persistent middle ear effusion, which may be associated with hearing loss.
- Not all episodes of AOM require antibiotic treatment.

Chapter 106

Otitis Externa

- Otitis externa is most frequently caused by *Pseudomonas aeruginosa*.

Chapter 107

Croup (Laryngotracheobronchitis)

- Croup (laryngotracheobronchitis) is the most common infection of the middle respiratory tract; it is typically caused by parainfluenza virus and presents with stridor.
- The differential diagnosis of croup includes a foreign body, tracheitis, epiglottitis, tracheomalacia, and a vascular ring.

Chapter 108

Pertussis

- Pertussis typically lasts 6-8 weeks; it is marked by catarrhal, paroxysmal, and convalescent stages and can lead to apnea and severe respiratory distress in infants.
- Pertussis is associated with lymphocytosis and post-tussive emesis.

Chapter 109

Bronchiolitis

- Bronchiolitis is a common lower respiratory infection in children <2 years of age, is typically caused by respiratory syncytial virus (RSV), and requires only supportive treatment.
- The differential diagnosis of bronchiolitis includes asthma, heart failure, pneumonia, foreign body, and congenital airway or lung anomalies.

Chapter 110

Pneumonia

- *Streptococcus pneumoniae* is the most common bacterial cause of pneumonia outside the neonatal period and is the target of antibiotic selection for community-acquired pneumonia.
- Diagnostic evaluation for children hospitalized for pneumonia often includes complete blood count (CBC), blood culture, chest radiography, and occasionally rapid viral diagnostic testing.
- Amoxicillin or ampicillin are first-line antibiotics selections for community-acquired pneumonia in children.

Chapter 111

Infective Endocarditis

- Streptococci are the most common cause of native valve endocarditis in children, whereas staphylococci are more common in those with prosthetic material.
- If infectious endocarditis is suspected, multiple optimal-volume blood cultures should be obtained prior to starting antimicrobial therapy.

Chapter 112

Acute Gastroenteritis

- Management of acute gastroenteritis should include supportive care (correcting dehydration and electrolyte abnormalities) and not antibiotics in most circumstances.
- Enterohemorrhagic *Escherichia coli* producing Shiga-toxin causes hemolytic uremic syndrome characterized by microangiopathic hemolytic anemia, thrombocytopenia, and acute kidney injury.
- Nucleic acid amplification tests (NAAT) are the tests of choice for the most common causes of viral and bacterial gastroenteritis.
- When indicated, first-line therapy for traveler's diarrhea in children is azithromycin.

Chapter 113

Viral Hepatitis

- Various types of viral hepatitis are difficult to distinguish during acute infection; most have a nonspecific prodromal phase followed by an icteric phase. Often acute illness with hepatitis A virus (HAV), HBV, and HCV is mild or even asymptomatic in children.

- Vaccines are available to prevent HAV and HBV infection.
- HBV and HCV infection may become chronic with a risk for cirrhosis or hepatic cancer.

Chapter 114

Urinary Tract Infection

- *Escherichia coli* accounts for the vast majority of pediatric urinary tract infections.
- A renal ultrasound should be performed in young children to detect scarring, reflux, and congenital renal anomalies.
- Urinary tract infection (UTI) diagnosis requires a positive urine culture.
- Urine leukocyte esterase and nitrite testing aids in the diagnosis of a UTI.
- Nonspecific vaginitis is the most common cause of vulvovaginitis in prepubertal girls.

Chapter 115

Vulvovaginitis

- **Bacterial vaginosis** represents disruption of the normal vaginal flora with reduction in lactobacillus and overgrowth of other organisms.
- Nonspecific vaginitis is the most common cause of vulvovaginitis in prepubertal girls.

Chapter 116

Sexually Transmitted Infections

- There is increasing antibiotic resistance in *Neisseria gonorrhoeae*. Outpatient treatment of gonococcal urethritis or

endocervicitis should include a single intramuscular (IM) dose of ceftriaxone in combination with a single oral dose of azithromycin 1 g to treat potential co-infection with *Chlamydia trachomatis* and prevent the emergence of resistance in *N. gonorrhoeae*.

- Chlamydia is the most frequently diagnosed bacterial sexually transmitted infection (STI) in adolescents and accounts for most cases of nongonococcal urethritis and cervicitis.
- Chlamydial cervicitis is often asymptomatic.

Chapter 117

Osteomyelitis

- *Staphylococcus aureus* is the most common bacterial cause of osteomyelitis and is the target of antibiotic selection for this condition.
- Magnetic resonance imaging is the most sensitive diagnostic imaging test for osteomyelitis and will identify lesions early in the course of disease.
- An antistaphylococcal agent (nafcillin, oxacillin, or cefazolin) is the preferred empiric therapy for osteomyelitis in areas where methicillin-resistant *S. aureus* rates are low.

Chapter 118

Infectious Arthritis

- *Staphylococcus aureus* is the most common bacterial cause of septic arthritis and is the target of antibiotic selection for this condition.
- Diagnostic evaluation for septic arthritis should include joint aspirate for cell count, Gram stain, and culture.
- An antistaphylococcal agent (nafcillin, oxacillin, or cefazolin) is

the preferred empiric therapy for septic arthritis in areas where methicillin-resistant *S. aureus* rates are low.

Chapter 119

Ocular Infections

- All newborns should receive prophylaxis for ophthalmia neonatorum, typically with erythromycin 0.5% ointment, which will prevent gonococcal but not chlamydial ophthalmia.
- Chlamydia conjunctivitis in the newborn is treated with oral antibiotics to prevent chlamydial pneumonia.
- Neonatal conjunctivitis due to gonococcus is treated with IM or IV ceftriaxone.
- Conjunctivitis and or keratitis in patients who use contact lenses may be due to pseudomonas.

Chapter 120

Infection in the Immunocompromised Person

- The presence of fever with neutropenia, even in the absence of other symptoms, demands prompt and thorough evaluation and empiric antimicrobial therapy.
- Fever is often the only sign of serious infection in immunocompromised patients.
- Rectal tenderness or pain on defecation may suggest a perianal abscess.
- The central line exit site and subcutaneous track should be inspected and blood drawn for culture from each lumen to detect line infections.
- Pneumonia, sinusitis, and bacteremia are the most common sites of infection in patients with fever and neutropenia.

Chapter 121

Infections Associated With Medical Devices

- The major complication of indwelling medical devices such as central lines, ventriculo-peritoneal shunts, and urinary catheters is infection (health care–associated infections).
- Antibiotic-lock therapy may be used to aid in treatment or prevention of catheter line infections.

Chapter 122

Zoonoses and Vector Borne Infections

- Lyme disease (*Borrelia burgdorferi*) is the most common tick-borne infection in the United States.
- Early treatment of erythema migrans almost always prevents progression to later stages of Lyme disease. The most common reason patients “recur” or do not respond to treatment is that the initial diagnosis was incorrect.
- Ehrlichiosis and anaplasmosis presents like Rocky Mountain Spotted fever.
- Rocky Mountain Spotted Fever is a severe life-threatening illness that has a 20-80% case fatality rate if untreated.
- Dengue hemorrhagic fever is seen in patients with a previous infection with Dengue virus.

Chapter 123

Parasitic Diseases

- Chemoprophylaxis for malaria is necessary for all visitors to and residents of the tropics who have not lived there since infancy.
- Malaria is characterized by febrile paroxysms.
- Long-term relapse with malaria occurs because of persistent

hepatic infection with either *Plasmodium vivax* or *P. ovale*.

Chapter 124

Tuberculosis

- The diagnosis of *Mycobacterium tuberculosis* infection can be difficult. Young children under 5 should have a purified protein derivative (PPD) test, whereas older children can have a PPD or interferon-gamma release assay (IGRA). Both may not be positive during active infection.
- Pulmonary tuberculosis initially presents as a pulmonary infiltrate with hilar adenopathy.
- Bone or brain involvement with tuberculosis (TB) occurs due to hematogenous spread following primary pulmonary TB.
- Reactivation of TB occurs most often in adolescents and patients exposed to corticosteroids or anti-TNF antibodies.

Chapter 125

Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

- Vertical transmission of HIV, from mother to child, is now an uncommon occurrence in the United States due to the effectiveness of preventative measures including early maternal diagnosis, maternal treatment during pregnancy and delivery, postnatal prophylactic treatment of the infant, and avoidance of breast feeding.
- Perinatal acquired HIV presents with failure to thrive, lymphadenopathy, hepatosplenomegaly, parotitis, diarrhea, and opportunistic infections.
- Sexually active adolescents are the highest risk group of becoming HIV positive.

CHAPTER 126

Digestive System Assessment

History

After identifying the major gastrointestinal (GI) symptom, the onset and progression should be determined (improved, unchanged, worsening). Characterization of signs and symptoms should identify factors that trigger or alleviate the symptom; the timing, frequency, and duration of symptoms; relationship to meals and defecation; and associated symptoms (e.g., fever or weight loss). Other key history includes exposures to others (family, school contacts, pets), travel, environmental exposure, and impact of illness on the child (school absences, weight loss).

Physical Examination

The history may suggest a diagnosis and direct the evaluation, which should include a full examination as well as a thorough abdominal examination. Extraintestinal disorders may produce GI manifestations (e.g., emesis with group A streptococcal pharyngitis, abdominal pain with lower lobe pneumonia). The examination should begin with a careful external inspection for abdominal distention, bruising or discoloration, abnormal abdominal veins, jaundice, surgical scars, and ostomies. Abnormalities of intensity and pitch of bowel sounds can occur with bowel obstruction. When palpating for tenderness, the examiner should note location, facial expression, guarding, and rebound tenderness. Palpation can also detect enlargement of the liver or spleen as well as feces and masses. If detected, organomegaly should be measured (with a tape measure), noting abnormal firmness or contour. A rectal examination, including inspection for fissures, skin tags, abscesses, and fistulous openings, should be performed for children with history suggesting constipation, GI bleeding, abdominal pain, chronic diarrhea, and suspicion of inflammatory bowel disease (IBD). Digital rectal examination should include assessment of anal sphincter

tone, anal canal size and elasticity, tenderness, extrinsic masses, presence of fecal impaction, and caliber of the rectum. Stool should be tested for occult blood.

Screening Tests

A **complete blood count** may provide evidence for inflammation (white blood cell [WBC] and platelet count), poor nutrition or bleeding (hemoglobin, red blood cell volume, reticulocyte count), and infection (WBC number and differential, presence of toxic granulation). Serum electrolytes, blood urea nitrogen (BUN), and creatinine help define hydration status. Tests of liver dysfunction include total and direct bilirubin, alanine aminotransferase, aspartate aminotransferase for evidence of hepatocellular injury, and γ -glutamyltransferase or alkaline phosphatase for evidence of bile duct injury. **Hepatic synthetic function** can be assessed by coagulation factor levels, prothrombin time, and albumin level. Pancreatic enzyme tests (amylase, lipase) provide evidence of pancreatic injury or inflammation. Urinalysis can gauge dehydration and identify a possible source of protein loss.

Diagnostic Imaging

Radiology

A plain abdominal x-ray to document excessive retained stool when history is consistent with constipation and encopresis is not necessary, as physical examination alone can confirm the diagnosis.

Endoscopy

Endoscopy permits the direct visualization of the interior of the gut. **Video endoscopes** may be used even in very small infants by pediatric gastroenterologists. **Wireless capsule endoscopy** (Fig. 126.1) enables visualization of lesions beyond the reach of conventional endoscopes.

FIGURE 126.1 Wireless capsule endoscopy: Aphthous ulcers (*arrows*) in jejunum diagnostic of Crohn disease in patient with negative findings on upper endoscopy and colonoscopy.

Consultation with a pediatric gastroenterologist for endoscopy is recommended for further evaluation of suspected esophageal or gastric inflammation unresponsive to medications, to confirm the diagnosis of eosinophilic esophagitis or celiac disease, to evaluate GI bleeding, to investigate suspected IBD, or to screen for polyp disorders. In addition, a trained endoscopist can remove esophageal and gastric foreign bodies and place feeding tubes.

Common Manifestations of Gastrointestinal Disorders

Abdominal Pain

Decision-Making Algorithm

Abdominal Pain

General Considerations

Abdominal pain can result from injury to the intraabdominal organs or overlying somatic structures in the abdominal wall, or from extraabdominal diseases. **Visceral pain** results when autonomic nerves within the gut detect injury, transmitting sensation by nonmyelinated fibers. The pain is vague, dull, slow in onset, and poorly localized. A variety of stimuli, including normal peristalsis and various intraluminal chemical and osmotic states, activate these fibers to some degree. Regardless of the stimulus, visceral pain is perceived when a threshold of intensity or duration is crossed. Lower degrees of activation may result in perception of nonpainful or perhaps vaguely uncomfortable sensations, whereas more intensive stimulation of these fibers results in pain. Overactive sensation may be the basis of some kinds of abdominal pain, such as **functional abdominal pain** and **irritable bowel syndrome (IBS)**.

In contrast to visceral pain, **somatic pain** results when overlying body structures are injured. Somatic structures include the parietal peritoneum, fascia, muscles, and skin of the abdominal wall. In contrast to pain emanating from visceral injury, somatic nociceptive fibers are myelinated and are capable of rapid transmission of well-localized painful stimuli. When intraabdominal processes cause inflammation or injury to the parietal peritoneum or abdominal wall structures, poorly localized visceral pain becomes well-localized somatic pain. For example, in acute appendicitis, the initial activation of visceral nociceptive fibers yields poorly localized discomfort in the midabdomen. When the inflammatory process extends to the overlying parietal peritoneum, the pain becomes severe and localizes to the right lower quadrant. This is called **somatoparietal pain**.

Referred pain is a painful sensation in a body region distant from the true source of pain. The location of referred pain is predictable based on the locus of visceral injury. Stomach pain is referred to the epigastric and retrosternal regions, and liver and pancreas pain is referred to the epigastric region. Gallbladder pain often is referred to the region below the right scapula. Somatic pathways stimulated by small bowel visceral afferents affect the periumbilical area, and colonic injury results in infraumbilical referred pain.

Acute Abdominal Pain

Distinguishing Features

Acute abdominal pain can signal the presence of a dangerous intraabdominal

process (e.g., appendicitis or bowel obstruction) or may originate from extraintestinal sources (e.g., lower lobe pneumonia or urinary tract stone). Not all episodes of acute abdominal pain require emergency intervention. Appendicitis and volvulus, for example, must be ruled out as quickly as possible. Few patients presenting with acute abdominal pain actually have a surgical emergency, but they must be separated from cases that can be managed conservatively.

Initial Diagnostic Evaluation

Table 126.1 lists a diagnostic approach to acute abdominal pain in children. Events that occur with a discrete, abrupt onset, such as passage of a stone, perforation of a viscus, or infarction, result in a sudden **onset of pain**. Gradual onset of pain is common with infectious or inflammatory causes, such as appendicitis and IBD.

TABLE 126.1

Diagnostic Approach to Acute Abdominal Pain

HISTORY	
Onset	Sudden or gradual, prior episodes, association with meals, history of injury
Nature	Sharp versus dull, colicky or constant, burning
Location	Epigastric, periumbilical, generalized, right or left lower quadrant, change in location over time
Associated symptoms	Fever, vomiting (bilious?), diarrhea (bloody?), abdominal distention
Extraintestinal symptoms	Cough, dyspnea, dysuria, urinary frequency, flank pain
Course of symptoms	Worsening or improving, change in nature or location of pain, aggravating and alleviating factors, last menstrual period
PHYSICAL EXAMINATION	
General position	Growth and nutrition, general appearance, hydration, degree of discomfort, body position
Abdominal	Tenderness, distention, bowel sounds, rigidity, guarding, mass
Genitalia	Testicular torsion, hernia, pelvic inflammatory disease, ectopic pregnancy
Surrounding structures	Breath sounds, rales, rhonchi, wheezing, flank tenderness, tenderness of abdominal wall structures, ribs, costochondral joints
Rectal examination	Perianal lesions, stricture, tenderness, fecal impaction, blood
LABORATORY	
CBC, C-reactive protein, ESR	Evidence of infection or inflammation
AST, ALT, GGT, bilirubin	Biliary or liver disease

Amylase, lipase	Pancreatitis
Urinalysis	Urinary tract infection; bleeding due to stone, trauma, or obstruction
Pregnancy test (older females)	Ectopic pregnancy
RADIOLOGY	
Plain flat and upright abdominal films	Bowel obstruction, appendiceal fecalith, free intraperitoneal air, kidney stones, constipation, mass
CT scan	Intraabdominal or pelvic abscess, appendicitis, Crohn disease, pancreatitis, gallstones, kidney stones
Barium enema	Intussusception, malrotation
Ultrasound	Gallstones, appendicitis, intussusception, pancreatitis, kidney stones
Endoscopy	Colitis
Upper endoscopy	Suspected peptic ulcer or esophagitis

ALT, Alanine aminotransferase; *AST*, aspartate aminotransferase; *CBC*, complete blood count; *CT*, computed tomography; *ESR*, erythrocyte sedimentation rate; *GGT*, γ -glutamyltransferase.

A standard group of laboratory tests usually is performed for acute abdominal pain (see [Table 126.1](#)). An abdominal x-ray series evaluates for bowel obstruction, fecalith, or nephrolithiasis. Ultrasound or computed tomography (CT) can visualize the appendix if appendicitis is suspected but the diagnosis remains in doubt. If the initial evaluation suggests intussusception, a barium or pneumatic (air) enema may be used to diagnose and treat this condition (see [Chapter 129](#)).

Differential Diagnosis

[Table 126.2](#) lists the differential diagnosis of acute abdominal pain in children. The urgent task of the clinician is to rule out surgical emergencies. In young children, malrotation with volvulus, incarcerated hernia, congenital anomalies, and intussusception are common concerns. In older children and teenagers, appendicitis is more common. An acute surgical abdomen is characterized by signs of peritonitis, including tenderness, abdominal wall rigidity, guarding, and absent or diminished bowel sounds. Helpful characteristics of onset, location, referral, and quality of pain are noted in [Table 126.3](#).

TABLE 126.3**Distinguishing Features of Abdominal Pain in Children**

DISEASE	ONSET	LOCATION	REFERRAL	QUALITY	COMMENTS
Functional: irritable bowel syndrome	Recurrent	Periumbilical, splenic and hepatic flexures	None	Dull, crampy, intermittent; duration 2 hr	Family stress, school phobia, diarrhea and constipation; hypersensitive to pain from distention
Esophageal reflux	Recurrent, after meals, at bedtime	Substernal	Chest	Burning	Sour taste in mouth; Sandifer syndrome
Duodenal ulcer	Recurrent, before meals, at night	Epigastric	Back	Severe burning, gnawing	Relieved by food, milk, antacids; family history important; gastrointestinal bleeding
Pancreatitis	Acute	Epigastric- hypogastric	Back	Constant, sharp, boring	Nausea, emesis, marked tenderness

Intestinal obstruction	Acute or gradual	Periumbilical–lower abdomen	Back	Alternating cramping (colic) and painless periods	Distention, obstipation, bilious emesis, increased bowel sounds
Appendicitis	Acute	Periumbilical or epigastric; localizes to right lower quadrant	Back or pelvis if retrocecal	Sharp, steady	Nausea, emesis, local tenderness, ± fever, avoids motion
Meckel diverticulum	Recurrent	Periumbilical–lower abdomen	None	Sharp	Hematochezia; painless unless intussusception, diverticulitis, or perforation
Inflammatory bowel disease	Recurrent	Depends on site of involvement		Dull cramping, tenesmus	Fever, weight loss, ±hematochezia
Intussusception	Acute	Periumbilical–lower abdomen	None	Cramping, with painless periods	Guarded position with knees pulled up, currant jelly stools, lethargy
Lactose intolerance	Recurrent with milk products	Lower abdomen	None	Cramping	Distention, gaseousness, diarrhea
Urolithiasis	Acute, sudden	Back	Groin	Severe, colicky pain	Hematuria
Pyelonephritis	Acute, sudden	Back	None	Dull to sharp	Fever, costochondral tenderness, dysuria, urinary frequency, emesis
Cholecystitis and cholelithiasis	Acute	Right upper quadrant	Right shoulder	Severe, colicky pain	Hemolysis ± jaundice, nausea, emesis

Functional Abdominal Pain and Irritable Bowel Syndrome

Decision-Making Algorithms

Abdominal Pain
Vomiting

Recurrent abdominal pain is a common problem, affecting more than 10% of all children. The peak incidence occurs between ages 7 and 12 years. Although

the differential diagnosis of recurrent abdominal pain is fairly extensive (Table 126.4), most children do not have a serious (or even identifiable) underlying illness causing the pain.

Eosinophilic esophagitis*

*Common.

Differential Diagnosis

Children with **functional abdominal pain** characteristically have pain almost daily. The pain is not associated with meals or relieved by defecation and is often associated with a tendency toward anxiety and perfectionism. Symptoms often result from stress at school or in novel social situations. The pain often is worst in the morning and often prevents or delays children from attending school. **IBS**

is a subset of functional abdominal pain, characterized by onset of pain at the time of a change in stool frequency or consistency, a stool pattern fluctuating between diarrhea and constipation, and relief of pain with defecation. Symptoms in IBS are linked to gut motility. Pain is commonly accompanied in both groups of children by school avoidance, secondary gains, anxiety about imagined causes, lack of coping skills, and disordered peer relationships (Table 126.5).

TABLE 126.5

Rome III Criteria for Pediatric Functional Gastrointestinal Syndromes

A. DIAGNOSTIC CRITERIA FOR CHILDHOOD FUNCTIONAL ABDOMINAL PAIN
<p>Must include all of the following:*</p> <ol style="list-style-type: none"> 1. Episodic or continuous abdominal pain 2. Insufficient criteria for other functional gastrointestinal diseases 3. No evidence of an inflammatory, anatomical, metabolic, or neoplastic process that explains the subject's symptoms
*Criteria fulfilled at least once per week for at least 2 mo before diagnosis
B. DIAGNOSTIC CRITERIA FOR CHILDHOOD FUNCTIONAL ABDOMINAL PAIN SYNDROME
<p>Must include functional abdominal pain at least 25% of the time and 1 or more of the following:*</p> <ol style="list-style-type: none"> 1. Some loss of daily functioning 2. Additional somatic symptoms such as headache, limb pain, or difficulty sleeping
*Criteria fulfilled at least once per week for at least 2 mo before diagnosis
C. DIAGNOSTIC CRITERIA FOR IRRITABLE BOWEL SYNDROME
<p>Must include all of the following:*</p> <ol style="list-style-type: none"> 1. Abdominal discomfort (an uncomfortable sensation not described as pain) or pain associated with 2 or more of the following at least 25% of the time: <ol style="list-style-type: none"> a. improved with defecation b. onset associated with change in frequency of stool c. onset associated with a change in form (appearance) of stool 2. No evidence of an inflammatory, anatomical, metabolic, or neoplastic process that explains the subject's symptoms
*Criteria fulfilled at least once per week for at least 2 mo before diagnosis
D. DIAGNOSTIC CRITERIA FOR ABDOMINAL MIGRAINE
<p>Must include all of the following:*</p> <ol style="list-style-type: none"> 1. Paroxysmal episodes of intense, acute periumbilical pain that lasts for 1 hr or more 2. Intervening periods of usual health lasting weeks to months. 3. The pain interferes with normal activities 4. The pain is associated with 2 or more of the following: <ol style="list-style-type: none"> a. anorexia b. nausea c. vomiting d. headache e. photophobia f. pallor 5. No evidence of an inflammatory, anatomical, metabolic, or neoplastic process considered that explains the subject's symptoms
*Criteria fulfilled 2 or more times in the preceding 12 mo

E. DIAGNOSTIC CRITERIA FOR CYCLIC VOMITING SYNDROME

Must include all of the following:

1. Two or more periods of intense nausea and unremitting vomiting or retching lasting hours to days
2. Return to usual state of health lasting weeks to months

F. FUNCTIONAL DIARRHEA

Must include all of the following

1. Daily painless, recurrent passage of three or more large, unformed stools
2. Symptoms lasting more than 4 wk
3. Onset of symptoms that begins between 6 and 36 mo of age
4. Passage of stools that occur during waking hours
5. There is no failure to thrive if caloric intake is adequate

Courtesy of the Rome Foundation.

Distinguishing Features

One needs to distinguish between functional pain/IBS and more serious underlying disorders. **Warning signs** for underlying illness are listed in [Table 126.6](#). If present, further investigation is necessary. Some laboratory evaluation is warranted even in the absence of warning signs. The initial evaluation recommended in [Table 126.7](#) is a sensible approach, avoiding unnecessary testing and providing ample sensitivity for most serious underlying disorders. While waiting for laboratory and ultrasound results, a 3-day trial of a lactose-free diet can evaluate for lactose intolerance. If tests are normal and no warning signs are present, testing should be stopped. If there are warning signs, progression of symptoms, or laboratory abnormalities that suggest a specific diagnosis, additional investigation may be warranted.

TABLE 126.6

Warning Signs of Underlying Illness in Recurrent Abdominal Pain

Vomiting
Abnormal screening laboratory study (anemia, hypoalbuminemia, inflammatory markers)
Fever
Bilious emesis
Growth failure
Pain awakening child from sleep
Weight loss
Location away from periumbilical region
Blood in stools or emesis
Delayed puberty

Nocturnal diarrhea
Dysphagia
Arthritis
Perianal disease
Family history of inflammatory bowel disease, celiac disease, or peptic ulcer disease

TABLE 126.7

Suggested Evaluation of Recurrent Abdominal Pain

INITIAL EVALUATION	FOLLOW-UP EVALUATION*
Complete history and physical examination Ask about “warning signs” (see Table 126.6) Determine degree of functional impairment (e.g., missing school) CBC ESR Amylase, lipase Urinalysis Abdominal ultrasound—examine liver, bile ducts, gallbladder, pancreas, kidneys, ureters Trial of 3-day lactose-free diet	CT scan of the abdomen and pelvis with oral, rectal, and intravenous contrast Celiac disease serology—endomysial antibody or tissue transglutaminase antibody Barium upper GI series with small bowel follow-through Endoscopy of the esophagus, stomach, and duodenum Colonoscopy

*Consider using one or more of these to investigate warning signs, abnormal laboratory tests, or specific or persistent symptoms.

CBC, Complete blood count; CT, computed tomography; ESR, erythrocyte sedimentation rate; GI, gastrointestinal.

Treatment of Recurrent Abdominal Pain

A child who is repeatedly kept home from school because of pain receives reinforcement in the form of being excused from responsibilities and withdraws from full social functioning. This tends to both increase anxiety and prolong the course. To break the cycle of pain and disability, the child with functional pain must be assisted in **returning to normal activities** immediately. Instead of being sent home from school with stomachaches, a child may be allowed to take a short break from class until symptoms abate. The child and parents should be informed that pain is likely to be worse on the day the child returns to school as anxiety worsens dysmotility and enhances pain perception. Medications may be helpful. **Fiber supplements** may help to manage symptoms of IBS. Probiotics and peppermint oil can be beneficial in treating IBS. In difficult and persistent cases, cognitive behavioral therapy, amitriptyline, or a selective serotonin reuptake inhibitor may be helpful. When significant anxiety or social

dysfunction persists, a mental health professional should be consulted.

Vomiting

Decision-Making Algorithm

Vomiting

Vomiting is a coordinated, sequential series of events that leads to forceful oral emptying of gastric contents. It is a common problem in children and has many causes. Vomiting should be distinguished from **regurgitation** of stomach contents, also known as gastroesophageal reflux (GER), chalasia, or “spitting up.” Although the end result of vomiting and regurgitation is similar, they have completely different characteristics. Vomiting is usually preceded by nausea and is accompanied by forceful gagging and retching. Regurgitation, on the other hand, is effortless and not preceded by nausea.

Differential Diagnosis

In neonates with true vomiting, congenital obstructive lesions should be considered. Allergic reactions to formula in the first 2 months of life may present with vomiting. **Infantile GER** (“spitting up”) occurs in most infants and can be large in volume, but is effortless, and these infants do not appear ill. **Pyloric stenosis** occurs in the first months of life and is characterized by steadily worsening, forceful vomiting that occurs immediately after feedings. A visibly distended stomach, often with visible peristaltic waves, is often seen before vomiting. Pyloric stenosis is more common in male infants; the family history may be positive. Other obstructive lesions, such as intestinal duplication cysts, atresias, webs, and midgut malrotation, should be considered. Metabolic disorders (e.g., organic acidemias, galactosemia, urea cycle defects, adrenogenital syndromes) may present with vomiting in infants. In older children with acute vomiting, viruses and food poisoning are common. Other infections, especially streptococcal pharyngitis, urinary tract infections, and otitis media, commonly result in vomiting. When vomiting is chronic, central nervous system (CNS) causes (increased intracranial pressure, migraine) must be considered. **Cyclic vomiting syndrome** or migraine may be the etiology of

recurrent vomiting. When abdominal pain or bilious emesis accompanies vomiting, evaluation for bowel obstruction, peptic disorders, and appendicitis must be immediately initiated.

Distinguishing Features

Table 126.8 lists common diagnoses that must be considered and their important historical features. Given the frequency of viral gastroenteritis as the etiology, it is important to be alert for unusual features that suggest another diagnosis. Viral gastroenteritis usually is not associated with severe abdominal pain or headache and does not recur at frequent intervals.

TABLE 126.8

Differential Diagnosis and Historical Features of Vomiting

DIFFERENTIAL DIAGNOSIS	HISTORICAL CLUES
Viral gastroenteritis	Fever, diarrhea, sudden onset, absence of pain
Gastroesophageal reflux	Effortless, not preceded by nausea, chronic
Hepatitis	Jaundice, history of exposure
Extragastrintestinal infections	
Otitis media	Fever, ear pain
Urinary tract infection	Dysuria, unusual urine odor, frequency, incontinence
Pneumonia	Cough, fever, chest discomfort
Allergic	
Milk or soy protein intolerance (infants)	Associated with particular formula or food, blood in stools
Other food allergy (older children)	
Peptic ulcer or gastritis	Epigastric pain, blood or coffee-ground material in emesis, pain relieved by acid blockade
Appendicitis	Fever, abdominal pain migrating to the right lower quadrant, tenderness
Pancreatitis	Severe epigastric abdominal pain
Anatomical obstruction	
Intestinal atresia	Neonate, usually bilious, polyhydramnios
Midgut malrotation	Pain, bilious vomiting, GI bleeding, shock
Intussusception	Colicky pain, lethargy, vomiting, currant jelly stools, mass occasionally
Duplication cysts	Colic, mass
Pyloric stenosis	Nonbilious vomiting, postprandial, <4 mo old, hunger, progressive weight loss

Bacterial gastroenteritis	Fever, often with bloody diarrhea
CNS	
Hydrocephalus	Large head, altered mental status, bulging fontanelles
Meningitis	Fever, stiff neck
Migraine syndrome	Attacks scattered in time, relieved by sleep; headache
Cyclic vomiting syndrome	Similar to migraine, usually no headache
Brain tumor	Morning vomiting, accelerating over time, headache, diplopia
Motion sickness	Associated with travel in vehicle
Labyrinthitis	Vertigo
Metabolic disease	Presentation early in life, worsens when catabolic or exposure to substrate
Pregnancy	Morning, sexually active, cessation of menses
Drug reaction or side effect	Associated with increased dose or new medication
Cancer chemotherapy	Temporarily related to administration of chemotherapeutic drugs
Eosinophilic esophagitis	May have dysphagia or abdominal pain

CNS, Central nervous system; GI, gastrointestinal.

Physical examination should include assessment of the child's hydration status, including examination of capillary refill, moistness of mucous membranes, and skin turgor (see [Chapter 38](#)). The chest should be auscultated for evidence of rales or other signs of pulmonary involvement. The abdomen must be examined carefully for distention, organomegaly, bowel sounds, tenderness, and guarding. A rectal examination and testing stool for occult blood should be considered.

Laboratory evaluation of vomiting should include serum electrolytes, tests of renal function, complete blood count, amylase, lipase, and liver function tests. Additional testing may be required immediately when history and examination suggest a specific etiology. Ultrasound is useful to look for pyloric stenosis, gallstones, renal stones, hydronephrosis, biliary obstruction, pancreatitis, malrotation, intussusception, and other anatomical abnormalities. CT may be indicated to rule out appendicitis or to observe structures that cannot be visualized well by ultrasound. Barium studies can show obstructive or inflammatory lesions of the gut and can be therapeutic, as in the use of contrast enemas for intussusception (see [Chapter 129](#)).

Treatment needs to address the consequences and the causes of the vomiting. Dehydration must be treated with fluid resuscitation. This can be accomplished in most cases with oral fluid-electrolyte solutions, but intravenous (IV) fluids may be required. Electrolyte imbalances should be corrected by appropriate choice of fluids. Underlying causes should be treated when possible.

The use of **antiemetic medications** is controversial. These drugs should not be prescribed until the etiology of the vomiting is known, and then only for severe symptoms. Anticholinergics (e.g., scopolamine) and antihistamines (e.g., dimenhydrinate) are useful for the prophylaxis and treatment of motion sickness. Drugs that block serotonin 5-HT₃ receptors, such as ondansetron and granisetron, are frequently used for viral gastroenteritis and can improve tolerance of oral rehydration therapy. They are helpful for chemotherapy-induced vomiting, often combined with dexamethasone. No antiemetic should be used in patients with surgical emergencies or when a specific treatment of the underlying condition is possible. Correction of dehydration, ketosis, and acidosis is helpful to reduce vomiting in most patients with viral gastroenteritis.

Acute and Chronic Diarrhea

Decision-Making Algorithm

Diarrhea

Diarrhea is a major cause of childhood morbidity and mortality worldwide. Deaths from diarrhea are rare in industrialized countries but are common elsewhere. **Acute diarrhea** is a major problem when it occurs with malnutrition or in the absence of basic medical care (see [Chapter 30](#)). In North America, most acute diarrhea is viral and is self-limited, requiring no diagnostic testing or specific intervention. Bacterial agents tend to cause much more severe illness and typically are seen in food-associated outbreaks or in regions with poor public sanitation. Bacterial enteritis should be suspected when there is **dysentery** (bloody diarrhea with fever) and whenever severe symptoms are present. These infections can be diagnosed by stool culture or other assays for specific pathogens. **Chronic diarrhea** lasts more than 2 weeks and has a wide range of possible causes, including serious and benign conditions that are more difficult to diagnose.

Parents use the word *diarrhea* to describe loose or watery stools, excessively frequent stools, or stools that are large in volume. Constipation with overflow incontinence can be mislabeled as diarrhea. A more exact definition of diarrhea is excessive daily stool liquid volume (>10 mL stool/kg body weight/day). Stool

texture, volume, and frequency help to characterize the episode of diarrhea.

Differential Diagnosis

Diarrhea may be classified by etiology or by physiological mechanisms (secretory or osmotic). Etiological agents include viruses, bacteria or their toxins, chemicals, parasites, malabsorbed substances, and inflammation. [Table 126.9](#) lists common causes of diarrhea in childhood. **Secretory diarrhea** occurs when the intestinal mucosa directly secretes fluid and electrolytes into the stool and is the result of inflammation (e.g., IBD, chemical stimulus). Secretion also is stimulated by mediators of inflammation and by various hormones, such as vasoactive intestinal peptide secreted by a neuroendocrine tumor. Cholera is a secretory diarrhea stimulated by the enterotoxin of *Vibrio cholerae*, which causes increased levels of cyclic adenosine monophosphate (cAMP) within enterocytes and leads to secretion into the small-bowel lumen.

TABLE 126.9

Differential Diagnosis of Diarrhea

	INFANT	CHILD	ADOLESCENT
ACUTE			
Common	Gastroenteritis*	Gastroenteritis*	Gastroenteritis*
	Systemic infection	Food poisoning	Food poisoning
	Antibiotic associated (?)	Systemic infection Antibiotic associated	Antibiotic associated
Rare	Primary disaccharidase deficiency Hirschsprung toxic colitis Adrenogenital syndrome		Hyperthyroidism
CHRONIC			
Common	Postinfectious secondary lactase deficiency Cow's milk/soy protein intolerance Chronic nonspecific diarrhea of infancy (toddler's diarrhea) Celiac disease Cystic fibrosis AIDS enteropathy	Postinfectious secondary lactase deficiency Irritable bowel syndrome Celiac disease Lactose intolerance Giardiasis Inflammatory bowel disease	Irritable bowel syndrome Inflammatory bowel disease Lactose intolerance Giardiasis Laxative abuse (anorexia nervosa) Celiac disease
	Rare	Primary immune defects Familial villous atrophy (?) Secretory tumors	Acquired immune defects Secretory tumor Pseudo-obstruction

Congenital chloridorrhea	Factitious
Acrodermatitis enteropathica Lymphangiectasia Abetalipoproteinemia Eosinophilic gastroenteritis Short-bowel syndrome Autoimmune enteropathy/IPEX-like disorders Factitious	AIDS enteropathy

*Gastroenteritis includes viral (rotavirus, norovirus, astrovirus) and bacterial (*Salmonella*, *Shigella*, *Escherichia coli*, *Clostridium difficile*, *Yersinia*, *Campylobacter*, other) agents.

AIDS, Acquired immunodeficiency syndrome; *IPEX*, immune dysregulation, polyendocrinopathy, enteropathy, X-linked.

Osmotic diarrhea occurs after malabsorption of an ingested substance, which “pulls” water into the bowel lumen. A classic example is the diarrhea of lactose intolerance. Osmotic diarrhea also can result from generalized maldigestion, such as that seen with pancreatic insufficiency or with intestinal injury. Certain nonabsorbable laxatives, such as polyethylene glycol and milk of magnesia, also cause osmotic diarrhea. Fermentation of malabsorbed substances (e.g., lactose) often occurs, resulting in gas, cramps, and acidic stools. A common cause of chronic loose stools in early childhood is **functional diarrhea**, commonly known as **toddler's diarrhea**. This condition is defined by frequent watery stools in the setting of normal growth and weight gain and is caused by excessive intake of sweetened liquids overwhelming the disaccharide absorptive capacity of the intestine. Diarrhea typically improves tremendously when the child's beverage intake is reduced or changed.

Distinguishing Features

Decision-Making Algorithm

Diarrhea

Stools are isosmotic, even in osmotic diarrhea, because of the relatively free exchange of water across the intestinal mucosa. Osmoles present in the stool are a mixture of electrolytes and other osmotically active solutes. To determine whether the diarrhea is osmotic or secretory, the **osmotic gap** is calculated:

$$\text{Osmotic gap} = 290 - 2([\text{Na}^+] + [\text{K}^+])$$

Assuming the stool is isosmotic (an osmolarity of 290 mOsm/L), the measured stool sodium and potassium (and their associated anions, accounting for an equal amount) accounts for much of the osmolality. Secretory diarrhea is characterized by an osmotic gap of less than 50. A number significantly higher than 50 defines osmotic diarrhea and indicates that malabsorbed substances other than electrolytes account for fecal osmolarity.

Another way to differentiate between osmotic and secretory diarrhea is to stop all feedings (in hospitalized patients receiving IV fluids). If the diarrhea stops completely while the child is NPO (nothing by mouth), the patient has osmotic diarrhea. A child with a pure secretory diarrhea would continue to have massive stool output. Neither method for classifying diarrhea works perfectly, because most diarrheal illnesses are a mixture of secretory and osmotic components. Viral enteritis damages the intestinal lining, causing malabsorption and osmotic diarrhea. The associated inflammation results in release of mediators that cause excessive secretion. A child with viral enteritis may have decreased stool volume while NPO, but the secretory component of the diarrhea persists until the inflammation resolves.

The **history** should include the onset of diarrhea, number and character of stools, estimates of stool volume, and presence of other symptoms, such as blood in the stool, fever, and weight loss. Recent travel and exposures should be documented, dietary factors should be investigated, and a list of medications recently used should be obtained. Factors that seem to worsen or improve the diarrhea should be determined. **Physical examination** should be thorough, evaluating for abdominal distention, tenderness, quality of bowel sounds, presence of blood in the stool or a large fecal mass on rectal examination, and anal sphincter tone.

Laboratory testing should include stool culture and complete blood count if bacterial enteritis is suspected. If diarrhea occurs after a course of antibiotics, a *Clostridium difficile* toxin assay should be ordered; if stools are reported to be oily or fatty, fecal fat content or fecal elastase to test for pancreatic insufficiency should be measured. Tests for specific diagnoses should be sent when appropriate (e.g., serum antibody tests for celiac disease; colonoscopy for suspected ulcerative colitis). A trial of lactose restriction for several days or lactose breath hydrogen testing is helpful in the evaluation of lactose intolerance.

Constipation and Encopresis

Decision-Making Algorithm

Constipation

Constipation is a common problem in childhood. When a child is thought to be constipated, his parents may be concerned about straining with defecation, hard stool consistency, large stool size, decreased stool frequency, fear of passing stools, or any combination of these. Physicians define **constipation** as *two or fewer stools per week or passage of hard, pellet-like stools for at least 2 weeks*. A common pattern of constipation is **functional constipation**, which is characterized by two or fewer stools per week, voluntary withholding of stool, and infrequent passage of large-diameter, often painful stools. Children with functional fecal retention often exhibit “retentive posturing” (standing or sitting with legs extended and stiff or crossed legs) and have associated fecal incontinence caused by leakage of retained stool (**encopresis**).

Differential Diagnosis

The differential diagnosis is listed in [Table 126.10](#). **Functional constipation** commonly occurs during toilet training, when the child is unwilling to defecate on the toilet. Retained stool becomes harder and larger over time, leading to painful defecation. This aggravates voluntary withholding of stool, with perpetuation of the constipation.

TABLE 126.10

Common Causes of Constipation and Characteristic Features

CAUSES OF CONSTIPATION	CLINICAL FEATURES
Hirschsprung disease	<i>History:</i> Failure to pass stool in first 24 hr, abdominal distention, vomiting, symptoms of enterocolitis (fever, foul-smelling diarrhea, megacolon). Not associated with large-caliber stools or encopresis <i>Examination:</i> Snug anal sphincter, empty, contracted rectum. May have explosive release of stool as examiner's finger is withdrawn <i>Laboratory:</i> Absence of ganglion cells on rectal suction biopsy specimen, absent relaxation of the internal sphincter, “transition zone” from narrow distal bowel to dilated proximal bowel on barium enema

Functional constipation	<p><i>History:</i> No history of significant neonatal constipation, onset at potty training, large-caliber stools, retentive posturing, may have encopresis</p> <p><i>Examination:</i> Normal or reduced sphincter tone, dilated rectal vault, fecal impaction, soiled underwear, palpable fecal mass in left lower quadrant</p> <p><i>Laboratory:</i> No abnormalities, barium enema would show dilated distal bowel</p>
Anorectal and colonic malformations Anal stenosis Anteriorly displaced anus Imperforate anus Colonic stricture	<p><i>History:</i> Constipation from birth due to abnormal anatomy</p> <p><i>Examination:</i> Anorectal abnormalities are shown easily on physical examination Anteriorly displaced anus is found chiefly in females, with a normal-appearing anus located close to the posterior fourchette of the vagina</p> <p><i>Laboratory:</i> Barium enema shows the anomaly</p>
Multisystem disease Muscular dystrophy Cystic fibrosis Diabetes mellitus Developmental delay Celiac disease	<p><i>History:</i> Presence of other symptoms or prior diagnosis</p> <p><i>Examination:</i> Specific abnormalities may be present that directly relate to the underlying diagnosis</p> <p><i>Laboratory:</i> Tests directed at suspected disorder confirm the diagnosis</p>
Spinal cord abnormalities Meningomyelocele Tethered cord Sacral teratoma or lipoma	<p><i>History:</i> History of swelling or exposed neural tissue in the lower back, history of urinary incontinence</p> <p><i>Examination:</i> Lax sphincter tone due to impaired innervation, visible or palpable abnormality of lower back usually (but not always) present</p> <p><i>Laboratory:</i> Bony abnormalities often present on plain x-ray. Magnetic resonance imaging (MRI) of spinal cord reveals characteristic abnormalities</p>
Drugs Narcotics Psychotropics	<p><i>History:</i> Recent use of drugs known to cause constipation (lead poisoning, opiates)</p> <p><i>Examination:</i> Features suggest functional constipation</p> <p><i>Laboratory:</i> No specific tests available</p>

Hirschsprung disease is characterized by delayed meconium passage in newborns, abdominal distention, vomiting, occasional fever, and foul-smelling stools. This condition is caused by failure of ganglion cells to migrate into the distal bowel, resulting in spasm and functional obstruction of the aganglionic segment. Only about 6% of infants with Hirschsprung disease pass meconium in the first 24 hours of life, compared with 95% of normal infants. Most affected babies rapidly become ill with symptoms of enterocolitis or obstruction. Affected older children do not pass large-caliber stools because of rectal spasm, and they do not have encopresis. Other causes of constipation include spinal cord abnormalities, hypothyroidism, drugs, cystic fibrosis, and anorectal malformations (see [Table 126.10](#)). A variety of systemic disorders affecting metabolism or muscle function can result in constipation. Children with **developmental disabilities** have a great propensity for constipation because of diminished capacity to cooperate with toileting, reduced effort or control of pelvic floor muscles during defecation, and diminished perception of the need to pass stool.

Distinguishing Features

[Table 126.10](#) includes typical characteristics of the common causes of constipation. Congenital malformations usually cause symptoms from birth. Functional constipation is overwhelmingly the most common diagnosis in older patients. Constipation in older children often begins after starting school, when free and private access to toilets may be restricted. Use of some drugs, especially opiates and some psychotropic medications, also is associated with constipation.

For a few specific causes of constipation, directed diagnostic testing can make the diagnosis. A narrowed, aganglionic distal bowel and dilated proximal bowel on barium enema suggests Hirschsprung disease. Rectal suction biopsy confirms the absence of ganglion cells in the rectal submucosal plexus, with hypertrophy of nerve fibers. Lack of internal anal sphincter relaxation can be shown by anorectal manometry in Hirschsprung disease. Hypothyroidism is diagnosed by examination and by thyroid function testing. Anorectal malformations are easily detected by rectal examination. Cystic fibrosis (meconium ileus) is diagnosed by sweat chloride determination or *CFTR* gene mutation analysis (see [Chapter 137](#)). Most children with constipation have functional constipation and do not have any laboratory abnormality. Examination reveals normal or reduced anal sphincter tone (owing to stretching by passage of large stools). Fecal impaction is usually present, but a large-caliber, empty rectum may be found if a stool has just been passed.

Evaluation and Treatment of Functional Constipation

In most cases of constipation, the history is consistent with functional constipation—absence of neonatal constipation, active fecal retention, and infrequent, large stools with soiling. In these patients, no testing other than a good physical examination is necessary. Young children with painful defecation must have a prolonged course of stool softener therapy to alleviate fear of defecation. The child should be asked to sit on the toilet for a few minutes on awakening in the morning and immediately after meals, when the colon is most active and it is easiest to pass a stool. Use of a positive reinforcement system for taking medication and sitting on the toilet is helpful for younger children. The stool softener chosen should be non-habit forming, safe, and palatable. Polyethylene glycol and milk of magnesia are the most commonly used agents.

Gastrointestinal Bleeding

Decision-Making Algorithm

Gastrointestinal Bleeding

GI tract bleeding can be an emergency when large-volume bleeding is present, but even the presence of small amounts of blood in stool or emesis is sufficient to cause concern. Evaluation of bleeding should include confirmation that blood truly is present, estimation of the amount of bleeding, stabilization of the patient's intravascular blood volume, localization of the source of bleeding, and appropriate treatment of the underlying cause. When bleeding is massive, it is crucial that the patient receive adequate resuscitation with fluid and blood products before moving ahead with diagnostic testing.

Differential Diagnosis

GI bleeding has different causes at different ages ([Table 126.11](#)).

TABLE 126.11

Causes and Distinguishing Characteristics of Gastrointestinal Bleeding

AGE	TYPE OF BLEEDING	CHARACTERISTICS
NEWBORN		
Ingested maternal blood*	Hematemesis or rectal, large	Apt test indicates adult hemoglobin is present, cracked maternal nipples
Peptic disease	Hematemesis, amount varies	Blood found in stomach on lavage
Coagulopathy	Hematemesis or rectal, bruising, other sites	History of home birth (no vitamin K)
Allergic colitis*	Streaks of bloody mucus in stool	Eosinophils in feces and in rectal mucosa
Necrotizing enterocolitis	Rectal	Sick infant with tender and distended abdomen
Duplication cyst	Hematemesis	Cystic mass in abdomen on imaging study
Volvulus	Hematemesis, hematochezia	Acute tender, distended abdomen
INFANCY TO 2 YEARS OLD		
Peptic disease	Usually hematemesis, rectal possible	Epigastric pain, coffee-ground emesis
Esophageal varices	Hematemesis	History or evidence of liver disease
Intussusception*	Rectal bleeding	Crampy pain, distention, mass
Meckel diverticulum*	Rectal	Massive, bright red bleeding; no pain

Bacterial enteritis*	Rectal	Bloody diarrhea, fever
NSAID injury	Usually hematemesis, rectal possible	Epigastric pain, coffee-ground emesis
>2 YEARS OLD		
Peptic disease	See above	See above
Esophageal varices	See above	See above
NSAID injury*	See above	See above
Inflammatory bowel disease	Usually rectal	Crampy pain, poor weight gain, diarrhea
Bacterial enteritis*	See above	See above
Pseudomembranous colitis	Rectal	History of antibiotic use, bloody diarrhea
Juvenile polyp	Rectal	Painless, bright red blood in stool; not massive
Meckel diverticulum*	See above	See above
Nodular lymphoid hyperplasia	Rectal	Streaks of blood in stool, no other symptoms
Mallory-Weiss syndrome*	Hematemesis	Bright red or coffee-ground, follows retching
Hemolytic uremic syndrome	Rectal	Thrombocytopenia, anemia, uremia
Hemorrhoids	Rectal	Dilated external veins, blood with wiping

*Common.

NSAID, Nonsteroidal antiinflammatory drug.

Distinguishing Features

Red substances in foods, beverages, or medications (such as cefdinir) occasionally can be mistaken for blood. A test for occult blood is worth performing whenever the diagnosis is in doubt.

The GI tract may not be the source of the observed fecal blood. A history of cough and examination of the mouth, nostrils, and lungs is needed to exclude these as a source of hematemesis. Blood in the toilet or diaper may be coming from the urinary tract, vagina, or even a severe diaper rash. If the bleeding is GI, it is important to determine the source as high in the GI tract or distal to the ligament of Treitz. Vomited blood is always proximal. Rectal bleeding may be coming from anywhere in the gut. When dark clots or melena are seen mixed with stool, a higher location is suspected, whereas bright red blood on the surface of stool probably is coming from lower in the colon. When upper GI tract bleeding is suspected, a nasogastric tube may be placed and gastric contents

aspirated for evidence of recent bleeding.

The location and hemodynamic significance of the bleeding can also be assessed by history and examination. The parents should be asked to quantify the bleeding. Details of associated symptoms should be sought. Assessment of the vital signs including orthostatic changes when bleeding volume is large, pulses, capillary refill, and assessment of pallor of the mucous membranes provides valuable information. Laboratory assessment and imaging studies should be ordered as indicated ([Table 126.12](#)).

TABLE 126.12

Evaluation of Gastrointestinal Bleeding

LABORATORY INVESTIGATION
All Patients
CBC and platelet count
Coagulation tests: prothrombin time, partial thromboplastin time
Tests of liver dysfunction: AST, ALT, GGT, bilirubin
Occult blood test of stool or vomitus
Blood type and crossmatch
Evaluation of Bloody Diarrhea
Stool culture, <i>Clostridium difficile</i> toxin
Sigmoidoscopy or colonoscopy
CT with contrast
Evaluation of Rectal Bleeding With Formed Stools
External and digital rectal examination
Sigmoidoscopy or colonoscopy
Meckel scan
Mesenteric arteriogram
Video capsule endoscopy
INITIAL RADIOLOGIC EVALUATION
All Patients
Abdominal x-ray series
Evaluation of Hematemesis
Barium upper GI series if endoscopy not available
Evaluation of Bleeding With Pain and Vomiting (Bowel Obstruction)
Abdominal x-ray series
Pneumatic or contrast enema

ALT, Alanine aminotransferase; *AST*, aspartate aminotransferase; *CBC*, complete blood count; *CT*, computed tomography; *GGT*, γ -glutamyltransferase; *GI*, gastrointestinal.

Treatment

Treatment of GI bleeding should begin with an initial assessment, rapid stabilization, and a logical sequence of diagnostic tests. When a treatable cause is identified, specific therapy should be started. In many cases, the amount of blood is small, and no resuscitation is required. For children with large-volume bleeds, the **ABCs** of resuscitation (airway, breathing, circulation) should be addressed first (see [Chapters 38](#) and [40](#)). Oxygen should be administered and the airway protected with an endotracheal tube if massive hematemesis is present. Fluid boluses and transfusion with packed red blood cells as required should be administered through two large-bore IVs. Frequent reassessment should continue to ensure maintenance of physiological stability ([Fig. 126.2](#)).

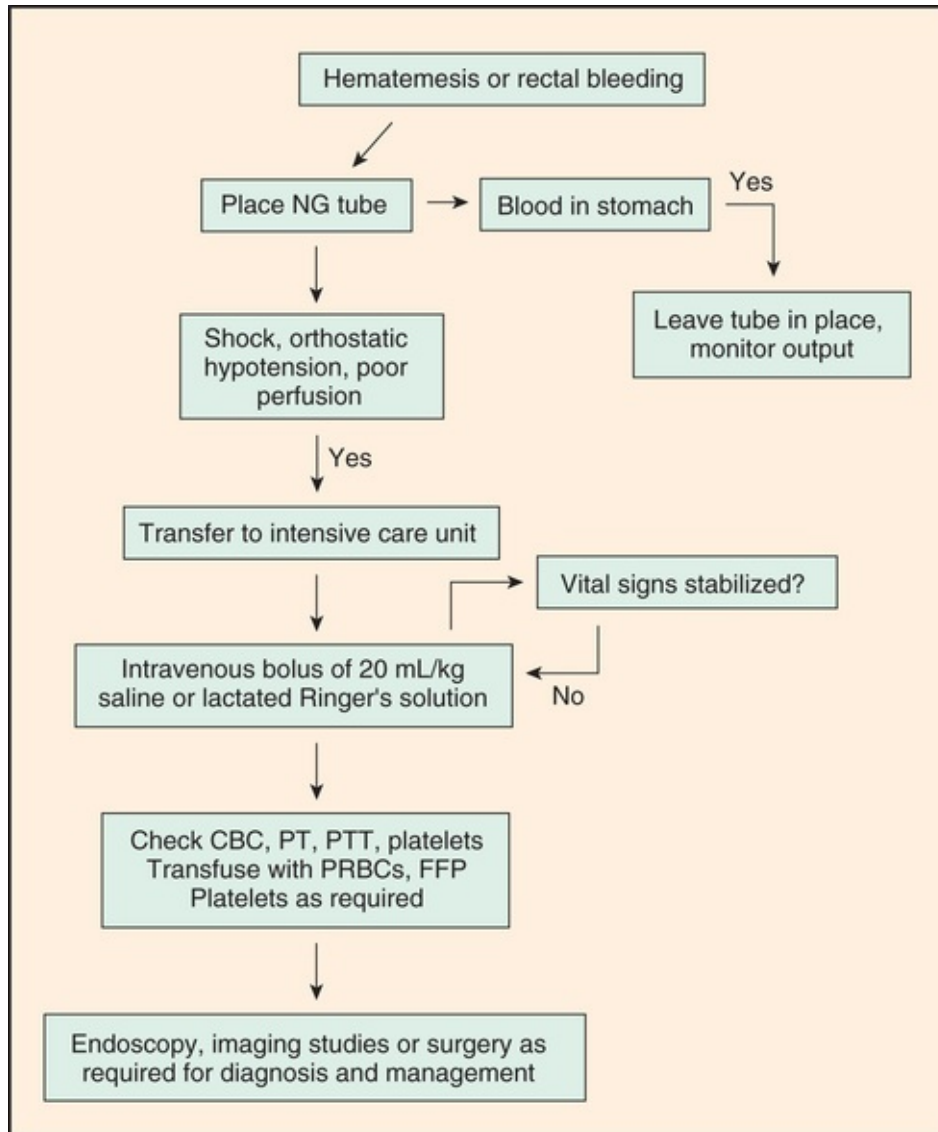

FIGURE 126.2 Initial management of gastrointestinal bleeding. *CBC*, Complete blood count; *FFP*, fresh frozen plasma; *NG*, nasogastric; *PRBCs*, packed red blood cells; *PT*, prothrombin time; *PTT*, partial thromboplastin time.

CHAPTER 127

Oral Cavity

Effects of Systemic Disease on the Oral Cavity

Medications taken for a variety of conditions may cause oral abnormalities. Drugs with anticholinergic properties diminish saliva production and increase the risk of dental caries and parotitis. Tetracyclines taken before the eruption of the permanent teeth stain the enamel. Excessive fluoride in vitamin preparations or in drinking water can result in mottled teeth. Gingival hypertrophy may be caused by cyclosporine, phenytoin, and calcium channel blockers.

Gastroesophageal reflux disease (GERD) can lead to substantial enamel erosion and caries. Neonatal hyperbilirubinemia can result in discoloration of the deciduous teeth. Renal failure is associated with mottled enamel of the permanent teeth. Congenital syphilis causes marked abnormalities in the shape of teeth, especially incisors and molars. Celiac disease can result in enamel defects. Crohn disease is associated with oral aphthous ulcers. Abnormal pigmentation of the lips and buccal mucosa is seen with Peutz-Jeghers syndrome and Addison disease. Candidiasis is seen commonly with immunodeficiency disorders and diabetes. Leukemic infiltrates result in gum hyperplasia and bleeding; treatment of neoplastic conditions can cause severe mucositis. Some tumors, including lymphoma, may present as mass lesions of the buccal cavity.

Osteogenesis imperfecta is associated with abnormal dentin and risk of caries. Children with *ectodermal dysplasias* commonly have malformed or missing teeth. Pierre Robin and Stickler syndromes are associated with micrognathia and cleft palate. Disorders resulting in facial dysmorphism can have a profound effect on dental occlusion and mandibular function. Examples include mandibulofacial dysostosis, Crouzon syndrome, conditions associated with dwarfism, and others.

Deciduous and Primary Teeth

Most infants are born without teeth. *Natal teeth* are present at birth, are usually supernumerary, and may be poorly attached. Usually, no treatment is necessary, but removal by a dentist may be needed if they are causing difficulties with feeding or injuries to the tongue. [Table 127.1](#) presents the ages when normal **deciduous teeth** are acquired. The lower central incisors are typically the first to erupt, followed by the upper central incisors, lateral incisors, first molars, and bicuspid. **Delayed eruption** may occur in association with hypopituitarism, hypothyroidism, osteopetrosis, Gaucher disease, Down syndrome, cleidocranial

dysplasia, and rickets. Deciduous teeth begin to be replaced by the permanent teeth at around age 6 years. The sequence of replacement is similar to that of the appearance of deciduous teeth.

TABLE 127.1

Time of Eruption of the Primary and Permanent Teeth

TOOTH TYPE	PRIMARY, AGE (mo)		PERMANENT, AGE (yr)	
	UPPER	LOWER	UPPER	LOWER
Central incisor	6 ± 2	7 ± 2	7-8	6-7
Lateral incisor	9 ± 2	7 ± 2	8-9	7-8
Cuspids	18 ± 2	16 ± 2	11-12	9-10
First bicuspid	—	—	10-11	10-12
Second bicuspid	—	—	10-12	11-12
First molars	14 ± 2	12 ± 2	6-7	6-7
Second molars	24 ± 2	20 ± 2	12-13	11-13
Third molars	—	—	17-21	17-21

Dental Caries

Etiology

Dental caries, commonly referred to as “cavities,” occurs as a result of interactions between the tooth enamel, dietary carbohydrates, and oral flora. There is increased susceptibility if the enamel is abnormal or hypoplastic. Bacteria (*Streptococcus mutans*) that can adhere to and colonize the teeth, survive at low pH, and produce acids during fermentation of carbohydrates cause dental caries. The diet has a significant role. A classic example is “bottle mouth,” or **baby bottle caries**. This condition results when infants are allowed to have a bottle in the mouth for prolonged periods, especially during sleep, and with sweet beverages or milk in the bottle. Bacteria then have continuous substrate for acid production and can destroy multiple teeth, especially the upper incisors. Sticky sweet foods, such as candy, have the same effect.

Epidemiology and Treatment

Risk of caries is associated with lack of dental care and poor socioeconomic

status and, predictably, is greatest in developing countries. Baby bottle caries are seen in 50-70% of low-income infants. Treatment of caries is with dental restorative surgery. The carious portion is removed and filled with silver amalgam or plastic. If the damage is severe, a protective crown may be required; extraction of the tooth may be necessary when not salvageable. If not properly treated, dental decay results in inflammation and infection of the dental pulp and surrounding alveolar bone, which can lead to abscess and facial space infections.

Prevention

Avoiding inappropriate use of bottles and excessive sweets is a commonsense remedy for baby bottle caries. Oral hygiene offers some protection, but young children (<8 years old) do not have the ability to brush their own teeth adequately; brushing should be done by the parents. Fluoride supplementation of community water supplies to a concentration of 1 ppm is highly effective in reducing dental caries. Home water supplies, such as from a well, should have the fluoride content tested before supplements are prescribed. If the child spends part of the day at another location, the total fluoride concentration from all sources must be considered before prescribing any oral supplements. Excessive fluoride supplementation causes fluorosis, a largely cosmetic defect of chalky white marks and brown staining of the teeth.

The American Academy of Pediatrics recommends that primary care physicians apply fluoride varnish to the teeth of all children every 3-6 months, starting at the emergence of the first tooth. Fluoride varnish is a concentrated fluoride preparation that adheres to the teeth on contact with saliva. It is painted onto the teeth with a small brush, after first drying the tooth with a gauze pad, and has a prolonged cavity-prevention effect.

Cleft Lip and Palate

Epidemiology

Cleft lip and palate occur separately or together and affect approximately 1 in 700 infants. It is more common in Asians (1 : 500) and least common in Africans (1 : 2,500). Clefting occurs with two possible patterns: isolated soft tissue cleft palate or cleft lip with or without associated clefts of the hard palate. Isolated cleft palate is associated with a higher risk of other congenital malformations. The combined cleft lip/palate type has a male predominance.

Etiology

Cleft lip is due to hypoplasia of the mesenchymal tissues with subsequent failure of fusion. There is a strong genetic component; the risk is highest in children with affected first-degree relatives. Monozygotic twins are affected with only 60% concordance, suggesting other nongenomic factors. Environmental factors during gestation also increase risk, including drugs (phenytoin, valproic acid, thalidomide), maternal alcohol and tobacco use, dioxins and other herbicides, and possibly high altitude. Chromosomal and nonchromosomal syndromes are associated with clefting, as are specific genes in some families.

Clinical Manifestations and Treatment

Cleft lip can be unilateral or bilateral and associated with cleft palate and defects of the alveolar ridge and dentition. When present, palatal defects allow direct communication between the nasal and oral cavities, creating problems with speech and feeding. Management includes squeeze-bottle feedings, special nipples, nipples with attached shields to seal the palate, and gastrostomy in severe cases. Surgical closure of the cleft lip is usually done by 3 months of age. Closure of the palate follows, usually before 1 year of age. Missing teeth are replaced by prostheses. Cosmetic results are often good, but depend on the severity of the defect.

Complications

Speech is nasal as a result of the cleft palate. Surgical treatment is effective, but sometimes does not restore palatal function completely. Speech therapy or, occasionally, the use of a speech-assisting appliance may help. Frequent episodes of otitis media are common, as are defects of teeth and the alveolar ridge.

Thrush

Epidemiology

Oropharyngeal *Candida albicans* infection, or thrush, is common in healthy neonates. The organism may be acquired in the birth canal or from the environment. Persistent infection is common in breast fed infants as a result of

colonization or infection of the mother's nipples. Thrush in healthy older patients can occur but should suggest the possibility of an immunodeficiency, broad-spectrum antibiotic or inhaled steroid use, or diabetes.

Clinical Manifestations

Thrush is easily visible as white plaques, often with a “fuzzy” appearance, on oral mucous membranes. When scraped with a tongue depressor, the plaques are difficult to remove and the underlying mucosa is inflamed and friable. Clinical diagnosis is usually adequate but may be confirmed by fungal culture or potassium hydroxide smear. Oropharyngeal candidiasis is sometimes painful (especially if associated with esophagitis) and can interfere with feeding.

Treatment

Thrush is treated with topical nystatin or an azole antifungal agent such as fluconazole. When the mother's breasts are infected and painful, consideration should be given to treating her at the same time. Because thrush is commonly self-limited in newborns, withholding therapy in asymptomatic infants and treating only persistent or severe cases is a reasonable approach.

CHAPTER 128

Esophagus and Stomach

Gastroesophageal Reflux

Etiology and Epidemiology

Decision-Making Algorithms

Cough
Wheezing
Abdominal Pain
Vomiting

Gastrointestinal Bleeding

Gastroesophageal reflux (GER) is defined as the effortless retrograde movement of gastric contents upward into the esophagus or oropharynx. In infancy, GER is not always an abnormality. **Physiological GER** (“spitting up”) is normal in infants younger than 8-12 months old. Nearly half of all infants are reported to spit up between 2 and 4 months of age. Infants who regurgitate meet the criteria for physiological GER so long as they maintain adequate nutrition and have no signs of respiratory complications or esophagitis. Contributing factors of infantile GER include liquid diet; horizontal body position; short, narrow esophagus; small, noncompliant stomach; frequent, relatively large-volume feedings; and an immature lower esophageal sphincter (LES). As infants grow, they spend more time upright, eat more solid foods, develop a longer and larger diameter esophagus, have a larger and more compliant stomach, and experience lower caloric needs per unit of body weight. As a result, most infants stop spitting up by 9-12 months of age.

Gastroesophageal reflux *disease* (GERD) occurs when GER leads to troublesome symptoms or complications such as poor growth, pain, or breathing difficulties. GERD occurs in a minority of infants but is often implicated as the cause of fussiness. GERD is seen in fewer than 5% of older children. In older children, normal protective mechanisms against GER include antegrade esophageal motility, tonic contraction of the LES, and the geometry of the gastroesophageal junction. Abnormalities that cause GER in older children and adults include reduced tone of the LES, transient relaxations of the LES, esophagitis (which impairs esophageal motility), increased intraabdominal pressure, cough, respiratory difficulty (asthma or cystic fibrosis), and hiatal hernia.

Clinical Manifestations

Decision-Making Algorithms

Cough
Hoarseness
Wheezing

Abdominal Pain Failure to Thrive

The presence of GER is easy to observe in an infant who spits up. In older children, the refluxate is usually kept down by reswallowing, but GER may be suspected by associated symptoms, such as heartburn, cough, epigastric abdominal pain, dysphagia, wheezing, aspiration pneumonia, hoarse voice, failure to thrive, and recurrent hiccoughs or belching. In severe cases of esophagitis, there may be laboratory evidence of anemia and hypoalbuminemia secondary to esophageal bleeding and inflammation.

When esophagitis develops as a result of acid reflux, esophageal motility and LES function are impaired further, creating a cycle of reflux and esophageal injury.

Laboratory and Imaging Studies

A clinical diagnosis is often sufficient in children with classic effortless regurgitation and no complications. Diagnostic studies are indicated if there are persistent symptoms or complications or if other symptoms suggest the possibility of GER in the absence of regurgitation. A child with recurrent pneumonia, chronic cough, or apneic spells without overt emesis may have occult GER. A **barium upper gastrointestinal (GI) series** helps to rule out gastric outlet obstruction, malrotation, or other anatomical contributors to GER. Because of the brief nature of the examination, a negative barium study does *not* rule out GER, nor does it rule it in as it is normal to have some reflux into the esophagus many times per day. A **24-hour esophageal pH probe monitoring** uses a pH electrode placed transnasally into the distal esophagus, with continuous recording of esophageal pH. Data typically are gathered for 24 hours and analyzed for the number and temporal pattern of acid reflux events. **Esophageal impedance monitoring** records the migration of electrolyte-rich gastric fluid in the esophagus. **Endoscopy** is useful to evaluate for esophagitis, esophageal stricture, and anatomical abnormalities.

Treatment

In otherwise healthy young infants, no treatment is necessary. For infants with

complications of GER, an H₂ blocker or proton-pump inhibitor may be offered (Table 128.1), but these have shown little benefit in infants with uncomplicated GER and/or fussiness. Prokinetic drugs, such as metoclopramide, occasionally are helpful by enhancing gastric emptying and increasing LES tone, but they are seldom effective and may lead to complications. When severe symptoms persist despite medication, or if life-threatening aspiration is present, surgical intervention may be required. Fundoplication procedures, such as the Nissen operation, are designed to enhance the antireflux anatomy of the LES. In children with a severe neurological defect who cannot tolerate oral or gastric tube feedings, placement of a feeding jejunostomy may be considered as an alternative to fundoplication. In older children, lifestyle changes should be discussed, including cessation of smoking, weight loss, not eating before bed or exercise, and limiting intake of caffeine, carbonation, and high-fat foods. However, proton pump inhibitor therapy is more effective in reducing symptoms and supports healing.

TABLE 128.1

Treatment of Gastroesophageal Reflux

THERAPIES	COMMENTS
CONSERVATIVE THERAPIES	
Towel on caregiver's shoulder	Cheap, effective; useful only for physiological reflux
Thickened feedings	Reduces number of episodes, enhances nutrition
Smaller, more frequent feedings	Can help some; be careful not to <i>underfeed</i> child
Avoidance of tobacco smoke and alcohol	Always a good idea; may help reflux symptoms
Abstaining from caffeine	Inexpensive, offers some benefit
Positional therapy—upright in seat, elevate	Prone positioning with head of crib or bed up is helpful, but <i>not</i> for young infants because of risk of SIDS
Weight loss when indicated	Increased weight (especially abdominal) increases intraabdominal pressure, leading to reflux
MEDICAL THERAPY	
Proton pump inhibitor	Effective medical therapy for heartburn and esophagitis
H ₂ -receptor antagonist	Reduces heartburn, less effective for healing esophagitis
Metoclopramide	Enhances stomach emptying and LES tone; real benefit is often minimal
SURGICAL THERAPY	
Nissen or other fundoplication procedure	For life-threatening or medically unresponsive cases

GERD, Gastroesophageal reflux disease; *LES*, lower esophageal sphincter; *SIDS*, sudden infant death syndrome.

Eosinophilic Esophagitis

Etiology and Epidemiology

This chronic immune-mediated disorder is characterized by infiltration of eosinophils into the mucosa of the esophagus. It is thought to be triggered by non-immunoglobulin (Ig)E-mediated allergic reactions to ingested foods or aeroallergens. Eosinophilic esophagitis (EoE) may have a familial component; no specific gene has yet been identified. Incidence appears to be increasing with estimated prevalence of more than 4 per 10,000 children. It may be more common in males than females and in patients with history of atopy.

Clinical Manifestations

The presentation of EoE often varies with age. In young children, it may present with oral aversion, vomiting, and failure to thrive. In school-age children, it may present with vague abdominal pain or vomiting. In adolescents and adults, it presents with dysphagia and food impactions. These symptoms are attributed to the inflammatory response in the esophagus leading to edema and poor esophageal motility.

Laboratory and Imaging Studies

Diagnosis requires multilevel esophageal biopsies via flexible endoscopy with the finding of more than 15 eosinophils per high-power field ([Fig. 128.1](#)). Treatment with high-dose proton pump inhibitor therapy is recommended to exclude the possibility that findings are secondary to severe acidic esophageal injury or by evaluating for acid reflux by pH probe testing. Gross findings at endoscopy may include normal appearance, or esophageal furrowing, trachealization, and eosinophilic abscesses ([Fig. 128.2](#)). A barium study may reveal a food impaction in an acutely symptomatic patient or esophageal stricture in someone with chronic disease.

FIGURE 128.1 Histological image of eosinophilic esophagitis. Note the large number of eosinophils within the lamina propria.

FIGURE 128.2 Endoscopic picture of eosinophilic esophagitis. White plaques on the surface are collections of eosinophils (eosinophilic abscesses). Linear furrowing is also seen.

Treatment and Prognosis

Exposure to identified causative antigens needs to be eliminated. Identification can be difficult, as typical allergy testing (skin prick, RAST, and immunocap assays) only identifies IgE-mediated antigens. Atopic patch testing may be more reliable but is not standardized and can be difficult to perform. One approach is to eliminate cow's milk, soy, wheat, eggs, peanuts, and fish/shellfish from the diet ("Six food elimination diet"), as these are the most common causative dietary antigens. Repeat endoscopies are often necessary to document efficacy of these eliminations. An elemental diet can also be used and is very effective, but often requires either nasogastric or gastrostomy administration because of its poor palatability.

Systemic glucocorticoids can decrease symptoms, but long-term use is discouraged due to concerns for potential complications. Swallowed "topical" glucocorticoids administered via a metered-dose inhaler (fluticasone) or mixed as a slurry (budesonide) have shown benefit. *Candida* esophagitis or oral thrush are the most common side effects.

Endoscopy can be used to relieve food impactions and to dilate esophageal strictures secondary to EoE. The prognosis for EoE is largely unknown. Symptoms tend to wax and wane over time.

Complications

Failure to thrive or weight loss may be seen due to difficulty in eating. Food impactions are a common complication in the older child and may require endoscopic removal. Chronic inflammation of the esophagus can predispose to esophageal strictures and possibly dysplasia.

Esophageal Atresia and Tracheoesophageal Fistula

Etiology and Epidemiology

The esophagus and trachea develop in close proximity to each other during weeks 4-6 of fetal life. Defects in the mesenchyme separating these two structures result in a tracheoesophageal fistula (TEF), often in association with other anomalies (renal, heart, spine, limbs). This defect occurs in about 1 in 3,000 live births. TEF is not thought to be a genetic defect.

Clinical Manifestations

The most common forms of TEF occur with esophageal atresia; the “H-type” TEF without atresia is uncommon, as is esophageal atresia without TEF (Fig. 128.3). Associated defects include the **VACTERL** association—vertebral anomalies (70%), anal atresia (imperforate anus) (50%), cardiac anomalies (30%), **TEF** (70%), renal anomalies (50%), and limb anomalies (polydactyly, forearm defects, absent thumbs, syndactyly) (70%). A single-artery umbilical cord is often present. Infants with esophageal atresia have a history of polyhydramnios, exhibit drooling, and have mucus and saliva bubbling from the nose and mouth. Patients with a TEF are vulnerable to aspiration pneumonia. When TEF is suspected, the first feeding should be delayed until a diagnostic study is performed.

FIGURE 128.3 Various types of tracheoesophageal fistulas (TEF) with relative frequency (%).

Laboratory and Imaging Studies

The simplest test for TEF is to gently attempt to place a 10F or larger tube via the mouth into the stomach. The passage of the tube is blocked at the level of the atresia. A chest x-ray reveals the tube coiled in the esophageal pouch. Air can be injected through the tube to outline the atretic pouch. Barium should not be used because of extreme risk of aspiration, but a tiny amount of dilute water-soluble contrast agent can be given carefully, then suctioned when the defect is clearly shown.

Treatment and Prognosis

The treatment of TEF is surgical. The fistula is divided and ligated. The esophageal ends are approximated and anastomosed. In some cases, primary anastomosis cannot be performed because of a long gap between the proximal and distal esophagus. Various techniques have been described to treat this problem, including pulling up the stomach, elongating the esophagus by myotomy, and simply delaying esophageal anastomosis and providing continuous suction to the upper pouch while allowing for growth.

Complications

The surgically reconstructed esophagus is not normal and is prone to poor motility, GER, anastomotic stricture, recurrent fistula, and leakage. The trachea also is malformed; tracheomalacia and wheezing are common.

Esophageal Foreign Bodies

Etiology and Epidemiology

Young children often place nonfood items in their mouths. When these items are swallowed, they may become lodged in the esophagus at the thoracic inlet or at the LES. The most common objects are coins. Smaller coins may pass harmlessly into the stomach, where they rarely cause symptoms. Other common esophageal foreign bodies include food items, small toys or toy parts, disk batteries, and other small household items. Children with a prior history of esophageal atresia or with poor motility secondary to GER or EoE are more prone to food impactions, which seldom occur in the normal esophagus.

Clinical Manifestations

Some children are asymptomatic, but most exhibit some degree of drooling, food refusal, or chest discomfort. Older children usually can point to the region of the chest where they feel the object to be lodged. Respiratory symptoms tend to be minimal, but cough or wheezing may be present, especially when the esophagus is completely blocked by a large object, such as a piece of meat, which presses on the trachea.

Diagnosis

Plain chest and abdominal radiographs should be taken when foreign body ingestion is suspected. Metallic objects are easily visualized. A plastic object often can be seen if the child is given a small amount of dilute x-ray contrast material to drink, although endoscopy is probably safer and more definitive.

Treatment

Endoscopy is ultimately necessary in most cases to remove a retained esophageal foreign body. Various devices can be used to remove the object, depending on its size, shape, and location. Coins usually are grasped with special-purpose forceps and removed. Nets, baskets, and snares also are available. Whenever objects that may threaten the airway are being recovered, endoscopy should be performed with endotracheal intubation and under general anesthesia. Removal is usually not necessary if the object is small and in the stomach as it will most likely pass without complication. Endoscopy is emergent for removal of any esophageal foreign body if symptomatic or if the ingested foreign body is a suspected disc battery in the esophagus or multiple magnets located in the upper intestinal tract.

Complications

Sharp objects may lacerate or perforate the esophagus; smooth objects present for a long time also may result in perforation due to ulceration. Corrosive objects, such as zinc-containing pennies and disc batteries, can cause considerable local tissue injury and esophageal perforation. Magnets can lead to perforation and fistula formation when they connect between adjacent loops of bowel.

Caustic Injuries and Pill Ulcers

Etiology and Epidemiology

In adolescents, caustic ingestion injuries are usually the result of suicide attempts. In toddlers, ingestion of household cleaning products typically is accidental. Injurious agents include drain cleaners, toilet bowl cleaners, dishwasher and laundry detergents, and powerful bleaching agents. Childproof lids for commercial products offer some protection, but have not eliminated the problem. Lye-based drain cleaners, especially liquid products, cause the worst injuries because they are swallowed easily and liquefy tissue rapidly. Full-thickness burns can occur in seconds. Granular products are less likely to cause esophageal injury during accidental exposures because they burn the tongue and lips and often are expelled before swallowing. Less caustic agents, such as bleach and detergents, cause less serious injury. **Pill ulcers** occur when certain medications (tetracyclines and nonsteroidal antiinflammatory drugs [NSAIDs]) are swallowed without sufficient liquids, allowing prolonged direct contact of the pill with the esophageal mucosa.

Clinical Manifestations

Caustic burns cause immediate and severe mouth pain. The child cries out, drools, spits, and usually drops the container immediately. Burns of the lips and tongue are visible almost immediately. These burns clearly indicate the possibility of esophageal involvement, although esophageal injury can occur in the absence of oral burns. Symptoms may not be present; further evaluation by endoscopy usually is indicated with any significant history of caustic ingestion. Pill injury causes severe chest pain and often prominent odynophagia (painful swallowing) and dysphagia.

Laboratory and Imaging Studies

A chest x-ray should be obtained to rule out aspiration and to inspect for mediastinal air. The child should be admitted to the hospital and given intravenous (IV) fluids until endoscopy. The true extent of burns may not be endoscopically apparent immediately, but delayed endoscopy can increase the risk of perforation. Most endoscopists perform the initial endoscopy soon after injury, when the patient has been stabilized. The extent of injury and severity of

the burn should be carefully determined. Risk of subsequent esophageal strictures is related to the degree of burn and whether the injury is circumferential.

Treatment

A nasogastric tube can be placed over a guide wire at the time of the initial endoscopy to provide a route for feeding and to stent the esophagus. Systemic steroid use has not been found to be beneficial in reducing stricture formation. Broad-spectrum antibiotics should be prescribed if infection is suspected.

Complications

Esophageal strictures, if they occur, usually develop within 1-2 months and can be treated with endoscopic dilation. There is a risk of perforation during dilation. When esophageal destruction is severe, surgical reconstruction of the esophagus using stomach or intestine may be necessary.

Pyloric Stenosis

Etiology and Epidemiology

Decision-Making Algorithm

Vomiting

Pyloric stenosis is an acquired condition caused by hypertrophy and spasm of the pyloric muscle, resulting in gastric outlet obstruction. It occurs in 6-8 per 1,000 live births, has a 5-to-1 male predominance, and is more common in first-born children. Its cause is unknown.

Clinical Manifestations

Infants with pyloric stenosis typically begin vomiting during the first weeks of life, but onset may be delayed. The emesis becomes increasingly frequent and forceful as time passes. Vomiting differs from spitting up because of its

extremely forceful and often projectile nature. The vomited material never contains bile, because the gastric outlet obstruction is proximal to the duodenum. This feature differentiates pyloric stenosis from most other obstructive lesions of early childhood. Affected infants are ravenously hungry early in the course of the illness but become more lethargic with increasing malnutrition and dehydration. The stomach becomes massively enlarged with retained food and secretions, and gastric **peristaltic waves** are often visible in the left upper quadrant. A hypertrophied pylorus (the “olive”) may be palpated. As the illness progresses, very little of each feeding is able to pass through the pylorus, and the child becomes progressively thinner and more dehydrated.

Laboratory and Imaging Studies

Decision-Making Algorithm

Alkalemia

Repetitive vomiting of purely gastric contents results in loss of hydrochloric acid; the classic laboratory finding is a **hypochloremic, hypokalemic metabolic alkalosis** with elevated blood urea nitrogen (BUN) secondary to dehydration. Jaundice with unconjugated hyperbilirubinemia may also occur. Plain abdominal x-rays typically show a huge stomach and diminished or absent gas in the intestine (Fig. 128.4). Ultrasound examination shows marked elongation and thickening of the pylorus (Fig. 128.5). A barium upper GI series also may be obtained whenever doubt about the diagnosis exists; this shows a “string sign” caused by barium moving through an elongated, constricted pyloric channel.

FIGURE 128.4 Pyloric Stenosis. Note the huge, gas-filled stomach extending across the midline, with minimal air in the intestine downstream. (Courtesy Warren Bishop, MD.)

FIGURE 128.5 Ultrasound image of infant with pyloric stenosis. Large, fluid-filled stomach (S) is seen at right, with an elongated, thickened pylorus. The length of the pylorus is marked by the *red arrows*; the wall thickness is marked by the *yellow arrows*.

Treatment

Treatment of pyloric stenosis includes IV fluid and electrolyte resuscitation followed by surgical pyloromyotomy. Before surgery, dehydration and hypochloremic alkalosis must be corrected, generally with an initial normal saline fluid bolus followed by infusions of half-normal saline containing 5% dextrose and potassium chloride when urine output is observed. In pyloromyotomy (often by laparoscope), the pyloric muscle is incised longitudinally to release the constriction.

Peptic Disease

Etiology and Epidemiology

Acid-related injury can occur in the esophagus, stomach, or duodenum. [Table 128.2](#) lists risk factors for **peptic ulcer disease** in children. *Helicobacter pylori* is responsible for more than half of ulcers in the stomach and duodenum in adults. *H. pylori* plays a significant but lesser role in childhood ulcer disease. Risk factors for acquisition of *H. pylori* are low socioeconomic status and poor sanitation, with the highest incidence in developing countries. **Nonulcer dyspepsia** includes upper abdominal symptoms (pain, bloating, nausea, early satiety) in the absence of gastric or duodenal ulceration. Nonulcer dyspepsia is *not* associated with *H. pylori* infection. GER (see [Chapter 128](#)) allows acidic gastric contents to injure the esophagus, resulting in **esophagitis**. Esophagitis is characterized by retrosternal and epigastric burning pain and is best diagnosed by endoscopy. It can range from minimal, with only erythema and microscopic inflammation on biopsy, to superficial erosions and finally, to frank ulceration.

TABLE 128.2

Risk Factors for Peptic Ulcer Disease

<i>Helicobacter pylori</i> infection
Drugs
NSAIDs, including aspirin
Tobacco use
Bisphosphonates
Potassium supplements
Family history
Sepsis
Head trauma
Burn injury
Hypotension

NSAIDs, Nonsteroidal antiinflammatory drugs.

Clinical Manifestations

Typical symptoms are listed in [Table 128.3](#). The presence of recurrent burning epigastric and retrosternal pain is a risk factor for esophagitis. With duodenal ulcers, pain typically occurs several hours after meals and often awakens patients at night. Eating tends to relieve the pain. Gastric ulcers differ in that pain is commonly aggravated by eating, resulting in weight loss. GI bleeding from either can occur. Many patients report symptom relief with antacids or acid

blockers.

TABLE 128.3

Peptic Disorders, Symptoms, and Clinical Investigation

SYNDROME AND ASSOCIATED SYMPTOMS	CLINICAL INVESTIGATION
ESOPHAGITIS	
Retrosternal and epigastric location	Endoscopy
Burning pain	Therapeutic trial of acid-blocker therapy
Sensation of regurgitation	
Dysphagia, odynophagia	pH probe study
NONULCER DYSPEPSIA	
Upper abdominal location	Endoscopy
Fullness	Therapeutic trial of acid-blocker therapy
Bloating	Upper GI series to ligament of Treitz—rule out malrotation
Nausea	CBC, ESR, amylase, lipase, abdominal ultrasound
PEPTIC ULCER DISEASE	
“Alarm” symptoms	Endoscopy—mandatory with alarm symptoms
Weight loss	Test for <i>Helicobacter pylori</i>
Hematemesis	
Melena, heme-positive stools	CBC, ESR, amylase, lipase, abdominal ultrasound
Chronic vomiting	
Microcytic anemia	
Nocturnal pain	
Other symptoms—same as for esophagitis and nonulcer dyspepsia	

CBC, Complete blood count; ESR, erythrocyte sedimentation rate; GI, gastrointestinal.

Laboratory and Imaging Studies

Endoscopy can be used to diagnose the underlying condition. Empiric therapy with H₂ blockers or proton pump inhibitors can be used but may delay diagnosis of conditions such as *H. pylori*. For patients with chronic epigastric pain, the possibilities of inflammatory bowel disease, anatomical abnormality such as malrotation, pancreatitis, and biliary disease should be ruled out by appropriate testing when suspected (see [Chapter 126](#) and [Table 128.3](#) for recommended studies). Testing for *H. pylori* can be performed by biopsy during endoscopy with use of a urease test or presence histologically on tissue. If endoscopy is not done, noninvasive tests for infection can be done with reasonable accuracy with

H. pylori fecal antigen and ¹³C urea breath tests.

Treatment

If *H. pylori* is present in association with ulcers, it should be treated with a multidrug regimen, such as omeprazole-clarithromycin-metronidazole, omeprazole-amoxicillin-clarithromycin, or omeprazole-amoxicillin-metronidazole, given twice daily for 1-2 weeks. Other proton pump inhibitors may be substituted when necessary. Bismuth compounds are effective against *H. pylori* and can be considered. In North America, only the subsalicylate salt is available, the use of which raises some concerns about Reye syndrome and potential salicylate toxicity. Tetracycline is useful in adults but should be avoided in children less than 8 years of age. In the absence of *H. pylori*, esophagitis and peptic ulcer disease are treated with a proton-pump inhibitor, which yields higher rates of healing than H₂ receptor antagonists. Gastric and duodenal ulcers heal in 4-8 weeks in at least 80% of patients. Esophagitis requires 4-5 months of proton pump inhibitor treatment for optimal healing.

Cyclic Vomiting Syndrome

Etiology and Epidemiology

Decision-Making Algorithm

Vomiting

Cyclic vomiting syndrome (CVS) presents with intermittent episodes of prolonged nausea and vomiting with periods of health in between. It can occur at any age but is diagnosed most frequently in preschool to school-age children. It is thought to be a migraine variant; many patients have a positive family history of migraines, and some with CVS will eventually develop migraine headaches. Triggers to an episode often include viral illnesses, lack of sleep, stressful or exciting events (holidays, birthdays, vacations), physical exhaustion, and menses.

Clinical Manifestations

Episodes can start at any time but will often start in the early morning hours. Episodes are similar to each other in timing and duration. Repetitive vomiting can last hours to days. Patients can also have abdominal pain, diarrhea, and headaches. Those affected are typically pale, listless, and prefer to be left alone. They may have photo- or phonophobia.

Laboratory and Imaging Studies

There are no specific tests for CVS, which is diagnosed based on the history and the exclusion of other disorders. Diagnoses that should be considered include malrotation with intermittent volvulus, uteropelvic junction (UPJ) obstruction, EoE, intracranial mass lesions, and metabolic disorders. Rome III criteria for diagnosis are outlined in [Table 126.5](#).

Treatment

For the acute episode, supportive treatment includes hydration; dark, quiet environment; and antiemetics such as ondansetron. In addition, abortive therapy using antimigraine medications such as NSAIDs and triptans can be used. For those with frequent or prolonged episodes, prophylactic therapy can be used, such as cyproheptadine, tricyclic antidepressants, beta blockers, or topiramate.

CHAPTER 129

Intestinal Tract

Malrotation

Etiology and Epidemiology

During early fetal life, the midgut is attached to the yolk sac and loops outward into the umbilical cord. Beginning at around 10 weeks' gestation, the bowel re-enters the abdomen and rotates counterclockwise around the superior mesenteric artery until the cecum arrives in the right lower quadrant. The duodenum rotates

behind the artery and terminates at the **ligament of Treitz** in the left upper quadrant. The base of the mesentery becomes fixed along a broad attachment posteriorly, running from the cecum to the ligament of Treitz (**Fig. 129.1A**). When rotation is incomplete or otherwise abnormal, “malrotation” is present. Incomplete rotation occurs when the cecum stops near the right upper quadrant and the duodenum fails to move behind the mesenteric artery; this results in an extremely narrow mesenteric root (see **Fig. 129.1B**) that makes the child susceptible to midgut **volvulus**, causing intestinal obstruction or mesenteric artery occlusion and intestinal infarction (**Fig. 129.2**). It is also common for abnormal mesenteric attachments (Ladd bands) to extend from the cecum across the duodenum, causing partial obstruction.

A **FIGURE 129.1** (A) Normal rotation of the midgut. Note the long axis of mesenteric attachment (*line*). (B) Midgut malrotation. Note the narrow mesentery, which predisposes to volvulus, and the presence of Ladd bands extending across the duodenum from the abnormally elevated cecum. (From Donellan WJ, ed. *Abdominal Surgery of Infancy and Childhood*. Luxembourg: Harwood Academic; 1996:43/6, 43/8.)

FIGURE 129.2 Malrotation with volvulus. Midgut is twisted around the mesentery, with an area of darker, ischemic intestine visible. (Courtesy Robert Soper, MD.)

Clinical Manifestations

Decision-Making Algorithms

Abdominal Pain
Vomiting
Gastrointestinal Bleeding

About 60% of children with malrotation present with symptoms of bilious vomiting during the first month of life. The remaining 40% presents later in infancy or childhood. The emesis initially may be due to obstruction by Ladd bands without volvulus. When midgut volvulus occurs, the venous drainage of the gut is impaired; congestion results in ischemia, pain, tenderness, and often bloody emesis and stools. The bowel undergoes ischemic necrosis, and the child may appear septic. Physicians must be alert to the possibility of volvulus in patients with vomiting and fussiness or abdominal pain.

Laboratory and Imaging Studies

Plain abdominal x-rays generally show evidence of obstruction. Abdominal ultrasound may show evidence of malrotation. An upper gastrointestinal (GI)

series shows the absence of a typical duodenal “C-loop,” with the duodenum instead remaining on the right side of the abdomen. Abnormal placement of the cecum on follow-through (or by contrast enema) confirms the diagnosis. Laboratory studies are nonspecific, showing evidence of dehydration, electrolyte loss, or evidence of sepsis. A decreasing platelet count is a common indicator of bowel ischemia.

Treatment

Treatment is surgical. The bowel is untwisted, and Ladd bands and other abnormal membranous attachments are divided. The mesentery is spread out and flattened against the posterior wall of the abdomen by moving the cecum to the left side of the abdomen. Sutures may be used to hold the bowel in position, but postoperative adhesions tend to hold the mesentery in place, resulting in a broad attachment and eliminating the risk of recurrent volvulus. Necrotic bowel is resected and, at times, results in short gut syndrome.

Intestinal Atresia

Etiology and Epidemiology

Decision-Making Algorithms

Abdominal Pain
Vomiting

Congenital partial or complete blockage of the intestine is a developmental defect that occurs in about 1 in 1,500 live births. Atresia occurs in several forms (Fig. 129.3). One or more segments of bowel may be missing completely, there may be varying degrees of obstruction caused by webs or stenosis, or there may be obliteration of the lumen in cordlike bowel remnants. The end result is obstruction with upstream dilation of the bowel and small, disused intestine distally. When obstruction is complete or high grade, bilious vomiting and abdominal distention are present in the newborn period. In lesser cases, as in “windsock” types of intestinal webs, the obstruction is partial, and symptoms are more subtle. Duodenal atresia is associated with other anomalies in more than

half of infants. Down syndrome is the most common associated disorder but can also be associated with biliary, cardiac, renal, or vertebral anomalies. Jejunal and ileal atresia can be seen in meconium ileus secondary to cystic fibrosis.

FIGURE 129.3 Types of intestinal atresia. **(A)** Internal web; **(B)** cordlike remnant connecting proximal and distal bowel; **(C)** interrupted bowel with V-shaped mesenteric defect; **(D)** “apple peel” atresia with surviving bowel spiraling around a marginal artery; **(E)** multiple atresias. (From Grosfeld JL, Ballantine TVN, Shoemaker R. Operative management of intestinal atresia based on pathologic findings. *J Pediatr Surg.* 1979;14:368–375.)

Clinical Manifestations

Intestinal atresia presents with a history of polyhydramnios, abdominal distention, and bilious vomiting in the neonatal period. If intestinal perforation is

present, peritonitis and sepsis may develop.

Laboratory and Imaging Studies

Plain abdominal x-rays may localize the area of atresia and identify evidence of perforation, such as free air or calcifications typical of meconium peritonitis. Duodenal atresia appears as a double-bubble sign (gas in the stomach and enlarged proximal duodenum), with no gas distally. Atresias of the distal intestine are characterized by longer segments of dilated, air-filled bowel. Contrast studies are helpful if plain films are not sufficient. Atresia may be a complication of **meconium ileus** associated with cystic fibrosis. Laboratory evaluation for **cystic fibrosis** (see [Chapter 137](#)) is indicated in cases of small bowel atresia. A complete blood count, serum electrolytes, liver functions, and amylase should be measured to identify dehydration, pancreatitis, and other complications.

Treatment

The treatment of intestinal atresia is surgical, but surgery must be preceded by adequate hemodynamic stabilization of the patient. Intravenous (IV) fluids, nasogastric suction, and broad-spectrum antibiotics should be given.

Other Congenital Disorders

Gastroschisis is an abdominal wall defect, not involving the umbilicus, through which intestinal contents have herniated. In contrast to omphalocele, the bowel is not covered by peritoneum or amniotic membrane. As a result, prolonged contact with the amniotic fluid typically causes a thick, exudative covering (a “peel”) on the exposed bowel. Gastroschisis is not associated with extraintestinal anomalies, but segments of intestinal atresia are common. After surgical reduction of the defect, return of normal bowel function may be slow and requires prolonged parenteral nutrition for infants with long atretic segments (short-bowel syndrome) and infants with a thick peel.

Omphalocele is an abdominal wall defect through the umbilicus caused by failure of the intestine to return to the abdomen during fetal life. The bowel remains within the umbilical cord and is covered by peritoneum and amniotic membranes. This defect is associated with other congenital anomalies, especially

cardiac defects, **Beckwith-Wiedemann syndrome**, and intestinal complications. Treatment is surgical closure, which sometimes must be performed in stages to fit the bowel into a congenitally small abdominal cavity.

Anorectal malformations, including imperforate anus and its variants, are embryological defects recognized at birth by the absence of a normal anal opening. Evaluation of these infants should include observation for emergence of meconium from the urethra or fistulas on the perineum. A urinary catheter should be placed if urinary distention is present. In low lesions, a fistulous opening that drains meconium is present on the perineum. Low lesions commonly are associated with fistulization between the bowel and bladder, vagina, or urethra. Lateral plain x-rays show the level of the defect and show gas in the bladder caused by a fistula. Initial treatment is a colostomy to divert the fecal flow, with subsequent reconstruction. The internal sphincter muscle is functionally absent in high lesions, and continence after repair is difficult to achieve. All children with imperforate anus require magnetic resonance imaging (MRI) of the lumbosacral spinal cord because of high incidence of tethered spinal cord. Urological dysfunction is common and should be evaluated.

Hirschsprung disease is a motility defect caused by failure of ganglion cell precursors to migrate into the distal bowel during fetal life. The aganglionic distal segment does not exhibit normal motility and is functionally obstructed secondary to spasm. In 75% of cases, the involved segment is limited to the rectosigmoid; total colonic involvement is seen in 8%. Rarely, long segments of small bowel also are aganglionic. "Ultrashort" segment involves only a few centimeters of distal rectum. About 95% of normal infants pass stool spontaneously by 24 hours of age; 95% of infants with Hirschsprung disease do not. Symptoms of distal bowel obstruction occur with distention and bilious vomiting. If the diagnosis is not made quickly, **enterocolitis** can result, associated with a high rate of mortality. Diagnosis is based on examination and one or more diagnostic studies. Abdominal distention is present in most cases. Digital rectal examination reveals an empty rectum that clenches around the examiner's finger, giving the impression of an elongated sphincter. When the finger is withdrawn, a powerful gush of retained stool is often expelled. A deep **rectal biopsy** specimen obtained surgically or by using a suction biopsy instrument is required for diagnosis. When no ganglion cells are shown in the submucosal plexus, accompanied by nerve trunk hyperplasia, the diagnosis is certain. **Barium enema** and **anorectal manometry** may be used before biopsy, but false-negative and false-positive results can occur. Therapy is surgical. When

the bowel is markedly distended or inflamed, an initial colostomy usually is performed above the aganglionic segment, followed weeks later by one of several definitive repair procedures. The transanal pull-through excises the aganglionic bowel and creates a primary colorectal anastomosis without laparotomy. This procedure can be considered in patients with uncomplicated involvement limited to the rectosigmoid region.

Meckel diverticulum is a remnant of the fetal omphalomesenteric duct and is an outpouching of the distal ileum present in 1-2% of the population. Although most diverticula are asymptomatic throughout life, some cause massive, painless GI bleeding. Ectopic gastric tissue within the diverticulum causes ulceration of mucosa in the adjacent ileum. Meckel diverticulum may be a lead point for intussusception or may enable twisting (volvulus) of neighboring bowel around its vascular supply. Diverticulitis mimics appendicitis. Diagnosis may be made in most cases by technetium scan (Meckel scan), which labels the acid-producing mucosa. Because not all diverticula are seen, ultrasound, barium enteroclysis, or video capsule endoscopy may be useful. When the level of suspicion is high, surgical or laparoscopic investigation is warranted. The treatment is surgical excision.

Inflammatory Bowel Disease

Epidemiology and Etiology

Decision-Making Algorithms

Abdominal Pain
Diarrhea
Fever and Rash
Pubertal Delay

The peak incidence of inflammatory bowel disease (IBD) in children is in the second decade of life. IBD includes Crohn disease (CD), which can involve any part of the gut, and ulcerative colitis (UC), which affects only the colon. The incidence of IBD is increasing, especially in industrialized countries, for reasons that are unclear. It is more common in northern latitudes. IBD is uncommon in

tropical and Third World countries. It is more common in Jewish than in other ethnic populations. Genetic factors play a role in susceptibility, with significantly higher risk if there is a family history of IBD. Having a first-degree relative with IBD increases the risk about 30-fold. Susceptibility has been linked to some human leukocyte antigen (HLA) subtypes, and linkage analysis has identified multiple other susceptibility loci on several chromosomes. Environmental factors (not yet identified) also seem to play a role because there is often nonconcordance among monozygotic twins. Dietary and infectious triggers have been proposed but not yet proven. Smoking increases the risk as well as the severity of CD and decreases the risk for UC.

Clinical manifestations depend on the region of involvement. UC involves only the colon, whereas CD can include the entire gut from mouth to anus. **Colitis** from either condition results in diarrhea; blood and mucus in the stool; urgency; and *tenesmus*, a sensation of incomplete emptying after defecation. When colitis is severe, the child often awakens from sleep to pass stool. **Toxic megacolon** is a life-threatening complication characterized by fever, abdominal distention and pain, massively dilated colon, anemia, and low serum albumin owing to fecal protein losses. Symptoms of colitis always are present in UC and usually suggest the diagnosis early in its course. Extraintestinal manifestations of UC occur in a few patients and may include primary sclerosing cholangitis, arthritis, uveitis, and pyoderma gangrenosum (Table 129.1).

TABLE 129.1

Comparison of Crohn Disease and Ulcerative Colitis

FEATURE	CROHN DISEASE	ULCERATIVE COLITIS
Malaise, fever, weight loss	Common	Sometimes
Rectal bleeding	Sometimes	Usual
Abdominal mass	Common	Rare
Abdominal pain	Common	Common
Perianal disease	Common	Rare
Ileal involvement	Common	None (backwash ileitis)
Strictures	Common	Unusual
Fistula	Common	Very rare
Skip lesions	Common	Not present
Transmural involvement	Usual	Not present
Crypt abscesses	Variable	Usual

Intestinal granulomas	Common	Rarely present
Risk of cancer*	Increased	Greatly increased
Erythema nodosum	Common	Less common
Mouth ulceration	Common	Rare
Osteopenia at onset	Yes	No
Autoimmune hepatitis	Rare	Yes
Sclerosing cholangitis	Rare	Yes

*Colonic cancer, cholangiocarcinoma, lymphoma in Crohn disease.

Symptoms can be subtle in CD. **Small bowel involvement** in CD is associated with loss of appetite, crampy postprandial pain, poor growth, delayed puberty, fever, anemia, and lethargy. Symptoms may be present for some time before the diagnosis is made. Severe CD with fibrosis may cause partial or complete small bowel obstruction. Perineal abnormalities, including skin tags and fistulas, are another feature distinguishing CD from UC. Other extraintestinal manifestations of CD include arthritis, erythema nodosum, and uveitis or iritis.

Laboratory and Imaging Studies

Blood tests should include complete blood count, albumin, erythrocyte sedimentation rate, and C-reactive protein (Table 129.2). Anemia and elevated platelet counts are typical. Testing for abnormal serum antibodies can be helpful in diagnosing IBD and in discriminating between the colitis of CD and UC. Serological testing for IBD may be considered but is not recommended for screening due to poor sensitivity. Elevated fecal calprotectin or positive lactoferrin testing indicates intestinal inflammation. These tests have a high negative predictive value but are not specific to IBD.

TABLE 129.2

Diagnostic Studies for Inflammatory Bowel Disease

STUDIES	INTERPRETATION
BLOOD TESTS	
CBC with WBC differential	Anemia, elevated platelets suggest IBD
ESR	Elevated in many, but not all, IBD patients
C-reactive protein	Elevated in many, but not all, IBD patients

Albumin	May be low in IBD due to fecal loss
ASCA	Found in about 50% of CD patients and few UC patients
Atypical p-ANCA	Found in most UC patients and few CD patients
Anti-OmpC	Found in some UC and CD patients, rare in non-IBD
Anti-C Bir1	Found in about 50% of CD patients
STOOL STUDIES	
Fecal calprotectin and lactoferrin	Elevated in IBD and can differentiate from functional disorders
IMAGING STUDIES	
Upper GI series with SBFT	Evaluate for ileal and jejunal CD
CT scan	Used to detect abscess, small bowel involvement
Magnetic resonance enterography	Used to detect bowel thickening, inflammation, and strictures as well as abscesses and fistulas
ENDOSCOPY	
Upper endoscopy	Evaluate for CD of esophagus, stomach, and duodenum; obtain tissue for histological diagnosis
Colonoscopy	Show presence or absence of colitis and terminal ileal CD; obtain tissue for histology
Video capsule endoscopy	Emerging role in diagnosis of small bowel CD, more sensitive than upper GI series with SBFT

Anti-OmpC, Antibody to outer membrane protein C; *ASCA*, anti-*Saccharomyces cerevisiae* antibody; atypical p-ANCA, atypical perinuclear staining by antineutrophil cytoplasmic antibody; *CBC*, complete blood count; *CD*, Crohn disease; *CT*, computed tomography; *ESR*, erythrocyte sedimentation rate; *GI*, gastrointestinal; *IBD*, inflammatory bowel disease; *SBFT*, small bowel follow-through; *UC*, ulcerative colitis; *WBC*, white blood cell.

In patients with suspected IBD, upper endoscopy and colonoscopy are recommended. Colonoscopic findings in UC include diffuse carpeting of the distal or entire colon with tiny ulcers and loss of haustral folds. Within the involved segment, no skip areas are present. In CD, ulcerations tend to be much larger and deeper with a linear, branching, or aphthous appearance; skip areas are usually present. **Upper endoscopy** cannot evaluate the jejunum and ileum, but is more sensitive than contrast studies in identifying proximal CD involvement. Other methods to detect small bowel involvement include **video capsule endoscopy**; upper GI series with small bowel follow through; computed tomography (CT) scanning, which can detect small bowel disease as well as abscesses; and **MR enterography**, which has the advantage of no radiation and good sensitivity for finding active bowel disease.

Treatment

Ulcerative Colitis

UC is treated with the aminosalicylate drugs, which deliver **5-aminosalicylic acid** (5-ASA) to the distal gut. Because it is rapidly absorbed, pure 5-ASA (mesalamine) must be specially packaged in coated capsules or pills or taken as a suppository to be effective in the colon. Other aminosalicylates (sulfasalazine, olsalazine, and balsalazide) use 5-ASA covalently linked to a carrier molecule. Sulfasalazine is the least expensive, but side effects resulting from its sulfapyridine component are common. When aminosalicylates alone cannot control the disease, steroid therapy may be required to induce remission. Whenever possible, steroids should not be used for long-term therapy. An immunosuppressive drug, such as **6-mercaptopurine** or **azathioprine**, is useful to spare excessive steroid use in difficult cases. More potent immunosuppressives, such as cyclosporine or anti-tumor necrosis factor (TNF) agents such as infliximab, may be used as rescue therapy when other treatments fail. Surgical colectomy with ileoanal anastomosis is an option for unresponsive severe disease or electively to end chronic symptoms and to reduce the risk of colon cancer, which is increased in patients with UC.

Crohn Disease

Inflammation in CD typically responds less well to aminosalicylates; oral or IV steroids are more important in inducing remission. To avoid the need for repetitive steroid therapy, immunosuppressive drugs, usually either azathioprine, 6-mercaptopurine, or methotrexate, are often started soon after diagnosis. CD that is difficult to control may be treated with agents that block the action of TNF α such as infliximab or adalimumab. Other antibodies that inhibit white blood cell (WBC) migration or action, such as vedolizumab, also show promise. Exclusive enteral nutrition can be an effective therapy for CD. Patients take formula as their sole source of nutrition for months as a steroid-sparing therapy. Other diets such as the specific carbohydrate diet continue to be studied as a possible therapy. As with UC, surgery is sometimes necessary, usually because of obstructive symptoms, abscess, or severe, unremitting symptoms. Because surgery is not curative in CD, its use must be limited, and the length of bowel resection must be minimized.

Celiac Disease

Etiology and Epidemiology

Celiac disease is an injury to the mucosa of the small intestine caused by the ingestion of **gluten** (a protein component) from wheat, rye, barley, and related grains. In its severe form, celiac disease causes malabsorption and malnutrition. The availability of more sensitive and specific serological testing has revealed many patients with few or no GI symptoms who have early, attenuated, or latent disease. Incidence of celiac disease is estimated at 1%, but only a small proportion has been diagnosed. The disease is seen in association with type 1 diabetes, thyroiditis, Turner syndrome, and trisomy 21.

Clinical Manifestations

Decision-Making Algorithms

Diarrhea
Pubertal Delay
Failure to Thrive

Symptoms can begin at any age when gluten-containing foods are given. Diarrhea, abdominal bloating, failure to thrive, irritability, decreased appetite, and ascites caused by hypoproteinemia are classic. Children may be minimally symptomatic or may be severely malnourished. Constipation is found in a few patients, probably because of reduced intake. A careful inspection of the child's growth curve and evaluation for reduced subcutaneous fat and abdominal distention are crucial. Celiac disease should be considered in any child with chronic abdominal complaints, short stature, poor weight gain, or delayed puberty. Extraintestinal manifestations include osteopenia, arthritis or arthralgias, ataxia, dental enamel defects, elevated liver enzymes, dermatitis herpetiformis, and erythema nodosum.

Laboratory and Imaging Studies

Serological markers include IgA antiendomysial antibody and IgA tissue transglutaminase antibody. Because IgA deficiency is common in celiac disease, total serum IgA also must be measured to document the accuracy of these tests.

In the absence of IgA deficiency, either test yields a sensitivity and specificity of 95%. An endoscopic **small bowel biopsy** is essential to confirm the diagnosis and should be performed while the patient is still ingesting gluten. The biopsy specimen shows various degrees of villous atrophy (short or absent villi), mucosal inflammation, crypt hyperplasia, and increased numbers of intraepithelial lymphocytes. When there is any question about response to treatment, a repeat biopsy specimen may be obtained several months later. Other laboratory studies should be performed to rule out complications, including complete blood count, calcium, phosphate, vitamin D, iron, total protein and albumin, and liver function tests. Mild elevations of the transaminases are common and should normalize with dietary therapy.

Treatment

Treatment consists of complete elimination of gluten from the diet. Consultation with a dietitian experienced in celiac disease is helpful, as is membership in a celiac disease support group. Lists of prepared foods that contain hidden gluten are particularly important for patients to use. Starchy foods that are safe include rice, soy, tapioca, buckwheat, potatoes, and (pure) oats. Many resources also are available via the Internet to help families cope with the large changes in diet that are required. Most patients respond clinically within a few weeks with weight gain, improved appetite, and improved sense of well-being. Histological improvement lags behind clinical response, requiring several months to normalize.

Milk and Soy Protein Intolerance (Allergic Colitis)

See [Chapter 34](#).

Intussusception

Etiology and Epidemiology

Intussusception is the “telescoping” of a segment of proximal bowel (the intussusceptum) into downstream bowel (the intussusciens). Most cases occur in infants 1-2 years old; in this age group, nearly all cases are idiopathic. Viral-

induced lymphoid hyperplasia may produce a lead point in these children. In older children, the proportion of cases caused by a pathological lead point increases. In young children, **ileocolonic** intussusception is common; the ileum invaginates into the colon, beginning at or near the ileocecal valve. When pathological lead points are present, the intussusception may be ileoileal, jejunoileal, or jejunojejunal.

Clinical Manifestations

Decision-Making Algorithms

Abdominal Pain
Gastrointestinal Bleeding
Irritable Infant

An infant with intussusception has sudden onset of crampy abdominal pain; the infant's knees draw up, and the infant cries out and exhibits pallor with a colicky pattern occurring every 15-20 minutes. Feedings are refused. As the intussusception progresses and obstruction becomes prolonged, bilious vomiting becomes prominent and the dilated, fatigued intestine generates less pressure and less pain. As the intussuscepted bowel is pulled further and further into the downstream intestine by motility, the mesentery is pulled with it and becomes stretched and compressed. The venous outflow from the intussusceptum is obstructed, leading to edema, weeping of fluid, and congestion with bleeding. Third space fluid losses and “currant jelly” stools result. Another unexpected feature of intussusception is **lethargy**. Between episodes of pain, the infant is glassy-eyed and groggy and appears to have been sedated. A sausage-shaped mass caused by the swollen, intussuscepted bowel may be palpable in the right upper quadrant or epigastrium.

Laboratory and Imaging Studies

The diagnosis depends on the direct demonstration of bowel-within-bowel. A simple way of showing this is by abdominal ultrasound. If the ultrasound is positive, or if good visualization has not been achieved, a pneumatic or contrast

enema under fluoroscopy is indicated. This is a potentially useful way to both identify and **treat** intussusception. Air and barium can show the intussusception quickly and, when administered with controlled pressure, usually can reduce it completely. The success rate for pneumatic reduction is higher than for hydrostatic reduction with barium and approaches 90%, if done when symptoms have been present for less than 24 hours. The pneumatic enema has the additional advantages over barium of not preventing subsequent radiologic studies and having no risk of causing barium peritonitis if perforation occurs. Nonoperative reduction should not be attempted if the patient is unstable or has evidence of pre-existing perforation or peritonitis.

Treatment

Therapy must begin with placement of an IV catheter and a nasogastric tube. Before radiologic intervention is attempted, the child must have adequate **fluid resuscitation** to correct the often severe dehydration caused by vomiting and third space losses. Ultrasound may be performed before the fluid resuscitation is complete. Surgical consultation should be obtained early as the surgeon may prefer to be present during nonoperative reduction. If pneumatic or hydrostatic reduction is successful, the child should be admitted to the hospital for overnight observation of possible recurrence (risk is 5-10%). If reduction is not complete, emergency surgery is required. The surgeon attempts gentle manual reduction but may need to resect the involved bowel after failed radiologic reduction because of severe edema, perforation, a pathological lead point (polyp, Meckel diverticulum), or necrosis.

Appendicitis

Etiology and Epidemiology

Appendicitis is the most common surgical emergency in childhood. The prevalence of appendicitis varies by age with the peak in the second decade. Appendicitis begins with obstruction of the lumen, most commonly by fecal matter (fecalith), but appendiceal obstruction also can occur secondary to hyperplasia of lymphoid tissue associated with viral infections or, rarely, the presence of neoplastic tissue, such as an appendiceal carcinoid tumor. Trapped bacteria proliferate and begin to invade the appendiceal wall, inducing inflammation and secretion. The obstructed appendix becomes engorged, its

blood supply is compromised, and it finally ruptures. The entire process is rapid, with appendiceal rupture usually occurring within 48 hours of the onset of symptoms.

Clinical Manifestations

Decision-Making Algorithms

Abdominal Pain
Vomiting

Classic appendicitis begins with **visceral pain**, localized to the periumbilical region. Nausea and vomiting occur soon after, triggered by the appendiceal distention. As the inflammation begins to irritate the parietal peritoneum adjacent to the appendix, **somatic pain** fibers are activated, and the pain localizes to the right lower quadrant. Examination of the patient reveals a tender right lower quadrant. Voluntary guarding is present initially, progressing to rigidity, then to rebound tenderness with rupture and peritonitis. These classic findings may not be present, especially in young children or if the appendix is retrocecal, covered by omentum, or in another unusual location. Clinical prediction rules have been developed for the diagnosis of appendicitis. The Alvarado/MANTRELS rule is scored by 1 point for each of the following: migration of pain to the right lower quadrant, anorexia, nausea/vomiting, rebound pain, temperature of at least 37.3°C, and WBC shift to greater than 75% neutrophils; 2 points are given for each of tenderness in the right lower quadrant and leukocytosis greater than 10,000/ μ L. Children with a score of 4 or less are unlikely to have appendicitis; a score of 7 or greater increases the likelihood that the patient has appendicitis. When classic history and physical examination findings are present, the patient is taken to the operating room. When doubt exists, imaging is helpful to rule out complications (right lower quadrant abscess, liver disease) and other disorders, such as mesenteric adenitis and ovarian or fallopian tube disorders. If the evaluation is negative and some doubt remains, the child should be admitted to the hospital for close observation and serial examinations.

Laboratory and Imaging Studies

The history and examination are often enough to make the diagnosis, but laboratory and imaging studies are helpful when the diagnosis is uncertain (Table 129.3). A WBC count greater than 10,000/mm³ is found in 89% of patients with appendicitis and 93% with perforated appendicitis. This criterion is met by 62% of abdominal pain patients without appendicitis. Urinalysis is done to rule out urinary tract infection, and x-rays of the chest or the kidney-ureter-bladder (KUB) rule out lower lobe pneumonia masquerading as abdominal pain. Amylase, lipase, and liver enzymes are done to look for pancreatic or liver and gallbladder disease. The plain abdominal x-ray may reveal a calcified fecalith, which strongly suggests the diagnosis. When these studies are inconclusive, imaging is indicated with an abdominal ultrasound or CT scan, which may reveal the presence of an enlarged, thick-walled appendix with surrounding fluid. A diameter of more than 6 mm is considered diagnostic.

TABLE 129.3

Diagnostic Studies in Suspected Appendicitis

ALT, Alanine aminotransferase; *AST*, aspartate aminotransferase; *CBC*, complete blood count; *CT*, computed tomography; *GGT*, γ -glutamyltransferase; *KUB*, kidney-ureter-bladder.

Treatment

Treatment of appendicitis is usually surgical. Laparoscopic appendectomy is curative if performed before perforation. With perforation, a course of postoperative IV antibiotics is required. Broad-spectrum coverage is necessary to cover the mixed bowel flora. In low-risk patients with nonperforated

appendicitis, some centers have a nonsurgical approach and use high dose broad-spectrum intravenous antibiotics in a hospital setting.

CHAPTER 130

Liver Disease

Cholestasis

Etiology and Epidemiology

Cholestasis is defined as reduced bile flow and is characterized by elevation of the conjugated, or direct, bilirubin fraction. This condition must be distinguished from physiological neonatal jaundice, in which the direct bilirubin is never elevated (see [Chapter 62](#)). Neonatal jaundice that is secondary to unconjugated hyperbilirubinemia is the result of immature hepatocellular excretory function or hemolysis, which increases the production of bilirubin. When direct bilirubin is elevated, many potentially serious disorders must be considered ([Fig. 130.1](#), [Table 130.1](#)). Emphasis must be placed on the rapid diagnosis of treatable and potentially imminently lethal disorders, especially biliary atresia and metabolic disorders, such as galactosemia or tyrosinemia.

JAUNDICE

Unconjugated Hyperbilirubinemia

Hemolysis and Reticulocytosis

Positive Coombs test
 ABO and Rh incompatibility
 Autoimmune, systemic lupus erythematosus
 Drug-induced and idiopathic acquired hemolytic anemia

Negative Coombs test
 RBC enzyme defect (G6PD deficiency)
 Hemoglobinopathy (sickle cell anemia)
 RBC membrane defect (hereditary spherocytosis)
 Hemolytic-uremic syndrome
 Wilson disease

No Hemolysis

Gilbert syndrome
 Physiological jaundice of the newborn
 Breast milk jaundice
 Crigler-Najjar syndrome
 Hypothyroidism
 Pyloric stenosis
 Internal hemorrhage

Obstructive

Alagille syndrome
 Nonsyndromic paucity of intrahepatic bile ducts
 Biliary atresia
 Choledochal cyst
 Cholelithiasis
 Tumor/neoplasia
 Bile duct stenosis
 Spontaneous bile duct perforation
 Bile-mucus plug
 Congenital hepatic fibrosis

Infectious

Hepatitis A, B, C, D, E, G
 Cytomegalovirus
 Herpes simplex 1, 2, 6
 Epstein-Barr virus
 Coxsackievirus
 ECHO virus
 Measles
 Varicella

Modified from Balistreri WF. Liver disease in infancy and childhood. In: Schiff ER, Sorrell MF, Maddrey WC, eds. *Schiff's Diseases of the Liver*. 8th ed. Philadelphia: Lippincott-Raven; 1999:1370; Suchy FJ. Approach to the infant with cholestasis. In: Suchy FJ, Sokol RJ, Balistreri WF, eds. *Liver Disease in Children*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2001:188.

Clinical Manifestations

Decision-Making Algorithm

Jaundice

The jaundice of **extrahepatic biliary atresia** (biliary atresia) usually is not

evident immediately at birth, but develops in the first week or two of life. The reason is that extrahepatic bile ducts are usually present at birth but are then destroyed by an idiopathic inflammatory process. Aside from jaundice, these infants do not initially appear ill. The liver injury progresses rapidly to cirrhosis; symptoms of portal hypertension with splenomegaly, ascites, muscle wasting, and poor weight gain are evident by a few months of age. If surgical drainage is not performed successfully early in the course (ideally by 2 months), progression to liver failure is inevitable.

Neonatal hepatitis is characterized by an ill-appearing infant with an enlarged liver and jaundice. There is no specific diagnostic test. If liver biopsy is performed, the presence of hepatocyte giant cells is characteristic. Cytomegalovirus, herpes simplex virus, and syphilis must be ruled out. Hepatobiliary scintigraphy typically shows slow hepatic uptake with eventual excretion of isotope into the intestine. These infants have a good prognosis overall, with spontaneous resolution occurring in most.

α_1 -Antitrypsin deficiency presents with clinical findings indistinguishable from neonatal hepatitis. Only about 10-20% of all infants with the genetic defect exhibit neonatal cholestasis. Of these affected infants, about 20-30% develop chronic liver disease, which may result in cirrhosis and liver failure. Life-threatening α_1 -antitrypsin deficiency occurs in only 3-5% of affected pediatric patients. α_1 -Antitrypsin deficiency is the leading metabolic disorder requiring liver transplantation.

Alagille syndrome is characterized by chronic cholestasis with the unique liver biopsy finding of *paucity of bile ducts* in the portal triads. Associated abnormalities in some (syndromic) types include peripheral pulmonic stenosis or other cardiac anomalies; hypertelorism; unusual facies with deep-set eyes, prominent forehead, and a pointed chin; butterfly vertebrae; and a defect of the ocular limbus (*posterior embryotoxon*). Cholestasis is variable but is usually lifelong and associated with hypercholesterolemia and severe pruritus. Progression to end-stage liver disease is uncommon. Liver transplantation sometimes is performed electively to relieve severe and uncontrollable pruritus.

Laboratory and Imaging Studies

The laboratory approach to diagnosis of a neonate with cholestatic jaundice is presented in [Table 130.2](#). Noninvasive studies may aid a rapid diagnosis. Early imaging studies are performed to evaluate for biliary obstruction and other

anatomical lesions that may be surgically treatable. When necessary to rule out biliary atresia or to obtain prognostic information, liver biopsy is a final option (Fig. 130.2).

TABLE 130.2

Laboratory and Imaging Evaluation of Neonatal Cholestasis

EVALUATION	RATIONALE
INITIAL TESTS	
Total and direct bilirubin	Elevated direct fraction confirms cholestasis
AST, ALT	Hepatocellular injury
GGT	Biliary obstruction/injury
RBC galactose-1-phosphate uridylyltransferase	Galactosemia
α_1 -Antitrypsin level	α_1 -Antitrypsin deficiency
Urinalysis and urine culture	Urinary tract infection can cause cholestasis in neonates
Blood culture	Sepsis can cause cholestasis
Serum amino acids	Aminoacidopathies
Urine organic acids	Organic acidurias
Very-long-chain fatty acids	Zellweger syndrome, peroxisomal disorders
Carnitine profile	Mitochondrial and fatty acid oxidation disorders
Sweat chloride or CF mutation analysis	Cystic fibrosis
Urine culture for cytomegalovirus	Congenital cytomegalovirus infection
INITIAL IMAGING STUDY	
Abdominal ultrasound	Choledochal cyst, gallstones, mass lesion, Caroli disease
SECONDARY IMAGING STUDY	
Hepatobiliary scintigraphy	Evaluate for biliary atresia
Pathology	
Percutaneous liver biopsy	Biliary atresia, idiopathic giant cell hepatitis, α_1 -antitrypsin deficiency

ALT, Alanine aminotransferase; *AST*, aspartate aminotransferase; *CF*, cystic fibrosis; *GGT*, γ -glutamyltransferase; *RBC*, red blood cell.

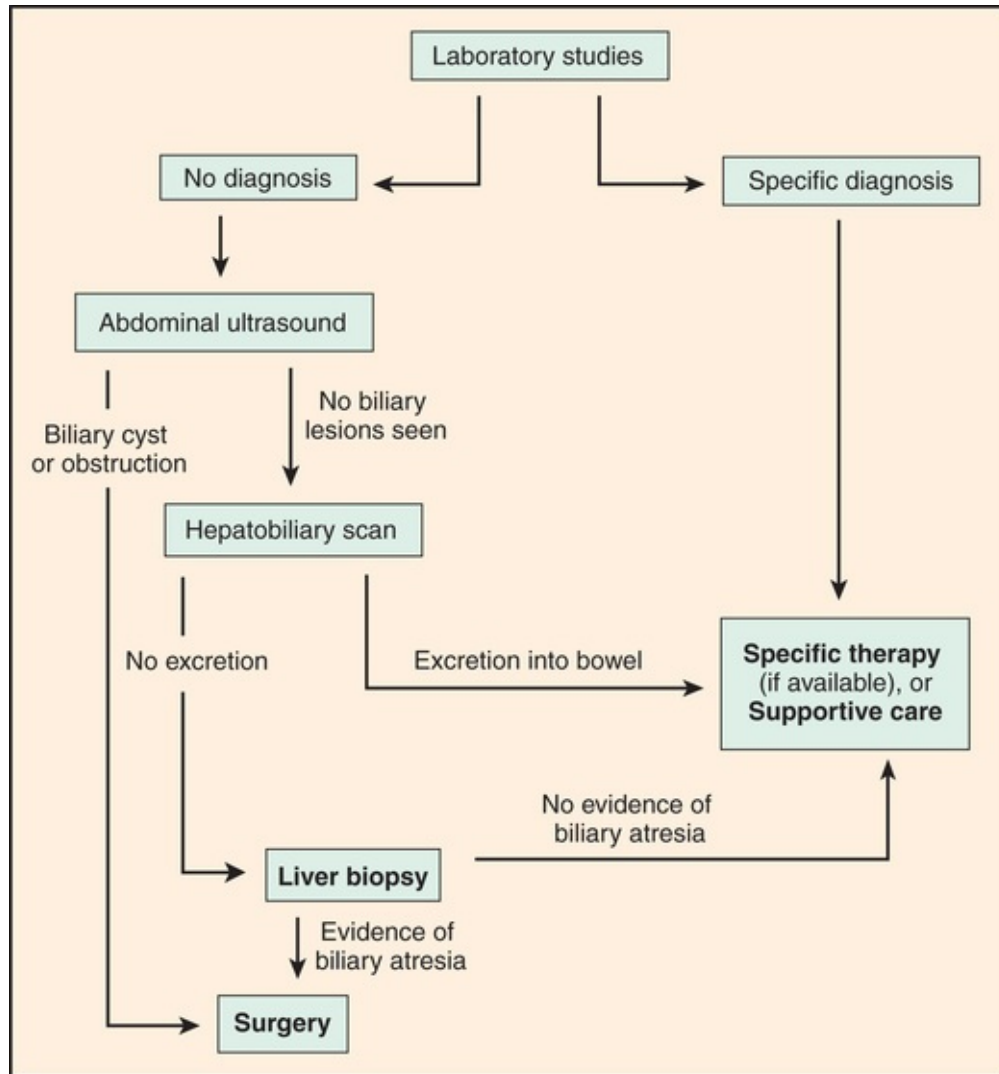

FIGURE 130.2 Flow chart for evaluation of neonatal cholestasis.

Treatment

Treatment of extrahepatic biliary atresia is the surgical **Kasai procedure**, in which the fibrotic extrahepatic bile duct remnant is removed and replaced with a roux-en-Y loop of jejunum. This operation must be performed before 3 months of age to have the best chance of success. Even so, the success rate is low; many children require liver transplantation. Some metabolic causes of neonatal cholestasis are treatable by dietary manipulation (galactosemia) or medication (tyrosinemia); all affected patients require supportive care. This includes fat-soluble vitamin supplements (vitamins A, D, E, and K) and formula containing medium-chain triglycerides, which can be absorbed without bile salt-induced

micelles. Choleric agents, such as ursodeoxycholic acid, may improve bile flow in some conditions.

Viral Hepatitis

See [Chapter 113](#).

Fulminant Liver Failure

Etiology and Epidemiology

Fulminant liver failure is defined as severe liver disease with onset of hepatic encephalopathy within 8 weeks after initial symptoms, in the absence of chronic liver disease. Etiology includes viral hepatitis, metabolic disorders, autoimmune hepatitis, ischemia, neoplastic disease, and toxins ([Table 130.3](#)).

Clinical Manifestations

Decision-Making Algorithm

Hepatomegaly

Liver failure is a multisystem disorder with complex interactions among the liver, kidneys, vascular structures, gut, central nervous system (CNS), and immune function. Hepatic encephalopathy is characterized by varying degrees of impairment (Table 130.4). Respiratory compromise occurs as severity of the failure increases and requires early institution of ventilatory support. Hypoglycemia resulting from impaired glycogenolysis and gluconeogenesis must be prevented. Renal function is impaired, and frank renal failure, or **hepatorenal syndrome**, may occur. This syndrome is characterized by low urine output, azotemia, and low urine sodium content. Ascites develops secondary to hypoalbuminemia and disordered regulation of fluid and electrolyte homeostasis. Increased risk of infection occurs and may cause death. Esophageal varices may cause significant hemorrhage, whereas hypersplenism from portal hypertension may produce thrombocytopenia.

TABLE 130.4**Stages of Hepatic Encephalopathy**

STAGE I

Alert and awake

Agitated and distractible

Infants and young children—irritable and fussy

Normal reflexes

Tremor, poor handwriting

Obeys age-appropriate commands

STAGE II

Confused and lethargic

Combative or inappropriate euphoria

Hyperactive reflexes

Asterixis present

Purposeful movements, but may not obey commands

STAGE III

Stuporous but arousable

Sleepy

Incoherent speech

Motor response to pain

Hyperreflexic

Hyperventilation

Asterixis present

STAGE IV

Unconscious, not arousable

Unresponsive or responds nonpurposefully to pain

Reflexes hyperactive

Irregular respirations

Pupil response sluggish

STAGE V

Unconscious

Hypoactive reflexes

Flaccid muscle tone

Apneic

Pupils fixed

Laboratory and Imaging Studies

Coagulation tests and serum albumin are used to follow hepatic synthetic function. These tests are confounded by administration of blood products and clotting factors. Vitamin K should be administered to maximize the liver's ability to synthesize factors II, VII, IX, and X. In addition to monitoring prothrombin time and partial thromboplastin time, many centers measure factor V serially as a sensitive index of synthetic function. Renal function tests, electrolytes, serum ammonia, blood counts, and urinalysis also should be followed. In the setting of acute liver failure, liver biopsy may be indicated to ascertain the nature and degree of injury and estimate the likelihood of recovery. In the presence of coagulopathy, biopsy must be done using a transjugular or surgical approach.

Treatment

Because of the life-threatening and complex nature of this condition, management must be carried out in an intensive care unit at a liver transplant center. Treatment of acute liver failure is supportive; the definitive lifesaving therapy is liver transplantation. Supportive measures are listed in [Table 130.5](#). Efforts are made to treat metabolic derangements, avoid hypoglycemia, support respiration, minimize hepatic encephalopathy, and support renal function.

TABLE 130.5

Treatment of Fulminant Liver Failure

Hepatic encephalopathy	Avoid sedatives Lactulose via nasogastric tube—start with 1-2 mL/kg/day, adjust dose to yield several loose stools per day Rifaximin or neomycin Enemas if constipated Mechanical ventilation if stage III or IV
Coagulopathy	Fresh frozen plasma only if active bleeding, monitor coagulation studies frequently Platelet transfusions as required
Hypoglycemia	Intravenous glucose supplied with $\geq 10\%$ dextrose solution, electrolytes as appropriate
Ascites	Restrict fluid intake to 50-60% maintenance Restrict sodium intake to 0.5-1 mEq/kg/day Monitor central venous pressure to maintain adequate intravascular volume (avoid renal failure)
Renal failure	Maintain adequate intravascular volume, give albumin if low Diuretics Vasoconstrictors Dialysis or hemofiltration

Chronic Liver Disease

Etiology and Epidemiology

Chronic liver disease in childhood is characterized by the development of cirrhosis and its complications, and by progressive hepatic failure. Causative conditions may be congenital or acquired. Major congenital disorders leading to chronic disease include biliary atresia, tyrosinemia, untreated galactosemia, and α_1 -antitrypsin deficiency. In older children, hepatitis B or C virus, autoimmune hepatitis, Wilson disease, primary sclerosing cholangitis, cystic fibrosis, and biliary obstruction secondary to choledochal cyst are leading causes.

Clinical Manifestations

Decision-Making Algorithms

- Gastrointestinal Bleeding
- Jaundice
- Abdominal Masses
- Bleeding

Chronic liver disease is characterized by the consequences of portal hypertension, impaired hepatocellular function, and cholestasis. **Portal hypertension** caused by cirrhosis results in risk of gastrointestinal bleeding, ascites, and reduced hepatic blood flow. Blood entering the portal vein from the splenic and mesenteric veins is diverted to collateral circulation that bypasses the liver, enlarging these previously tiny vessels in the esophagus, stomach, and abdomen. **Esophageal varices** are particularly prone to bleed, but bleeding also can occur from hemorrhoidal veins, engorged gastric mucosa, and gastric varices. **Ascites** develops as a result of weeping of a high-pressure ultrafiltrate from the surfaces of the viscera and is at risk of becoming infected (spontaneous bacterial peritonitis); ascites can often be massive and interfere with patient comfort and respiration. The spleen enlarges secondary to impaired splenic vein

outflow, causing excessive scavenging of platelets and white blood cells; this increases the patient's susceptibility to bleeding and infection.

Impaired hepatocellular function is associated with coagulopathy unresponsive to vitamin K, low serum albumin, elevated ammonia, and **hepatic encephalopathy**. The diversion of portal blood away from the liver via collateral circulation worsens this process. Malaise develops and contributes to poor nutrition, leading to muscle wasting and other consequences.

Chronic cholestasis causes debilitating pruritus and deepening jaundice. The reduced excretion of bile acids impairs absorption of fat calories and fat-soluble vitamins, which contributes to the poor nutritional state. Deficiency of vitamin K impairs production of clotting factors II, VII, IX, and X and increases the risk of bleeding. Vitamin E deficiency leads to hematological and neurological consequences unless corrected.

Laboratory and Imaging Studies

Laboratory studies include specific tests for diagnosis of the underlying illness and testing to monitor the status of the patient. Children presenting for the first time with evidence of chronic liver disease should have a standard investigation (Table 130.6). Monitoring should include coagulation tests, electrolytes and renal function testing, complete blood count with platelet count, transaminases, alkaline phosphatase, and γ -glutamyltransferase at appropriate intervals. Frequency of testing should be tailored to the pace of the patient's illness. Ascites fluid can be tested for infection by culture and cell count and generally is found to have an albumin concentration lower than that of serum.

TABLE 130.6

Laboratory and Imaging Investigation of Chronic Liver Disease

METABOLIC TESTING
Serum α_1 -antitrypsin level
α_1 -Antitrypsin phenotype if low serum level
Serum ceruloplasmin
Sweat chloride, CF gene tests if CF suspected
Testing for other specific conditions as indicated by clinical/laboratory findings
VIRAL HEPATITIS
HBsAg

Hepatitis B viral DNA, HBeAg if HBsAg positive

Hepatitis C antibody

Hepatitis C antibody confirmatory test if positive

Hepatitis C viral RNA, genotype if antibody confirmed

AUTOIMMUNE HEPATITIS

Antinuclear antibody

Liver-kidney microsomal antibody

Anti-smooth muscle antibody

Antineutrophil cytoplasmic antibody

Total serum IgG (usually elevated)

TESTS TO EVALUATE LIVER FUNCTION AND INJURY

Prothrombin time and partial thromboplastin time

Serum ammonia

CBC with platelet count

Serum albumin

AST, ALT, GGT, alkaline phosphatase

Total and direct bilirubin

Serum cholyglycine or bile acids

Serum cholesterol

Ultrasound examination of liver and bile ducts

Doppler ultrasound of hepatic vessels*

Magnetic resonance cholangiography*

Magnetic resonance angiography of hepatic vessels*

Percutaneous or endoscopic cholangiography*

Liver biopsy*

ANATOMICAL EVALUATION

Ultrasound of liver, pancreas, and biliary tree

Consider magnetic resonance cholangiography or ERCP if evidence of biliary process

Liver biopsy—as required for diagnosis or prognosis

TESTS TO EVALUATE NUTRITIONAL STATUS

Height, weight, skinfold thickness

25-Hydroxyvitamin D level

Vitamin A level

Vitamin E level

Prothrombin time and partial thromboplastin time before and after vitamin K administration

Serum albumin and prealbumin

*Perform when indicated to obtain specific anatomical information.

ALT, Alanine aminotransferase; *AST*, aspartate aminotransferase; *CBC*, complete blood count; *CF*, cystic fibrosis; *ERCP*, endoscopic retrograde cholangiopancreatography; *GGT*, γ -glutamyltransferase; *HBeAg*, hepatitis B early antigen; *HBsAg*, hepatitis B surface antigen; *Ig*, immunoglobulin.

Treatment

Treatment of chronic liver disease is complex. Supportive care for each of the many problems encountered in these patients is outlined in [Table 130.7](#). Ultimately, survival depends on the availability of a donor liver and the patient's candidacy for transplantation. When transplantation is not possible or is delayed, palliative procedures, such as portosystemic shunts, can be considered. The transjugular intrahepatic portosystemic shunt is an expandable stent placed between the hepatic vein and a branch of the portal vein within the hepatic parenchyma. This procedure is performed using catheters inserted via the jugular vein and is entirely nonsurgical. All portosystemic shunts carry increased risk of hepatic encephalopathy.

TABLE 130.7

Management of Chronic Liver Disease

PROBLEM	CLINICAL MANIFESTATIONS	DIAGNOSTIC TESTING	TREATMENT
Gastrointestinal variceal bleeding*	Hematemesis, rectal bleeding, melena, anemia	CBC, coagulation tests, Doppler ultrasound, magnetic resonance angiography, endoscopy	Somatostatin (octreotide) infusion, variceal band ligation or sclerotherapy, propranolol to reduce portal pressure, acid-blocker therapy, TIPSS or surgical portosystemic shunt if transplant not possible
Ascites	Abdominal distention, shifting dullness and fluid wave, respiratory compromise, spontaneous bacterial peritonitis	Abdominal ultrasound, diagnostic paracentesis; measure ascites fluid albumin (and serum albumin), cell count, WBC differential, culture fluid in blood culture bottles	Restrict sodium intake to 0.5-1 mEq/kg/day, restrict fluids, monitor renal function, treat peritonitis and portal hypertension Central portosystemic shunt may be required
Nutritional compromise	Muscle wasting, fat-soluble vitamin deficiencies, poor or absent weight gain, fatigue	Coagulation studies, serum albumin, 25-hydroxyvitamin D level, vitamin E level, vitamin A level	Fat-soluble vitamin supplements: vitamins A, D, E, and K; use water-soluble form of vitamins. Supplemental feedings—nasogastric or parenteral if necessary
Hepatic encephalopathy	Irritability, confusion, lethargy, somnolence, coma	Serum ammonia	Lactulose orally or via nasogastric tube, avoid narcotics and sedatives, liver transplantation

*May also have peptic ulcerations.

CBC, Complete blood count; TIPSS, transjugular intrahepatic portosystemic shunt; WBC, white blood cell.

Selected Chronic Hepatic Disorders

Wilson Disease

Decision-Making Algorithms

Jaundice
Hepatomegaly
Involuntary Movements
Hypocalcemia

Wilson disease is characterized by abnormal storage of copper in the liver, leading to hepatocellular injury, CNS dysfunction, and hemolytic anemia. It is an autosomal recessive trait caused by mutations in the *ATP7B* gene. The encoded protein of this gene functions as an ATP-driven copper pump. The **diagnosis** is made by identifying depressed serum levels of ceruloplasmin, elevated 24-hour urine copper excretion, the presence of Kayser-Fleischer rings in the iris, evidence of hemolysis, and elevated hepatic copper content. In any single patient, one or more of these measures may be normal. **Clinical presentation** also varies, but seldom occurs before age 3 years. Neurological abnormalities may predominate, including tremor, decline in school performance, worsening handwriting, and psychiatric disturbances. Anemia may be the first noted symptom. Hepatic presentations include appearance of jaundice, spider hemangiomas, portal hypertension and its consequences, and fulminant hepatic failure. **Treatment** consists of administration of copper-chelating drugs (penicillamine or trientine), with monitoring of urine copper excretion at intervals. Zinc salts often replace chelating agents after chelation therapy has successfully reduced excessive body copper stores. Adequate therapy must be continued for life to prevent liver and CNS deterioration.

Autoimmune Hepatitis

Immune-mediated liver injury may be primary or occur in association with other

autoimmune disorders, such as inflammatory bowel disease or systemic lupus erythematosus. **Diagnosis** is made on the basis of elevated serum total IgG and the presence of an autoantibody, most commonly antinuclear, anti-smooth muscle, or anti-liver-kidney microsomal antibody. Liver biopsy specimen shows the presence of a plasma cell-rich portal infiltrate with piecemeal necrosis. **Treatment** consists of corticosteroids initially, usually with the addition of an immunosuppressive drug after remission is achieved. Steroids are tapered gradually as tolerated to minimize glucocorticoid side effects. Many patients require lifelong immunosuppressive therapy, but some may be able to stop medications after several years under careful monitoring for recurrence.

Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease is characterized by the presence of macrovesicular fatty change in hepatocytes on biopsy. Varying degrees of inflammation and portal fibrosis may be present. This disorder occurs in obese children, sometimes in association with insulin-resistant (type 2) diabetes and hyperlipidemia. Children with marked obesity, with or without type 2 diabetes, who have elevated liver enzymes and no other identifiable liver disease are likely to have this condition. Nonalcoholic fatty liver disease can progress to significant fibrosis. Treatment is with weight loss and exercise. Vitamin E may have some benefit. Efforts should be made to control blood glucose and hyperlipidemia and promote weight loss. In general, the rate of progression to end-stage liver disease is slow.

CHAPTER 131

Pancreatic Disease

Pancreatic Insufficiency

Etiology and Epidemiology

The cause of inadequate pancreatic digestive function in 95% of cases is **cystic fibrosis** (see [Chapter 137](#)). The defect in *CFTR* chloride channel function results

in thick secretions in the lungs, intestines, pancreas, and bile ducts. In the pancreas, there is destruction of pancreatic function, often before birth. Some mutations result in less severe defects in *CFTR* function and later onset of lung disease and pancreatic insufficiency. Less common causes of pancreatic insufficiency are *Shwachman-Diamond* syndrome and *Pearson* syndrome in developed countries and severe malnutrition in developing countries.

Clinical Manifestations

Decision-Making Algorithm

Failure to Thrive

Children with pancreatic exocrine insufficiency have many bulky, foul-smelling stools each day, usually with visible oil or fat. They typically have voracious appetites because of massive malabsorption of calories from fat, complex carbohydrates, and proteins. Failure to thrive is uniformly present if diagnosis and treatment are not accomplished rapidly. It is important to distinguish children with malabsorption due to pancreatic disease from children with intestinal disorders that interfere with digestion or absorption. Appropriate testing should be performed to rule out conditions such as celiac disease and inflammatory bowel disease if any doubt about the state of pancreatic sufficiency exists.

Laboratory and Imaging Studies

Testing of pancreatic function is difficult. Direct measurement of enzyme concentrations in aspirated pancreatic juice is not routine and is technically difficult. Stools can be tested for the presence of maldigested fat, which usually indicates poor fat digestion. Measuring fecal fat can give either a qualitative assessment of fat absorption (fecal Sudan stain) or a semiquantitative measurement (72-hour fecal fat determination) of fat maldigestion. Another way to assess pancreatic function is to test for the presence of pancreatic enzymes in the stool. Of these, measuring **fecal elastase-1** by immunoassay seems to be the most accurate method of assessment. Depressed fecal elastase-1 concentration

correlates well with the presence of pancreatic insufficiency.

Treatment

Replacement of missing pancreatic enzymes is the best available therapy. Pancreatic enzymes are available as capsules containing enteric-coated microspheres. The coating on these spheres is designed to protect the enzymes from gastric acid degradation. For children unable to swallow capsules, the contents may be sprinkled on a spoonful of soft food, such as applesauce. Excessive use of enzymes must be avoided because high doses (usually >6,000 U/kg/meal) can cause colonic fibrosis. In infants, typical dosing is 2,000-4,000 U of lipase/120 mL of formula. In children younger than 4 years old, 1,000 U/kg/meal is given. For older children, 500 U/kg/meal is usual. This dose may be adjusted upward as required to control steatorrhea, but a dose of 2,500 U/kg/meal should not be exceeded. Use of H₂-receptor antagonists or proton pump inhibitors can increase the efficacy of pancreatic enzymes by enhancing their release from the microspheres and reducing inactivation by acid.

Acute Pancreatitis

Etiology and Epidemiology

The exocrine pancreas produces numerous proteolytic enzymes, including trypsin, chymotrypsin, and carboxypeptidase. These are produced as inactive proenzymes to protect the pancreas from autodigestion. Trypsin is activated after leaving the pancreas by enterokinase, an intestinal brush border enzyme. After activation, trypsin cleaves other proteolytic proenzymes into their active states. Protease inhibitors found in pancreatic juice inhibit early activation of trypsin; the presence of self-digestion sites on the trypsin molecule allows for feedback inactivation. Pancreatitis occurs when digestive enzymes are activated inside the pancreas, causing injury. Triggers for acute pancreatitis differ between adults and children. In the adult patient, most episodes are related to alcohol abuse or gallstones. In children, most cases are idiopathic or due to medications. Some cases are caused by pancreatic sufficient cystic fibrosis, hypertriglyceridemia, biliary microlithiasis, trauma, or viral infection. Collagen vascular disorders and parasite infestations are responsible for the remainder ([Table 131.1](#)).

TABLE 131.1

Causes of Acute Pancreatitis in Children

OBSTRUCTIVE

Cholelithiasis and biliary sludge
Choledochal cyst
Pancreas divisum
Anomalous junction of biliary and pancreatic ducts

OTHER

Trauma

Hyperlipidemia

Hypercalcemia

Autoimmune

Clinical Manifestations

Decision-Making Algorithms

Abdominal Pain

Vomiting

Hyponatremia

Hypocalcemia

Acute pancreatitis presents with relatively rapid onset of pain, usually in the epigastric region. The pain may radiate to the back and is nearly always aggravated by eating. The patient moves frequently to find a position of comfort. Nausea and vomiting occur in most cases. Pain is typically continuous and quite severe, usually requiring narcotics. Severe pancreatitis can lead to hemorrhage, visible as ecchymoses in the flanks (Grey Turner sign) or periumbilical region (Cullen sign). Rupture of a minor pancreatic duct can lead to development of a pancreatic pseudocyst, characterized by persistent severe pain and tenderness and a palpable mass. With necrosis and fluid collections, patients experiencing severe pancreatitis are prone to infectious complications, and the clinician must be alert for fever and signs of sepsis.

Laboratory and Imaging Studies

The diagnosis of acute pancreatitis is based on 2 of the following 3 criteria:

abdominal pain consistent with the disease (severe epigastric pain typically), serum amylase and/or lipase greater than 3 times the upper limit of normal, and/or characteristic findings on imaging. Acute pancreatitis can be difficult to diagnose. Pancreatic enzymes are released into the blood during pancreatic injury. Nonspecific elevations of the enzymes are common. As acute pancreatitis progresses, the amylase level tends to decline faster than lipase, making the latter a good choice for diagnostic testing late in the course of the disease.

Because enzyme levels are not 100% sensitive or specific, imaging studies are important for the diagnosis of pancreatitis. In acute pancreatitis, edema is present in all but the mildest cases. Ultrasound is capable of detecting this edema and should be performed as part of the overall diagnostic approach. If overlying bowel gas obscures the pancreas, a computed tomography (CT) scan allows complete visualization of the gland. CT scans should be done with oral and intravenous (IV) contrast agents to facilitate interpretation. Ultrasound and CT also can be used to monitor for the development of **pseudocysts** and for evidence of ductal dilation secondary to obstruction. The other important reason to perform imaging studies early in the course of pancreatitis is to rule out gallstones; the liver, gallbladder, and common bile duct all should be visualized. Magnetic resonance cholangiopancreatography may be used to detect anatomical variants causing pancreatitis.

Treatment

There are no proven specific therapies for acute pancreatitis. If a predisposing etiology is found, such as a drug reaction or a gallstone obstructing the sphincter of Oddi, this should be specifically treated. Fluid resuscitation is necessary because of vomiting and third space losses. Pain relief should be provided. Oral, nasogastric, or nasojejunal feedings can begin early if tolerated and may improve outcome. If this is not possible, parenteral nutrition is an option. Fewer complications and more rapid recovery occur with enteral feedings compared with parenteral nutrition. Antibiotics should be considered if the patient is febrile, has extensive pancreatic necrosis, or has laboratory evidence of infection. A broad-spectrum antibiotic, such as imipenem, is considered the best choice.

Chronic Pancreatitis

Etiology and Epidemiology

Chronic pancreatitis is defined as recurrent or persistent attacks of pancreatitis, which have resulted in irreversible morphological changes in pancreatic structure. These include scarring of the ducts with irregular areas of narrowing and dilation (beading), fibrosis of parenchyma, and loss of acinar and islet tissue. Pancreatic exocrine insufficiency and diabetes mellitus may result from unremitting chronic pancreatitis. Most patients have discrete attacks of acute symptoms occurring repeatedly, but chronic pain may be present. The causes of chronic pancreatitis include hereditary pancreatitis and milder phenotypes of cystic fibrosis associated with pancreatic sufficiency. Familial disease is caused by one of several known mutations in the trypsinogen gene. These mutations obliterate autodigestion sites on the trypsin molecule, inhibiting feedback inhibition of trypsin digestion. Genetic testing is readily available for these mutations. Genetic testing for cystic fibrosis can be performed, but must include screening for the less common mutations associated with pancreatic sufficiency. Sweat chloride testing is less expensive and is abnormal in most. Less commonly, mutations in the *SPINK1* gene, which codes for pancreatic trypsin inhibitor, and *PRSS1*, a mutation of cationic trypsinogen, or *CTRC*, a mutation in chymotrypsin C are found.

Clinical Manifestations

Children with chronic pancreatitis initially present with recurring attacks of acute pancreatitis. Injury to the pancreatic ducts predisposes these children to continued attacks owing to scarring of small and large pancreatic ducts, stasis of pancreatic secretions, stone formation, and inflammation. Loss of pancreatic exocrine and endocrine tissue over time can lead to exocrine and endocrine deficiency. More than 90% of the pancreatic mass must be destroyed before exocrine deficiency becomes clinically apparent; this is a late complication that does not occur in all cases. Chronic pain is a serious problem in most affected individuals. These patients have many episodes; many do not require hospitalization.

Laboratory and Imaging Studies

Laboratory diagnosis of chronic pancreatitis is similar to acute pancreatitis, but with more severe loss of pancreatic tissue, it becomes less likely that the patient

presents with elevation of amylase or lipase. Monitoring also should include looking for consequences of chronic injury, including diabetes mellitus and compromise of the pancreatic and biliary ducts. Pancreatic and biliary imaging has been accomplished by endoscopic retrograde cholangiopancreatography (ERCP). ERCP offers the possibility of therapeutic intervention to remove gallstones, dilate strictures, and place stents to enhance flow of pancreatic juice. Magnetic resonance cholangiopancreatography is an alternative to ERCP. Plain abdominal x-rays may show pancreatic calcifications. Diagnostic testing for the etiology of chronic pancreatitis should include genetic testing for hereditary pancreatitis and cystic fibrosis and sweat chloride determination.

Treatment

Treatment is largely supportive. Potential but unproven therapies include the use of daily pancreatic enzyme supplements, octreotide (somatostatin) to abort early attacks, low-fat diets, and daily antioxidant therapy. Care must be taken that extreme diets do not result in nutritional deprivation. Interventional ERCP to dilate large strictures and remove stones and surgical pancreatic drainage procedures to decompress dilated pancreatic ducts by creating a side-to-side pancreaticojejunostomy may have some value.

CHAPTER 132

Peritonitis

Etiology and Epidemiology

The peritoneum consists of a single layer of mesothelial cells that covers all intraabdominal organs. The portion that covers the abdominal wall is derived from the underlying somatic structures and is innervated by somatic nerves. The portion covering the viscera is derived from visceral mesoderm and is innervated by nonmyelinated visceral afferents. Inflammation of the peritoneum, or peritonitis, usually is caused by infection but may result from exogenous irritants introduced by penetrating injuries or surgical procedures, radiation, and endogenous irritants such as meconium. Infectious peritonitis can be an acute

complication of intestinal inflammation and perforation, as in appendicitis, or it can occur secondary to contamination of pre-existing ascites associated with renal, cardiac, or hepatic disease. In this setting, when there is no other intraabdominal source, it is referred to as **spontaneous bacterial peritonitis**. Spontaneous bacterial peritonitis is usually due to pneumococcus and less often to *Escherichia coli*.

Clinical Manifestations

Decision-Making Algorithm

Abdominal Pain

Peritonitis is characterized on examination by marked abdominal tenderness. Rebound tenderness also generally is quite pronounced. The patient tends to move very little owing to intense peritoneal irritation and pain. Fever is not always present, and absence of fever should not be regarded as contradictory to the diagnosis. Patients who are taking corticosteroids for an underlying condition, such as nephrotic syndrome, are likely to have little fever and reduced tenderness.

Laboratory and Imaging Studies

Blood tests should focus on identifying the nature of the inflammation and its underlying cause. An elevated white blood cell count, erythrocyte sedimentation rate, and C-reactive protein suggest infection. In children older than 5 years, appendicitis is the leading cause. Total serum protein, albumin, and urinalysis should be ordered to rule out nephrotic syndrome. Liver function tests should be performed to rule out chronic liver disease causing ascites. The best way to diagnose suspected peritonitis is to sample the peritoneal fluid with a needle or catheter (paracentesis). Peritoneal fluid in spontaneous bacterial peritonitis has a high neutrophil count of greater than 250 cells/mm³. Other tests that should be run on the peritoneal fluid include amylase (to rule out pancreatic ascites), culture, albumin, and lactate dehydrogenase concentration. For culture, a large sample of fluid should be placed into aerobic and anaerobic blood culture bottles

immediately on obtaining the sample.

Appendicitis may be identified by ultrasound or computed tomography (CT) scan. When other intraabdominal emergencies are suspected, such as midgut volvulus, meconium ileus, peptic disease, or any other condition predisposing to intestinal perforation, specific testing should be performed.

Treatment

Peritonitis caused by an intraabdominal surgical process, such as appendicitis or a penetrating wound, must be managed surgically. Spontaneous bacterial peritonitis should be treated with a broad-spectrum antibiotic with good coverage of resistant pneumococcus and enteric bacteria. Cefotaxime is generally effective as initial therapy while awaiting culture and sensitivity results. Anaerobic coverage with metronidazole should be added whenever a perforated viscus is suspected.

Pearls for Practitioners

Chapter 126

Digestive System Assessment

- Take a careful history and perform a thorough but focused physical examination, using your findings to form a diagnostic hypothesis and plan.
- Surgical emergencies, such as bowel obstruction or appendicitis, must be identified rapidly in children with acute abdominal pain. Common distinguishing characteristics include pain that is accompanied by vomiting, tenderness, abdominal wall rigidity, or

guarding.

- Extraintestinal disorders (lower lobe pneumonia, pyelonephritis) may produce abdominal pain.
- When evaluating recurrent abdominal pain, a complete work-up must include not only a medical evaluation, but also assessment of functional impairment, such as missing school, and consideration of psychosocial factors influencing the pain.
- Recurrent abdominal pain is seen in 10% of school age children and is often functional.
- For patients with emesis, remember to distinguish between true vomiting (forceful retching, preceded usually by nausea) from regurgitation (effortless, usually no nausea) when considering the differential diagnosis.
- Emesis in a neonate suggests a gastrointestinal (GI) obstruction such as pyloric stenosis or volvulus; an inborn error of metabolism should be considered in the presence of acidosis, hypoglycemia, or hyperammonemia.
- When treating a patient with significant gastrointestinal bleeding, focus on fluid resuscitation and tissue oxygenation/perfusion as your first priority.
- Acute diarrhea is often due to viral gastroenteritis (rotavirus, norovirus). Dysentery often presents with fever, pain, and diarrhea with blood and mucus.
- Painless rectal bleeding in a 2-year-old would suggest a Meckel diverticulum; older patients may also have a polyp.

Chapter 127

Oral Cavity

- Many systemic disorders affect the oral cavity, which careful examination can demonstrate. Examples include Peutz-Jeghers syndrome, Crohn disease, gastroesophageal reflux disease

(GERD), Addison disease, and leukemia.

- Deciduous teeth erupt in a predictable sequence and age. Significant delayed eruption may be associated with hypothyroidism, Down syndrome, and other disorders.
- Cleft lip and palate are common birth defects; combined cleft lip and palate is more common in males and isolated cleft palate is more likely to be associated with other congenital malformations.

Chapter 128

Esophagus and Stomach

- As many as half of infants will have physiological reflux. The majority of infants do not benefit from acid reduction therapy.
- Gastroesophageal reflux *disease* occurs when there are complications of reflux such as poor growth, esophagitis, abdominal or chest pain, or respiratory problems.
- Reflux cannot be diagnosed based on imaging as this is only a snapshot in time. Upper gastrointestinal series evaluates for anatomical abnormalities.
- In an older child who has not improved with lifestyle changes, a trial with a proton pump inhibitor is recommended.
- Eosinophilic esophagitis should be considered in children with poor feeding or growth, chronic abdominal pain or vomiting, and in children with dysphagia or recurrent food impactions.
- Diagnosis of eosinophilic esophagitis requires endoscopy and biopsy. Overlap of findings is seen with gastroesophageal reflux disease.
- Treatment of eosinophilic esophagitis includes dietary changes or topical glucocorticoid therapy.
- The six food elimination diet (cow milk, soy, wheat, egg, peanuts, fish/shellfish) has been recommended as an approach to eosinophilic esophagitis (EoE).

- A neonate with poor feeding and drooling with a nasogastric tube on x-ray coiled in the neck most likely has a tracheoesophageal fistula.
- Button batteries in the esophagus must be removed immediately. Two or more ingested magnets should be removed as soon as possible due to risk of perforation.
- Infants with pyloric stenosis develop hypochloremic, hypokalemic metabolic alkalosis.
- The diagnosis of pyloric stenosis may be made with abdominal ultrasonography.
- *Helicobacter pylori* cannot be reliably tested by blood tests. Urea breath hydrogen testing, endoscopy with biopsies, and fecal antigen testing can be considered.
- Cyclic vomiting syndrome is a migraine variant that leads to repeated bouts of repetitive vomiting over hours to days.

Chapter 129

Intestinal Tract

- Bile-stained emesis in an infant may suggest a volvulus.
- Intestinal malrotation may lead to a volvulus with subsequent intestinal infarction.
- Passage of first meconium after 24 hours of life should raise suspicion for Hirschsprung disease.
- Hirschsprung disease is diagnosed by suction rectal biopsy.
- Duodenal atresia is associated with trisomy 21 and prematurity. There may also be polyhydramnios.
- Suspect Crohn disease in a child with poor growth, delayed puberty, fatigue, and abdominal pain. Initial testing may show anemia, thrombocytosis, elevated sedimentation rate and C-reactive protein, and hypoalbuminemia, but can be normal.
- Fecal calprotectin is an inflammatory marker of intestinal

inflammation. Normal fecal calprotectin makes inflammatory bowel disease diagnosis unlikely.

- Recommended serological testing for celiac disease is the tissue transglutaminase antibody immunoglobulin A (IgA).

Confirmation of the diagnosis by duodenal biopsy is recommended prior to initiating a gluten-free diet.

- Celiac disease is associated with type 1 diabetes, thyroiditis, Turner syndrome, and trisomy 21.

- Intussusception is a common cause of acute colicky abdominal pain in toddlers; there may also be rectal bleeding and intestinal obstruction.

- The diagnosis of intussusception is suggested by abdominal ultrasonography but confirmed and treated by barium or air enema.

- Appendicitis can occur at any age but is most common in adolescents and young adults.

- Periumbilical pain followed by nausea followed by right lower quadrant pain is suggestive of appendicitis.

Chapter 130

Liver Disease

- Infants with jaundice that persists beyond a few weeks of life should have both total and direct (conjugated) bilirubin measured to assure that cholestasis is not missed.

- Neonatal giant cell hepatitis may be due to cytomegalovirus (CMV), herpes simplex, or syphilis.

- Alpha 1 antitrypsin deficiency may present like neonatal hepatitis.

- Alagille syndrome presents with chronic cholestasis due to paucity of bile ducts and is associated with itch, butterfly vertebra, and ocular posterior embryotoxon.

- Cholestasis in infants requires prompt investigation to identify treatable causes such as biliary atresia, choledochal cyst, and certain disorders of metabolism.
- Work-up of hepatitis in children requires consideration of more than just the classic hepatitis viruses and should include evaluation for autoimmune hepatitis, Wilson disease, and biliary obstruction, as well as measures of liver function.
- Wilson disease is associated with low serum ceruloplasmin and elevated urine copper.
- Consultation with a major referral center should be sought for any child with acute severe hepatitis or chronic hepatitis.

Chapter 131

Pancreatic Disease

- Fecal elastase is the preferred test for pancreatic insufficiency.
- Cystic fibrosis is the most common cause of pancreatic insufficiency in the United States.
- The diagnosis of acute pancreatitis is based on symptoms of severe epigastric abdominal pain and tenderness, increase of amylase and/or lipase more than three times the upper limit of normal, and/or imaging findings of pancreatic inflammation.
- Complications of pancreatitis include shock, pancreatic pseudocyst formation, and pancreatic abscess.
- Patients with pancreatitis may feed enterally if tolerated.
- In patients with recurrent pancreatitis, consider hereditary disorders such as cystic fibrosis or familial pancreatitis involving mutations in *CFTR*, *PRSS1*, *SPINK1* or *CTRC*.

Chapter 132

Peritonitis

- Acute abdominal pain must be investigated rapidly with a comprehensive history and physical examination.
- When peritonitis is suspected, appropriate laboratory and imaging studies should be ordered to reveal underlying conditions, such as appendicitis.
- Nephrotic syndrome, heart failure, and chronic liver disease are associated with an increased risk of spontaneous bacterial peritonitis due to chronic presence of ascites.
- Spontaneous bacterial peritonitis is most commonly caused by *Streptococcus pneumoniae* or by *Escherichia coli*.
- Paracentesis is required to accurately diagnose pancreatitis.
- Analysis of ascites fluid obtained with a needle should include culture, cell count with differential, amylase, albumin, and lactate dehydrogenase.

Pectus Excavatum; Pneumothorax; Pleural Effusion; Parapneumonic Effusion

Acute and chronic respiratory diseases are common in pediatrics. Children with respiratory problems typically present with symptoms, although abnormal imaging may at times precede physical findings. The underlying etiology of

childhood respiratory diseases includes the following: genetic abnormalities (e.g., cystic fibrosis); anatomical differences (e.g., laryngomalacia); incomplete maturation (e.g., bronchopulmonary dysplasia); iatrogenic effects (e.g., ventilator-associated injury); immunological disorders (e.g., severe combined immunodeficiency); infectious diseases (e.g., croup or pneumonia); environmental exposures (e.g., pollutants); and extrapulmonary consequences (e.g., congenital heart disease). The optimal functioning of the entire respiratory system allows children not only to survive but to thrive.

CHAPTER 133

Respiratory System Assessment

Anatomy of the Respiratory System

Air enters the **nose** and passes over the large surface area of the **nasal turbinates**, which warm, humidify, and filter the inspired air. Secretions draining from the paranasal sinuses are carried to the **pharynx** by the mucociliary action of the ciliated respiratory epithelium. Enlarged lymphoid tissue can obstruct airflow through the nasopharynx (adenoids) or the posterior pharynx (tonsils).

The **epiglottis** protects the larynx during swallowing by deflecting material toward the esophagus. The **arytenoid cartilages**, which assist in opening and closing the vocal folds, are less prominent in children than in adults. The opening formed by the vocal folds (the **glottis**) is V-shaped, with the apex of the V being anterior. Below the vocal folds, the walls of the **subglottic space** converge toward the cricoid portion of the trachea. In children under 3 years of age, the cricoid ring is the narrowest portion of the airway. In older children and adults it is the glottis. C-shaped cartilage, extending approximately 320 degrees around the airway circumference, supports the **trachea** and **mainstem bronchi**. The posterior wall of the trachea is membranous, allowing airway caliber to change during inspiration and expiration. Beyond the lobar bronchi, cartilaginous support of the airways becomes discontinuous but persists until the terminal **bronchioles**. Airway formation and branching is complete at birth, although length and caliber continue to increase until final adult height is

achieved.

The right lung has three lobes (upper, middle, lower) and comprises approximately 55% of the total lung volume. The left lung has two lobes (upper, lower); the inferior division of the left upper lobe, the lingula, is analogous to the right middle lobe. The **lung parenchyma**, where gas exchange occurs, is comprised of the respiratory bronchioles, alveolar ducts, and alveoli. **Oxygen** (O₂) and **carbon dioxide** (CO₂) must traverse alveolar and capillary membranes and the **interstitium** to maintain adequate oxygenation and ventilation to meet the metabolic demands of the body.

The pediatric lung has tremendous capacity for growth. A full-term infant has approximately 25 million alveoli; an adult nearly 300 million alveoli. The growth of new alveoli occurs during the first 2 years of life and is complete by 8 years of age. After this time, lung volume increases primarily by increase in alveolar dimensions, with new alveoli rarely formed.

Pulmonary Physiology

Pulmonary Mechanics

The major function of the lungs is to exchange O₂ and CO₂ between the atmosphere and the blood. The anatomy of the airways, mechanics of the respiratory muscles and rib cage, nature of the alveolar-capillary interface, pulmonary circulation, tissue metabolism, and neuromuscular control of ventilation all influence gas exchange.

Air enters the lungs when intrathoracic pressure is less than atmospheric pressure. Negative intrathoracic pressure is generated by contraction and lowering of the **diaphragm** during normal inspiration. The accessory muscles of inspiration (**external intercostal**, **scalene**, and **sternocleidomastoid muscles**) are not used during quiet breathing but are recruited during exercise or in disease states to raise and enlarge the rib cage. Exhalation is normally passive, but with active exhalation the **abdominal** and **internal intercostal muscles** are recruited.

During normal breathing at rest, lung volumes are usually in the midrange of inflation ([Fig. 133.1](#)). **Tidal volume (TV)** is the amount of air inspired with each *relaxed* breath. The volume of gas retained in the lung at the end of a *relaxed* exhalation is the **functional residual capacity (FRC)**. This gas volume maintains exchange of O₂ between breaths. **Total lung capacity (TLC)** is the volume of gas in the lungs at the end of *maximal* inhalation and **residual volume**

(RV) is the volume of gas left in the lungs at the end of a *maximal* exhalation. **Vital capacity (VC)** is the maximal amount of air that can be forcibly expelled from the lungs and is the difference between TLC and RV.

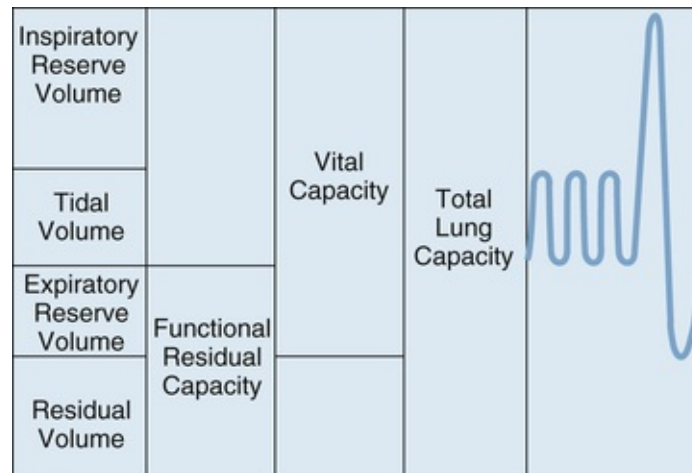

FIGURE 133.1 Lung volumes and capacities. Vital capacity and its subdivisions can be measured by spirometry, but calculation of residual volume requires measurement of functional residual capacity by body plethysmography, helium dilution, or nitrogen washout. (From Andreoli TE, Bennett JC, Carpenter CJ, et al., eds. *Cecil Essentials of Medicine*. 4th ed. Philadelphia: WB Saunders; 1997:127.)

Airway resistance is influenced by the diameter and length of the conducting airways, the viscosity of gas, and the nature of the airflow. During quiet breathing, airflow in the smaller airways is laminar (streamlined). At higher flow rates, turbulent flow increases resistance. Resistance is inversely proportional to the fourth power of the radius of the airway, so relatively small changes in airway diameter can result in large changes in airway resistance. Excessive airway secretions, bronchospasm, mucosal edema, stenosis, foreign bodies, loss of airway wall integrity (bronchiectasis), and airway compression may all produce symptomatic increases in airway resistance. Diseases that impact airway resistance, particularly lower airway resistance, fall into the category of **obstructive airways disease**.

Lung compliance (change in volume for a given change in pressure) is a measure of the ease with which the lung can be inflated. Processes that decrease lung compliance (surfactant deficiency, pulmonary fibrosis, pulmonary edema) may lead to **restrictive lung disease**. Restrictive lung disease can also result from respiratory muscle weakness, pleural disease (effusion, inflammation, or mass), thoracic stiffness (scoliosis), and abdominal distention.

Respiratory Gas Exchange

Alveolar ventilation is defined as the exchange of CO₂ between the alveoli and ambient air. Normally, about 30% of each tidal breath fills the conducting airways (**anatomical dead space**). Because the anatomical dead space is relatively constant, increasing the TV generally increases the efficacy of ventilation. Conversely, if TV decreases, then the dead space/TV ratio increases and alveolar ventilation decreases.

Gas exchange depends on alveolar ventilation, **pulmonary capillary blood flow**, and the **diffusion** of gases across the alveolar-capillary membrane. Exchange of CO₂ is determined by alveolar ventilation, whereas the exchange of O₂ is influenced primarily by the regional matching of ventilation (V) with pulmonary blood flow (Q) (V/Q matching). V/Q matching is maintained, in part, by **hypoxic pulmonary vasoconstriction** (local constriction of the pulmonary vessels in areas that are underventilated). There are five causes of **hypoxemia** (Table 133.1). Disorders resulting in **V/Q mismatching** (such as pneumonia and atelectasis) are the most common causes of hypoxemia in children.

TABLE 133.1

Causes of Hypoxemia

CAUSE	EXAMPLE(S)	PaO ₂	PaCO ₂	PaO ₂ IMPROVES WITH SUPPLEMENTAL OXYGEN
Ventilation-perfusion mismatch	Asthma Bronchopulmonary dysplasia Pneumonia Atelectasis	↓	Normal, ↓, or ↑	Yes
Hypoventilation	Apnea Narcotic overdose Neuromuscular disease	↓	↑	Yes
Extrapulmonary shunt	Cyanotic heart disease	↓	Normal or ↑	No
Intrapulmonary shunt	Pulmonary arteriovenous malformation Atelectasis	↓	Normal or ↑	No
Low FiO ₂	High altitude	↓	↓	Yes
Diffusion defect	Scleroderma Hepatopulmonary syndrome Pulmonary fibrosis	↓	Normal	Yes

FiO_2 , Fraction of inspired oxygen; $Paco_2$, arterial partial pressure of carbon dioxide; Pao_2 , arterial partial pressure of oxygen.

Lung Defense Mechanisms

The lungs are constantly exposed to particles and infectious agents. The **nose** is the primary filter for large particles. Particles less than 10 μm in diameter may reach the trachea and bronchi and deposit on the mucosa. Particles less than 1 μm may reach the alveoli. **Ciliated epithelium** lining the airways from the larynx to the bronchioles continuously propels a thin layer of mucus toward the mouth. **Alveolar macrophages** and **polymorphonuclear cells** engulf particles and pathogens that have been opsonized by locally secreted immunoglobulin (Ig)A antibodies or transudated serum antibodies.

Cough is a critically important mechanism for protecting the lungs from infection. It may be voluntary or generated by reflex irritation of the nose, sinuses, pharynx, larynx, trachea, bronchi, or bronchioles. Cough is a rapid, forceful expiration intended to clear the airways of debris and secretions. Effective cough requires the ability to (1) inhale to near TLC, (2) close and open the glottis, and (3) contract abdominal muscles to forcibly exhale. Loss of the ability to cough, as with neuromuscular weakness, results in poor secretion clearance and predisposes to atelectasis and pneumonia. Persistent cough suggests chronic irritation at any of these sites due to infectious (e.g., chronic bronchitis), allergic (e.g., postnasal drip, asthma), or chemical (e.g., inhalation or aspiration) triggers.

History

Common respiratory complaints in children include cough, labored or noisy breathing, chest pain, and exercise intolerance. The complete respiratory history includes **onset**, **duration**, and **frequency** of symptoms. It is important to obtain information concerning severity (hospitalizations, missed school days) and pattern (acute, chronic, or intermittent), including factors leading to worsening or improvement. Exposure to others with respiratory illness and **environmental factors** (such as pet dander, tobacco smoke, or chemical fumes) should be reviewed. For infants, a **feeding history** should be obtained, including questions of coughing or choking with eating or drinking. Family history should include questions about asthma and atopy, immune deficiencies, and cystic fibrosis.

Decision-Making Algorithm

Cough

Cough

A thorough history focused on the factors above is perhaps the most useful tool in determining the underlying etiology of cough. Morning cough may be due to the accumulation of excessive secretions during the night from sinusitis, allergic rhinitis, or bronchial infection. Nighttime cough is a hallmark of asthma and can also be caused by gastroesophageal reflux disease or postnasal drip. Cough with exercise is highly suggestive of exercise-induced asthma/bronchospasm. Habit cough can masquerade as organic disease but should disappear when children are distracted or during sleep. Paroxysmal cough (especially associated with cyanosis) suggests pertussis, whereas a repetitive, staccato cough occurs in chlamydial infections in infants. A harsh, brassy, seal-like cough suggests croup, tracheomalacia, or psychogenic (habit) cough. Sudden onset of cough after a choking episode suggests foreign body aspiration.

Physical Examination

Decision-Making Algorithms

Stridor
Wheezing
Cyanosis

Clothing should be removed from the upper half of the child's body so that the thorax may be inspected while maintaining modesty for adolescents. It is optimal to observe the respiratory pattern, rate, and work of breathing while the child is quiet, noting the shape and symmetry of the chest wall and the anteroposterior (AP) diameter.

Any factor that impairs respiratory mechanics is likely to increase the **respiratory rate**. However, nonrespiratory causes of tachypnea include fever,

pain, and anxiety. Respiratory rates vary with age (Table 133.2).

TABLE 133.2

Normal Respiratory Rates by Age

AGE	RESPIRATORY RATE (BREATHS PER MINUTE)
Birth-9 months	30-60
9 months-2 years	24-40
2-5 years	20-36
5-12 years	14-26
12 years-adult	12-20

It is important to observe the respiratory **pattern** and **degree of effort** (work of breathing). Abnormal respiratory patterns are detailed in Table 133.3. Increased work of breathing can be described as inspiratory (**intercostal, supraclavicular, or substernal retractions, nasal flaring**) or expiratory (use of abdominal muscles to actively exhale). Causes of increased work of breathing during inspiration include extrathoracic airway obstruction (laryngomalacia, croup, subglottic stenosis) and/or decreased pulmonary compliance (e.g., pneumonia, pulmonary edema). Increased expiratory work of breathing usually indicates intrathoracic airway narrowing (e.g., asthma, tracheomalacia). **Grunting** (forced expiration against a partially closed glottis) is often seen in small children with respiratory distress but may also be a manifestation of pain.

TABLE 133.3

Abnormal Breathing Patterns

PATTERN	FEATURES	CAUSES
Tachypnea	Respiratory rate > normal for age	Restrictive physiology, fever, increased metabolic demands, stress
Bradypnea	Respiratory rate < normal for age	Sleep, sedating medications, CNS injury, metabolic alkalosis
Hyperpnea	Increased depth of breathing, normal rate	Stress, exercise, metabolic acidosis
Periodic breathing	Brief pauses (<10 sec) followed by rapid, shallow breaths	Normal variant for preterm and term infants, prominent in sleep
Kussmaul respiration	Increased rate, increased tidal volume, regular deep respiration	Metabolic acidosis, especially diabetic ketoacidosis, uremia
Cheyne-Stokes respiration	Cyclic pattern of waxing and waning of depth of breathing interposed with apnea	CNS injury (brainstem), elevated intracranial pressure, heart failure, uremia

Biot respiration	Rapid, deep respiration followed by apnea	CNS injury or infection
Apneustic respiration	Long inspiration with short or staccato expiration	Brainstem lesion
Agonal respiration	Slow rate, variable tidal volume	Shock, sepsis, or asphyxia

CNS, Central nervous system.

When attempting to determine the cause of a respiratory complaint, it is useful to auscultate over all potential sites of pathology, including the nose and mouth, neck, large airways (central chest and back), and all lobes of both lungs (anterior and posterior, upper and lower, as well as lateral chest wall).

Stridor is a harsh, monophonic sound caused by a partially obstructed large airway, more commonly heard on inspiration and localized to the neck. **Wheezing** is produced by partial obstruction of the smaller lower airways, more commonly heard during exhalation and localized to the chest. Wheezes can be monophonic and low-pitched (usually from large, central airways) or high-pitched and musical (from small peripheral airways). Secretions in the intrathoracic airways may produce wheezing but more commonly result in irregular sounds called **rhonchi**. Fluid or secretions in small airways may produce sounds characteristic of crumpling cellophane (**crackles** or **rales**). Having the child take a deep breath and exhale forcefully will accentuate many abnormal lung sounds. **Decreased, absent, or asymmetric breath sounds** may be due to atelectasis, lobar consolidation (pneumonia), thoracic mass, or a pleural effusion. Observation of respiratory rate, work of breathing, tracheal and cardiac deviation, and chest wall motion, combined with percussion and auscultation, help to identify intrathoracic disease ([Table 133.4](#)).

TABLE 133.4

Physical Signs of Pulmonary Disease

DISEASE PROCESS	MEDIASTINAL DEVIATION	CHEST MOTION	VOCAL FREMITUS	PERCUSSION	BREATH SOUNDS
Consolidation	No	Reduced over area	Increased	Dull	Bronchial or reduced
Bronchospasm	No	Hyperexpansion with limited motion	Normal or decreased	Hyperresonant	Normal to decreased
Atelectasis	Shift toward affected side	Reduced over area	Decreased	Dull	Reduced
Pneumothorax	With tension: shift to	Reduced over PMI	None	Resonant	None

	the opposite side				
Pleural effusion	If large: shift to opposite side	Reduced over area	None or reduced	Dull	None
Interstitial process	No	Reduced	Normal to increased	Normal	Normal

*In egophony, e sounds like a (may be a sign of consolidation but also is associated with moderate-sized pleural effusions).

†In pectoriloquy, words/voice sounds clearer over the affected site (associated with consolidation and cavitory lesions).

PMI, Point of maximum impulse.

Modified from Andreoli TE, Bennett JC, Carpenter CJ, et al., eds. *Cecil Essentials of Medicine*. 4th ed. Philadelphia: WB Saunders; 1997:115.

Digital clubbing (Fig. 133.2) is seen in cystic fibrosis and in other, less common chronic pulmonary diseases (such as interstitial lung disease). It is not associated with asthma, so its presence should heighten concern for other diagnoses. Clubbing may also be present in nonpulmonary chronic diseases (cardiac, gastrointestinal, or hematological) or, rarely, as a familial trait.

FIGURE 133.2 Clubbing of the fingers. There is increased curvature and loss of nail angle. This child has cystic fibrosis. (From Lissauer T, Clayden G, eds. *Illustrated Textbook of Pediatrics*. 4th ed. London: Mosby; 2012. Fig 2.6a.)

Diagnostic Measures

Imaging Techniques

Chest radiographs are useful in assessing respiratory disease in children. In

addition to determining lung abnormalities, they provide information about the bony thorax (rib or vertebral abnormalities), the heart (cardiomegaly, pericardial effusion), and the great vessels (right aortic arch/vascular rings, rib notching). Chest radiographs should be obtained in both the posteroanterior (PA) and lateral projections and, if possible, following a full inspiration. Estimation of lung hyperinflation based on a single PA view is unreliable; flattened diaphragms and an increased AP diameter on lateral projection are a better indicator of hyperinflation. Increased density on chest radiograph can usually be classified as *blood, water, pus, or tissue*, with clinical features (e.g., fever or known cardiac disease) necessary to reach final conclusions. **Expiratory** and **decubitus views** may be useful to detect partial bronchial obstruction due to an aspirated foreign body, because the affected lung or lobe does not deflate on exhalation. Decubitus films can also help to differentiate pleural effusion from alveolar infiltrate.

A **barium esophagram** may be valuable in diagnosing disorders of swallowing (dysphagia) and esophageal motility, vascular rings (esophageal compression), tracheoesophageal fistulas, and, to a lesser extent, gastroesophageal reflux. When evaluating for a tracheoesophageal fistula, contrast material must be instilled under pressure via a catheter with the distal tip situated in the esophagus (see [Chapter 128](#)).

Computed tomography (CT) of the chest is the imaging tool of choice for evaluating masses, interstitial lung disease, and bronchiectasis, as well as delineating pleural from parenchymal lesions. CT scans with intravenous contrast provide excellent information about the pulmonary vasculature and great vessels, are useful for characterizing congenital pulmonary malformations, and can detect pulmonary embolism. The speed of current CT scanners makes it possible to scan most children without sedating them; however, sedation may be required in infants and toddlers to decrease motion artifact. **Magnetic resonance imaging (MRI)**, useful in visualizing cardiac and great vessel anatomy and mediastinal lesions, is less useful for evaluation of pulmonary parenchymal lesions. **Ultrasonography** can be used to delineate some intrathoracic masses and is the imaging procedure of choice for assessing size and character of parapneumonic effusion/empyema. It is also useful for assessing diaphragmatic motion in small children.

Measures of Respiratory Gas Exchange

A properly performed **arterial blood gas** analysis provides information about

the effectiveness of both oxygenation and ventilation. As arterial samples are difficult to obtain, capillary and venous blood samples are more commonly used. Capillary or venous samples should not be used to assess oxygenation. The partial pressure of carbon dioxide (PCO_2) from a capillary sample is similar to that from arterial blood. The PCO_2 in venous samples is approximately 6 mm Hg higher than arterial PCO_2 .

There are both respiratory and metabolic causes of acidosis (see [Chapter 37](#)). In the presence of an alkalosis or acidosis, respiratory compensation (altering PCO_2 to maintain a normal pH) can occur within minutes, but renal compensation (altering the serum bicarbonate level) may not be complete for several days. Since both the respiratory and metabolic compensation are incomplete, pH will remain on the side of the primary insult (whether acidosis or alkalosis).

Pulse oximetry measures the O_2 saturation of hemoglobin by measuring the blood absorption of two or more wavelengths of light. It is noninvasive, easy to use, and reliable. Because of the shape of the oxyhemoglobin dissociation curve, O_2 saturation does not decrease much until the partial pressure of oxygen (PO_2) reaches approximately 60 mm Hg. Pulse oximetry may not accurately reflect true O_2 saturation when abnormal hemoglobin is present (carboxyhemoglobin, methemoglobin), when perfusion is poor, or if no light passes through to the photodetector (nail polish).

The measurement of PCO_2 is accomplished most reliably by blood gas analysis. However, there are noninvasive monitors that record exhaled PCO_2 (**end-tidal CO_2**), which is representative of alveolar PCO_2 . End-tidal PCO_2 measurements are most commonly used in intubated and mechanically ventilated patients, but some devices can measure PCO_2 at the nares. **Transcutaneous electrodes** can be used to monitor PCO_2 at the skin surface, but are less accurate. Noninvasive techniques of CO_2 measurement are best suited for detecting trends rather than for providing absolute values.

Pulmonary Function Testing

Measurement of lung volumes and airflow rates using **spirometry** are important in assessing pulmonary disease. Most children above 6 years of age can perform spirometry. The patient inhales to TLC and then forcibly exhales until no more air can be expelled. During the forced expiratory maneuver, **forced vital**

capacity (FVC), forced expired volume in the first second (FEV₁), and forced expiratory flow (FEF) rates are measured. These are compared to predicted values based on patient age, gender, and race, but rely mostly on height. Severity of disease is quantified by calculated percentage of predicted values. The **peak expiratory flow rate (PEFR)** can be obtained with a simple hand-held device and may be useful for home monitoring of older children with asthma; however, it is *highly dependent on patient effort*, and values must be interpreted with caution. Measurement of **TLC, FRC, and RV** require **body plethysmography**. Helium dilution can also measure TLC and RV by determining the magnitude of dilution of inhaled helium in the air within the lung, but may underestimate air trapping.

Abnormal results on pulmonary function testing can be used to categorize **obstructive** (low flow rates and/or increased RV) or a **restrictive lung disease** (low FVC and TLC, with relative preservation of flow rates). When the FEV₁ is decreased to a greater extent than the FVC (**FEV₁/FVC ratio** <80%), obstructive lung disease is diagnosed. The mean midexpiratory flow rate (**FEF_{25-75%}**) is a more sensitive measure of small airways disease than the FEV₁, but is also more variable. Spirometry can detect reversible airway obstruction characteristics of asthma when a significant improvement in FEV₁ (>12%) or in FEF_{25-75%} (>25%) following inhalation of a bronchodilator is measured. **Inhalation challenge tests** using methacholine, histamine, or cold, dry air are used to assess airway hyperreactivity but require sophisticated equipment and special expertise and should only be performed in a pulmonary function laboratory with experienced technicians.

Endoscopic Evaluation of the Airways

Endoscopic evaluation of the upper airways (**nasopharyngoscopy**) is performed with a flexible fiberoptic nasopharyngoscope to assess adenoid size, patency of the nasal passages, and abnormalities of the glottis. It is especially useful in evaluating stridor and assessing vocal cord motion/function and does not require sedation. Endoscopic evaluation of the subglottic space and intrathoracic airways can be done with either a flexible or rigid bronchoscope under anesthesia. **Flexible bronchoscopy** is useful in identifying dynamic or static airway abnormalities (stenosis, malacia, endobronchial lesions, excessive secretions) and to obtain airway samples for culture (**bronchoalveolar lavage**). **Rigid**

bronchoscopy is the method of choice for removing foreign bodies from the airways and performing other interventions, such as airway dilation. Transbronchial biopsies are rarely performed in children.

Examination of Sputum

Sputum specimens may be useful in evaluating lower respiratory tract infections but are difficult to obtain in children. Specimens containing large numbers of squamous epithelial cells or heavily contaminated with upper airway secretions may yield misleading results. Sputum in patients with lower respiratory tract bacterial infections often contains polymorphonuclear leukocytes and one predominant organism on culture. If sputum cannot be obtained, then bronchoalveolar lavage may be necessary for microbiologic diagnosis in selected situations. In patients with CF who are unable to expectorate sputum, specially processed throat cultures are used as surrogates for lower airway cultures.

Lung Biopsy

When less invasive methods fail to provide diagnoses in patients with pulmonary disease, a lung biopsy may be required. Concern for childhood interstitial lung disease, atypical infection (especially in an immunocompromised host), and evaluation of a mass/malformation are the most common indications for biopsy. CT-guided **needle biopsy** performed by an interventional radiologist is an option if limited histology is needed and the lesion is amenable to percutaneous approach (e.g., fungal nodules). Either a **thoracoscopic procedure** or a **thoracotomy** is preferred if thorough histological evaluation is desired.

Therapeutic Measures

Oxygen Administration

Any child in respiratory distress should be treated with **supplemental oxygen** at concentration sufficient to maintain *acceptable* O₂ saturation levels. Normal O₂ saturation is greater than 95%; however, lower saturations may be appropriate in certain clinical scenarios, such as preterm birth or congenital heart disease. It is not necessary to achieve 100% saturation. Patients requiring supplemental O₂ should be monitored with pulse oximetry, intermittently or continuously, or with

arterial blood gas measurements of PO_2 to allow titration to the lowest required O_2 concentration. The actual fraction of inspired oxygen (**FiO₂**) delivered to the patient can be quite variable and is affected by the delivery device used, device position, the child's size, and respiratory pattern.

For long-term administration of O_2 , a **nasal cannula** is the most widely used device, as it enables patients to eat and speak unhindered by the O_2 delivery system. **Humidified high flow nasal cannula** (HFNC) allows the provider to deliver greater flow rates of blended gas at a specific FiO₂. Though its use began in neonates as an alternative to continuous positive airway pressure (CPAP), it is now commonly used across the pediatric age spectrum. Depending on the size of the patient, the type of cannulae and device used, HFNC can deliver modest positive pressure, relieve dyspnea, and purge CO₂ from anatomical dead space to improve alveolar ventilation in addition to providing oxygenation. There are very limited options for provision of HFNC outside the hospital at this time. Supplemental O_2 may also be delivered by a variety of mask systems including a **simple mask** (delivers O_2 in L/min), a **Venturi mask** (blends to a specific FiO₂), and a **non-rebreather mask** with reservoir that can provide nearly 100% O_2 .

Aerosol Therapy

Therapeutic agents such as bronchodilators, corticosteroids, and antibiotics can be delivered to the lower respiratory tract by **dry powder inhaler** (DPI), **metered-dose inhaler** (MDI), or **nebulizer**. All of these devices are designed to generate small particles that can bypass the filtering action of the upper airway and deposit in the lower airways. Many factors influence drug deposition including patient technique, device used, age of the child, and breathing pattern. Nebulizers should be used with a face mask (infants) or mouthpiece (children and teens) to minimize loss of drug to ambient air. Plastic holding chambers (**spacers**) are available for all ages and should always be used with MDIs. DPIs require a single rapid, deep inhalation for optimal drug delivery, which is difficult for children under 6 years of age. MDIs and nebulizers are equally effective in delivering medications only if the technique is correct, so it is important to review this frequently and carefully with families ([Fig 133.3](#)).

FIGURE 133.3 Inhaled drug delivery in children. *A*, Proper use of a nebulizer with mouthpiece and *B*, Metered-dose inhaler with space and face mask. (*A*, From Hopper T. *Mosby's Pharmacy Technician*. 2nd ed. St Louis: Mosby; 2007. Fig 25.7; *B*, From Hockenberry MJ, Wilson D, eds. *Wong's Essentials of Pediatric Nursing*. 8th ed. St Louis: Mosby; 2009. Fig 23.5.)

Chest Physiotherapy and Clearance Techniques

When disease processes impair normal ciliary and cough function, **airway clearance therapy** may help maintain airway patency and secretion mobilization. Most methods work by moving secretions toward the central airways, from which they can be expectorated. **Chest percussion** or **pneumatic vests** are often used in young or neurologically impaired children; whereas older children can operate hand-held devices that generate expiratory back-pressure and vibration (*TheraPEP*, *Flutter*, *Acapella*, and *Aerobika*). Pneumatic (therapy) vests may also be used in older children and adolescents, especially those with cystic fibrosis. Children who are too weak to generate an effective cough benefit from the use of a mechanical insufflation-exsufflation device (CoughAssist), used in conjunction with chest physiotherapy. Chest physiotherapy is generally not beneficial for patients with asthma or pneumonia, and its effectiveness in patients with atelectasis has not been clearly established.

Intubation

If the upper airway is obstructed or mechanical ventilation is needed, it may be necessary to provide the patient with an **artificial airway**. This is best done by placing an endotracheal tube via the mouth or nose into the trachea (**intubation**).

Endotracheal tubes can damage the larynx and the airways if the tubes are of improper size and are not carefully maintained. The cricoid ring is the narrowest segment of a child's airway and is completely surrounded by cartilage, which makes it vulnerable to damage and subglottic stenosis. If the pressure created by the tube against the airway mucosa exceeds capillary filling pressure (roughly 35 cm H₂O), mucosal ischemia develops, leading to necrosis. Therefore a small air leak should always be maintained around the endotracheal tube to minimize the risk of mucosal damage. No clear guidelines are available regarding how long pediatric patients can be intubated without sustaining airway damage or when conversion to tracheostomy is indicated.

Intubation alters the physiology of the respiratory tract in many ways, not all of which are beneficial. It interferes with the humidification, warming, and filtration of inspired air and stimulates secretion production. Providing adequate humidification of inspired air and appropriate suctioning of the tube reduce the probability of occlusion by secretions. In addition to endotracheal tubes, the **laryngeal mask airway (LMA)** can be used to provide mechanical ventilation. This device consists of a tube with a soft mask at the distal end that is placed over the larynx, creating a seal without the trachea being instrumented. Although less invasive, the LMA is less secure, so it is generally limited to procedural anesthesia.

Tracheostomy

Tracheostomy is the surgical placement of an artificial airway into the trachea below the larynx. Congenital or acquired upper airway obstruction (see [Chapter 135](#)) is the most common indication for tracheostomy in children. In addition, if prolonged mechanical ventilation is required, elective tracheostomy can be performed to increase patient comfort and facilitate nursing care. Many children with tracheostomy tubes can be cared for at home, provided the caregivers are well trained and adequately equipped. Because the tracheostomy tube hampers the ability to phonate and may become occluded with secretions, leading to life-threatening airway obstruction, the child must be monitored carefully at all times.

Mechanical Ventilation

Patients who are unable to maintain adequate gas exchange may require

mechanical ventilation. Most modes of mechanical ventilation involve inflation of the lungs with gas using positive pressure. The inspiratory phase is active (air is pushed in), and exhalation is passive.

Mechanical ventilation often requires an artificial airway, although it can be provided *noninvasively* via tight-fitting nasal or full face masks. **Noninvasive ventilation** is particularly useful in patients with obstructive sleep apnea and neuromuscular disease who require support only part of the day or night, but it can also be used to assist ventilation continuously for patients in acute respiratory failure from a variety of causes.

No method of mechanical ventilation truly simulates natural breathing. All methods have their drawbacks and complications. Positive pressure is transmitted to the entire thorax and may impede venous return to the heart. The airways and lung parenchyma may be damaged by inflation pressures and high concentrations of inspired O_2 . In general, inflation pressures should be limited to those necessary to provide sufficient lung expansion for adequate ventilation and the prevention of atelectasis. Pressure-cycled and volume-cycled ventilators (conventional ventilation) are the most widely used modalities in pediatrics. High-frequency jet ventilation and high-frequency oscillatory ventilation are used often in neonatology and may be used in patients with severe lung disease who are failing conventional mechanical ventilation.

CHAPTER 134

Control of Breathing

Ventilation is controlled primarily by **central chemoreceptors** located in the medulla that respond to intracellular pH and PCO_2 levels (Fig. 134.1). To a lesser extent, ventilation is modulated by **peripheral receptors** located in the carotid and aortic bodies which respond predominantly to PO_2 . The central receptors are quite sensitive. Small acute changes in $Paco_2$ normally result in significant changes in **minute ventilation**. The ventilatory drive is not increased when the PCO_2 is chronically elevated, as the intracellular pH returns to normal levels following compensatory increases in the bicarbonate level. The peripheral receptors do not stimulate ventilation until the Pao_2 decreases to approximately

60 mm Hg. These receptors become important in patients with chronic PaCO_2 elevation who may have a blunted ventilatory response to CO_2 .

FIGURE 134.1 Schematic representation of the respiratory control system. The respiratory neurons in the brainstem receive information from the chemoreceptors, peripheral sensory receptors, and cerebral cortex. This information is integrated, and the resulting neural output is transmitted to the diaphragms and lungs. The sign denotes stimulation of the receptor. (From Andreoli TE, Bennett JC, Carpenter CJ, et al, eds. *Cecil Essentials of Medicine*. 4th ed. Philadelphia: WB Saunders; 1997:171.)

The output of the central respiratory center also is modulated by reflex mechanisms. Full lung inflation temporarily inhibits inspiratory effort in infants (**Hering-Breuer reflex**) through vagal afferent fibers. Other reflexes from the airways and intercostal muscles may influence the depth and frequency of respiratory efforts (see [Fig. 134.1](#)).

Apnea

Decision-Making Algorithm

Apnea

Etiology

Apnea is defined as the cessation of airflow due to either: lack of respiratory effort (**central apnea**) or upper airway obstruction (**obstructive apnea**; [Table 134.1](#)). Central apnea is more common in infants, and obstructive apnea, especially during sleep, is more common in older children.

TABLE 134.1

Categories of Apnea

DISEASE	EXAMPLE(S)	MECHANISM	SIGNS	TREATMENT
Apnea of prematurity	Premature (<36 wk)	Central control, upper airway obstruction	Apnea, bradycardia	Caffeine, HFNC, CPAP, intubation
Central apnea/hypoventilation	CCHS, Arnold-Chiari malformation	Abnormal central control	Apnea	Mechanical ventilation or BiPAP
Obstructive sleep apnea	Obesity, adenotonsillar hypertrophy, Pierre Robin sequence, Down syndrome, cerebral palsy	Upper airway obstruction due to excess tissue, loss of pharyngeal tone, or crowded anatomy	Snoring, restless sleep, poor school performance, behavior problems, mouth breathing	Adenotonsillectomy, CPAP or BiPAP, uvulopalatoplasty, tracheostomy
Breath holding spells	<3 yr old who turns blue after crying, may have syncope	Prolonged expiratory apnea; reflex anoxic seizures	Cyanosis, syncope, brief tonic-clonic movements after cyanosis	Reassurance; condition is self-limiting. Must exclude seizure disorder

BiPAP, Bi-level positive airway pressure; *CCHS*, congenital central hypoventilation syndrome; *CPAP*, continuous positive airway pressure; *HFNC*, high flow nasal cannula.

Central apnea lasting less than 10 seconds is common in healthy infants and can be present in normal children during sleep, especially after a sigh breath. Central pauses lasting longer than 15-20 seconds are considered abnormal. Premature infants can have **apnea of prematurity**, which consists of recurrent apneic episodes that are often of central origin, although they can be mixed central/obstructive. Apnea of prematurity should resolve by 44 weeks postconceptional age. Central apnea outside of infancy is a rare occurrence and warrants evaluation.

Congenital central hypoventilation syndrome (**CCHS**) is a rare genetic disorder in which there is profound loss of respiratory control during sleep leading to primary central apnea, hypercarbia, and hypoxemia. Most patients

with CCHS have a defect in the **PHOX2B** gene, which is necessary for autonomic nervous system development. Infants with CCHS typically have respiratory difficulties within the first several weeks of life although it can also present later in childhood. CCHS is associated with an increased risk of Hirschsprung disease and neural crest tumors (neuroblastoma). Other genetic syndromes associated with abnormal central respiratory control include Rett, Joubert, and Prader-Willi syndromes and tuberous sclerosis. Secondary causes of central apnea and hypoventilation are more common and include medications impairing central respiratory drive (narcotics), increased intracranial pressure, central nervous system (CNS) tumors, myelomeningocele and/or Arnold-Chiari malformation, and mitochondrial/metabolic disorders.

Breath holding spells are a form of apnea occurring when a young child is awake, usually triggered by emotional stress. They often follow a sustained exhalation, so can be associated with cyanosis and loss of consciousness that is quite alarming. The return of spontaneous breathing usually occurs quickly. Most breath holding spells are benign and lessen over time, but seizures and disorders of central respiratory control should be considered.

Obstructive sleep apnea syndrome (OSA) affects 2-3% of young children with peak prevalence at 2-8 years of age. It is caused by complete or partial upper airway obstruction during sleep. Control of breathing is usually preserved, although infants and others with immature respiratory control may have obstructive and central apnea together. Restless sleep, behavioral problems, and inattention/hyperactivity are more common in young children than the classic adult findings of daytime hypersomnolence and loud snoring. Some children experience poor somatic growth due to interruption of normal growth hormone production during deep sleep. A small subset can have significant hypoxemia and hypercarbia leading to morning headaches, and if untreated, pulmonary hypertension and cor pulmonale. Not all children who snore have OSA, and not all children who have OSA snore. Thus when the diagnosis is in question, it should be confirmed with a polysomnogram (PSG).

PSG is the only definitive test for evaluation of obstructive and central sleep apnea. It involves continuous recording of electroencephalogram (EEG) and electrooculogram for sleep staging, oronasal airflow and pressure, audible snore, chest and abdominal wall excursion, leg and chin electromyogram, electrocardiogram, pulse oximetry, and capnography. The measured score from a PSG is the **apnea-hypopnea index (AHI)** or number of times in an hour of sleep that the child has cessation or reduction of airflow of a significant magnitude to

negatively affect oxygenation or sleep stage. An AHI less than 1 is the generally accepted norm for pediatric patients although the decision to treat often hinges on the severity of daytime impairment. Measured AHI is typically worse in rapid eye movement (REM) sleep and when the child is supine, so an ideal study captures all sleep stages and positions.

Adenotonsillar hypertrophy is the most common cause of OSA in young children, with peak age 2-5 years. Other risk factors for OSA include obesity, premature birth, craniofacial malformations, trisomy 21, and neuromuscular diseases. Treatment of OSA starts with determining whether the child will benefit from adenoidectomy, with or without tonsillectomy. If surgical intervention is not indicated or fails to alleviate the problem, then the use of continuous positive airway pressure (**CPAP**) or bi-level positive airway pressure (**BiPAP**) via nasal interfaces can be used to distend the upper airway during sleep. This requires a tight-fitting nasal mask, which may not be well tolerated in young children. Supplemental oxygen can blunt hypoxemia in milder cases of OSA but does not alter obstruction and sleep fragmentation. In extreme cases, especially those associated with craniofacial abnormalities or hypotonia, tracheostomy may be indicated.

Brief Resolved Unexplained Events

A **brief resolved unexplained event (BRUE)** is defined as a <1 minute, self-limited episode with one or more of the following features: (1) cyanosis or pallor, (2) absent or irregular breathing, (3) change in tone, or (4) altered level of responsiveness in an infant <1 year of age. Importantly, BRUE differs from the previously used diagnostic term *apparent life-threatening event (ALTE)* in that it includes only episodes with cyanosis (not rubor) and/or altered responsiveness and does not include caregiver perception of the event as “life-threatening.” The label BRUE should be used only when no other explanation for the event is identified on detailed history and physical examination. Historical data suggests that a cause could be identified in >50% of ALTE events, thus the new category of BRUE is quite small. History and exam should focus on the most common identifiable causes of abnormal breathing episodes in infancy including gastroesophageal reflux, CNS pathology (seizures, intracranial bleeding from accidental or nonaccidental trauma), and infection (respiratory syncytial virus [RSV], pertussis, and serious bacterial infections). Cardiovascular events (arrhythmia) and metabolic derangements are among diagnoses that may not be

recognized on initial history and examination; however, these are quite uncommon.

Infants >2 months of age and born at >32 weeks gestation who experience a single, <1 minute, self-limited (no cardiopulmonary resuscitation [CPR] required) BRUE are considered at *low risk* for undiagnosed serious condition or repeat event. An electrocardiogram and pertussis screening may be considered in this low-risk group. Additional diagnostic tests (e.g., metabolic panel, complete blood count, imaging, polysomnography [PSG], and EEG) and hospital admission for cardiorespiratory monitoring are not recommended. Offering parents infant CPR instruction and attempting to alleviate anxiety surrounding the event are recommended. There is no consensus on evaluation and management of the high-risk infant with BRUE at this time. Careful history and physical examination should be used to guide differential diagnosis and assessment. Cardiorespiratory monitoring for 12-24 hours in the hospital can provide more detailed information on respiratory and cardiac patterns while allowing time to gather additional history and perform repeat examinations.

Of note, PSG in infants previously categorized as ALTE generally show nonspecific differences compared to control groups; thus it is not considered a useful tool for diagnosis unless clinical suspicion of OSA is high. PSG, home oximetry, and home cardiorespiratory monitoring are not helpful in predicting risk or preventing sudden infant death syndrome (SIDS) so should not be recommended for this purpose.

Sudden Infant Death Syndrome

Etiology and Epidemiology

SIDS is defined as the *unexpected* death of an infant younger than 1 year of age in which the cause remains *unexplained* after autopsy, death scene investigation, and review of clinical history. The risk of SIDS is higher in male, premature, and low birth weight infants; infants born to impoverished mothers; and mothers who smoke cigarettes or have abused drugs. The risk of SIDS is increased threefold to fivefold in siblings of infants who have died of SIDS and is highest during the winter. SIDS is rare before 4 weeks or after 6 months of age and is most common between 2 and 4 months. The incidence of SIDS has decreased dramatically since the 1980s.

A variety of unproven mechanisms have been proposed to explain SIDS.

Current theories for a predisposition to SIDS include cellular brainstem abnormalities and maturational delay related to neural or cardiorespiratory control. Prone (chest down) position during sleep and exposure to maternal smoking both alter heart rate variability and arousal response, which may contribute to the risk of SIDS. A portion of SIDS deaths may be due to prolongation of the Q-T interval, abnormal CNS control of respiration, and CO₂ rebreathing from sleeping face down (especially in soft bedding). Importantly, there is no association between BRUE/ALTE and SIDS.

Differential Diagnosis

See [Table 134.2](#) for the differential diagnosis of SIDS.

GASTROINTESTINAL
Gastroesophageal reflux ^{*,‡} Midgut volvulus/shock [*]

^{*}Obvious or suspected at autopsy.

[†]Relatively common.

‡Diagnostic test required.

Prevention

SIDS is associated with prone position during sleep, especially on soft bedding, excess insulation, and bed sharing. There has been a significant decline in SIDS with the **back-to-sleep program** and avoiding soft bedding. Thus all parents should be instructed to place their infants in the supine position (on their backs/chest up) unless there are medical contraindications. All loose, soft bedding should be excluded from sleep space, and parents who share beds with their infants should be counseled on the risks, especially if consuming alcohol. Counseling for cessation of maternal cigarette smoking, both during and after pregnancy, is recommended. Breast feeding, pacifier use, and sharing a room (in separate beds) have been identified as protective. Though there are many commercial devices marketed for prevention, such as sleep positioners and home oximeters, none have been proven to reduce SIDS risk.

CHAPTER 135

Upper Airway Obstruction

Etiology

Upper airway obstruction (UAO), which is defined as blockage of any part of the airway located above the thoracic inlet, ranges from nasal obstruction due to the common cold to life-threatening obstruction of the larynx or upper trachea. In children, nasal obstruction is usually more of a nuisance than a danger because the mouth can serve as an airway, but it may be a serious problem for neonates, who breathe predominantly through their noses. The differential diagnosis of airway obstruction varies with patient age and can also be subdivided into **supraglottic**, **glottic**, and **subglottic** causes ([Tables 135.1 to 135.3](#)).

TABLE 135.1

Age-Related Differential Diagnosis of Sub-Acute Upper Airway Obstruction

NEWBORN
Choanal atresia Rhinitis neonatorum Micrognathia (Pierre Robin syndrome, Treacher Collins syndrome, DiGeorge syndrome) Macroglossia (Beckwith-Wiedemann syndrome, hypothyroidism, Pompe disease, trisomy 21) Pharyngeal collapse Laryngeal web Vocal cord paralysis/paresis (idiopathic, birth trauma or central nervous system pathology) Congenital subglottic stenosis Nasal encephalocele
INFANCY
Chronic or recurrent rhinitis (infection, acid reflux, irritant) Laryngomalacia (most common) Subglottic stenosis (congenital or acquired, e.g., after intubation) Laryngeal web or cyst Laryngeal papillomatosis Airway hemangioma Vascular rings/slings
TODDLERS
Chronic or recurrent rhinitis (infection, allergy, irritant) Hypertrophied tonsils and adenoids (most common) Spasmodic croup Laryngeal papillomatosis Vascular rings/slings
OLDER CHILDREN
Chronic or recurrent rhinitis (infection, allergic, irritants) Hypertrophied tonsils and adenoids (most common) Paradoxical vocal fold movement Infectious mononucleosis

TABLE 135.2

Common Causes of Acute Upper Airway Obstruction

DIAGNOSIS	AGE	HISTORY	EXAM	IMAGING AND LABS	TREATMENT
INFECTIOUS					
Croup (<i>parainfluenza</i> and other viruses)	6 mo-3 yr	Fever, URI	Nontoxic, stridor, barky cough, hoarse	Steeple sign	Aerosolized epinephrine, systemic steroids, cool mist
Epiglottitis (<i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> ; respiratory viruses)	2-6 yr	High fever, rapid onset, no cough, unable to swallow	Toxic, agitated, tripod sitting, drooling, stridor	Thumb sign Leukocytosis	Intubation, antibiotics
Bacterial tracheitis	Any age	High fever,	Toxic, anxious, ±	Ragged tracheal	Intubation,

(<i>Staphylococcus aureus</i> , <i>Moraxella catarrhalis</i>)		rapid onset, no URI symptoms	stridor, ± cough	border Leukocytosis	antibiotics
Retropharyngeal abscess (<i>S. aureus</i> , <i>Group A strep.</i> , <i>oral anaerobes</i>)	<6 yr	Fever, insidious onset, sore throat, no URI/cough	Moderately toxic, drooling, arched neck, inflamed pharynx	Thickened retropharyngeal space Leukocytosis	Antibiotics, surgical drainage
Peritonsillar abscess (<i>Group A strep.</i> , <i>oral anaerobes</i>)	>8 yr	Fever, sudden worsening, sore throat, trismus	Moderately toxic, “hot potato” voice, drooling, asymmetric tonsil swelling	Imaging not needed Leukocytosis	Antibiotics, surgical drainage
NONINFECTIOUS					
Angioedema	Any age	No fever, sudden onset, urticarial, facial swelling, ± allergen exposure	Nontoxic (unless anaphylaxis), ± stridor, hoarse, facial edema	Steeple sign	Aerosolized or intradermal epinephrine, systemic steroids antihistamines
Spasmodic croup	6 mo-6 yr	Sudden onset, no fever/URI, recurrent, often nocturnal	Nontoxic, ± stridor, hoarse, barky cough	Often normal	Aerosolized epinephrine, antihistamines, antacids, systemic steroids
Foreign body	6 mo-5 yr	Sudden onset, cough and choke	Nontoxic, anxious, stridor, aphonic, brassy cough	Radiopaque object may be seen	Rigid bronchoscopy

URI, Upper respiratory tract infection (with coryza, sneezing).

TABLE 135.3

Differentiating Supraglottic From Subglottic Causes of Acute Airway Obstruction

FEATURE	SUPRAGLOTTIC OBSTRUCTION	SUBGLOTTIC OBSTRUCTION
Common clinical syndromes	Epiglottitis, peritonsillar and retropharyngeal abscess	Croup, angioedema, foreign body, bacterial tracheitis
Stridor	Quiet	Loud

Voice	Muffled	Hoarse
Dysphagia	Yes	No
Tripod or arching posture	Yes	No
Barking cough	No	Yes
Toxic	Yes	No, unless tracheitis
Trismus	Some	No
Droling	Yes	No

Modified from Davis H, Gartner JC, Galvis AG, et al. Acute upper airway obstruction: croup and epiglottitis. *Pediatr Clin North Am.* 1981;28:859–880.

Clinical Manifestations

Decision-Making Algorithms

Hoarseness
Stridor

UAO is more pronounced during inspiration because the negative pressure generated collapses the upper airway, increasing resistance and turbulent airflow that creates an inspiratory noise. Children with UAO may have increased inspiratory work of breathing manifested by **suprasternal retractions**. The respiratory noise most commonly associated with UAO is **stridor**, a harsh sound caused by the vibration of the airway structures. Stridor often decreases during sleep because of lower inspiratory flow rates, and increases during feeding, excitement, and agitation because of higher flow rates. Occasionally stridor may also be present on exhalation. Hoarseness or aphonia with stridor suggests **vocal cord** involvement. **Stertor** is a low-pitched sound like a snore and suggests implosion of pharyngeal soft tissue structures.

Diagnostic Studies

Radiographic evaluation of a child with stridor is rarely helpful. On anteroposterior (AP) views of the neck taken with the head in extension, the subglottic space should be symmetrical and the lateral walls of the airway should

fall away steeply. Asymmetry suggests subglottic stenosis or a mass lesion, whereas tapering suggests subglottic edema. However, these findings may be subtle. In the child with stertor or snoring, lateral views of the neck and nasopharynx may provide information about tonsil or adenoid hypertrophy. Computed tomography (CT) scans of the upper airway can help delineate the site of the obstruction when soft tissue mass (e.g., tonsillar abscess) is suspected, but may require sedation in younger children. Flexible nasopharyngoscopy/laryngoscopy, which can be done without sedation, is extremely useful in assessing airway patency, the presence of adenoid tissue or vocal cord and other airway lesions, and laryngomalacia.

Differential Diagnosis

Choanal Stenosis (Atresia)

Choanal stenosis/atresia is a congenital problem presenting in the neonatal period. It may be bilateral or unilateral and is relatively rare. Neonates are generally obligate nose breathers, so obstruction of nasal passages can cause significant respiratory distress, especially when feeding. Crying bypasses the obstruction because crying infants breathe through their mouths. Inability to easily pass a small catheter through the nostrils should raise the suspicion of choanal atresia. The diagnosis is confirmed by CT scan and by inspecting the area directly with a flexible nasopharyngoscope. An oral airway may be useful in the short term, but the definitive treatment is surgery.

Croup (Laryngotracheobronchitis)

Decision-Making Algorithm

Stridor

Epiglottitis

Decision-Making Algorithm

Stridor

See [Chapter 107](#).

Bacterial Tracheitis

See [Chapter 107](#).

Laryngomalacia

Decision-Making Algorithm

Stridor

Etiology

Laryngomalacia is due to exaggerated collapse of the glottic structures, especially the epiglottis and arytenoid cartilages, during inspiration. It is the most common cause of stridor in infants. It may be due to decreased muscular tone of the larynx and surrounding structures or to immature cartilaginous structures. It usually does not result in significant respiratory distress, but occasionally it is severe enough to cause apnea, hypoventilation, hypoxemia, and difficulty feeding.

Clinical Manifestations

The primary sign of laryngomalacia is **inspiratory stridor** with little or no expiratory component. The stridor is typically loudest when the infant is feeding or active and decreases when the infant is relaxed or placed prone, or when the neck is flexed. Any condition that increases upper airway inflammation will exacerbate laryngomalacia, including viral respiratory infections, dysphagia (swallowing dysfunction), and gastroesophageal reflux. Laryngomalacia normally peaks by 3-5 months of age and resolves between 6 and 12 months of

age. However, occasionally it can persist in otherwise normal children up until 24 months of age, and even longer in children with underlying conditions, especially those with neurological diseases affecting control of upper airway muscles (such as cerebral palsy).

Diagnostic Studies

In many infants with presumed laryngomalacia, the diagnosis can be tentatively established by history and physical examination. If the patient follows the typical course for laryngomalacia, then no further work-up is necessary. However, to firmly establish the diagnosis, which is important in more severe or atypical cases, the patient should undergo flexible nasopharyngoscopy to assess the patency and dynamic movement (collapse) of the larynx and surrounding structures. This procedure can also identify vocal cord abnormalities and airway lesions above the vocal cords.

Treatment

In most cases, no therapy is required for laryngomalacia. The infant should be observed closely during times of respiratory infection for evidence of respiratory compromise. Infants with severe laryngomalacia resulting in hypoventilation, hypoxia, or growth failure may benefit from a surgical procedure (aryepiglottoplasty) or, in extreme cases, a tracheostomy to bypass the upper airway.

Subglottic Stenosis

Decision-Making Algorithm

Stridor

Etiology

Subglottic stenosis is the narrowing of the portion of the trachea immediately below the vocal cords. It may be congenital but more often is acquired. Endotracheal intubation, especially prolonged or repeated intubation required in some premature infants, can lead to inflammation and scarring of the subglottic

space.

Clinical Manifestations

Subglottic stenosis can present as stridor that is **biphasic** (on both inspiration and expiration) but usually more prominent on inspiration. With increasing respiratory effort, the stridor becomes louder. Very small infants may not be able to breathe with enough force to generate a sound. Subglottic stenosis may also be associated with a barking cough similar to that noted with croup. Respiratory infections can cause subglottic edema, exacerbating the clinical manifestations of subglottic stenosis.

Diagnostic Studies

Definitive diagnosis requires endoscopic evaluation, either by flexible or rigid bronchoscopy.

Treatment

Mild subglottic stenosis can be managed conservatively and may improve sufficiently with airway growth alone. More severe cases require surgical intervention. Depending on the nature of the lesion, endoscopic laser treatment may be effective. Other surgical options include tracheoplasty and cricoid split procedures. A tracheostomy tube may be required to bypass the subglottic space until the airway is patent enough to allow adequate airflow.

Mass Lesions

Upper airway mass lesions are relatively uncommon. The most common laryngeal tumor in childhood is the **hemangioma**, which usually presents before 6 months of age and is often able to be treated medically (see [Chapter 194](#)). Definitive diagnosis requires endoscopy. If the obstruction is severe, a tracheostomy tube may be needed until the lesion spontaneously involutes or improves with therapy.

Laryngeal webs are the result of failed recanalization of the glottic airway in utero, whereas **laryngeal cysts** typically occur as a consequence of airway trauma (intubation). Both can produce biphasic stridor and are best identified by bronchoscopy. **Foreign body** should be considered in any infant or child capable of ingesting small objects who develops acute onset of stridor.

Juvenile laryngeal papillomatosis is a rare condition of benign tumors caused by human papillomavirus (HPV)-6 and HPV-11 acquired at birth from maternal genital warts. Clinical manifestations usually start in infancy and include biphasic stridor and hoarse voice/cry. The lesions are most commonly located in the larynx, but they can spread distally into the trachea, large bronchi, and even to the lung parenchyma. Treatment options, which are limited and rarely curative, include laser therapy and interferon. Tracheostomy may be required to ensure an adequate airway but should be avoided if possible as there is risk of seeding of the distal airways with tumor.

Vocal Cord Paralysis

Decision-Making Algorithm

Stridor

Etiology

Vocal cord paralysis is an important cause of laryngeal dysfunction. Paralysis may be unilateral or bilateral and is more often caused by damage to the recurrent laryngeal nerve than by a central lesion. The left recurrent laryngeal nerve passes around the aortic arch and is more susceptible to damage than the right laryngeal nerve. Peripheral nerve injury may be caused by trauma (neck traction during delivery of infants or thoracic surgical procedures) and mediastinal lesions. Central causes include Arnold-Chiari malformation (meningomyelocele), hydrocephalus, and intracranial hemorrhage.

Clinical Manifestations

Vocal cord paralysis presents as biphasic stridor and alterations in voice and cry, including a weak cry (in infants), hoarseness, and aphonia. Children with vocal cord paralysis are at risk for aspiration, often manifested as coughing/choking with drinking and coarse airway sounds audibly and by auscultation.

Treatment and Prognosis

Patients with traumatic injury to the recurrent laryngeal nerve often have

spontaneous improvement over time, usually within 3-6 months. If the paralyzed vocal cord has not recovered within 1 year of the injury, then it is likely to be permanently damaged. In some cases, Gelfoam injection of a paralyzed vocal cord can reposition the cord to improve phonation and airway protection. Patients with vocal cord paralysis resulting in severe airway obstruction and aspiration may require tracheostomy tube placement.

Adenoidal and Tonsillar Hypertrophy

Etiology

The most common cause of chronic UAO in children is hypertrophy of the adenoids and tonsils. Adenoidal and tonsillar hyperplasia may be aggravated by recurrent infection, allergy, and inhaled irritants.

Clinical Manifestations

The signs of adenoidal and tonsillar hypertrophy are mouth breathing, snoring, and, in some patients, obstructive sleep apnea (see [Chapter 134](#)). The eustachian tubes enter the nasopharynx at the choanae and can be obstructed by enlarged adenoids, predisposing to recurrent or persistent otitis media.

Diagnostic Studies

Adenoidal hypertrophy is assessed by a lateral radiograph of the nasopharynx or by flexible nasopharyngoscopy.

Treatment

If the adenoids or tonsils are large and thought to be significantly contributing to UAO, then the most effective treatment is removal. Because the adenoids are not a discrete organ but rather consist of lymphoid tissue, regrowth is possible, especially in preschool children. If the tonsils are large and the obstruction is severe, then removing the tonsils in addition to the adenoids may be necessary.

CHAPTER 136

Lower Airway, Parenchymal, and

Pulmonary Vascular Diseases

Etiology

There are many causes of lower airway diseases (Table 136.1). Lower airway diseases often result in airway obstruction. The most common lower airway disease in children is **asthma**, which results in variable and recurring symptoms, diffuse bronchial obstruction from airway inflammation, and hyperresponsiveness of bronchial smooth muscle leading to airway constriction. Virus-induced wheezing episodes are common, especially in children under 3 years of age. Wheezing that is localized to one area of the chest suggests focal airway obstruction (foreign body aspiration or extrinsic compression).

TABLE 136.1

Causes of Wheezing in Childhood

ACUTE
Asthma Exercise-induced asthma Hypersensitivity reactions Infection (e.g., bronchiolitis) Inhalation of irritant gases or particulates Descending aspiration Foreign body (airway or esophageal) Aspiration of gastric contents (ascending aspiration)
CHRONIC OR RECURRENT
Asthma (see under acute) Hypersensitivity reactions, allergic bronchopulmonary aspergillosis (seen only in children with either asthma or cystic fibrosis) Vocal cord dysfunction Recurrent aspiration/swallowing dysfunction (dysphagia) Retained foreign body Gastroesophageal reflux Bronchopulmonary dysplasia Bronchitis, bronchiectasis Cystic fibrosis Primary ciliary dyskinesia Bronchiolitis obliterans Pulmonary edema (congestive heart failure) Bronchomalacia/tracheomalacia Vascular ring Pulmonary artery dilatation (absent pulmonary valve) Bronchial or pulmonary cysts/masses Lymph nodes (tuberculosis, lymphoma) Endobronchial masses/tumors (carcinoid)

Clinical Manifestations

Decision-Making Algorithm

Wheezing

A wheeze is a continuous sound that is produced by vibration of airway walls and generally has a more musical quality than does stridor. In contrast to upper airway obstruction, obstruction below the thoracic inlet causes more wheezing on expiration than on inspiration. Intrathoracic pressure is increased relative to atmospheric pressure during exhalation, which collapses the intrathoracic airways and accentuates airway narrowing on expiration. Expiratory airflow through obstructed intrathoracic airways leads to wheeze, prolonged expiratory phase, and increased abdominal work of breathing. In patients with chronic airway infection (e.g., cystic fibrosis), the bronchi become permanently damaged and dilated (bronchiectasis). Patients with bronchiectasis have episodes of cough, often productive of purulent sputum, and may have inspiratory crackles.

Diagnostic Studies

When asthma is suspected, empiric trials of therapy (bronchodilators, short courses of oral corticosteroids, long-term use of inhaled corticosteroids) are useful in arriving at a diagnosis. In children older than 6 years, pulmonary function tests (spirometry) can assess airflow obstruction and response to bronchodilators. **Radiographic evaluation** is not needed with each episode of wheezing, but those with significant respiratory distress, fever, history consistent with foreign body aspiration, or focal auscultatory findings should have posteroanterior (PA) and lateral chest radiographs obtained. Generalized **hyperinflation**, indicated by flattening of the diaphragms and an increased anteroposterior (AP) chest diameter, suggests diffuse obstruction of the small airways. Localized hyperinflation, especially on expiratory views, suggests localized bronchial obstruction (foreign body or an anatomical anomaly).

Dysphagia leading to aspiration and airway inflammation can present with persistent wheezing. This is best assessed with a **videofluoroscopic swallowing study**. Gastroesophageal reflux may aggravate asthma and may lead to wheezing in very young children, especially if it is associated with aspiration. Infants with persistent wheezing despite empiric treatment with asthma therapy may benefit from an airway evaluation with **flexible bronchoscopy**.

Differential Diagnosis

Asthma

Decision-Making Algorithm

Wheezing

See [Chapter 78](#).

Tracheomalacia

Etiology

Tracheomalacia is a floppy trachea due to lack of structural integrity of the tracheal wall. The tracheal cartilaginous rings normally extend through an arc of approximately 320 degrees, maintaining rigidity of the trachea during changes in intrathoracic pressure. With tracheomalacia, the cartilaginous rings may not extend as far around the circumference (leaving the membranous posterior trachea wider than usual), may be completely absent, or may be present but damaged. These abnormalities can result in excessive collapse of the trachea, most pronounced during expiration. Tracheomalacia is the most common congenital tracheal abnormality and may be congenital (tracheoesophageal fistula or bony dysplasia syndromes) or acquired (long-term mechanical ventilation). Tracheomalacia must be differentiated from extrinsic tracheal compression by masses or vascular structures. Localized tracheomalacia may persist after the trachea has been relieved of extrinsic compression.

Clinical Manifestations

With tracheomalacia, the tracheal collapse may only be apparent during forced exhalation or with cough. It is commonly aggravated by respiratory infections. The airway collapse causes a harsh, monophonic wheeze compared to the polyphonic wheeze more often seen in asthma. Secretions may be retained behind the segment of malacia, predisposing to infection. Infants with severe tracheomalacia may completely collapse their tracheas during agitation, resulting in cyanotic episodes that resemble breath holding spells. The voice is normal, as is inspiratory effort. In older children, the hallmark sign is a brassy, barking cough due to the vibration of the tracheal walls. The expiratory noises of tracheomalacia are often mistakenly ascribed to asthma or bronchiolitis, and the barking cough is often misdiagnosed as croup.

Treatment

Infants with mild to moderate tracheomalacia usually require no intervention. Tracheomalacia improves with airway growth as the lumen increases in diameter and the tracheal wall becomes more firm. The treatment of older symptomatic children is geared toward treating the precipitating cause for cough and providing supportive care. Antibiotics may be necessary to treat concurrent infection. Children, especially infants, with severe tracheomalacia may require tracheostomy tubes to administer continuous positive airway pressure (CPAP), which serves to stent open the airway. Custom-length tracheostomy tubes are used to bypass the site of collapse. Surgical techniques such as slide tracheoplasty may benefit short segments of severe malacia. Aortopexy has been used to limit anterior collapse but does not treat posterior tracheal membrane collapse. Historically, surgically placed airway stents have been problematic in children because airway stents may erode and migrate, do not grow with children, and serve as a source of fixed stenosis and obstruction. Newer absorbable airway external splints and internal stents with 3D-printing technology are under active investigation for treatment of severe pediatric tracheomalacia.

Tracheoesophageal Fistula

See [Chapter 128](#).

Extrinsic Tracheal Compression

Compression of the trachea by vascular structures or masses can cause significant respiratory compromise. Tracheal compression by aberrant great vessels (aorta, innominate artery) may cause wheezing, stridor, cough, and dyspnea. Incomplete vascular rings are often asymptomatic and incidentally found, but anterior tracheal compression can occur from an **anomalous innominate artery** that arises more distally than normal from the aortic arch. This usually results in mild respiratory symptoms. Surgical correction is rarely necessary. Complete vascular rings, which compress the esophagus posteriorly and the trachea anteriorly, include the double aortic arch and a right aortic arch with a persistent ligamentum arteriosum (most common). Both lesions have right-sided aortic arches, which may be visible on chest radiograph. In addition to respiratory symptoms, complete vascular rings may cause dysphagia as a result of esophageal compression. The diagnosis of vascular anomalies can often be made by a barium swallow, which identifies the esophageal compression ([Fig 136.1](#)). Bronchoscopy will identify a pulsatile compression of the airway, but the diagnostic procedures of choice are a computed tomography (CT) angiogram of the chest and great vessels or magnetic resonance angiogram (MRA). Definitive treatment of vascular rings requires surgical repair. Other causes of extrinsic tracheal compression include enlarged mediastinal lymph nodes (tuberculosis), mediastinal masses (teratoma, lymphoma, thymoma, germ cell tumors), and, rarely, cystic hygromas.

FIGURE 136.1 Vascular ring. Indentation of the posterior esophagus seen on barium swallow, lateral view. This child had a double aortic arch.

Foreign Body Aspiration

Epidemiology

Aspiration of foreign bodies into the trachea and bronchi is relatively common. The majority of children who aspirate foreign bodies are under 3 years of age. Patients with developmental delay or with older siblings are at increased risk. Because the right mainstem bronchus takes off at a less acute angle than the left mainstem bronchus, foreign bodies tend to lodge in right-sided airways. Some foreign bodies, especially nuts, can also lodge more proximally in the larynx or subglottic space, totally occluding the airway. Many foreign bodies are not radiopaque, which makes them difficult to detect radiographically. The most common foreign bodies aspirated by young children are food (especially nuts) and small toys. Coins more often lodge in the esophagus than in the airways. Older children have been known to aspirate rubber balloons, which can be life

threatening.

Clinical Manifestations

Decision-Making Algorithms

Cough
Stridor
Hemoptysis

Many children who aspirate foreign bodies have clear histories of choking, witnessed aspiration, or physical or radiographic evidence of foreign body aspiration. However, a proportion of patients have a negative history because the aspiration went unrecognized. Physical findings observed with acute foreign body aspiration may include cough, localized wheezing, unilateral absence of breath sounds, stridor, and, rarely, bloody sputum.

Most foreign bodies are small and quickly expelled, but some may remain in the lung for long periods of time and may come to medical attention because of persistent cough, sputum production, or recurrent unilateral pneumonia. Foreign body aspiration should be in the differential diagnosis of patients with persistent wheezing unresponsive to bronchodilator therapy, persistent atelectasis, recurrent or persistent pneumonia, or chronic cough without another explanation. Foreign bodies may also lodge in the esophagus and compress the trachea, thus producing respiratory symptoms. Therefore esophageal foreign bodies should be included in the differential diagnosis of infants or young children with persistent cough, stridor, or wheezing, particularly if dysphagia is present.

Diagnostic Studies

Radiographic studies will reveal the presence of radiopaque objects and can also identify focal air trapping, especially on expiratory views or decubitus films. Many foreign bodies are not radiopaque. Thus when foreign body aspiration is suspected, expiratory or lateral decubitus chest radiographs may identify air trapping on the affected, dependent side. If history or exam is suggestive of foreign body aspiration, the patient should undergo rigid bronchoscopy, typically performed by an otolaryngologist. Flexible bronchoscopy can be used to locate

an aspirated foreign body and may be useful when the presentation is not straightforward, but foreign body removal is best performed via rigid bronchoscopy.

Prevention

Common foods, including peanuts or other nuts, popcorn, uncooked carrots, or any foods difficult to break into small pieces, are at risk to be aspirated by infants and children, particularly before molar teeth have erupted. Older siblings should be counseled to keep small toys separate and not present younger children with small parts.

Bronchiolitis

Decision-Making Algorithm

Wheezing

See [Chapter 109](#).

Bronchopulmonary Dysplasia

See [Chapter 61](#).

Congenital Lung Anomalies

Congenital lobar emphysema (congenital lobar overinflation) consists of hyperinflation of one or more lobes of the lung. This overdistention may cause severe respiratory distress in the neonatal period due to compression of surrounding normal lung tissue, but it can also be asymptomatic and remain undiagnosed for years. Radiographically, it may be mistaken for a pneumothorax. Lobectomy may be required if respiratory distress is severe or progressive, but if the patient is asymptomatic, then surgical resection may not be indicated.

Congenital pulmonary airway malformations (CPAMs) are a spectrum of lesions arising during early lung development with histological appearance

ranging from simplified bronchial to complex cystic alveolar tissue, connected to the tracheobronchial tree. They are often first identified on antenatal ultrasound, and after birth can be inconspicuous on chest radiograph. CPAMs are nonfunctioning lung tissue and can have hybrid features of **pulmonary sequestration** (presence of systemic circulation connections). Although CPAM lesions can be stand-alone lesions, a substantial proportion of pulmonary sequestrations are hybrid CPAM lesions. Sequestrations without hybrid features are separate from the tracheobronchial tree and are classified as intrapulmonary (located in a normal lobe without its own pleura) and extrapulmonary (outside normal lung). CPAMs and sequestrations can coexist with other chest lesions including **congenital diaphragmatic hernia**. Sequestration is also associated with **Scimitar syndrome** (partial anomalous pulmonary venous return). Symptomatic neonates with respiratory distress, large lesions, or family history of features concerning for malignancy require further imaging. Though large malformations can cause neonatal respiratory distress, many are asymptomatic. Chest CT with contrast is the diagnostic test of choice ([Fig 136.2](#)) but may be delayed if the child is asymptomatic with close clinical follow-up for symptom development. Surgical resection is curative, but risk of infection or malignancy is not completely understood in these children. Conservative management with observation is a reasonable option for families with low risk.

FIGURE 136.2 Congenital pulmonary airway malformation. Coronal (A) and axial (B) computed tomography images of a right lower lobe congenital pulmonary airway malformation in a child who presented with recurrent pneumonias. The entire left lung and upper and middle lobes of the right lung are normal.

Pulmonary hypoplasia, or a relative decrease in amount of alveoli, may be

the result of a number of congenital insults, such as **congenital diaphragmatic hernia** (see [Chapter 61](#)) or unilateral congenital absence of a pulmonary artery. Alveolar growth occurs after birth, predominantly up to 3 years, but has been documented beyond 8 years of age.

Primary Ciliary Dyskinesia

Etiology

Primary ciliary dyskinesia (PCD, immotile cilia syndrome) is an inherited disorder in which there is absent or disordered movement of the cilia leading to a spectrum of clinical manifestations. This disorder affects approximately 1 in 15,000-20,000 live births, although the actual incidence may be higher because of a limited ability to definitively diagnose affected patients.

Clinical Manifestations

Clinical manifestations include neonatal respiratory distress, chronic cough, chronic nasal congestion, middle ear effusions, chronic pansinusitis, laterality defects (e.g., situs inversus), infertility, and bronchiectasis. Kartagener syndrome, the triad of **situs inversus**, **pansinusitis**, and **bronchiectasis**, accounts for approximately 50% of cases. Males are infertile as a result of immotile sperm. Because the cilia fail to beat normally, secretions accumulate in the airways, and endobronchial infection results. Chronic infection, if untreated, leads to bronchiectasis by early adulthood.

Diagnostic Studies

PCD diagnosis has historically relied on a combination of clinical features and ultrastructural analysis of respiratory cilia by electron microscopy, obtained from scrapings/biopsy of nasal or airway epithelium. Results may be difficult to interpret as chronic infection and inflammation may also lead to ultrastructural abnormalities in nasal cilia. The most common ultrastructural defect is the absence of dynein arms. A third of affected individuals have normal ciliary ultrastructure. The measurement of nasal nitric oxide has been used as a screening tool for PCD. Low nasal nitric oxide values (<77 nL/min) are consistent with PCD. High-speed video microscopy assesses ciliary beat frequency and pattern but requires specialized equipment and, currently, there is an absence of standardized reporting methods. PCD is generally autosomal

recessive. Currently 31 genes have been identified to explain approximately 60% of cases. The association of genetic defects and clinical phenotype is unknown.

Treatment

Treatment is geared toward treating infections and improving clearance of respiratory secretions. High-resolution chest CT scans are useful to confirm and monitor bronchiectasis. Surveillance cultures help identify organisms involved and guide antibiotic therapy. Sinus surgical procedures are often done to manage chronic sinusitis, but their benefit is questionable. Most children require placement of pressure equalization (PE) tubes for management of recurrent otitis media. Chest physiotherapy and prompt treatment of bacterial infections are helpful, but the course of the disease tends to be slowly progressive. Inhaled hypertonic saline may improve cough clearance and has been shown in the short term to improve lung function. Antiinflammatory antibiotics, such as low-dose macrolides, may reduce the number of exacerbations per year.

Pneumonia

Decision-Making Algorithms

- Cough
- Wheezing
- Hemoptysis
- Abdominal Pain
- Acidemia

See [Chapter 110](#).

Pulmonary Edema

Etiology

Pulmonary edema is the seepage of fluid into the alveolar and interstitial spaces. Capillary hydrostatic forces and interstitial osmotic pressures tend to push fluid into the air spaces, whereas plasma osmotic pressures and tissue mechanical forces tend to move fluid away from the air spaces. Under normal circumstances,

the sum of these forces favors absorption, so the alveolar and interstitial spaces remain dry. Fluid entering the alveoli is normally removed by pulmonary lymphatics. Pulmonary edema forms when transcapillary fluid flux exceeds lymphatic drainage. Reduced left ventricular function leads to pulmonary venous hypertension and increased capillary hydrostatic pressure, and fluid moves into the interstitial space and alveoli. Fluid initially enters the interstitial space around the terminal bronchioles, alveoli, and arterioles (**interstitial edema**), causing increased lung stiffness and premature closure of bronchioles on expiration. If the process continues, fluid then enters the alveoli, further reducing compliance and resulting in **intrapulmonary shunting** (alveolar units that are perfused but not ventilated). Decreased ventilation (hypercarbia) is a late finding.

Pulmonary edema is most commonly due to heart failure from left ventricular or biventricular dysfunction. Pulmonary hypertension (PH) and associated cor pulmonale (right ventricular dysfunction) do not usually cause pulmonary edema as the increased vascular resistance is proximal to the capillary bed. Increased capillary permeability, seen in disease states such as sepsis and acute respiratory distress syndrome, can lead to pulmonary edema. Pulmonary edema may also occur with excessive swings in intrathoracic pressure, as seen after tracheal foreign body aspiration or severe obstruction from hypertrophied tonsils and adenoids (**postobstructive pulmonary edema**). Pulmonary edema may also be present in conditions with decreased serum oncotic pressure (hypoalbuminemia); after administration of large volumes of intravenous (IV) fluids, especially if there is capillary injury; with ascent to high altitude (**high-altitude pulmonary edema**); and after central nervous system injury (**neurogenic pulmonary edema**).

Clinical Manifestations

Decision-Making Algorithm

Cough

The clinical manifestations of pulmonary edema are **dyspnea**, tachypnea, and cough (can occur with frothy, pink-tinged sputum). As the edema worsens, there is increased work of breathing and hypoxemia; diffuse inspiratory crackles can

be heard on auscultation.

Diagnostic Studies

Chest radiographs may reveal diffuse hazy infiltrates, classically in a perihilar pattern, but these findings may be obscured by underlying lung disease. Interstitial edema (**Kerley B lines**) may be seen, especially at the lung bases.

Treatment and Prognosis

Treatment and prognosis depend on the cause of the pulmonary edema and response to therapy. Patients should be positioned in an upright posture and given supplemental O₂. Diuretic therapy and rapidly acting IV inotropic agents may be helpful in cardiogenic pulmonary edema. CPAP or intubation with positive pressure ventilation using high positive end-expiratory pressures (PEEP) may be required.

Acute Respiratory Distress Syndrome

See [Chapter 39](#).

Pulmonary Arterial Hypertension and Cor Pulmonale

Etiology

PH is defined as a mean pulmonary artery pressure ≥ 25 mm Hg in children >3 months of age at sea level. Pediatric PH is categorized into five groups based on the World Health Organization classification, similar to adult PH. Group 1 is pulmonary arterial hypertension (PAH) due to diseases within veins and small pulmonary muscular arteries such as persistent PH of the newborn, congenital heart disease (including those with excessive pulmonary blood flow due to left-to-right cardiac shunting), exposure to various drugs (e.g., cocaine, amphetamines), and **idiopathic pulmonary arterial hypertension** (IPAH, previously called primary PH). Hereditary IPAH is also in this group and has been linked with the bone morphogenetic receptor-2 (*BMPR2*) gene. Group 2 is caused by dysfunction of the left heart such as valvular disease. Group 3 is secondary to lung disease or chronic hypoxia, including upper airway obstruction resulting in obstructive sleep apnea and hypoxemia. In Group 4, PH

is secondary to chronic pulmonary thromboembolism. Group 5 includes PH of unclear but multifactorial diseases, including some autoimmune diseases and metabolic diseases. The Panama Classification is a new pediatric-specific system that includes ten categories to capture the heterogeneity of pulmonary hypertensive vascular disease from the fetus to adolescent (e.g., perinatal pulmonary vascular maladaptation, multifactorial pulmonary hypertensive vascular disease in congenital malformation syndromes, diffuse pediatric lung disease). This classification system is promising, but has yet to be tested and validated for utility and accuracy.

Prolonged PH may lead to irreversible changes in the intima and media of the pulmonary arterioles. PH strains the right side of the heart, which leads to hypertrophy and dilation of the right ventricle. Altered structure and/or function of the right heart from PH is known as **cor pulmonale**. The most common causes of cor pulmonale in children are chronic lung diseases, especially severe bronchopulmonary dysplasia and severe, untreated obstructive sleep apnea (with chronic hypoxia).

Clinical Manifestations and Diagnostic Studies

PAH should be suspected with developmental anatomical abnormalities or historical exposures (e.g., congenital diaphragmatic hernia, prolonged hypoxemia). Exertional dyspnea and unexplained syncope are presenting symptoms. In addition to the other physical findings associated with pulmonary and cardiac diseases, an accentuated pulmonary component of the second heart sound may be heard. Definitive diagnosis is made by cardiac catheterization, but echocardiography may confirm the presence of right ventricular hypertrophy, ventricular dysfunction, interventricular septal flattening, and tricuspid insufficiency, which can be used to estimate the pulmonary artery pressures. Cardiac magnetic resonance imaging can be useful in diagnosis and to assess changes in ventricular function and size. Lung biopsy may be considered for children with PAH suspected of diffuse lung disease, pulmonary venoocclusive disease, or vasculitis.

Treatment and Prognosis

Treatment should focus on the underlying condition of known causes of PH, such as lung volume optimization in persistent PH of the newborn, or therapy with diuretics and salt/fluid restriction in heart failure. In all conditions of PH

and PAH, the relief of hypoxemia with supplemental O₂ therapy can be therapeutic as a pulmonary vasodilator. Medications for pulmonary vasodilation such as short-term inhaled nitric oxide may be helpful in some patients. Continuous infusions of prostacyclin may be helpful, both acutely and chronically, and is available in inhaled, subcutaneous, and IV forms. Endothelium antagonists may be beneficial. Unfortunately, many patients with the idiopathic form of PAH have progressive courses, and lung or heart-lung transplantation may be the only treatment option.

Pulmonary Hemorrhage

Etiology

Pulmonary hemorrhage is a rare but potentially life-threatening condition in children. It can be due to bleeding from the airways (hemangiomas, bronchial vessel bleeds) or from diffuse capillary bleeding (alveolar hemorrhage). Alveolar hemorrhage is usually due to diffuse capillary disruption/inflammation caused by autoimmune disorders but can occur in isolation without systemic manifestations (**pulmonary capillaritis**). Airway bleeding can be due to airway hemangiomas, pulmonary arteriovenous malformations (e.g., hereditary hemorrhagic telangiectasia), and bronchial artery collaterals, which develop in some patients with chronic lung infections (e.g., cystic fibrosis). **Idiopathic pulmonary hemosiderosis** is a rare disorder characterized by recurrent alveolar bleeding, iron deficiency anemia, and hemosiderin-laden macrophages in the lung, which can be identified microscopically with the use of special iron-staining techniques in bronchoalveolar lavage or lung biopsy specimens. Although the term *hemosiderosis* is sometimes used interchangeably with pulmonary hemorrhage, it is a pathological finding that results from bleeding anywhere in the lung, airway, pharynx, nasopharynx, or mouth leading to hemosiderin accumulation in the lung. **Pulmonary hemorrhage** is a preferable term for bleeding from an intrathoracic source.

Clinical Manifestations

Decision-Making Algorithm

Hemoptysis

The presentation of pulmonary hemorrhage is variable with a spectrum of asymptomatic radiographic abnormalities to life-threatening respiratory failure. **Hemoptysis**, although experienced by most children with pulmonary hemorrhage, can be absent in a third of individuals. It is important to rule out extrapulmonary sources of bleeding, including hematemesis and bleeding from the nasopharynx or mouth, as these are more common than true pulmonary hemorrhage. In addition to hemoptysis, the presenting signs and symptoms of pulmonary hemorrhage include cough, wheeze, shortness of breath, pallor, fatigue, cyanosis, and fever. Episodic pulmonary hemorrhage frequently manifests as recurrent respiratory symptoms associated with pulmonary infiltrates on chest radiographs. Symptomatic **airway hemorrhage** may result in significant hemoptysis with few radiographic changes, whereas **alveolar bleeding** often causes profound respiratory symptoms, hypoxemia, diffuse infiltrates on radiographs, and minimal hemoptysis. Some patients experience a localized bubbling sensation in the chest, which may be helpful in differentiating local from diffuse sources of pulmonary bleeding. Physical examination findings may include locally or diffusely decreased breath sounds, cyanosis, and crackles on auscultation.

The **differential diagnosis** of pulmonary hemorrhage includes alveolar and airway bleeding. The causes of alveolar (capillary) bleeding can be divided into immune-mediated and non-immune-mediated categories. Immune-mediated causes include antineutrophil cytoplasmic autoantibodies (ANCA)-associated vasculitides, isolated pulmonary capillaritis, antiglomerular basement membrane disease, drug-induced vasculitis, and other connective tissue diseases. Nonimmune mediated causes include idiopathic pulmonary hemosiderosis, clotting disorders, infection, inhalation injury, and cardiac conditions associated with elevated pulmonary venous and capillary pressures ([Table 136.2](#)). Alveolar hemorrhage following bone marrow transplant can occur from immune-mediated causes and from complications of diffuse alveolar damage. Rarely, a previously well infant will present with life-threatening acute alveolar hemorrhage. Often no cause is found, and, once the acute episode resolves, the infant returns to normal. Most of these infants never have a second bleeding episode. Hemoptysis can have cardiovascular, pulmonary, or immunological causes (see [Table 136.2](#)).

TABLE 136.2

Differential Diagnosis of Hemoptysis-Pulmonary Hemorrhage

CARDIOVASCULAR DISORDERS
Heart failure with pulmonary edema Pulmonary hypertension with Eisenmenger syndrome Mitral stenosis Venoocclusive disease Arteriovenous malformation (Osler-Weber-Rendu syndrome) Pulmonary embolism Portal vein obstruction
PULMONARY DISORDERS
Bronchogenic cyst Bronchopulmonary sequestration Pneumonia (bacterial, mycobacterial, fungal, parasitic, or viral) Bronchiectasis (cystic fibrosis, primary ciliary dyskinesia, immunodeficiency, retained foreign body) Tracheobronchitis Lung abscess Tumor (adenoma, carcinoid, hemangioma, metastasis) Trauma (contusion, laceration)
IMMUNE DISORDERS
Henoch-Schönlein purpura Pulmonary capillaritis Idiopathic pulmonary hemosiderosis Antiglomerular basement membrane disease (Goodpasture) Granulomatosis with polyangiitis (formerly known as Wegener granulomatosis) Systemic lupus erythematosus Polyarteritis nodosa
OTHER CONDITIONS/FACTORS
Coagulopathy (Von Willebrand) Toxic inhalation (nitrogen dioxide, pesticides, crack cocaine) Post-bone marrow transplantation Catamenial hemoptysis (females)

Diagnostic Studies

It is important to perform a thorough upper airway examination to rule out epistaxis. Sometimes this requires nasopharyngoscopy. If extrapulmonary sources of bleeding have been excluded, then a chest radiograph, CT angiogram of the chest, bronchoscopy, echocardiogram, and evaluation for rheumatologic/autoimmune diseases follow, especially to consider antglomerular basement membrane disease, granulomatosis with polyangiitis, Henoch-Schönlein purpura, and systemic lupus erythematosus.

Treatment

The management of acute episodes of pulmonary bleeding includes the administration of supplemental O₂, blood transfusions, and, often with acute

alveolar hemorrhages, mechanical ventilation with PEEP to tamponade the bleeding. Treatment is directed toward the underlying disorders and providing supportive care. In bronchial arterial bleeding, arteriography with vessel embolization has been shown to be successful.

Pulmonary Embolism

Etiology

Pulmonary embolism is rare in children. When it occurs, it is often associated with indwelling central venous catheters, oral contraceptives, or hypercoagulable states. Other risk factors, such as trauma, surgery, immobilization, systemic lupus erythematosus, and cancer, may lead to deep vein thromboses (DVTs) and pulmonary embolism.

Clinical Manifestations

Because the pulmonary vascular bed is distensible, small emboli, even if multiple, may be asymptomatic unless they are infected (septic emboli) and cause pulmonary infection. Large emboli may cause acute dyspnea, pleuritic chest pain, cough, and hemoptysis. Tachypnea, tachycardia, and unilateral calf swelling may be present. **Hypoxia** is common, as are nonspecific ST-segment and T-wave changes on the electrocardiogram (ECG). The P₂ heart sound may be increased.

Diagnostic Studies

Although the chest x-ray is usually normal, atelectasis or cardiomegaly may be seen. The measurement of D dimers can be used as a screening test, but it must be interpreted in light of the probability of a pulmonary embolism. If the D dimer is normal and the probability for embolism is low, then no further work-up may be necessary. However, if the D dimer is elevated, or if it is normal but the probability of embolism is moderate or high, then the diagnostic test of choice is a **CT angiogram of the chest**. Ventilation-perfusion scans may reveal defects in perfusion without matching ventilation defects, but they are difficult to perform in young children. Doppler or compression ultrasonography can be useful in assessing patients for lower extremity DVTs. For definitive diagnosis of pulmonary embolism, the gold standard is still **pulmonary angiography**, although with the improvement in CT angiography, angiograms are now rarely

necessary. Children with pulmonary embolism without an obvious cause should be evaluated for hypercoagulable states, the most common of which is factor V Leiden.

Treatment

To treat pulmonary embolism, the patient should be anticoagulated, usually with low-molecular-weight heparin or unfractionated heparin. Although rare, if pulmonary embolism is extensive and hemodynamically compromising, thrombolytic agents such as tissue plasminogen activator should be considered. All patients should receive supplemental O₂, and it is important to treat the predisposing factors.

CHAPTER 137

Cystic Fibrosis

Etiology and Epidemiology

Cystic fibrosis (CF) is a life-shortening autosomal recessive disorder that affects over 70,000 individuals worldwide. Although found predominantly in people of European descent, CF is reported among all races and ethnicities. The gene for CF, located on the long arm of chromosome 7, encodes for the **cystic fibrosis transmembrane conductance regulator (CFTR)**, a chloride channel located on the apical surface of epithelial cells. CFTR is important for the proper movement of salt and water across cell membranes and maintaining the appropriate composition of various secretions, especially in the airways, liver, and pancreas. The most common mutation is a deletion of three base pairs resulting in the absence of phenylalanine at the 508 position (Phe508del, F508del). Nearly 2,000 mutations of the *CFTR* gene have been identified to date.

The secretory and absorptive characteristics of epithelial cells are affected by abnormal CFTR, resulting in the clinical manifestations of CF. The altered chloride ion conductance in the sweat gland results in excessively high sweat sodium and chloride levels. This is the basis for the sweat chloride test, which is still the standard diagnostic test for this disorder. It is positive (elevated sweat

chloride ≥ 60 mEq/L) in 99% of patients with CF. Abnormal airway secretions make the airway more prone to colonization with bacteria. Defects in CFTR may also reduce the function of airway defenses and promote bacterial adhesion to the airway epithelium. This ultimately leads to chronic airway infections and eventually to bronchial damage (bronchiectasis).

Clinical Manifestations

Decision-Making Algorithms

- Hemoptysis
- Constipation
- Hepatomegaly
- Failure to Thrive
- Hyponatremia

CF is a chronic progressive disease that can present with protein and fat malabsorption (failure to thrive, hypoalbuminemia, steatorrhea), liver disease (cholestatic jaundice), or chronic respiratory infection ([Table 137.1](#)). Many infants in the United States are currently diagnosed by newborn screening (available in all 50 states and the District of Columbia since 2010). Older children have traditionally presented with pulmonary manifestations such as chronic cough, poorly controlled asthma, and chronic respiratory infections, but recurrent pancreatitis, nasal polyps, and chronic sinusitis can also be presenting manifestations. The respiratory epithelium of patients with CF exhibits marked impermeability to chloride and an excessive reabsorption of sodium. This leads to thicker airway secretions, resulting in airway obstruction and impaired mucociliary transport. This, in turn, leads to endobronchial colonization with bacteria, especially *Staphylococcus aureus* and *Pseudomonas aeruginosa*. Chronic bronchial infection results in persistent or recurrent cough that is often productive of sputum, especially in older children. Chronic airway infection leads to airway obstruction and bronchiectasis and, eventually, to pulmonary insufficiency and premature death. The median age of survival is currently >40 years. **Digital clubbing** is common in patients with CF, even in those without significant lung disease. Chronic sinusitis and **nasal polyposis** are common.

TABLE 137.1**Complications of Cystic Fibrosis**

RESPIRATORY COMPLICATIONS
Bronchiectasis, bronchitis, bronchiolitis, pneumonia Hemoptysis Pneumothorax Nasal polyps Sinusitis Cor pulmonale (associated with chronic hypoxemia) Respiratory failure Atypical mycobacterial infection Allergic bronchopulmonary aspergillosis
GASTROINTESTINAL COMPLICATIONS
Pancreatic insufficiency Meconium ileus/peritonitis (infants) Intestinal atresia (infants) Distal intestinal obstruction syndrome (non-neonatal obstruction) Rectal prolapse Fibrosing colonopathy (strictures) Recurrent pancreatitis Hepatic cirrhosis (portal hypertension, esophageal varices, hypersplenism) Neonatal obstructive jaundice Hepatic steatosis Gastroesophageal reflux Cholelithiasis Growth failure (malabsorption) Fat-soluble vitamin deficiency states (vitamins A, K, E, D) Cystic fibrosis–related diabetes Malignancy (rare)
OTHER COMPLICATIONS
Infertility Delayed puberty Dehydration–heat exhaustion Electrolyte disturbances (hyponatremic hypochloremic metabolic alkalosis) Hypertrophic osteoarthropathy–arthritis Pseudotumor cerebri Digital clubbing

Pulmonary infections with *P. aeruginosa* and some strains of *Burkholderia cepacia* are difficult to treat and may be associated with accelerated clinical deterioration. **Allergic bronchopulmonary aspergillosis (ABPA)** is a hypersensitivity reaction to *Aspergillus* in the CF airways. It causes airway inflammation/obstruction and aggravates CF lung disease. The treatment for ABPA is systemic corticosteroids (prednisone) and antifungal agents (itraconazole). Minor hemoptysis is usually due to airway infection, but major hemoptysis is often caused by bleeding from bronchial artery collateral vessels in damaged/chronically infected portions of the lung. Pneumothoraces can occur

in patients with advanced lung disease.

Ninety percent of patients with CF are born with **exocrine pancreatic insufficiency**. The inspissation of mucus and subsequent destruction of the pancreatic ducts result in the inability to excrete pancreatic enzymes into the intestine. This leads to malabsorption of proteins, sugars (to a lesser extent), and especially fat. Fat malabsorption manifests clinically as **steatorrhea** (large, foul-smelling stools), deficiencies of fat-soluble vitamins (A, D, E, and K), and failure to thrive. Protein malabsorption can present early in infancy as hypoproteinemia and peripheral edema. Approximately 10% of patients with CF are born with intestinal obstruction caused by inspissated meconium (**meconium ileus**). In older patients, intestinal obstruction may result from thick inspissated mucus in the intestinal lumen (**distal intestinal obstruction syndrome [DIOS]**). In adolescent or adult patients, progressive pancreatic damage can lead to enough islet cell destruction to cause **insulin deficiency**. This initially presents as glucose intolerance, but true diabetes that requires insulin therapy (**CF-related diabetes**) may develop. The failure of the sweat ducts to conserve sodium and chloride may lead to hyponatremia and hypochloremic metabolic alkalosis, especially in infants. Inspissation of mucus in the reproductive tract leads to reproductive dysfunction in both males and females. In males, congenital absence of the vas deferens and azoospermia are nearly universal. In females, secondary amenorrhea is often present as a result of chronic illness and reduced body weight. Fertility can be diminished by malnutrition and abnormal cervical mucus, but women with CF can conceive.

All infants with a positive newborn screen and/or with meconium ileus should be evaluated for CF. The diagnosis of CF should be seriously considered in any infant presenting with failure to thrive, cholestatic jaundice, chronic respiratory symptoms, or electrolyte abnormalities (hyponatremia, hypochloremia, metabolic alkalosis). CF should be in the differential diagnosis of children with chronic respiratory or gastrointestinal symptoms, especially if there is digital clubbing. Any child with nasal polyps, especially those younger than 12 years, should be evaluated for CF. All siblings of patients with CF should also be evaluated.

Diagnostic Studies

Readily available commercial DNA tests detect many CF mutations, but because there are nearly 2,000 identified mutations (and some of unknown clinical

significance), DNA analysis will not detect all cases of CF. All U.S. states have newborn screening for CF, based either on elevated immunoreactive trypsinogen (IRT) levels or DNA tests, identifying the majority of infants with CF, but there are both false-positive and false-negative results. Therefore the diagnostic test of choice is still the sweat test. Indications for performing a **sweat test** are listed in [Table 137.2](#). The following criteria should be met to establish the diagnosis of CF:

TABLE 137.2

Indications for Sweat Testing

RESPIRATORY
Chronic or recurrent cough Chronic or recurrent pneumonia Recurrent bronchiolitis Recurrent wheezing/difficult to control asthma Recurrent or persistent atelectasis Hemoptysis <i>Pseudomonas aeruginosa</i> in the respiratory tract (if not explained by other factors, e.g., tracheostomy or prolonged intubation)
GASTROINTESTINAL
Meconium ileus Neonatal intestinal obstruction (meconium plug, atresia) Steatorrhea, malabsorption Hepatic cirrhosis in childhood (including any manifestations such as esophageal varices or portal hypertension) Cholestatic jaundice in infancy Pancreatitis Rectal prolapse Fat-soluble vitamin deficiency states (A, D, E, K) Hypoproteinemia, hypoalbuminemia, peripheral edema unexplained by other causes Prolonged, direct-reacting neonatal jaundice
MISCELLANEOUS
Positive newborn screen (sweat testing performed after 2 wk of age and >2 kg if asymptomatic) Digital clubbing Failure to thrive Family history of cystic fibrosis (e.g., in sibling or cousin) Salty taste of skin (typically noted by parent on kissing affected child—from salt crystals formed after evaporation of sweat) Hyponatremic hypochloremic alkalosis in infants Nasal polyps Recurrent sinusitis Aspermia Absent vas deferens

- The presence of one or more typical clinical features of CF (chronic pulmonary disease, characteristic gastrointestinal and

nutritional abnormalities, salt loss syndromes, or obstructive azoospermia) AND

- Two elevated sweat chloride tests performed at an accredited CF Foundation certified laboratory (positive if the value is ≥ 60 mEq/L, borderline if 30-59 mEq/L, and negative if < 30 mEq/L, with adequate sweat collection) OR
- Two mutations known to cause CF identified by DNA analysis OR
- A characteristic abnormality in ion transport across nasal epithelium demonstrated in vivo (nasal potential difference testing)

For those identified by positive newborn screening or because a sibling has CF, positive sweat chloride testing or the presence of known disease-causing DNA mutations are the only criteria required for diagnosis, as clinical symptoms may not be manifested early in life.

Although the sweat test is both specific and sensitive for CF, it is subject to technical problems with both false-positive and false-negative results (Table 137.3). Cutoff diagnostic measurements evolve as more disease-causing DNA mutations are identified. Other supportive tests include the measurement of bioelectrical potential differences across nasal epithelium (not widely available) and measurement of fecal elastase levels. Low fecal elastase levels indicate exocrine pancreatic insufficiency. CF genotyping done by commercial laboratories identifies approximately 95% of patients with CF, but there are mutations that are not identified by standard testing. Not all mutations in CFTR are considered disease-causing, and some have uncertain prognostic consequences. Some infants identified by newborn screening with borderline sweat tests and mutations of uncertain consequence are considered to have CFTR-related metabolic syndrome (CRMS). Older children that present with atypical clinical features and borderline sweat tests may be considered nonclassic CF or mild variant CF.

TABLE 137.3

Causes of False-Positive and False-Negative Results on Sweat Testing

--

FALSE-POSITIVE
Adrenal insufficiency Eczema Ectodermal dysplasia Nephrogenic diabetes insipidus Hypothyroidism Fucosidosis Mucopolysaccharidosis Dehydration Malnutrition Poor technique/inadequate sweat collection Type I glycogen storage disease Panhypopituitarism Pseudohypoaldosteronism Hypoparathyroidism Prostaglandin E ₁ administration
FALSE-NEGATIVE
Edema Poor technique/inadequate sweat collection

Identification of carriers (heterozygotes) and prenatal diagnosis of children with the $\Delta F508$ and other common mutations is offered at most medical centers. Prenatal testing techniques can identify more than 90% of carriers. Prenatal detection of a known CF genotype may be accomplished by amniocentesis or chorionic villus sampling.

Treatment

The treatment of CF is multifactorial. Most maintenance therapies are directed toward the gastrointestinal and pulmonary complications. Presently, there is no effective single cure for CF. Precision therapies, known as CFTR modulators, target genotype-specific functional defects of the CFTR protein. Ivacaftor, the first CFTR modulator approved by the U.S. Food and Drug Administration (FDA), is a small molecule potentiator that improves CFTR function in a small group of CF individuals who have an abnormal gating mechanism of their CFTR protein, contributing to sustained health improvements including lung function. The second FDA-approved medication is a combination of ivacaftor and lumacaftor, approved for individuals with two copies of the most common CFTR mutation, F508del. It has been associated with a modest but significant improvement in lung function, improved body mass index, and a decrease in hospitalizations for pulmonary exacerbations. Clinical trials are actively underway for the next generation of CFTR modulators.

Treatment with CFTR modulator therapy does not preclude management of

pulmonary complications. Management of pulmonary exacerbations is directed toward facilitating clearance of secretions from the airways and minimizing the effects of chronic bronchial infection. Airway secretion clearance techniques (**chest physiotherapy**) help remove mucus from the airways, and aerosolized DNAse and 7% hypertonic saline, both delivered by nebulizer, decrease the viscosity of mucus. **Antibiotic therapy** is important in controlling chronic infection. Monitoring pulmonary bacterial flora via airway cultures and providing aggressive therapy with appropriate antibiotics (oral, aerosolized, and intravenous [IV]) help to slow the progression of lung disease. Patients often require 2-3-week courses of high-dose IV antibiotics and aggressive chest physiotherapy to treat pulmonary exacerbations. Antibiotics are selected based on organisms identified by sputum culture. If patients are unable to provide sputum, then a throat culture for CF pathogens can be used to direct therapy. Common infecting organisms include *P. aeruginosa* and *S. aureus*.

Exocrine pancreatic insufficiency is treated with enteric-coated pancreatic enzyme capsules, which contain lipase and proteases. Patients with CF are encouraged to follow high-calorie diets, often with the addition of nutritional supplements. Even with optimal pancreatic enzyme replacement, stool losses of fat and protein may be high. Fat should not be withheld from the diet, even when significant steatorrhea exists. Rather, pancreatic enzyme doses should be titrated to optimize fat absorption, although there is a limit to the doses that should be used. Lipase dosages exceeding 2,500 U/kg per meal are concerning because they have been associated with **fibrosing colonopathy**. Fat-soluble vitamins (A, D, E, and K) are recommended, preferably in a water-miscible form.

Newborns with **meconium ileus** may require surgical intervention, but some can be managed with contrast (Gastrografin) enemas. Intestinal obstruction in CF patients beyond the neonatal period is often due to DIOS, which may need to be treated with courses of oral laxatives (polyethylene glycol) or, in more refractory cases, with Gastrografin enemas. Pancreatic enzyme dosage adjustment, adequate hydration, and dietary fiber may help prevent recurrent episodes. Patients with CF-related diabetes are treated with insulin, primarily to improve nutrition and prevent dehydration, as ketoacidosis is rare. Although transaminase elevation is common in patients with CF, only 1-3% of patients have progressive cirrhosis resulting in portal hypertension. Cholestasis may be treated with the bile salt ursodeoxycholic acid. Portal hypertension and esophageal varices due to cirrhosis of the liver are managed, when necessary, with portal vein shunting procedures or liver transplantation. Patients with

symptomatic sinus disease and nasal polyps not responding to medical management may require surgical intervention.

The management of CF is complex and is best coordinated by medical teams at accredited CF centers. More than 50% of the CF population are now adults, highlighting the importance of a successful transition of pediatric patients to adult centers. As with other severe chronic diseases, management of CF patients requires a multidisciplinary team working with patients and their families to maintain an optimistic, comprehensive, and aggressive approach to treatment.

CHAPTER 138

Chest Wall and Pleura

Thoracic scoliosis, when it is severe (curve >60 degrees), can be associated with chest wall deformity and limitation of chest wall movement (see [Chapter 202](#)). This, in turn, can lead to decreased lung volumes (restrictive lung disease), ventilation-perfusion mismatching, hypoventilation, and even respiratory failure (see [Chapter 39](#)). Surgical correction of scoliosis may prevent further loss of lung function, but it rarely improves pulmonary function beyond presurgical levels.

Pectus Excavatum and Carinatum

Pectus Excavatum

Sternal concavity (**pectus excavatum**), a common chest wall deformity in children, is usually not associated with significant pulmonary compromise. Patients with pectus excavatum generally come to medical attention because of concerns over the appearance of the chest. However, occasionally, if severe, it may result in restrictive lung disease, obstructive defects, and/or decreased cardiac function. Adolescents with pectus excavatum may complain of exercise intolerance. Routine spirometry is often normal but may show decreased vital capacity consistent with restrictive lung disease. The main reason for surgical correction is generally to improve appearance (cosmetic reasons), although in some cases surgical repair is justified to improve cardiac function and exercise

tolerance.

Pectus Carinatum

Pectus carinatum is an abnormality of chest wall shape in which the sternum bows out. It is not associated with abnormal pulmonary function. Underlying pulmonary disease may contribute to the deformity. It can be observed after cardiac surgery performed via midsternal approach. Surgical correction of this condition is rarely indicated, but occasionally is done for cosmetic purposes.

Pneumothorax

Etiology

Pneumothorax, which is the accumulation of air in the pleural space, may result from external trauma or from leakage of air from the lungs or airways. **Spontaneous primary pneumothorax** (no underlying cause) occurs in teenagers and young adults, more commonly in tall, thin males and smokers. Factors predisposing to **secondary pneumothorax** (underlying cause identified) include barotrauma from mechanical ventilation, asthma, cystic fibrosis, trauma to the chest, and severe necrotizing pneumonia.

Clinical Manifestations

Decision-Making Algorithm

Chest Pain

The most common signs and symptoms of pneumothorax are chest and shoulder pain and dyspnea. If the pneumothorax is caused by air that enters the pleural space during inspiration and cannot escape, mediastinal shift and functional lung compression may occur, resulting in **tension pneumothorax** with severe respiratory distress and hemodynamic changes (reduced venous return to the heart). Subcutaneous emphysema may result when the air leak communicates with the mediastinum. Physical findings associated with pneumothorax include decreased breath sounds on the affected side, a tympanic

percussion note, and evidence of mediastinal shift (deviation of the point of maximal impact [PMI] and trachea away from the side of the pneumothorax). If the pneumothorax is small, there may be few or no clinical findings. However, the patient's clinical condition can deteriorate rapidly if the pneumothorax expands, especially if the air in the pleural space is under pressure (**tension pneumothorax**). This is a life-threatening condition that can result in death if the pleural space is not decompressed by evacuation of the pleural air.

Diagnostic Studies

The presence of a pneumothorax can usually be confirmed by upright chest radiographs. Computed tomography (CT) scans of the chest are useful in quantifying the size of pneumothoraces and differentiating air within the lung parenchyma (cystic lung disease) from air in the pleural space and for identifying subpleural blebs that may be present in spontaneous recurrent pneumothoraces. However, CT scans are generally not necessary unless chest x-rays suggest the need for further evaluation. In infants, transillumination of the chest wall may be of some use in making a rapid diagnosis of pneumothorax.

Treatment

The type of intervention depends on the size of the pneumothorax and the nature of the underlying disease. Small pneumothoraces (<20% of thorax occupied with pleural air) may not require intervention as they often resolve spontaneously. Inhaling high concentrations of supplemental O₂ may enhance reabsorption of pleural air by washing out nitrogen from the blood. Larger pneumothoraces and any tension pneumothorax require immediate drainage of the air, preferably via chest tube. In an emergency situation, a simple needle aspiration may suffice, although placement of a chest tube is often required for resolution. In patients with recurrent or persistent pneumothoraces, sclerosing the pleural surfaces to obliterate the pleural space (pleurodesis) may be necessary. This can be done either chemically, by instilling talc or sclerosis agents (doxycycline) through the chest tube, or mechanically, by surgical abrasion. Surgical approaches, such as open thoracotomy and video-assisted thoracoscopic surgery (VATS), enable visualization of the pleural space and resection of pleural blebs, when indicated. Airline travel and spirometry may be restricted for a period of time (2 weeks or longer) following radiographic resolution of the pneumothorax to minimize risk

of recurrence.

Pneumomediastinum

Pneumomediastinum results from the dissection of air from the pulmonary parenchyma into the mediastinum. It is usually a mild, self-limited process that does not require aggressive intervention. The most common causes in children are severe forceful coughing and acute asthma exacerbations. Common symptoms are chest pain and dyspnea. There are often no physical findings, although a crunching noise over the sternum can sometimes be appreciated on auscultation and subcutaneous emphysema may be detected about the neck. The diagnosis is confirmed by chest radiograph, and treatment is directed toward the underlying lung disease.

Pleural Effusion

Etiology

Fluid accumulates in the pleural space when the local hydrostatic forces that are pushing fluid out of the vascular space exceed the oncotic forces that are drawing fluid back into the vascular space. Pleural effusions can be transudates (intact membrane but abnormal hydrostatic or oncotic forces) or exudates (decreased integrity of the membrane due to inflammatory processes or impaired lymphatic drainage). There are relatively few causes of transudates, the primary ones being congestive heart failure and hypoproteinemia states, whereas the causes of exudates are numerous. Almost any pulmonary inflammatory process can result in pleural fluid accumulation. Among the most common causes of exudates are infection (e.g., tuberculosis, bacterial pneumonia), collagen vascular diseases (e.g., systemic lupus erythematosus), and malignancy. Chylous pleural effusions (elevated triglyceride levels) are seen with thoracic duct injury and abnormalities of lymphatic drainage (lymphangiomyomatosis, lymphangiectasia). Bacterial pneumonia can lead to an accumulation of pleural fluid (**parapneumonic effusion**). When this fluid is purulent or infected, then it is called an **empyema**, although often the terms parapneumonic effusion and empyema are used interchangeably. Parapneumonic effusion/empyema is the most common reason for effusion in children. Upright and decubitus chest radiograph ([Fig. 138.1](#)) can be useful for identifying parapneumonic effusion; however, chest ultrasound or CT is necessary for accurate estimates of fluid

volume and organization (loculation) if surgical drainage is being considered. Most parapneumonic effusions are due to pneumonia caused by *Streptococcus pneumoniae*, group A streptococci, or *Staphylococcus aureus*.

FIGURE 138.1 Parapneumonic effusion. *A*, Posterior-anterior chest radiograph showing dense opacification of the right hemithorax. *B*, On decubitus view, some of the density forms a horizontal layer indicating that there is pleural fluid in addition to pneumonia.

Clinical Manifestations

Decision-Making Algorithm

Chest Pain

Small pleural effusions may be asymptomatic, but if they are large enough to compress lung tissue, then they can cause dyspnea, tachypnea, and occasionally chest pain. Effusions due to infection are usually associated with fever, malaise, poor appetite, pleuritic chest pain, and splinting. Physical findings include tachypnea, decreased breath sounds, dullness to percussion, and decreased tactile fremitus. Large effusions may occupy more than half the hemithorax and cause a mediastinal shift away from the affected side, compromising respiratory status, particularly in young children.

Diagnostic Studies

The presence of pleural fluid can often be confirmed by chest radiograph. In addition to anteroposterior and lateral projections, a decubitus view should be done to assess for layering of fluid. Chest ultrasonography is useful for confirming the presence of the effusion and quantifying its size. CT scans of the chest can help differentiate pleural fluid from parenchymal lesions and pleural masses. Both ultrasonography and CT scans can determine whether parapneumonic effusions contain loculations (fibrous strands that compartmentalize the effusion).

The analysis of pleural fluid is useful in differentiating a transudate from an exudate. Routine tests on pleural fluid such as cell count, pH, protein, lactate dehydrogenase, and glucose characterize the effusions. Triglyceride levels, cytology, hematocrit, gram and acid-fast bacilli stain, culture, and adenosine deaminase levels can be useful in diagnosing chylous, malignant, and tuberculous effusions (Table 138.1). However, the yield of pleural fluid cultures is low. Transudative pleural effusions have a low specific gravity (<1.015) and protein content (<2.5 g/dL), low lactate dehydrogenase activity (<200 IU/L), and a low white blood cell (WBC) count with few polymorphonuclear cells. In contrast, exudates are characterized by high specific gravity and high protein (>3 g/dL) and lactate dehydrogenase (>250 IU/L) levels. They may also have a low pH (<7.2), low glucose level (<40 mg/dL), and a high WBC count with many lymphocytes or polymorphonuclear leukocytes.

TABLE 138.1

Pleural Fluid Analysis

EXUDATIVE EFFUSION BY LIGHT'S TRADITIONAL CRITERIA
Pleural fluid protein/serum protein ratio >0.5 OR Pleural fluid LDH/serum LDH ratio >0.6 OR Pleural fluid LDH >two thirds the upper limits of laboratory's normal serum LDH
CHYLOTHORAX
Triglycerides >110 mg/dL
TUBERCULOUS
Positive acid-fast bacilli stain, culture Pleural fluid protein >4 g/dL Pleural fluid adenosine deaminase level >35-50 U/L Pleural fluid glucose 30-50 mg/dL
HEMOTHORAX

LDH, Lactate dehydrogenase.

Treatment

Therapy is directed at the underlying condition causing the effusion and at relief of the mechanical consequences of the fluid collection. For small effusions, especially if they are transudates, no pleural drainage is required. Large effusions that are causing respiratory compromise should be drained. Transudates and most exudates, other than parapneumonic effusions, can be drained with a **chest tube**. With parapneumonic effusions/empyema, a chest tube alone is often not sufficient because the fluid may be thick and loculated. In such cases, pleural drainage is best achieved with either the administration of fibrinolytic agents via chest tubes or **VATS**. Approaches to parapneumonic effusions vary widely. Small effusions can be managed conservatively with intravenous antibiotics alone. Both fibrinolytic therapy via chest tubes and VATS can reduce morbidity and length of hospital stay, and many patients with moderate-sized parapneumonic effusions can be treated with chest tube drainage and intravenous antibiotics.

Pearls for Practitioners

Chapter 133

Respiratory System Assessment

- Airway branching is complete at birth; alveolar number increases through childhood.
- Resistance increases with reduction of airway diameter, leading to obstructive lung disease.
- Pulmonary compliance is reduced when lungs, pleura, or chest wall become stiff, leading to restrictive lung disease.
- Ventilation-perfusion (V/Q) mismatch is the most common cause of hypoxemia in children.
- A chest radiograph can provide valuable information about parenchymal, pleural, and airway disease and is recommended as first-line imaging for most patients with respiratory complaints.
- Spirometry is the pulmonary function test of choice for diagnosing asthma and other obstructive lung diseases; body plethysmography is needed to confirm restrictive lung disease.
- Flexible bronchoscopy is useful for evaluation of airway anatomy and obtaining lower respiratory samples; rigid bronchoscopy is required for foreign body removal.

Chapter 134

Control of Breathing

- Ventilation and oxygenation are regulated by central and peripheral chemoreceptors, with signal origin in the deep brainstem.
- Central apnea is more likely secondary (drugs, central nervous system tumor, or trauma) than primary (genetic syndrome).
- Apnea of prematurity should resolve by 44 weeks postmenstrual age.
- A brief resolved unexplained event (BRUE) is defined as a <1 minute, self-limited episode with cyanosis or pallor, irregular breathing, change in tone, or altered level of responsiveness occurring in an infant <1 year of age.

- The risk of sudden infant death syndrome (SIDS) is associated with preterm birth, maternal smoking, prone sleep position, and overinsulation.
- Obstructive sleep apnea is most commonly caused by adenotonsillar hypertrophy in children.
- Polysomnogram is the diagnostic test of choice for obstructive and central apnea.

Chapter 135

Upper Airway Obstruction

- Upper airway obstruction at the level of the glottis or subglottis produces stridor, typically worse when the child is awake and active.
- The most common cause of *noninfectious* stridor in infants is laryngomalacia.
- The most common cause of *infectious* stridor in infants and young children is croup (laryngotracheobronchitis).
- Upper airway obstruction at the level of the pharynx is usually due to soft tissue collapse or enlargement, leading to mouth breathing and snoring that is typically worse during sleep.
- The most common cause of *noninfectious* soft tissue upper airway obstruction in young children is adenotonsillar hypertrophy.
- Common infectious causes of soft tissue upper airway obstruction include retropharyngeal abscess and peritonsillar abscess.

Chapter 136

Lower Airway, Parenchymal, and Pulmonary Vascular Diseases

- The most common cause of lower airway disease in children is asthma.
- Asthma is a clinical disease of variable and recurring symptoms with airway inflammation and bronchial hyperresponsiveness.
- A wheeze is a continuous sound produced by small airway narrowing and is most pronounced on exhalation.
- Tracheomalacia is the most common tracheal abnormality, can be congenital or acquired, and often improves with growth.
- Vascular rings can be complete or incomplete, causing extrinsic tracheal compression, leading to wheezing, stridor, cough, or dyspnea.
- Foreign body aspiration typically occurs in children 1-4 years of age, often with nonradiopaque material such as food (e.g., nuts).
- Primary ciliary dyskinesia (PCD) is associated with chronic sinusitis, chronic otitis media, and recurrent pulmonary infections. Kartagener syndrome (situs inversus, pansinusitis, bronchiectasis) is seen in approximately 50% of cases of PCD.
- Pulmonary hypertension may lead to irreversible pulmonary vascular changes that strain the right heart and lead to cor pulmonale.
- Cor pulmonale is commonly caused by chronic lung disease, particularly severe bronchopulmonary dysplasia and untreated severe obstructive sleep apnea.
- Hemoptysis from pulmonary sources can occur from airway hemorrhage or alveolar bleeding.

Chapter 137

Cystic Fibrosis

- Cystic fibrosis (CF) is an autosomal recessive genetic disorder.
- The gene for CF encodes for a polypeptide, the cystic fibrosis transmembrane conductance regulator (CFTR), a chloride channel

located on the apical surface of epithelial cells.

- Defects in the CFTR gene result in abnormal movement of salt and water across cell membranes leading to thick secretions impacting multiple organ systems.
- Clinical manifestations of CF include chronic cough, recurrent pulmonary infections, failure to thrive, poor growth and weight gain, recurrent sinusitis, nasal polyposis, steatorrhea, recurrent pancreatitis, and rectal prolapse.
- Common pathogens in CF sputum are *Staphylococcus aureus* and *Pseudomonas aeruginosa*.
- Sweat chloride testing is the diagnostic test of choice and confirms diagnosis with newborn screening, genetic testing, and clinical symptoms.
- Management of CF includes enhancing airway clearance, medications to decrease mucus viscosity, treating airway infections, and improving nutritional status with pancreatic enzyme replacement therapy and nutritional supplements.
- Newer therapies are genotype-specific and improve the function of CFTR protein for some individuals with CF.

Chapter 138

Chest Wall and Pleura

- Severe thoracic scoliosis can lead to chest wall deformity that limits lung volumes and causes restrictive lung disease.
- Pectus excavatum (sternal concavity) and pectus carinatum (sternal extrusion) are common chest wall deformities that are typically not associated with significant pulmonary compromise.
- Pneumothorax is an accumulation of air in the pleural space that can occur spontaneously from leakage of air from the lung or airways.
- Pleural effusions can be transudative (e.g., heart failure) or

exudative (e.g., infection/empyema).

- Parapneumonic effusion in children is commonly associated with infection from *Streptococcus pneumoniae*, group A streptococci, or *Staphylococcus aureus*.

CHAPTER 139

Cardiovascular System Assessment

History

A **maternal history** of medication, drug, or alcohol use or excessive smoking may contribute to cardiac and other systemic findings. The **prenatal history** may reveal a maternal infection early in pregnancy (possibly teratogenic) or later in pregnancy (causing myocarditis or myocardial dysfunction in infants). Infants with heart failure exhibit poor **growth**, with weight being more significantly affected than height and head circumference.

Heart failure may present with **fatigue** or **diaphoresis** with feeds or fussiness. **Tachypnea** without significant dyspnea may be present. Older children with heart failure may have easy fatigability, **shortness of breath** on exertion, and, sometimes, orthopnea. Not keeping up with other children during play or exercise is a sign of **exercise intolerance**. Heart failure may be misdiagnosed as recurrent pneumonia, bronchitis, wheezing, or asthma.

A history of a **heart murmur** is important, but many well children have an innocent murmur at some time in their lives. Other cardiac symptoms include cyanosis, palpitations, chest pain, syncope, and near-syncope. A review of systems assesses for possible systemic diseases or congenital malformation syndromes that may cause cardiac abnormalities ([Tables 139.1](#) and [139.2](#)). Current and past medication use as well as history of drug use is important. **Family history** should be reviewed for hereditary diseases, early atherosclerotic heart disease, congenital heart disease, sudden unexplained deaths,

thrombophilia, rheumatic fever, hypertension, and hypercholesterolemia.

TABLE 139.1

Cardiac Manifestations of Systemic Diseases

SYSTEMIC DISEASE	CARDIAC COMPLICATIONS
Hunter-Hurler syndrome	Valvular insufficiency, heart failure, hypertension
Duchenne dystrophy	Cardiomyopathy, heart failure
Pompe disease	Short PR interval, cardiomegaly, heart failure, arrhythmias
Kawasaki disease	Coronary artery aneurysm, thrombosis, myocardial infarction, myocarditis
Marfan syndrome	Aortic and mitral insufficiency, dissecting aortic aneurysm
Juvenile rheumatoid arthritis	Pericarditis
Systemic lupus erythematosus	Pericarditis, Libman-Sacks endocarditis, congenital AV block
Lyme disease	Arrhythmias, myocarditis, heart failure
Graves disease (hyperthyroidism)	Tachycardia, arrhythmias, heart failure
Tuberous sclerosis	Cardiac rhabdomyoma
Neurofibromatosis	Pulmonic stenosis, coarctation of aorta

AV, Atrioventricular.

TABLE 139.2

Congenital Malformation Syndromes Associated With Congenital Heart Disease

SYNDROME	CARDIAC FEATURES
Trisomy 21 (Down syndrome)	Endocardial cushion defect, VSD, ASD, PDA
Trisomy 18	VSD, ASD, PDA, PS
Trisomy 13	VSD, ASD, PDA, dextrocardia
XO (Turner syndrome)	Coarctation of aorta, aortic stenosis
CHARGE association (coloboma, heart, atresia choanae, retardation, genital and ear anomalies)	TOF, aortic arch and conotruncal anomalies*
22q11 (DiGeorge) syndrome	Aortic arch anomalies, conotruncal anomalies*
VACTERL association [†] (vertebral, anal, cardiac, tracheoesophageal, radial, renal, limb anomalies)	VSD
Marfan syndrome	Dilated and dissecting aorta, aortic valve regurgitation, mitral valve prolapse
William syndrome	Supravalvular aortic stenosis, peripheral pulmonary stenosis
Infant of diabetic mother	Hypertrophic cardiomyopathy, VSD, conotruncal anomalies

Asplenia syndrome	Complex cyanotic heart lesions, anomalous pulmonary venous return, dextrocardia, single ventricle, single AV valve
Polysplenia syndrome	Azygos continuation of inferior vena cava, pulmonary atresia, dextrocardia, single ventricle
Fetal alcohol syndrome	VSD, ASD
Fetal hydantoin syndrome	TGA, VSD, TOF

*Conotruncal—tetralogy of Fallot, pulmonary atresia, truncus arteriosus, transposition of great arteries.

†VACTERL association is also known as VATER association, in which the limb anomalies are not included.

ASD, Atrial septal defect; *AV*, atrioventricular; *PDA*, patent ductus arteriosus; *PS*, pulmonic stenosis; *TGA*, transposition of great arteries; *TOF*, tetralogy of Fallot; *VSD*, ventricular septal defect.

Physical Examination

A complete cardiovascular examination starts in the supine position and includes evaluation in sitting and standing positions, when possible. **Inspection** is supplemented by **palpation** and **auscultation** to provide a complete examination.

The examination starts with vital signs. The normal **heart rate** varies with age and activity. Newborn resting heart rates are approximately 120 beats per minute, slightly higher in infants 3-6 months of age, and then gradually declining through adolescence to near 80 beats per minute. The range of normal for any given age is approximately 30 beats per minute above or below the average. Tachycardia may be a manifestation of anemia, dehydration, shock, heart failure, or dysrhythmia. Bradycardia can be a normal finding in patients with high vagal tone (athletes) but may be a manifestation of atrioventricular block. The **respiratory rate** of infants is best assessed while the infant is quiet. Respiratory rate may be increased when there is a left-to-right shunt or pulmonary venous congestion.

Normal **blood pressure** also varies with age. A properly sized cuff should have a bladder width that is at least 90% and a length that is 80-100% of the arm circumference. Initially, blood pressure in the right arm is measured. If elevated, measurements in the left arm and legs are indicated to evaluate for possible coarctation of the aorta. The **pulse pressure** is determined by subtracting the diastolic pressure from the systolic pressure. It is normally below 50 mm Hg or half the systolic pressure, whichever is less. A wide pulse pressure may be seen

with aortopulmonary connections (patent ductus arteriosus [PDA], truncus arteriosus, arteriovenous malformations), aortic insufficiency, or relative intravascular volume depletion (anemia, vasodilation with fever or sepsis). A narrow pulse pressure is seen with pericardial tamponade, aortic stenosis, and heart failure.

Inspection includes general appearance, nutritional status, circulation, and respiratory effort. Many chromosomal abnormalities and syndromes associated with cardiac defects have dysmorphic features or failure to thrive (see [Table 139.2](#)). Skin color must be assessed for **cyanosis** and pallor. Central cyanosis (tongue, lips) is associated with arterial desaturation; isolated peripheral cyanosis (hands, feet) is associated with normal arterial saturation and increased peripheral extraction of oxygen. Perioral cyanosis is a common finding, especially in pale infants or when infants and toddlers become cold. Chronic arterial desaturation results in **clubbing** of the fingernails and toenails. Inspection of the chest may reveal asymmetry or a prominent left precordium, suggesting chronic cardiac enlargement.

After inspection, **palpation** of pulses in all four extremities, the precordial activity, and the abdomen is performed. Pulses are assessed for rate, regularity, intensity, symmetry, and timing between upper and lower extremities. A good pedal pulse with normal right arm blood pressure effectively rules out coarctation of the aorta. The precordium should be assessed for apical impulse, **point of maximum impulse**, hyperactivity, and presence of a **thrill**. Abdominal palpation assesses liver and spleen size. The liver size provides an assessment of intravascular volume and is enlarged with systemic venous congestion. The spleen may be enlarged with infective endocarditis.

Auscultation is the most important part of the cardiovascular examination, but should supplement what already has been found by inspection and palpation. Systematic listening in a quiet room allows assessment of each portion of the cardiac cycle. In addition to heart rate and regularity, the heart sounds, clicks, and murmurs need to be timed and characterized.

Heart Sounds

S_1 is associated with closure of the mitral and tricuspid valves, is usually single, and is best heard at the lower left sternal border (LLSB) or apex ([Fig. 139.1](#)). Although it can normally be split, if a split S_1 is heard, the possibility of an ejection click or, much less commonly, an S_4 should be considered. S_2 is

associated with closure of the aortic and pulmonary valves. It should normally split with inspiration and be single with exhalation. Abnormalities of splitting and intensity of the pulmonary component are associated with significant anatomical and physiological abnormalities (Table 139.3). S_3 is heard in early diastole and is related to rapid ventricular filling. It is best heard at the LLSB or apex and may be a normal sound, but a loud S_3 is abnormal and heard in conditions with dilated ventricles. S_4 occurs late in diastole just before S_1 ; it is best heard at the LLSB/apex and is associated with decreased ventricular compliance. It is rare and is always abnormal.

FIGURE 139.1 Timing of heart murmurs. AV, Atrioventricular.

TABLE 139.3

Abnormal Second Heart Sound

--

SINGLE S₂
Pulmonary hypertension (severe) One semilunar valve (aortic atresia, pulmonary atresia, truncus arteriosus) Malposed great arteries (d-TGA, l-TGA) Severe aortic stenosis
WIDELY SPLIT S₂
Increased flow across valve (ASD, PAPVR) Prolonged flow across valve (pulmonary stenosis) Electrical delay (right bundle branch block) Early aortic closure (severe mitral regurgitation)
PARADOXICALLY SPLIT S₂
Severe aortic stenosis
ABNORMAL INTENSITY OF P2
Increased in pulmonary hypertension Decreased in severe pulmonary stenosis, tetralogy of Fallot

ASD, Atrial septal defect; *d-TGA*, dextro-transposition of the great arteries; *l-TGA*, levo-transposition of the great arteries; *PAPVR*, partial anomalous pulmonary venous return.

Clicks

A click implies a valvular abnormality or dilated great artery. It may be ejection or midsystolic in timing and may or may not be associated with a murmur. A midsystolic click is associated with mitral valve prolapse. **Ejection clicks** occur early in systole. Pulmonary ejection clicks are best heard at the left upper sternal border and vary in intensity with respiration. Aortic clicks are often louder at the apex, left midsternal border, or right upper sternal border and do not vary with respiration.

Murmurs

Decision-Making Algorithm

Heart Murmurs

Murmur evaluation should determine timing, duration, location, intensity, radiation, and frequency or pitch of the murmur. The timing determines a murmur's significance and can be used to develop a differential diagnosis (see [Fig. 139.1](#)). Murmurs should be classified as **systolic**, **diastolic**, or **continuous**.

Most murmurs are systolic and can be divided further into systolic ejection murmurs or holosystolic (also called pansystolic or regurgitant) murmurs. **Ejection murmurs** are crescendo-decrescendo with a short time between S_1 and the onset of the murmur (isovolumic contraction). Systolic ejection murmurs require the ejection of blood from the ventricle and may occur with aortic stenosis, pulmonary stenosis, atrial septal defects (ASDs), and coarctation of the aorta. **Holosystolic murmurs** have their onset with S_1 . The murmur has a plateau quality and may be heard with ventricular septal defects (VSDs) and mitral or tricuspid regurgitation. A *late regurgitant* murmur may be heard after a midsystolic click in mitral valve prolapse.

Murmurs are often heard along the path of blood flow. Ejection murmurs usually are best heard at the base of the heart, whereas holosystolic murmurs are louder at the LLSB and apex. Pulmonary ejection murmurs radiate to the back and axilla. Aortic ejection murmurs radiate to the neck. The **intensity** or loudness of a heart murmur is assessed as grade I through VI (Table 139.4). The **frequency** or pitch of a murmur provides information regarding the pressure gradient. The higher the pressure gradient across a narrowed area (valve, vessel, or defect), the faster the flow and higher the frequency of the murmur. Low-frequency murmurs imply low-pressure gradients and mild obstruction or less restriction to flow.

TABLE 139.4

Heart Murmur Intensity

GRADE	DESCRIPTION
Grade I	Very soft, heard in quiet room with cooperative patient
Grade II	Easily heard but not loud
Grade III	Loud but no thrill
Grade IV	Loud with palpable thrill
Grade V	Loud with thrill, audible with stethoscope at 45-degree angle
Grade VI	Loud with thrill, audible with stethoscope off chest 1 cm

Diastolic murmurs are much less common than systolic murmurs and should be considered abnormal. Early diastolic murmurs occur when there is regurgitation through the aortic or pulmonary valve. Mid-diastolic murmurs are caused by increased flow (ASD, VSD) or anatomical stenosis across the mitral or tricuspid valves.

Continuous murmurs are heard when there is flow through the entire cardiac cycle and are abnormal with one common exception, the **venous hum**. A PDA is the most common abnormal continuous murmur. Continuous murmurs can also be heard with coarctation of the aorta when collateral vessels are present.

Normal physiological or **innocent murmurs** are common, occurring in at least 80% of normal infants and children and are heard most often during the first 6 months of life, from 3-6 years of age, and in early adolescence. They have also been called benign, functional, vibratory, and flow murmurs. Characteristic findings of innocent murmurs include the quality of the sound, a lack of significant radiation, and a significant alteration in the intensity of the murmur with positional changes (Table 139.5). Most important, the cardiovascular history and examination are otherwise normal. The presence of symptoms, including failure to thrive or dysmorphic features, should make one more cautious about diagnosing a *normal* murmur. Diastolic, holosystolic, late systolic, and continuous (except for the venous hum) murmurs and the presence of a thrill are not normal.

TABLE 139.5

Normal or Innocent Heart Murmurs

MURMUR	CLINICAL FEATURES	USUAL AGE WHEN HEARD
Still's murmur/vibratory murmur	Systolic ejection murmur LLSB or between LLSB and apex Grades I-III/VI Vibratory, musical quality Intensity decreases in upright position	3-6 yr
Venous hum	Continuous murmur Infraclavicular region (right > left) Grades I-III/VI Louder with patient in upright position Changes with compression of jugular vein or turning head	3-6 yr
Carotid bruit	Systolic ejection murmur Neck, over carotid artery Grade I-III/VI	Any age
Adolescent ejection murmur	Systolic ejection murmur LUSB Grade I-III/VI Usually softer in upright position Does not radiate to back	8-14 yr
Normal peripheral pulmonary stenosis murmur	Systolic ejection murmur Axilla and back, LUSB/RUSB	Newborn-6 mo

LLSB, Left lower scapular border; *LUSB*, left upper scapular border; *RUSB*, right upper scapular border.

Laboratory and Imaging Tests

Pulse Oximetry

Mild desaturation that is not clinically apparent may be the only early finding in complex congenital heart defects. Comparing pulse oximetry between the right arm and a lower extremity may allow diagnosis of a ductal-dependent lesion in which desaturated blood flows right to left across a PDA to perfuse the lower body. This is now becoming a routine screening test in newborn infants to rule out congenital heart disease.

Electrocardiography

The 12-lead electrocardiogram (ECG) provides information about the **rate**, **rhythm**, **depolarization**, and **repolarization** of the cardiac cells and the size and wall thickness of the chambers. It should be assessed for rate, rhythm, axis (P wave, QRS, and T wave), intervals (PR, QRS, QTc; [Fig. 139.2](#)), and voltages (left atrial, right atrial, left ventricular, right ventricular) adjusted for the child's age.

FIGURE 139.2 Nomenclature of electrocardiogram waves and intervals.

The **P wave** represents atrial depolarization. A criterion for right atrial enlargement is an increase of the amplitude of the P wave, reflected best in lead II. The diagnosis of left atrial enlargement is made by prolongation of the second portion of the P wave, exhibited best in the chest leads.

The **PR interval**, measured from the beginning of the P wave to the beginning of the QRS complex, increases with age. Conduction time is shortened when the conduction velocity is increased (glycogen storage disease) or when the atrioventricular node is bypassed (Wolff-Parkinson-White syndrome). A prolonged PR interval usually indicates slow conduction through the atrioventricular node. Diseases in the atrial myocardium, the bundle of His, or the Purkinje system may also contribute to prolonged PR intervals.

The **QRS complex** represents ventricular depolarization. A greater ventricular volume or mass causes a greater magnitude of the complex. The proximity of the right ventricle to the chest surface accentuates that ventricle's contribution to the complex. Changes in the normal ECG occur with age. Normative data for each age group must be known to make a diagnosis from the ECG.

The **QT interval** is measured from the beginning of the QRS complex to the end of the T wave. The corrected QT interval (corrected for rate) should be less than 0.45 second ($QT_c = QT / \sqrt{\text{preceding R to R interval}}$). The interval may be prolonged in children with hypocalcemia or severe hypokalemia. It is also

prolonged in a group of children at risk for severe ventricular arrhythmias and sudden death (**prolonged QT syndrome**). Drugs such as quinidine and erythromycin may prolong the QT interval.

Chest Radiography

A systematic approach to reading a chest radiograph includes assessment of extracardiac structures, the shape and size of the heart, and the size and position of the pulmonary artery and aorta (Fig. 139.3). Assessment of the location and size of the heart and **cardiac silhouette** may suggest a cardiac defect. On a good inspiratory film, the cardiothoracic ratio should be less than 55% in infants under 1 year of age and less than 50% in older children and adolescents. An enlarged heart may be due to an increased volume load (left-right shunt) or due to myocardial dysfunction (dilated cardiomyopathy). The shape of the heart may suggest specific congenital heart defects. The most common examples are the *boot-shaped* heart seen with tetralogy of Fallot, the *egg-on-a-string* seen with dextroposed transposition of the great arteries, and the “snowman” seen with supracardiac total anomalous pulmonary venous return. The chest x-ray can aid in the assessment of **pulmonary blood flow**. Defects associated with left-to-right shunting have increased pulmonary blood flow (*shunt vascularity*) on x-ray. Right-to-left shunts have decreased pulmonary blood flow.

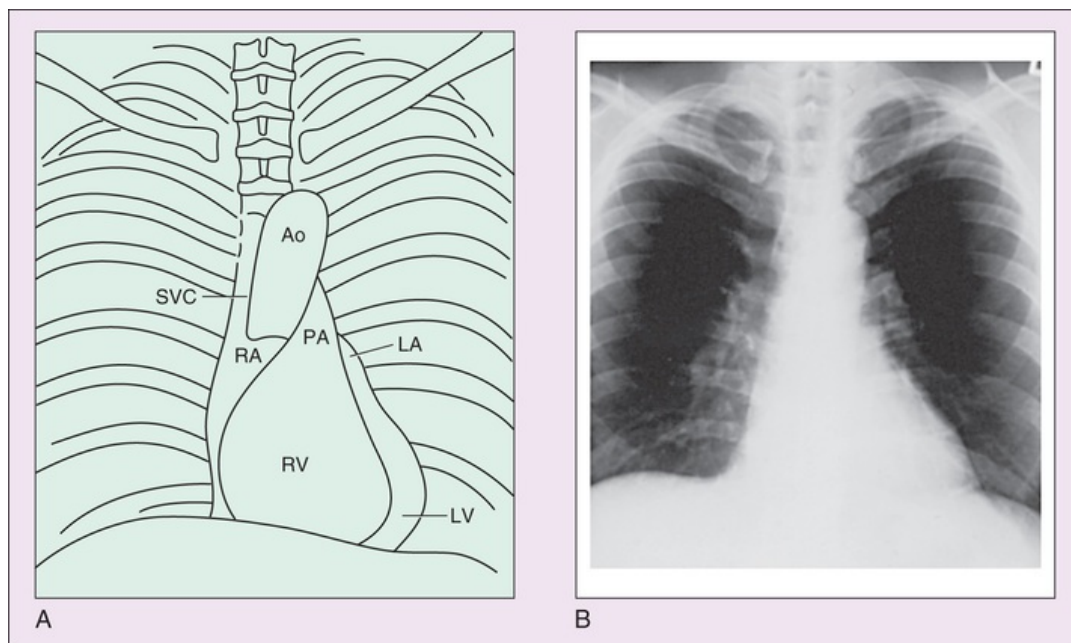

FIGURE 139.3 **A**, Parts of the heart whose outlines can be identified on a routine chest x-ray. **B**, Routine posteroanterior x-ray of the normal cardiac silhouette. *Ao*, Aorta; *LA*, left atrium; *LV*, left ventricle; *PA*, pulmonary artery; *RA*, right atrium; *RV*, right ventricle; *SVC*, superior vena cava. (From Andreoli TE, Carpenter CCJ, Plum F, et al, eds. *Cecil Essentials of Medicine*. 2nd ed. Philadelphia: WB Saunders; 1990.)

Echocardiography

Echocardiography has become the most important noninvasive tool in the diagnosis and management of cardiac disease, providing a full anatomical evaluation in most congenital heart defects (Fig. 139.4). Physiological data on the direction of blood flow can be obtained with the use of pulsed, continuous wave, and color flow Doppler. Imaging from multiple views provides an assessment of spatial relationships. Three-dimensional (3D) and four-dimensional (4D) imaging now allows reconstruction of the heart and manipulation of the images to provide more detail, especially with regard to valve structure and function. Prenatal or fetal echocardiography can diagnose congenital heart disease by 18 weeks of gestation and allows for delivery of the infant at a tertiary care hospital, improving the timeliness of therapy. Many congenital heart defects now are surgically repaired based on the echocardiogram without need for cardiac catheterization.

FIGURE 139.4 Four-chamber echocardiogram of an atrial septal defect. The defect margins are identified by the two *arrows*. *LA*, Left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle.

Transesophageal echocardiography (TEE) provides better imaging when transthoracic imaging is inadequate. It is used intraoperatively to assess results and cardiac function after surgery. TEE and intracardiac echocardiography are used to guide interventional catheterization and radiofrequency ablation of dysrhythmias.

Cardiac Catheterization

Cardiac catheterization is performed in patients who need additional anatomical information or precise hemodynamic information before operating or establishing a management plan. Pressures, oxygen saturations, and oxygen content are measured in each chamber and blood vessel entered (Fig. 139.5). This information is used to calculate systemic and pulmonary blood flow and resistance. Angiography is performed by injecting contrast material into selected sites to define anatomy and supplement noninvasive information. An increasing percentage of cardiac catheterizations are done to perform an intervention,

including balloon dilation of stenotic valves and vessels, ballooning and stenting of stenotic lesions, closure of collateral vessels by coil embolization, and device closure of PDAs, secundum ASDs, patent foramen ovaes, and muscular VSDs. Catheterization with electrophysiological studies allows for precise mapping of the electrical activity, can assess the risk of abnormal heart rhythms, and, often, is done in anticipation of radiofrequency ablation of the site of a dysrhythmia.

CHAPTER 140

Syncope

Decision-Making Algorithm

Syncope

Etiology

Syncope is the transient loss of consciousness and muscle tone that, by history, does not suggest other altered states of consciousness. Presyncope or near-syncope has many or all of the prodromal symptoms without loss of consciousness. Syncope is relatively common (Table 140.1) and is most commonly due to autonomic dysfunction. The frequency of episodes, the amount of stress, and the functional impairment caused by syncope vary. Most syncopal events are relatively benign but can represent a serious cardiac condition that may lead to death (see Table 140.1). The differential diagnosis for typical syncope includes seizure, metabolic cause (hypoglycemia), hyperventilation, atypical migraine, and breath holding.

TABLE 140.1

Syncope and Dizziness: Etiology

DIAGNOSIS	HISTORY	SIGNS/SYMPTOMS	DESCRIPTION	HEART RATE/BLOOD PRESSURE
Neurocardiogenic (vasodepressor)	At rest	Pallor, nausea, visual changes	Brief ± convulsion	↓/↓
OTHER VAGAL				
Micturition	Postvoiding	Pallor, nausea	Brief; convulsions rare	↓/↓
Hair grooming	Standing getting hair done or ears touched	Pallor, nausea, visual changes, lightheaded	Brief	
Cough (deglutition)	Paroxysmal cough	Cough	Abrupt onset	May not change
Carotid sinus	Tight collar, turned head	Vague, visual changes	Sudden onset, pallor	Usually ↓/↓
CARDIAC SYNCOPE				
LVOT obstruction	Exercise	± Chest pain, SOB	Abrupt during or after exertion, pallor	↑/↓
Pulmonary hypertension	Any time, especially exercise	SOB	Cyanosis and pallor	↑/↓
Myocarditis	Post-viral	SOB, chest pain, palpitations	Pallor	↑/↓

	infection exercise			
Tumor or mass	Recumbent, paroxysmal	SOB ± chest pain	Pallor	↑/↓
Coronary artery disease	Exercise	SOB ± chest pain	Pallor	↑/↓
Dysrhythmia	Any time	Palpitations ± chest pain	Pallor	↑ or ↑/↓

LVOT, Left ventricular outflow tract; *SOB*, shortness of breath; ±, with or without; (+), yes but not consistent or predictable.

From Lewis DA. Syncope and dizziness. In: Kliegman RM, ed. *Practical Strategies in Pediatric Diagnosis and Therapy*. Philadelphia: WB Saunders; 1996.

Clinical Manifestations

Typical syncopal events usually occur in the upright position or are related to changing position. Syncope may be associated with anxiety, pain, blood drawing or the sight of blood, fasting, a hot environment, or crowded places. The patient often appears pale. A prodrome, consisting of dizziness, lightheadedness, nausea, diaphoresis, visual changes (blacking out), or possibly palpitations, warns the patient and often prevents injury. Unconsciousness lasts for less than 1 minute. A return to normal consciousness occurs relatively quickly. Most of these syncopal episodes are vasovagal or neurocardiogenic in origin. The physical examination is normal.

Diagnostic Studies

Syncopal episodes may require no more than reassurance to the patient and family. If the episodes have a significant impact on daily activities, further evaluation may be indicated. An electrocardiogram (ECG) should be obtained with attention to the QTc and PR intervals (see [Chapter 139](#)). Although reassurance and increasing fluid and salt intake may be adequate to treat most cases of syncope, medical management is sometimes indicated.

CHAPTER 141

Chest Pain

Decision-Making Algorithm

Chest Pain

Etiology

Chest pain in the pediatric patient often generates a significant amount of patient and parental concern. Although chest pain is rarely cardiac in origin in children, common knowledge about atherosclerotic heart disease raises concerns about a child experiencing chest pain. Most diagnosable chest pain in childhood is musculoskeletal in origin. However, a significant amount remains idiopathic. Knowledge of the complete differential diagnosis is necessary to make an accurate assessment (Table 141.1).

TABLE 141.1

Differential Diagnosis of Pediatric Chest Pain

COMMON
Musculoskeletal Costochondritis Trauma or muscle overuse/strain Pulmonary Asthma (often exercise induced) Severe cough Pneumonia Gastrointestinal Reflux esophagitis Psychogenic Anxiety, hyperventilation Miscellaneous Precordial catch syndrome (Texidor twinge) Sickle cell vasoocclusive crisis Idiopathic
UNCOMMON/RARE
Cardiac Ischemia (coronary artery abnormalities, severe AS or PS, HOCM, cocaine) Infection/inflammation (myocarditis, pericarditis, Kawasaki disease) Dysrhythmia Musculoskeletal Abnormalities of rib cage/thoracic spine Tietze syndrome Slipping rib Tumor Pulmonary

Pleurisy
Pneumothorax, pneumomediastinum
Pleural effusion
Pulmonary embolism
Gastrointestinal
Esophageal foreign body
Esophageal spasm
Psychogenic
Conversion symptoms
Somatization disorders
Depression

AS, Aortic stenosis; *HOCM*, hypertrophic obstructive cardiomyopathy; *PS*, pulmonary stenosis.

Clinical Manifestations

Assessment of a patient with chest pain includes a thorough history to determine activity at the onset; the location, radiation, quality, and duration of the pain; what makes the pain better and worse during the time that it is present; and any associated symptoms. A family history and assessment of how much anxiety the symptom is causing are important and often revealing. A careful general physical examination should focus on the chest wall, heart, lungs, and abdomen. A history of chest pain associated with exertion, syncope, or palpitations or acute onset associated with fever suggests a cardiac etiology. Cardiac causes of chest pain are generally ischemic, inflammatory, or arrhythmic in origin.

Diagnostic Studies

Tests rarely are indicated based on the history. A chest x-ray, electrocardiogram (ECG), 24-hour Holter monitoring, echocardiogram, and exercise stress testing may be obtained based on history and examination. Referral to a pediatric cardiologist is based on the history, physical examination findings, family history, and, frequently, the level of anxiety in the patient or family members regarding the pain.

CHAPTER 142

Dysrhythmias

Decision-Making Algorithm

Palpitations

Etiology and Differential Diagnosis

Cardiac dysrhythmias or abnormal heart rhythms are uncommon in pediatrics but may be caused by infection and inflammation, structural lesions, metabolic abnormalities, and intrinsic conduction abnormalities (Table 142.1). Many pediatric dysrhythmias are normal variants that do not require treatment or even further evaluation.

TABLE 142.1

Etiology of Dysrhythmias

DRUGS
Intoxication (cocaine, tricyclic antidepressants, and others) Antiarrhythmic agents (proarrhythmic agents [quinidine]) Sympathomimetic agents (caffeine, theophylline, ephedrine, and others) Digoxin
INFECTION AND POSTINFECTION
Myocarditis Lyme disease Endocarditis Diphtheria Guillain-Barré syndrome Rheumatic fever
METABOLIC-ENDOCRINE
Electrolyte disturbances ($\downarrow K^+$, $\downarrow Ca^{2+}$, $\downarrow Mg^{2+}$) Cardiomyopathy Thyrotoxicosis Uremia Pheochromocytoma Porphyria Mitochondrial myopathies
STRUCTURAL LESIONS
Congenital heart defects Ventricular tumor Ventriculotomy Arrhythmogenic right ventricle (dysplasia)
OTHER CAUSES
Adrenergic-induced

Prolonged QT interval Maternal systemic lupus erythematosus Idiopathic Central venous catheter

Sinus rhythm originates in the sinus node and has a normal axis P wave (upright in leads I and aVF) preceding each QRS complex. Because normal rates vary with age, sinus bradycardia and sinus tachycardia are defined based on age. **Sinus arrhythmia** is a common finding in children and represents a normal variation in the heart rate associated with breathing. The heart rate increases with inspiration and decreases with expiration, producing a recurring pattern on the electrocardiogram (ECG) tracing. Sinus arrhythmia is normal and does not require further evaluation or treatment.

Atrial Dysrhythmias

A **wandering atrial pacemaker** is a change in the morphology of the P waves with variable PR interval and normal QRS complex. This is a benign finding, requiring no further evaluation or treatment.

Premature atrial contractions are relatively common prenatally and in infants. A premature P wave, usually with an abnormal axis consistent with its ectopic origin, is present. The premature atrial activity may be blocked (no QRS following it), conducted normally (normal QRS present), or conducted aberrantly (a widened, altered QRS complex). Premature atrial contractions are usually benign and, if present around the time of delivery, usually disappear during the first few weeks of life.

Atrial flutter and **atrial fibrillation** are uncommon dysrhythmias in pediatrics and usually present after surgical repair of complex congenital heart disease. They may also be seen in patients with myocarditis or in association with drug toxicity.

Supraventricular tachycardia (SVT) is the most common symptomatic dysrhythmia in pediatric patients. The rhythm has a rapid, regular rate with a narrow QRS complex. SVT in infants is often 280-300 beats per minute with slower rates for older children and adolescents. The tachycardia has an abrupt onset and termination. In a child with a structurally normal heart, most episodes are relatively asymptomatic other than a pounding heartbeat. If there is structural heart disease or the episode is prolonged (>12 hours), there may be an alteration in the cardiac output and development of symptoms of heart failure. Although most patients with SVT have structurally normal hearts and normal baseline

ECGs, some children have Wolff-Parkinson-White syndrome or preexcitation as the cause of the dysrhythmia.

Ventricular Dysrhythmias

Premature ventricular contractions (PVCs) are less common than premature atrial contractions in infancy but more common in older children and adolescents (Table 142.2). The premature beat is not preceded by a P wave, and the QRS complex is wide and bizarre. If the heart is structurally normal, and the PVCs are singleton, uniform in focus, and disappear with increased heart rate, they are usually benign and require no treatment. Any deviation from the presentation (history of syncope or a family history of sudden death) requires further investigation and possibly treatment with antiarrhythmic medications.

TABLE 142.2

Dysrhythmias in Children

TYPE	ELECTROCARDIOGRAM CHARACTERISTICS	TREATMENT
Supraventricular tachycardia	Rate usually >220 beats/min (range, 180-320 beats/min); abnormal atrial rate for age; P waves may be present and are related to QRS complex; normal, narrow QRS complexes unless aberrant conduction is present	Increase vagal tone (bag of ice water to face, Valsalva maneuver); adenosine; digoxin; sotalol; electrical cardioversion if acutely ill; catheter ablation
Atrial flutter	Atrial rate usually 300 beats/min, with varying degrees of block; sawtooth flutter waves	Digoxin, sotalol, cardioversion
Premature ventricular contraction	Premature, wide, unusually shaped QRS complex, with large inverted T wave	None if normal heart and if premature ventricular contractions disappear on exercise; lidocaine, procainamide
Ventricular tachycardia	>3 Premature ventricular beats; AV dissociation; fusion beats, blocked retrograde AV conduction; sustained if >30 sec; rate 120-240 beats/min	Lidocaine, amiodarone, procainamide, propranolol, cardioversion
Ventricular fibrillation	No distinct QRS complex or T waves; irregular undulations with varied amplitude and contour, no conducted pulse	Nonsynchronized cardioversion
Complete heart block	Atria and ventricles have independent pacemakers; AV dissociation; escape-pacemaker is at atrioventricular junction if congenital	Awake rate <55 beats/min in neonate or <40 beats/min in adolescent, or hemodynamic instability requires permanent pacemaker
First-degree heart block	Prolonged PR interval for age	Observe, obtain digoxin level if on therapy
Mobitz type I	Progressive lengthening of PR interval until P wave is not	Observe, correct underlying electrolyte

(Wenckebach) second-degree heart block	followed by conducted QRS complex	or other abnormalities
Mobitz type II second-degree heart block	Sudden nonconduction of P wave with loss of QRS complex without progressive PR interval lengthening	Consider pacemaker
Sinus tachycardia	Rate <240 beats/min	Treat cause (fever), remove sympathomimetic drugs

AV, Atrioventricular.

Ventricular tachycardia, defined as three or more consecutive PVCs, is also relatively rare in pediatric patients. Although there are multiple causes of ventricular tachycardia, it usually is a sign of serious cardiac dysfunction or disease. Rapid-rate ventricular tachycardia results in decreased cardiac output and cardiovascular instability. Treatment in symptomatic patients is synchronized cardioversion. Medical management with lidocaine or amiodarone may be appropriate in a conscious asymptomatic patient. Complete evaluation of the etiological picture is necessary, including electrophysiological study.

Heart Block

First-degree heart block is the presence of a prolonged PR interval. It is asymptomatic and, when present in otherwise normal children, requires no evaluation or treatment. **Second-degree heart block** is when some, but not all, of the P waves are followed by a QRS complex. Mobitz type I (also known as Wenckebach) is characterized by a progressive prolongation of the PR interval until a QRS complex is dropped. It is often seen during sleep, usually does not progress to other forms of heart block, and does not require further evaluation or treatment in otherwise normal children. Mobitz type II is present when the PR interval does not change, but a QRS is intermittently dropped. This form may progress to complete heart block and may require pacemaker placement. **Third-degree heart block**, whether congenital or acquired, is present when there is no relationship between atrial and ventricular activity. The ventricular rate is much slower than the atrial rate. **Congenital complete heart block** is associated with maternal collagen vascular disease (such as systemic lupus erythematosus or Sjögren syndrome) or congenital heart disease. The acquired form most often occurs after cardiac surgery but may be secondary to infection, inflammation, or drugs.

Treatment

Most atrial dysrhythmias require no intervention. Treatment of SVT depends on presentation and symptoms. Acute treatment of SVT in infants usually consists of **vagal maneuvers**, such as the application of cold (ice bag) to the face. Intravenous (IV) **adenosine** usually converts the dysrhythmia because the atrioventricular node forms a part of the re-entry circuit in most patients with SVT. In patients with cardiovascular compromise at the time of presentation, **synchronized cardioversion** is indicated using 1-2 J/kg. In patients with palpitations, it is important to document heart rate and rhythm during their symptoms before considering therapeutic options. The frequency, length, and associated symptoms during the episodes, as well as what is required to convert the rhythm, determine the need for ongoing treatment. Some patients require only education regarding the dysrhythmia and follow-up. Ongoing pharmacological management with either digoxin or a β -blocker is usually the first choice when treatment is needed. However, digoxin is contraindicated in patients with Wolff-Parkinson-White syndrome. Additional antiarrhythmic medications are rarely needed. In patients who are symptomatic or for those not wanting to take daily medications, **radiofrequency ablation** may be performed.

A variety of antiarrhythmic agents are used to treat ventricular dysrhythmias that require intervention ([Table 142.3](#)). Management of third-degree heart block depends on the ventricular rate and presence of symptoms. Treatment, if needed, often requires placement of a pacemaker.

TABLE 142.3

Classification of Drugs for Antiarrhythmia

CLASS ACTION		EXAMPLE(S)
I	Depression of phase of depolarization (velocity of upstroke of action potential); sodium channel blockade	
Ia	Prolongation of QRS complex and QT interval	Quinidine, procainamide, disopyramide
Ib	Significant effect on abnormal conduction	Lidocaine, mexiletine, phenytoin, tocainide
Ic	Prolongation of QRS complex and PR interval	Flecainide, propafenone, moricizine?
II	β blockade; slowing of sinus rate; prolongation of PR interval	Propranolol, atenolol, acebutolol
III	Prolongation of action potential; prolongation of PR, QT intervals, QRS	Bretylium, amiodarone, sotalol

	complex; sodium and calcium channel blockade	
IV	Calcium channel blockade; reduction in sinus and AV node pacemaker activity and conduction; prolongation of PR interval	Verapamil and other calcium channel blocking agents

AV, Atrioventricular.

CHAPTER 143

Acyanotic Congenital Heart Disease

Decision-Making Algorithm

Heart Murmurs

Etiology and Epidemiology

Congenital heart disease occurs in 8 per 1,000 births. The spectrum of lesions ranges from asymptomatic to fatal. Although most cases of congenital heart disease are multifactorial, some lesions are associated with chromosomal disorders, single gene defects, teratogens, or maternal metabolic disease (see [Table 139-2](#)).

Congenital heart defects can be divided into three pathophysiological groups ([Table 143.1](#)).

TABLE 143.1

Classification of Congenital Cardiac Defects

STENOTIC	SHUNTING		MIXING
	RIGHT → LEFT	LEFT → RIGHT	
Aortic stenosis	Tetralogy	Patent ductus arteriosus	Truncus
Pulmonary stenosis	Transposition	Ventricular septal defect	TAPVR
Coarctation of the aorta	Tricuspid atresia	Atrial septal defect	HLH

HLH, Hypoplastic left heart syndrome; TAPVR, total anomalous pulmonary venous return.

1. Left-to-right shunts
2. Right-to-left shunts
3. Obstructive, stenotic lesions

Acyanotic congenital heart disease includes left-to-right shunts resulting in an increase in pulmonary blood flow (patent ductus arteriosus [PDA], ventricular septal defect [VSD], atrial septal defect [ASD]) and obstructive lesions (aortic stenosis, pulmonary stenosis, coarctation of the aorta), which usually have normal pulmonary blood flow.

Ventricular Septal Defect

Etiology and Epidemiology

The ventricular septum is a complex structure that can be divided into four components. The largest component is the **muscular septum**. The inlet or posterior septum comprises **endocardial cushion tissue**. The subarterial or **supracristal septum** comprises conotruncal tissue. The **membranous septum** is below the aortic valve and is relatively small. VSDs occur when any of these components fail to develop normally (Fig. 143.1). VSD, the most common congenital heart defect, accounts for 25% of all congenital heart disease. **Perimembranous VSDs** are the most common of all VSDs (67%).

FIGURE 143.1 Ventricular septal defect. *AO*, Aorta; *LA*, left atrium; *LV*, left ventricle; *PA*, pulmonary artery; *RA*, right atrium; *RV*, right ventricle.

Although the location of the VSD is important prognostically and in approach to repair, the amount of flow crossing a VSD depends on the size of the defect and the pulmonary vascular resistance. Large VSDs are not symptomatic at birth because the pulmonary vascular resistance is normally elevated at this time. As the pulmonary vascular resistance decreases over the first 6-8 weeks of life, the amount of shunt increases, and symptoms may develop.

Clinical Manifestations

Small VSDs with little shunt are often asymptomatic but have a loud murmur. Moderate to large VSDs result in pulmonary overcirculation and heart failure. The typical physical finding with a VSD is a **pansystolic murmur**, usually heard best at the lower left sternal border. There may be a thrill. Large shunts increase flow across the mitral valve causing a **mid-diastolic murmur** at the apex. The splitting of S_2 and intensity of P_2 depend on the pulmonary artery pressure.

Imaging Studies

Electrocardiogram (ECG) and chest x-ray findings depend on the size of the VSD. Small VSDs usually have normal studies. Larger VSDs cause volume overload to the left side of the heart, resulting in ECG findings of left atrial and ventricular enlargement and hypertrophy. A chest x-ray may reveal cardiomegaly, enlargement of the left ventricle, an increase in the pulmonary artery silhouette, and increased pulmonary blood flow. Pulmonary hypertension due to either increased flow or increased pulmonary vascular resistance may lead to right ventricular enlargement and hypertrophy.

Treatment

Approximately one third of all VSDs close spontaneously. Small VSDs usually close spontaneously and, if they do not close, surgical closure may not be required. Initial treatment for moderate to large VSDs includes **diuretics** with some practitioners using **digoxin** and/or **afterload reduction**. Continued poor growth or pulmonary hypertension despite therapy requires closure of the defect.

Most VSDs are closed surgically, but some VSDs, especially muscular defects, can be closed with **devices** placed at cardiac catheterization.

Atrial Septal Defect

Etiology and Epidemiology

During the embryological development of the heart, a septum grows toward the endocardial cushions to divide the atria. Failure of septal growth or excessive reabsorption of tissue leads to ASDs (Fig. 143.2). ASDs represent approximately 10% of all congenital heart defects. A secundum defect, with the hole in the region of the foramen ovale, is the most common ASD. A **primum ASD**, located near the endocardial cushions, may be part of a complete atrioventricular canal defect or may be present with an intact ventricular septum. The least common ASD is the **sinus venosus defect**, which may be associated with anomalous pulmonary venous return.

FIGURE 143.2 Atrial septal defect. AO, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

Clinical Manifestations

The pathophysiology and amount of shunting depend on the size of the defect and the relative compliance of the both ventricles. Even with large ASDs and significant shunts, infants and children are rarely symptomatic. A prominent **right ventricular impulse** at the left lower sternal border (LLSB) often can be palpated. A soft (grade I or II) **systolic ejection murmur** in the region of the right ventricular outflow tract and a **fixed split S₂** (due to overload of the right ventricle with prolonged ejection into the pulmonary circuit) are often audible. A larger shunt may result in a mid-diastolic murmur at the LLSB as a result of the increased volume passing across the tricuspid valve.

Imaging Studies

ECG and chest x-ray findings reflect the **increased blood flow** through the right atrium, right ventricle, pulmonary arteries, and lungs. The ECG may show **right axis deviation** and **right ventricular enlargement**. A chest radiograph may show cardiomegaly, right atrial enlargement, and a prominent pulmonary artery.

Treatment

Medical management is rarely indicated. If a significant shunt is still present at around 3 years of age, closure is usually recommended. Many secundum ASDs can be closed with an ASD **closure device** in the catheterization laboratory. Primum and sinus venosus defects require **surgical closure**.

Patent Ductus Arteriosus

Etiology and Epidemiology

The ductus arteriosus allows blood to flow from the pulmonary artery to the aorta during fetal life. Failure of the normal closure of this vessel results in a PDA ([Fig. 143.3](#)). With falling pulmonary vascular resistance after birth, left-to-right shunting of blood and increased pulmonary blood flow occur. Excluding premature infants, PDAs represent approximately 5-10% of congenital heart disease.

FIGURE 143.3 Patent ductus arteriosus. AO, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

Clinical Manifestations

Symptoms depend on the amount of pulmonary blood flow. The magnitude of the shunt depends on the size of the PDA (diameter, length, and tortuosity) and the pulmonary vascular resistance. Small PDAs are asymptomatic; moderate to large shunts can produce the symptoms of heart failure as the pulmonary vascular resistance decreases.

The physical examination findings depend on the size of the shunt. A **widened pulse pressure** is often present as a result of the runoff of blood into the pulmonary circulation during diastole. A **continuous, machine-like murmur** can be heard at the left infraclavicular area, radiating along the pulmonary arteries and often well heard over the left side of the back. Larger shunts with increased flow across the mitral valve may result in a mid-diastolic murmur at the apex and a **hyperdynamic precordium**. Splitting of S_2 and intensity of P_2 depend on the pulmonary artery pressure. A thrill may be palpable.

Imaging Studies

ECG and chest x-ray findings are normal with small PDAs. Moderate to large shunts may result in a **full pulmonary artery silhouette** and **increased**

pulmonary vascularity. ECG findings vary from normal to evidence of left ventricular hypertrophy. If pulmonary hypertension is present, there is also right ventricular hypertrophy.

Treatment

Spontaneous closure of a PDA after a few weeks of age is uncommon in full-term infants. Moderate and large PDAs may be managed initially with **diuretics**, but they eventually require closure. Elective closure of small, hemodynamically insignificant PDAs is controversial. Most PDAs can be closed in the catheterization laboratory by either **coil embolization** or a PDA **closure device**.

Endocardial Cushion Defect

Etiology and Epidemiology

Endocardial cushion defects, also referred to as **atrioventricular canal defects** or atrioventricular septal defects, may be complete ([Fig. 143.4](#)), partial, or transitional. Abnormal development of the endocardial cushion tissue results in failure of the septum to fuse with the endocardial cushion; this results in **abnormal atrioventricular valves** as well. The complete defect results in a primum ASD, a posterior or inlet VSD, and a common atrioventricular valve with anterior and posterior bridging leaflets. Partial and transitional defects have two separate atrioventricular valves, usually with a “cleft” in the anterior leaflet of the left-sided valve. In addition to left-to-right shunting at both levels, there may be **atrioventricular valve insufficiency**.

FIGURE 143.4 Atrioventricular canal defects. AO, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

Clinical Manifestations

The symptoms of heart failure usually develop as the pulmonary vascular resistance decreases over the first 6-8 weeks of life. Symptoms may be earlier and more severe with significant atrioventricular valve insufficiency. Pulmonary hypertension is present due to the increased pulmonary blood flow and pulmonary vascular obstructive disease may develop early, especially in patients with Trisomy 21. The presence of murmurs varies depending on the amount of shunting at both atrial and ventricular levels. If there is a large VSD component, S_2 will be single. Growth is usually poor. This is the most common congenital heart defect in children with Trisomy 21.

Imaging Tests

The diagnosis usually is made with echocardiography. A chest radiograph reveals cardiomegaly with enlargement of all chambers and the presence of **increased vascularity**. An ECG reveals **left axis deviation** and **combined ventricular hypertrophy** and may show combined atrial enlargement.

Treatment

Initial management includes diuretics. Some practitioners use afterload reduction for treatment of heart failure but, ultimately, surgical repair of the defect is required.

Pulmonary Stenosis

Etiology

Pulmonary stenosis accounts for approximately 10% of all congenital heart disease and can be **valvular**, **subvalvular**, or **supravalvular** in nature. Pulmonary stenosis results from the failure of the development, in early gestation, of the three leaflets of the valve, insufficient resorption of infundibular tissue, or insufficient canalization of the peripheral pulmonary arteries.

Clinical Manifestations

Symptoms depend on the degree of obstruction present. Mild pulmonary stenosis is asymptomatic. Moderate to severe stenosis results in **exertional dyspnea** and easy **fatigability**. Newborns with severe stenosis may be more symptomatic and even cyanotic because of right-to-left shunting at the atrial level.

Pulmonary stenosis causes a systolic ejection murmur at the second left intercostal space, which radiates to the back. A thrill may be present. S₂ may be widely split with a quiet pulmonary component. With more severe pulmonary stenosis, an impulse at the lower left sternal border results from **right ventricular hypertrophy**. Valvular stenosis may result in a **click** that varies with respiration. Worsening stenosis causes an increase in the duration of the murmur and a higher frequency of the sound. The systolic ejection murmurs of **peripheral pulmonary stenosis** are heard distal to the site of obstruction in the pulmonary circulation, including radiation to the axillae and back.

Imaging Tests

ECG and chest x-ray findings are normal in mild stenosis. Moderate to severe stenosis results in **right axis deviation** and **right ventricular hypertrophy**. The heart size is usually normal on chest x-ray, although **dilation of the main pulmonary artery** may be seen. Echocardiography provides assessment of the

site of stenosis, degree of hypertrophy, valve morphology, as well as an estimate of the pressure gradient.

Treatment

Valvular pulmonary stenosis usually does not progress, especially if it is mild. **Balloon valvuloplasty** is usually successful in reducing the gradient to acceptable levels for more significant or symptomatic stenosis. **Surgical repair** is required if balloon valvuloplasty is unsuccessful or when subvalvular (muscular) stenosis is present.

Aortic Stenosis

Etiology and Epidemiology

Valvular, subvalvular, or supravalvular aortic stenosis represents approximately 5% of all congenital heart disease. Lesions result from failure of development of the three leaflets or failure of resorption of tissue around the valve.

Clinical Manifestations

Mild to moderate obstructions cause no symptoms. More severe stenosis results in easy fatigability, exertional chest pain, and syncope. Infants with critical aortic stenosis may present with symptoms of heart failure.

A **systolic ejection murmur** is heard at the right second intercostal space along the sternum and radiating into the neck. The murmur increases in length and becomes higher in frequency as the degree of stenosis increases. With valvular stenosis, a **systolic ejection click** often is heard, and a thrill may be present at the right upper sternal border or in the suprasternal notch. The aortic component of S_2 may be decreased in intensity.

Imaging Studies

ECG and chest x-ray findings are normal with mild degrees of stenosis. **Left ventricular hypertrophy** develops with moderate to severe stenosis and is detected on the ECG and chest x-ray. **Dilation** of the ascending aorta or aortic knob due to an intrinsic aortopathy may be seen on chest radiographs.

Echocardiography shows the site of stenosis, valve morphology, and the presence of left ventricular hypertrophy, and it allows an estimate of the pressure gradient.

Treatment

The degree of aortic stenosis frequently progresses with growth and age. Aortic insufficiency often develops or progresses. Serial follow-up with echocardiography is indicated. **Balloon valvuloplasty** is usually the first interventional procedure for significant stenosis. It is not as successful as pulmonary balloon valvuloplasty and has a higher risk of significant valvular insufficiency. **Surgical management** is necessary when balloon valvuloplasty is unsuccessful or significant valve insufficiency develops.

Coarctation of the Aorta

Etiology and Epidemiology

Coarctation of the aorta occurs in approximately 10% of all congenital heart defects. It is almost always **juxtaductal** in position. During development of the aortic arch, the area near the insertion of the ductus arteriosus fails to develop correctly, resulting in a narrowing of the aortic lumen.

Clinical Manifestations

Timing of presentation depends on the severity of obstruction and associated cardiac defects. Infants presenting with coarctation of the aorta frequently have hypoplastic aortic arches, abnormal aortic valves, and VSDs. They may be dependent on a PDA to provide descending aortic flow. Symptoms develop when the aortic ampulla of the ductus closes. Less severe obstruction causes no symptoms.

Symptoms, including poor feeding, respiratory distress, and shock, may develop before 2 weeks of age. Classically, the **femoral pulses** are weaker and delayed compared with the right radial pulse. The blood pressure in the lower extremities is lower than that in the upper extremities. However, if cardiac function is poor, these differences may not be as apparent until appropriate resuscitation is accomplished. In this situation, there may be no murmur, but an S_3 is often present.

Older children presenting with coarctation of the aorta are usually asymptomatic. There may be a history of **leg discomfort** with exercise, headache, or epistaxis. Decreased or absent lower extremity pulses, **hypertension** (upper extremity), or a murmur may be present. The murmur is typically best heard in the left interscapular area of the back. If significant collaterals have developed, continuous murmurs may be heard throughout the chest. An abnormal aortic valve is present approximately 50% of the time, causing a systolic ejection click and systolic ejection murmur of aortic stenosis.

Imaging Studies

The ECG and chest x-ray show evidence of right ventricular enlargement and hypertrophy in infantile coarctation with marked **cardiomegaly** and **pulmonary edema**. Echocardiography shows the site of coarctation and associated lesions. In older children, the ECG and chest x-ray usually show left ventricular hypertrophy and a mildly enlarged heart. **Rib notching** may also be seen in older children (>8 years of age) with large collaterals. Echocardiography shows the site and degree of coarctation, the presence of left ventricular hypertrophy, and the aortic valve morphology and function.

Treatment

Management of an infant presenting with cardiac decompensation includes intravenous infusion of **prostaglandin E₁** (chemically opens the ductus arteriosus), inotropic agents, diuretics, and other supportive care. **Balloon angioplasty** has been done, especially in critically ill infants, but **surgical repair** of the coarctation is most commonly performed. Ballooning and stenting of older patients with coarctation has become more accepted as primary therapy, but surgical repair remains a common form of management.

CHAPTER 144

Cyanotic Congenital Heart Disease

Decision-Making Algorithms

Cyanosis Heart Murmurs

Cyanotic congenital heart disease occurs when some of the systemic venous return crosses from the right side of the heart to the left and returns to the body without going through the lungs (**right-to-left shunt**). **Cyanosis**, the visible sign of this shunt, occurs when approximately 5 g/100 mL of reduced hemoglobin is present in systemic blood. Thus a polycythemic patient appears cyanotic with a higher oxygen saturation than a normocythemic patient. A patient with anemia requires a higher percentage of reduced hemoglobin (lower saturation) for the recognition of cyanosis.

The most common cyanotic congenital heart defects are the five *Ts*:

1. Tetralogy of Fallot
2. Transposition of the great arteries
3. Tricuspid atresia
4. Truncus arteriosus
5. Total anomalous pulmonary venous return

Other congenital heart defects that allow complete mixing of systemic and pulmonary venous return can present with cyanosis depending on the amount of pulmonary blood flow that is present. Many cyanotic heart lesions present in the neonatal period ([Table 144.1](#)).

TABLE 144.1

Categories of Presenting Symptoms and Signs in the Neonate

SYMPTOM/SIGN	PHYSIOLOGICAL CATEGORY	ANATOMICAL CAUSE	LESION
Cyanosis with respiratory distress	Increased pulmonary blood flow	Transposition	d-Transposition with or without associated lesions
Cyanosis without respiratory distress	Decreased pulmonary blood flow	Right heart obstruction	Tricuspid atresia Ebstein anomaly Pulmonary atresia Pulmonary stenosis Tetralogy of Fallot
Hypoperfusion	Poor cardiac output	Left heart obstruction	Total anomalous pulmonary venous return with

			obstruction Aortic stenosis Hypoplastic left heart syndrome
	Poor cardiac function	Normal anatomy	Cardiomyopathy Myocarditis
Respiratory distress with desaturation (not visible cyanosis)	Bidirectional shunting	Complete mixing	Truncus arteriosus AV canal Complex single ventricle (including heterotaxias) without pulmonary stenosis
Respiratory distress with normal saturation	Left-to-right shunting	Simple intracardiac shunt	ASD VSD PDA Aortopulmonary window AVM

ASD, Atrial septal defect; *AV*, atrioventricular; *AVM*, arteriovenous malformation; *PDA*, patent ductus arteriosus; *VSD*, ventricular septal defect.

Tetralogy of Fallot

Etiology and Epidemiology

Tetralogy of Fallot is the most common cyanotic congenital heart defect, representing about 10% of all congenital heart defects (Fig. 144.1). There are four structural defects: **ventricular septal defect (VSD)**, **pulmonary stenosis**, **overriding aorta**, and **right ventricular hypertrophy**. Tetralogy of Fallot is due to abnormal septation of the truncus arteriosus into the aorta and pulmonary artery that occurs early in gestation (3-4 weeks). The VSD is large, and the pulmonary stenosis is most commonly subvalvular or infundibular. It may also be valvular, supra-valvular, or, frequently, a combination of levels of obstruction.

FIGURE 144.1 Tetralogy of Fallot. AO, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

Clinical Manifestations

Infants initially may be acyanotic. A **pulmonary stenosis murmur** is the usual initial abnormal finding. The amount of right-to-left shunting at the VSD (and the degree of cyanosis) increases as the degree of pulmonary stenosis increases. With increasing severity of pulmonary stenosis, the murmur becomes shorter and softer. In addition to varying degrees of cyanosis and a murmur, a **single S₂** and **right ventricular impulse** at the left sternal border are typical findings.

When **hypoxic (Tet) spells** occur, they are usually progressive. During a spell, the child typically becomes restless and agitated and may cry inconsolably. An ambulatory toddler may squat. Hyperpnea occurs with gradually increasing cyanosis and loss of the murmur. In severe spells, prolonged unconsciousness and convulsions, hemiparesis, or death may occur. Independent of hypoxic spells, patients with unrepaired tetralogy of Fallot are at increased risk for cerebral thromboembolism and cerebral abscesses resulting, in part, from their right-to-left intracardiac shunt.

Imaging Studies

The electrocardiogram (ECG) usually has **right axis deviation** and **right**

ventricular hypertrophy. The classic chest x-ray finding is a **boot-shaped heart** created by the small main pulmonary artery and upturned apex secondary to right ventricular hypertrophy. Echocardiography shows the anatomical features, including the anatomical level and quantification of pulmonary stenosis. Coronary anomalies, most commonly a left anterior descending coronary artery arising from the right coronary artery and crossing the anterior surface of the right ventricular outflow tract, are present in 5% of patients with tetralogy of Fallot.

Treatment

The natural history of tetralogy of Fallot is progression of pulmonary stenosis and cyanosis. Treatment of hypoxic spells consists of oxygen administration and placing the child in the knee-chest position (to increase venous return). Traditionally, morphine sulfate is given (to relax the pulmonary infundibulum and for sedation). If necessary, the systemic vascular resistance can be increased acutely through the administration of an α -adrenergic agonist (phenylephrine). The occurrence of a cyanotic spell is an indication to proceed with surgical repair.

Complete surgical repair with VSD closure and removal or patching of the pulmonary stenosis can be performed in infancy. Occasionally, **palliative shunt surgery** between the subclavian artery and pulmonary artery is performed for complex forms of tetralogy of Fallot and more complete repair is done at a later time. **Subacute bacterial endocarditis prophylaxis** is indicated until 6 months after complete repair unless there is a residual VSD. Prophylaxis is then continued as long as there is a residual VSD.

Transposition of the Great Arteries

Etiology and Epidemiology

Although dextroposed transposition of the great arteries represents only about 5% of congenital heart defects, it is the most common cyanotic lesion to present in the newborn period (Fig. 144.2). Transposition of the great arteries is ventriculoarterial discordance secondary to abnormalities of septation of the truncus arteriosus. In dextroposed transposition, the aorta arises from the right ventricle, anterior and to the right of the pulmonary artery, which arises from the left ventricle. This results in desaturated blood returning to the right side of the

heart and being pumped back out to the body, while well-oxygenated blood returning from the lungs enters the left side of the heart and is pumped back to the lungs. Without mixing of the two circulations, death occurs quickly. Mixing can occur at the atrial (patent foramen ovale/atrial septal defect [ASD]), VSD, or great vessel (patent ductus arteriosus [PDA]) level.

FIGURE 144.2 Transposition of the great vessels. AO, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

Clinical Manifestations

A history of **cyanosis** is always present, although it depends on the amount of mixing. **Quiet tachypnea** and a **single S₂** are typically present. If the ventricular septum is intact, there may be no murmur.

Children with transposition and a large VSD have improved intracardiac mixing and less cyanosis. They may present with signs of heart failure. The heart is hyperdynamic, with palpable left and right ventricular impulses. A loud VSD murmur is heard. S₂ is single.

Imaging Studies

ECG findings typically include **right axis deviation** and **right ventricular**

hypertrophy. The chest x-ray reveals **increased pulmonary vascularity**, and the cardiac shadow is classically an **egg on a string** created by the narrow superior mediastinum. Echocardiography shows the transposition of the great arteries, the sites and amount of mixing, and any associated lesions.

Treatment

Initial medical management includes **prostaglandin E₁** to maintain ductal patency. If significant hypoxia persists on prostaglandin therapy, a **balloon atrial septostomy** improves mixing between the two circulations. Complete surgical repair is most often an **arterial switch**. The arterial switch usually is performed within the first 2 weeks of life, when the left ventricle can still maintain systemic pressure.

Tricuspid Atresia

Etiology and Epidemiology

Tricuspid atresia accounts for approximately 2% of all congenital heart defects (Fig. 144.3). The absence of the tricuspid valve results in a **hypoplastic right ventricle**. All systemic venous return must cross the atrial septum into the left atrium. A PDA or VSD is necessary for pulmonary blood flow and survival.

FIGURE 144.3 Tricuspid atresia with ventricular septal defect. *AO*, Aorta; *LA*, left atrium; *LV*, left ventricle; *PA*, pulmonary artery; *RA*, right atrium.

Clinical Manifestations

Infants with tricuspid atresia are usually **severely cyanotic** and have a **single S₂**. If a VSD is present, there may be a murmur. A diastolic murmur across the mitral valve may be audible. Frequently there is no significant murmur.

Imaging Studies

The ECG shows **left ventricular hypertrophy** and a **superior QRS axis** (between 0 and -90 degrees). The chest x-ray reveals a normal or mildly enlarged cardiac silhouette with **decreased pulmonary blood flow**. Echocardiography shows the anatomy, associated lesions, and source of pulmonary blood flow.

Treatment

Management initially depends on the presence of a VSD and the amount of antegrade blood flow to the lungs. If there is no VSD, or it is small, prostaglandin E₁ maintains pulmonary blood flow until surgery. Surgery is staged with an initial subclavian artery-to-pulmonary shunt (**Blalock-Taussig procedure**) typically followed by a two-stage procedure: **bidirectional cavopulmonary shunt (bidirectional Glenn)** and **Fontan procedure**. These surgeries direct systemic venous return directly to the pulmonary arteries.

Truncus Arteriosus

Etiology and Epidemiology

Truncus arteriosus occurs in less than 1% of all cases of congenital heart disease (Fig. 144.4). It results from the failure of septation of the truncus during the first 3-4 weeks of gestation. A single arterial trunk arises from the heart with a large VSD immediately below the truncal valve. The pulmonary arteries arise from the single arterial trunk either as a single vessel that divides or individually from the arterial trunk to the lungs.

FIGURE 144.4 Truncus arteriosus. AO, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

Clinical Manifestations

Varying degrees of cyanosis depend on the amount of pulmonary blood flow. If not diagnosed at birth, the infant may develop signs of heart failure as pulmonary vascular resistance decreases. The signs then include tachypnea and cough. Peripheral pulses are usually bounding as a result of the diastolic runoff into the pulmonary arteries. A single S_2 is due to the single valve. There may be a systolic ejection click, and there is often a **systolic murmur** at the left sternal border.

Imaging Studies

ECG findings include **combined ventricular hypertrophy** and **cardiomegaly**. A chest x-ray usually reveals **increased pulmonary blood** and may show displaced pulmonary arteries. Echocardiography defines the anatomy, including the VSD, truncal valve function, and origin of the pulmonary arteries.

Treatment

Medical management is usually needed and includes **anticongestive**

medications. Surgical repair includes VSD closure and placement of a conduit between the right ventricle and pulmonary arteries.

Total Anomalous Pulmonary Venous Return

Etiology and Epidemiology

Total anomalous pulmonary venous return accounts for about 1% of congenital heart disease (Fig. 144.5). Disruption of the development of normal pulmonary venous drainage during the third week of gestation results in one of four abnormalities. All of the pulmonary veins fail to connect to the left atrium and return abnormally via the right side of the heart. They may have **supracardiac**, **infracardiac**, **cardiac**, or **mixed drainage**. An atrial-level communication is required for systemic cardiac output and survival.

FIGURE 144.5 Total anomalous pulmonary venous return. AO, Aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary vein; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

Clinical Manifestations

The most important determinant of presentation is the presence or absence of

obstruction to the pulmonary venous drainage. Infants without obstruction have minimal cyanosis and may be asymptomatic. There is a hyperactive **right ventricular impulse** with a **widely split S₂** (owing to increased right ventricular volume) and a **systolic ejection murmur** at the left upper sternal border. There is usually a mid-diastolic murmur at the lower left sternal border from the increased flow across the tricuspid valve. Growth is relatively poor. Infants with **obstruction** present with cyanosis, marked tachypnea and dyspnea, and signs of right-sided heart failure including hepatomegaly. The obstruction results in little, if any, increase in right ventricular volume, so there may be no murmur or changes in S₂.

Imaging Studies

For infants without obstruction, the ECG is consistent with right ventricular volume overload. Cardiomegaly with increased pulmonary blood flow is seen on chest x-ray. Infants with obstructed veins have right axis deviation and right ventricular hypertrophy on ECG. On chest x-ray, the heart is normal or mildly enlarged with varying degrees of pulmonary edema that can appear similar to hyaline membrane disease or pneumonia. Echocardiography shows the volume-overloaded right side of the heart, right-to-left atrial level shunting, and common pulmonary vein site of drainage and degree of obstruction.

Treatment

At **surgery**, the common pulmonary vein is opened into the left atrium, and there is ligation of any vein or channel that had been draining the common vein.

Hypoplastic Left Heart Syndrome

Etiology and Epidemiology

Hypoplastic left heart syndrome accounts for 1% of all congenital heart defects (Fig. 144.6) but is the most common cause of death from cardiac defects in the first month of life. Hypoplastic left heart syndrome occurs when there is failure of development of the mitral or aortic valve or the aortic arch. A small left ventricle that is unable to support normal systemic circulation is a central finding, regardless of etiology. Associated degrees of hypoplasia of the ascending aorta and aortic arch are present. Left-to-right shunting occurs at the

atrial level.

FIGURE 144.6 Hypoplastic left side of the heart. AO, Aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PDA, patent ductus arteriosus; RA, right atrium; RV, right ventricle.

Clinical Manifestations

The newborn is dependent on right-to-left shunting at the ductus arteriosus for systemic blood flow. As the ductus arteriosus constricts, the infant becomes critically ill with signs and symptoms of heart failure from excessive pulmonary blood flow and obstruction of systemic blood flow. Pulses are diffusely weak or absent. S_2 is single and loud. There is usually no heart murmur. Cyanosis may be minimal, but **low cardiac output** gives a grayish color to the cool, mottled skin.

Imaging Studies

ECG findings include **right ventricular hypertrophy** with **decreased left ventricular forces**. The chest x-ray reveals **cardiomegaly** (with right-sided enlargement) and pulmonary venous congestion or pulmonary edema. Echocardiography shows the small left side of the heart, the degree of stenosis of the aortic and mitral valves, the hypoplastic ascending aorta, and the adequacy of left-to-right atrial flow and right-to-left ductal flow.

Treatment

Medical management includes **prostaglandin E₁** to open the ductus arteriosus, correction of acidosis, and ventilatory and blood pressure support as needed. **Surgical repair** is staged with the first surgery (Norwood or Sano procedure) done during the newborn period. Subsequent procedures create a systemic source for the pulmonary circulation (bidirectional Glenn and Fontan procedures), leaving the right ventricle to supply systemic circulation. There have been many modifications to all three stages of the repair. Prognosis for survival has improved significantly over the past two decades.

Complications of Congenital Heart Disease

Extracardiac complications are summarized in [Table 144.2](#).

TABLE 144.2

Extracardiac Complications of Cyanotic Congenital Heart Disease

PROBLEM	ETIOLOGY	THERAPY
Polycythemia	Persistent hypoxia	Phlebotomy
Relative anemia	Nutritional deficiency	Iron replacement
CNS abscess	Right-to-left shunting	Antibiotics, drainage
CNS thromboembolic stroke	Right-to-left shunting or polycythemia	Phlebotomy
Gingival disease	Polycythemia, gingivitis, bleeding	Dental hygiene
Gout	Polycythemia, diuretic agents	Allopurinol
Arthritis, clubbing	Hypoxic arthropathy	None
Pregnancy	Poor placental perfusion, poor ability to increase cardiac output	Bed rest
Infectious disease	Associated asplenia, DiGeorge syndrome	Antibiotics
	Fatal RSV pneumonia with pulmonary hypertension	Ribavirin, RSV immune globulin
Growth	Failure to thrive, increased oxygen consumption, decreased nutrient intake	Treat heart failure; correct defect early
Psychosocial adjustment	Limited activity, peer pressure; chronic disease, multiple hospitalizations, cardiac surgical techniques	Counseling

CNS, Central nervous system; *RSV*, respiratory syncytial virus.

CHAPTER 145

Heart Failure

Etiology and Epidemiology

The force generated by the cardiac muscle fiber depends on its contractile status and basal length, which is equivalent to the preload. As the preload (fiber length, left ventricular filling pressure, or volume) increases, myocardial performance (stroke volume and wall tension) increases up to a point (the normal Starling curve). The relationship is the **ventricular function curve** (Fig. 145.1). Alterations in the contractile state of the muscle lower the relative position of the curve but retain the relationship of fiber length to muscle work. The cardiac output equals stroke volume times the heart rate; thus heart rate is another important determinant of cardiac work. Additional factors also affect cardiac performance (Table 145.1).

FIGURE 145.1 Ventricular function curve illustrating the effect of inotropic agents or arterial vasodilators. In contrast to diuretics, the effect of digitalis or arterial vasodilator therapy in a patient with heart failure is movement onto another ventricular function curve, which is intermediate between the normal and the depressed curves. When the patient's ventricular function moves from A to B by the administration of one of these agents, the left ventricular end-diastolic pressure may also decrease because of improved cardiac function; further administration of diuretics or venodilators may shift the function further to the left along the same curve from B to C and eliminate the risk of pulmonary edema. A vasodilating agent that has arteriolar and venous dilating properties (e.g., nitroprusside) would shift this function directly from A to C. If this agent shifts the function from A to D because of excessive venodilation or the administration of diuretics, the

cardiac output may decrease too much, even though the left ventricular end-diastolic pressure would be normal (10 mm Hg) for a normal heart. Left ventricular end-diastolic pressures of 15-18 mm Hg are usually optimal in the failing heart to maximize cardiac output, but to avoid pulmonary edema. (From Andreoli TE, Carpenter CCJ, Griggs RC, Loscalzo J, eds. *Cecil Essentials of Medicine*. 5th ed. Philadelphia: Saunders; 2001.)

TABLE 145.1

†Decreases contractility.

From Andreoli TE, Carpenter CCJ, Griggs RC, Loscalzo J. *Cecil Essentials of Medicine*. 5th ed. Philadelphia: Saunders; 2001.

Heart failure occurs when the heart is unable to pump blood at a rate commensurate with metabolic needs (inadequate oxygen delivery). It may be due to a change in **myocardial contractility** that results in low cardiac output or to **abnormal loading conditions** being placed on the myocardium. The abnormal loading conditions may be **afterload** (pressure overload, such as with aortic stenosis, pulmonary stenosis, or coarctation of the aorta) or **preload**

(volume overload, such as in ventricular septal defect [VSD], patent ductus arteriosus (PDA), or valvular insufficiency). Volume overload is the most common cause of heart failure in children.

The age of presentation is helpful in creating the differential diagnosis (Table 145.2). In the first weeks of life, excessive afterload being placed on the myocardium is most common. Heart failure presenting around 2 months of age is usually due to increasing left-to-right shunts that become apparent as the pulmonary vascular resistance decreases. Acquired heart disease, such as myocarditis and cardiomyopathy, can present at any age.

Clinical Manifestations

Decision-Making Algorithm

Edema

Heart failure presents in infants as poor feeding, failure to thrive, tachypnea, and diaphoresis with feeding. Older children may present with shortness of breath, easy fatigability, and edema. The physical examination findings depend on whether pulmonary venous congestion, systemic venous congestion, or both are present. Tachycardia, a gallop rhythm, and thready pulses may be present with either cause. If left-sided failure is predominant, tachypnea, orthopnea, wheezing, and pulmonary edema are seen. Hepatomegaly, edema, and distended neck veins are signs of right-sided failure.

Imaging Studies

The absence of cardiomegaly on a chest x-ray usually rules out the diagnosis of heart failure. An echocardiogram assesses the heart chamber sizes, measures myocardial function, and diagnoses congenital heart defects when present.

Treatment

Initial treatment is directed at improving myocardial function and optimizing preload and afterload. Diuretics, inotropic support, and, often, **afterload**

reduction are employed (Table 145.3). Long-term therapy usually consists of diuretics followed by afterload reduction. Long-term therapy with **β-blockers** also may be beneficial, although this remains somewhat controversial in pediatric patients. Spironolactone is usually added to the medical regimen because of its effect on cardiac remodeling.

TABLE 145.3

Treatment of Heart Failure

THERAPY	MECHANISM
GENERAL CARE	
Rest	Reduces cardiac output
Oxygen	Improves oxygenation in the presence of pulmonary edema
Sodium, fluid restrictions	Decreases vascular congestion; decreases preload
DIURETICS	
Furosemide	Salt excretion at ascending loop of Henle; reduces preload; afterload reduces with control of hypertension; may also cause venodilation
Combination of distal tubule and loop diuretics	Greater sodium excretion
INOTROPIC AGENTS	
Digitalis	Inhibits membrane Na ⁺ , K ⁺ -ATPase and increases intracellular Ca ²⁺ , improves cardiac contractility, increases myocardial oxygen consumption
Dopamine	Releases myocardial norepinephrine plus a direct effect on β-receptor, may increase systemic blood pressure; at low infusion rates, dilates renal artery, facilitating diuresis
Dobutamine	β ₁ -Receptor agent; often combined with dopamine
Milrinone	Phosphodiesterase 3 inhibitor with positive inotropic properties and decreases vascular resistance/afterload
AFTERLOAD REDUCTION	
Hydralazine	Arteriolar vasodilator
Nitroprusside	Arterial and venous relaxation; venodilation reduces preload
Captopril/enalapril	Inhibition of angiotensin-converting enzyme; reduces angiotensin II production
OTHER MEASURES	
Mechanical counterpulsation	Improves coronary flow, afterload
Transplantation	Removes diseased heart
Extracorporeal membrane oxygenation	Bypasses heart
Carvedilol	β-Blocking agent

CHAPTER 146

Rheumatic Fever

Etiology and Epidemiology

Although uncommon in the United States, *acute* rheumatic fever remains an important preventable cause of cardiac disease. It is most common in children 6-15 years of age. It is due to an immunological reaction that is a delayed sequela of group A beta-hemolytic streptococcal infections of the pharynx. A family history of rheumatic fever and lower socioeconomic status are additional factors.

Clinical Manifestations

Decision-Making Algorithms

Heart Murmurs
Arthritis
Involuntary Movements
Fever and Rash

Acute rheumatic fever is diagnosed using the clinical and laboratory findings of the **revised Jones criteria** (Table 146.1). The presence of either two **major criteria** or one major and two **minor criteria**, along with evidence of an antecedent **streptococcal infection**, confirm a diagnosis of acute rheumatic fever. The infection often precedes the presentation of rheumatic fever by 2-6 weeks. Streptococcal antibody tests, such as the antistreptolysin O titer, are the most reliable laboratory evidence of prior infection.

TABLE 146.1

Major Jones Criteria for Diagnosis of Acute Rheumatic Fever^{*,†}

SIGN	COMMENTS
Polyarthriti	Common; swelling, limited motion, tender, erythema
	Migratory; involves large joints but rarely small or unusual joints, such as vertebrae
Carditis	Common; pancarditis, valves, pericardium, myocardium
	Tachycardia greater than explained by fever; new murmur of mitral or aortic insufficiency; Carey-Coombs mid-diastolic murmur; heart failure
Chorea (Sydenham disease)	Uncommon; manifests long after infection has resolved; more common in females; antineuronal antibody positive
Erythema marginatum	Uncommon; pink macules on trunk and proximal extremities, evolving to serpiginous border with central clearing; evanescent, elicited by application of local heat; nonpruritic
Subcutaneous nodules	Uncommon; associated with repeated episodes and severe carditis; located over extensor surface of elbows, knees, knuckles, and ankles, or scalp and spine; firm, nontender

*Minor criteria include fever (temperatures of 101-102°F [38.2-38.9°C]), arthralgias, previous rheumatic fever, leukocytosis, elevated erythrocyte sedimentation rate/C-reactive protein, and prolonged PR interval.

†One major and two minor, or two major, criteria with evidence of recent group A streptococcal disease (e.g., scarlet fever, positive throat culture, or elevated antistreptolysin O or other antistreptococcal antibodies) strongly suggest the diagnosis of acute rheumatic fever.

Arthritis is the most common major manifestation. It usually involves the large joints and is migratory. Arthralgia cannot be used as a minor manifestation if arthritis is used as a major manifestation. **Carditis** occurs in about 50% of patients. Tachycardia, a new murmur (mitral or aortic regurgitation), pericarditis, cardiomegaly, and signs of heart failure are evidence of carditis. **Erythema marginatum**, a serpiginous, nonpruritic, and evanescent rash, is uncommon, occurs on the trunk, and is brought out by warmth. **Subcutaneous nodules** are seen predominantly with chronic or recurrent disease. They are firm, painless, nonpruritic, mobile nodules found on the extensor surfaces of the large and small joints, the scalp, and the spine. **Chorea** (Sydenham chorea or St. Vitus dance) consists of neurological and psychiatric signs. It also is uncommon and often presents long after the infection.

Treatment and Prevention

Management of acute rheumatic fever consists of **benzathine penicillin** to eradicate the beta-hemolytic streptococcus, antiinflammatory therapy with **salicylates**, and **bed rest**. Additional supportive therapy for heart failure or chorea may be necessary. **Long-term penicillin prophylaxis**, preferably with intramuscular benzathine penicillin G, 1.2 million U every 28 days, is required.

Oral regimens for prophylaxis generally are not as effective. The prognosis of acute rheumatic fever depends on the degree of permanent cardiac damage. Cardiac involvement may resolve completely, especially if it is the first episode and the prophylactic regimen is followed. The severity of cardiac involvement worsens with each recurrence of rheumatic fever.

CHAPTER 147

Cardiomyopathies

Etiology

A cardiomyopathy is an intrinsic disease of the heart muscle and is not associated with other forms of heart disease (Table 147.1). There are three types of cardiomyopathy based on anatomical and functional features:

TABLE 147.1

Etiology of Myocardial Disease

FAMILIAL/HEREDITARY
<ul style="list-style-type: none"> Duchenne muscular dystrophy Other muscular dystrophies (Becker, limb-girdle) Myotonic dystrophy Kearns-Sayre syndrome (progressive external ophthalmoplegia) Carnitine deficiency syndromes Endocardial fibroelastosis Mitochondrial myopathy syndromes Familial dilated cardiomyopathy (dominant, recessive, X-linked) Familial hypertrophic cardiomyopathy Familial restrictive cardiomyopathy Pompe disease (glycogen storage)
INFECTIOUS (MYOCARDITIS)
<ul style="list-style-type: none"> Viral (e.g., coxsackievirus infection, mumps, Epstein-Barr virus infection, influenza, parainfluenza infection, measles, varicella, HIV infection) Bacterial (e.g., diphtheria, <i>Mycoplasma</i> infection, meningococcal disease, leptospirosis, Lyme disease, psittacosis, <i>Coxiella</i> infection, Rocky Mountain spotted fever) Parasitic (e.g., Chagas disease, toxoplasmosis)
METABOLIC/NUTRITIONAL/ENDOCRINE
<ul style="list-style-type: none"> Hypothyroidism Hyperthyroidism Pheochromocytoma

Mitochondrial myopathies and oxidative respiratory chain defects Type II, X-linked 3-methylglutaconic aciduria
CONNECTIVE TISSUE/GRANULOMATOUS DISEASE
Systemic lupus erythematosus Scleroderma Amyloidosis Rheumatic fever Sarcoidosis Dermatomyositis
DRUGS/TOXINS
Doxorubicin (Adriamycin) Ipecac Iron overload (hemosiderosis) Irradiation Cocaine Amphetamines
CORONARY ARTERIES
Anomalous left coronary artery Kawasaki disease
OTHER DISORDERS/CONDITIONS
Idiopathic Sickle cell anemia Endomyocardial fibrosis Right ventricular dysplasia

HIV, Human immunodeficiency virus.

1. Dilated
2. Hypertrophic
3. Restrictive

Dilated cardiomyopathies are the most common. They are often idiopathic, but they may be due to infection (echovirus or Coxsackie B virus) or be postinfectious, familial, or secondary to systemic disease or to cardiotoxic drugs. Hypertrophic cardiomyopathies are usually familial with autosomal dominant inheritance but may occur sporadically. Restrictive cardiomyopathies are rare; they may be idiopathic or associated with systemic disease ([Table 147.2](#)).

TABLE 147.2

Anatomical and Functional Features of Cardiomyopathies

FEATURE	DILATED	HYPERTROPHIC	RESTRICTIVE
Etiology	Infectious Metabolic	Sporadic Inherited (autosomal dominant)	Infiltrative (amyloidosis, sarcoidosis)

	Toxic Idiopathic		Noninfiltrative (idiopathic, familial) Storage disease (hemochromatosis, Fabry disease) Endomyocardial disease
Hemodynamics	Decreased systolic function	Diastolic dysfunction (impaired ventricular filling)	Diastolic dysfunction (impaired ventricular filling)
Treatment	Positive inotropes Diuretics Afterload reduction β -Blockers Antiarrhythmics Anticoagulants Cardiac transplantation	β -Blockers Calcium channel blockers	Diuretics Anticoagulants Cardiac transplantation

Clinical Manifestations

Decision-Making Algorithms

Chest Pain
Palpitations
Edema

Dilated cardiomyopathies result in enlargement of the left ventricle only or of both ventricles. Myocardial contractility is variably decreased. Children with dilated cardiomyopathy present with signs and symptoms of inadequate cardiac output and **heart failure**. Tachypnea and tachycardia are present on examination. Peripheral pulses are often weak because of a **narrow pulse pressure**. Rales may be audible on auscultation. The heart sounds may be muffled, and an S₃ is often present. Concurrent infectious illness may result in circulatory collapse and shock in children with dilated cardiomyopathies.

Hypertrophic cardiomyopathy is initially difficult to diagnose. Infants, but not older children, frequently present with signs of heart failure. Sudden death may be the initial presentation in older children. Dyspnea, fatigue, chest pain, syncope or near-syncope, and palpitations may be present. A murmur is heard in more than 50% of children referred after identification of an affected family member. Restrictive cardiomyopathies are relatively rare in pediatrics. Presenting symptoms usually include dyspnea exacerbated by a respiratory

illness, syncope, hepatomegaly, and an S₄ heart sound on examination.

Imaging Studies

Decision-Making Algorithm

Edema

Cardiomegaly usually is seen on chest radiographs for all three types of cardiomyopathies. The electrocardiogram (ECG) in dilated cardiomyopathy may have nonspecific ST-T wave changes and left ventricular hypertrophy. ECG evidence of right ventricular hypertrophy is present in 25% of children with cardiomyopathy. The ECG with hypertrophic cardiomyopathy is universally abnormal, but changes are nonspecific. Primary hypertrophic cardiomyopathy is associated with a prolonged QT interval. Children with restrictive cardiomyopathies may show atrial enlargement on the ECG. Echocardiography features vary by type of cardiomyopathy. Dilated cardiomyopathies result in left atrial and ventricular dilation, a decreased shortening fraction, and globally depressed contractility. Asymmetric septal hypertrophy and left ventricular outflow tract obstruction are seen in hypertrophic cardiomyopathies. Massive atrial dilation is seen in restrictive cardiomyopathies. Endomyocardial biopsy specimens, obtained while the patient is hemodynamically stable, identify histological type and allow tests for mitochondrial or infiltrative diseases.

Treatment

Supportive therapy, including **diuretics**, **inotropic medications**, and **afterload reduction**, is provided for all three types of cardiomyopathy. If a specific etiology can be identified, treatment is directed at the etiology. Symptomatic therapy with close monitoring and follow-up is crucial. Because of the high mortality rate associated with all forms of cardiomyopathy, **cardiac transplantation** must be considered.

Pericarditis

Etiology and Epidemiology

Pericarditis is inflammation of the parietal and visceral surfaces of the pericardium. It is most often viral in origin, with many viruses identified as causative agents. A bacterial etiology is rare but causes a much more serious and symptomatic pericarditis. *Staphylococcus aureus* and *Streptococcus pneumoniae* are the most likely bacterial causes. Pericarditis is associated with collagen vascular diseases, such as rheumatoid arthritis, and is seen with uremia (Table 148.1). **Postpericardiotomy syndrome** is a relatively common form of pericarditis that follows heart surgery.

TABLE 148.1

Etiology of Pericarditis and Pericardial Effusion

IDIOPATHIC (PRESUMED VIRAL) INFECTIOUS AGENTS
Bacterial

Drug reaction Pancreatitis After myocardial infarction Thalassemia Central venous catheter perforation Heart failure Hemorrhage (coagulopathy)

*Infectious or immune complex.

†Common (viral pericarditis or myopericarditis is probably the most common cause of acute pericarditis in a previously normal host).

From Sigman G. Chest pain. In: Kliegman RM, Greenbaum LA, Lye PS, eds. *Practical Strategies in Pediatric Diagnosis and Therapy*. 2nd ed. Philadelphia: Saunders; 2004. Tab 9-9.

Clinical Manifestations

Decision-Making Algorithm

Chest Pain

The symptoms of pericarditis ([Table 148.2](#)) depend on the amount of fluid in

the pericardial space and how fast it accumulates. A small effusion usually is well tolerated. A large effusion may be well tolerated if it accumulates slowly. The faster the fluid accumulates, the sooner the patient is hemodynamically compromised and develops symptoms.

TABLE 148.2

Manifestations of Pericarditis

SYMPTOMS
Chest pain (worsened if lying down or with inspiration) Dyspnea Malaise Patient assumes sitting position
SIGNS
Nonconstrictive
Fever Tachycardia Friction rub (accentuated by inspiration, body position) Enlarged heart by percussion and x-ray examination Distant heart sounds
Tamponade
<i>As above, plus:</i> Distended neck veins Hepatomegaly Pulsus paradoxus (>10 mm Hg with inspiration) Narrow pulse pressure Weak pulse, poor peripheral perfusion
Constrictive
Distended neck veins Kussmaul sign (inspiratory increase in jugular venous pressure) Distant heart sounds Pericardial knock Hepatomegaly Ascites Edema Tachycardia

Imaging and Laboratory Studies

Echocardiography is the most specific and useful diagnostic test for detection of pericardial effusions. A chest x-ray may reveal cardiomegaly. A large effusion creates a rounded, globular cardiac silhouette. The electrocardiogram (ECG) may show tachycardia, elevated ST segments, reduced QRS voltage, or electrical

alternans (variable QRS amplitude). The causative organism may be identified through viral titers, antistreptolysin O (ASO) titers, or diagnostic testing of the pericardial fluid.

Treatment

Pericardiocentesis is indicated for the treatment of hemodynamically significant effusions and to determine the etiology of the pericarditis. Additional treatment is directed at the specific etiology. There is no specific treatment for viral pericarditis other than **antiinflammatory medications**.

Pearls for Practitioners

Chapter 139

Cardiovascular System Assessment

- Rate of growth is one of the most valuable and objective signs of cardiovascular health.
 - In infants with heart failure, weight gain is more significantly affected than height and head circumference.

- Cardiovascular vital signs vary with age, and one needs to know or have a resource for “normal” for all age groups to be able to recognize/diagnose abnormal.
- Blood pressure should be routinely taken in the right arm and, if elevated, then taken in all four extremities.
 - The presence of a normal right arm blood pressure and normal pedal pulses effectively rules out coarctation of the aorta.
- Peripheral cyanosis (hands, feet, perioral), also known as acrocyanosis, is common in infants and needs to be differentiated from central cyanosis (tongue, lips).
- Murmurs are the noises made by turbulent blood flow and are very common in pediatric patients.
 - The timing of the murmur is most important in determining the significance of the murmur and developing a differential diagnosis.
 - Diastolic murmurs, holosystolic murmurs, continuous murmurs (with the exception of the venous hum), and murmurs with a palpable thrill are abnormal murmurs.
 - To be a normal (innocent) murmur, the cardiovascular history and remainder of the cardiovascular exam must be normal.
- A normal heart size on chest radiograph virtually rules out heart failure; however, a large heart is not diagnostic of heart failure.

Chapter 140

Syncope

- Syncope is the transient loss of consciousness and muscle tone and is typically associated with an upright position, prodromal symptoms, pale appearance, and brief loss of consciousness with rapid return to normal state of consciousness.

- Syncope occurring during exercise or with associated cardiac symptoms should be considered atypical until more extensively evaluated.

Chapter 141

Chest Pain

- Chest pain is common in Pediatrics but is rarely cardiac in origin. Up to one third of all Pediatric chest pain is idiopathic, with musculoskeletal chest pain being the most common cause of diagnosable chest pain.

Chapter 142

Dysrhythmias

- The most common symptomatic dysrhythmia in Pediatrics is supraventricular tachycardia.
- Sinus arrhythmia is common in children and represents a normal variation in heart rate with respiration.

Chapter 143

Acyanotic Congenital Heart Disease

- Congenital heart defects occur in about 1% of births and includes a wide spectrum of defects from asymptomatic to fatal lesions.
- Ventricular septal defect (VSD) is the most common congenital heart defect.
 - The amount of shunting at a VSD depends on the size of the defect and the pulmonary vascular resistance.
 - Large shunts are the result of excessive pulmonary blood flow (congestive heart failure), typically presenting with

tachypnea, fatigue, and diaphoresis with feeding and poor weight gain.

- Atrial septal defects (ASDs) rarely cause symptoms in childhood.
 - The amount of shunting at an ASD depends on the size of the defect and the relative compliance of the ventricles.
 - In addition to a systolic ejection murmur from increased flow across the pulmonary valve, a widely split second heart sound that does not vary with respiration is the classic exam finding associated with an ASD.
- A patent ductus arteriosus (PDA) results in volume overload of the left heart and shunting, which is dependent on the size of the PDA and the pulmonary vascular resistance.
- The most common congenital heart defect in children with Trisomy 21 is the endocardial cushion defect, which is also called atrioventricular canal defect or atrioventricular septal defect.
- Symptoms and management of pulmonary stenosis and aortic stenosis depend on the severity of the stenosis.
 - Pulmonary valve stenosis is rarely progressive; aortic valve stenosis is usually progressive.
- Coarctation of the aorta usually occurs in the juxtaductal region.
 - Symptoms and presentation depend on the severity of the obstruction and associated congenital heart defects.

Chapter 144

Cyanotic Congenital Heart Disease

- Clinical cyanosis occurs when >5 g/100 mL of reduced hemoglobin is present in the systemic blood.
- The most common cyanotic congenital heart defects are the five Ts: Tetralogy of Fallot, Transposition of the great arteries, Tricuspid atresia, Truncus arteriosus, and Total anomalous

pulmonary venous return.

- Tetralogy of Fallot is the most common cyanotic congenital heart defect. The degree of cyanosis and the murmur depend on the amount of pulmonary stenosis.
- Transposition of the great arteries is the most common cyanotic lesion to present in the newborn period.
- Congenital heart defects with a functionally single ventricle, such as tricuspid atresia and hypoplastic left heart syndrome (HLHS) require a staged surgical repair.
 - Survival of patients with HLHS—the most common cause of death from a cardiac defect in the first month of life—has improved dramatically with staged surgical and aggressive medical management.

Chapter 145

Heart Failure

- The most common cause, as well as the clinical manifestations of congestive heart failure, vary with age of presentation.
- Diseases/issues that impact preload, afterload, and contractility can all result in worsening cardiac performance and heart failure.
- Treatment of heart failure often includes diuresis, inotropic support, and afterload reduction.

Chapter 146

Rheumatic Fever

- Rheumatic fever remains an important, preventable cause of cardiac disease worldwide. Diagnosis of Rheumatic Fever is made using the clinical and laboratory findings of the revised Jones criteria.

Chapter 147

Cardiomyopathies

- There are three types of cardiomyopathy: (1) dilated (most common); (2) hypertrophic; and (3) restrictive.
- Supportive therapy, including diuretics, inotropic medications, and afterload reduction, are used in all three types.
- Cardiac transplantation must be considered due to the high mortality rate seen in all forms of cardiomyopathy.

Chapter 148

Pericarditis

- Pericarditis is inflammation of the parietal and visceral surfaces of the pericardium and is most often viral in origin.
 - The severity of symptoms depends on the amount of fluid present in the pericardial space and the rapidity with which the fluid accumulated.

CHAPTER 149

Hematology Assessment

History

A detailed history of the onset, severity, progression, associated symptoms, presence of systemic complaints, and exacerbating factors is crucial to the diagnosis of a blood disorder. In many blood disorders, a **detailed pedigree**

identifying a pattern of inheritance can point to the diagnosis.

Physical Examination and Common Manifestations

Decision-Making Algorithms

- Jaundice
- Anemia
- Bleeding
- Petechiae/Purpura
- Pancytopenia
- Failure to Thrive

The physical examination of patients with blood disorders first focuses on hemodynamic stability. Acute episodes of anemia may be life threatening, presenting with impairment of perfusion and cognitive status. The two most common findings of anemia include **pallor** and **jaundice**. The presence of **petechiae**, **purpura**, or deeper sites of **bleeding**, including generalized hemorrhage, indicates abnormalities of platelets, coagulation factors, or both. **Growth parameters** point to whether anemia is an acute or chronic process. Severe types of anemia, thrombocytopenia, and pancytopenia often are associated with congenital anomalies and a pattern of growth delay. Organ system involvement (especially **hepatosplenomegaly** and **lymphadenopathy**) or systemic illness points to a generalized illness as the cause for hematological abnormalities (Table 149.1).

TABLE 149.1

Presentation of Hematological Disorders

CONDITION	SYMPTOMS AND SIGNS	COMMON EXAMPLES
Anemia	Pallor, fatigue, heart failure, jaundice	Iron deficiency, hemolytic anemia
Polycythemia	Irritability, cyanosis, seizures, jaundice, stroke, headache	Cyanotic heart disease, infant of diabetic mother, cystic fibrosis
Neutropenia	Fever, pharyngitis, oral ulceration, cellulitis,	Congenital or drug-induced agranulocytosis,

	lymphadenopathy, bacteremia, gingivitis, perirectal infections	leukemia
Thrombocytopenia	Petechiae, ecchymosis, gastrointestinal hemorrhage, epistaxis	ITP, leukemia
Coagulopathy	Bruising, hemarthrosis, mucosal bleeding	von Willebrand disease, hemophilia, DIC
Thrombosis	Pulmonary embolism, deep vein thrombosis	Lupus anticoagulant; protein C, protein S, or antithrombin III deficiency; factor V Leiden, prothrombin 20210

DIC, Disseminated intravascular coagulation; *ITP*, idiopathic thrombocytopenic purpura.

Initial Diagnostic Evaluation

Diagnosis of pediatric blood disorders requires a detailed knowledge of normal hematological values that vary according to age and, after puberty, according to sex (Table 149.2). Directed by the history, physical examination, and screening laboratory studies, specific diagnostic testing can confirm the diagnosis.

TABLE 149.2

Hematological Values During Infancy and Childhood

Male	16.0	14-18	47	42-52			

WBCs, White blood cells.

Developmental Hematology

Hematopoiesis begins by 3 weeks of gestation with **erythropoiesis** in the yolk sac. By 2 months' gestation, the primary site of hematopoiesis migrates to the liver. By 5-6 months' gestation, the process shifts from the liver to the bone marrow. An extremely premature infant may have significant **extramedullary hematopoiesis** due to limited bone marrow hematopoiesis. During infancy, virtually all marrow cavities are actively hematopoietic and the proportion of hematopoietic to stromal elements is quite high. As the child grows, hematopoiesis moves to the central bones of the body (vertebrae, sternum, ribs, and pelvis), and the marrow is gradually replaced with fat. Hemolysis or marrow damage may lead to marrow repopulation of cavities where hematopoiesis previously had ceased or may delay the shift of hematopoiesis. Hepatosplenomegaly in patients with chronic hemolysis may signify extramedullary hematopoiesis. When a patient with cytopenia is being evaluated, a **bone marrow examination** provides valuable information about processes that lead to underproduction of circulating cells. In addition, bone marrow infiltration by neoplastic elements or storage cells often occurs in concert with infiltration in the spleen, liver, and lymph nodes.

The hematopoietic cells consist of the following:

1. Small compartment of **pluripotent progenitor stem cells** that resemble small lymphocytes and are capable of forming all myeloid elements
2. Large compartment of committed, proliferating cells of myeloid, erythroid, and megakaryocytic lineage
3. Large compartment of postmitotic maturing cells ([Fig. 149.1](#))

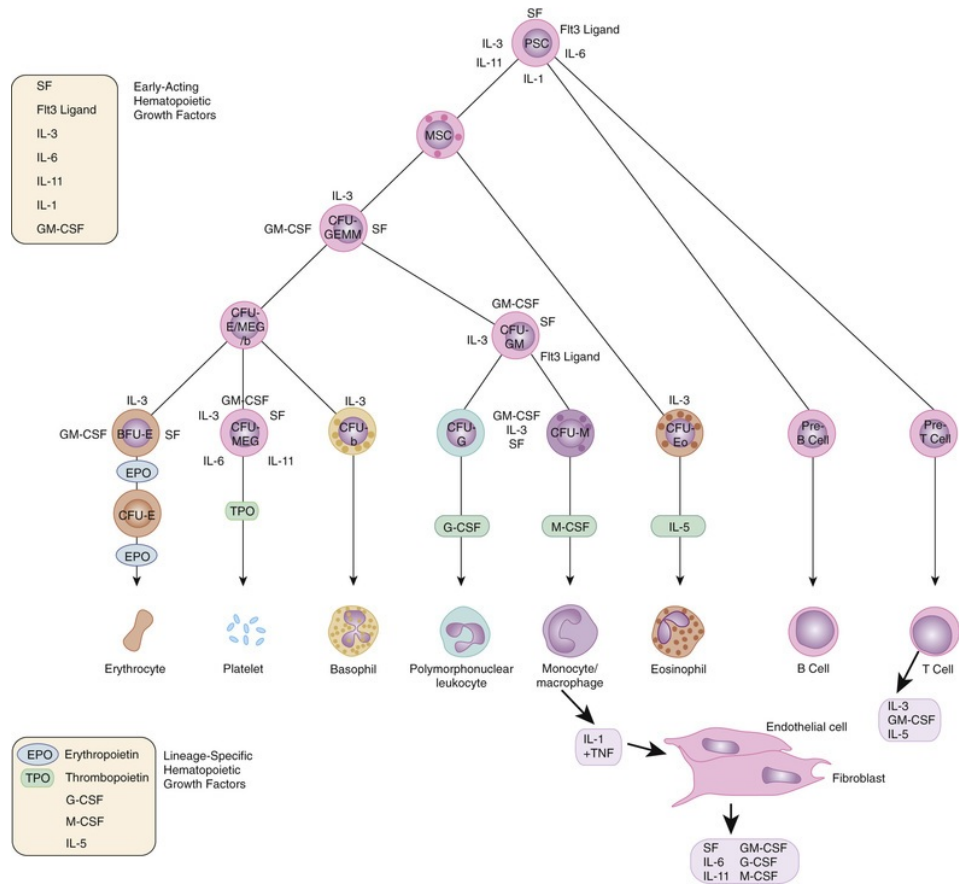

FIGURE 149.1 Major cytokine sources and actions that promote hematopoiesis. Cells of the bone marrow microenvironment, such as macrophages, endothelial cells, and reticular fibroblasts, produce macrophage colony-stimulating factor (*M-CSF*), granulocyte-macrophage colony-stimulating factor (*GM-CSF*), and granulocyte colony-stimulating factor (*G-CSF*) after stimulation. For all lineages, optimal development requires a combination of early and late acting factors. *BFU*, Burst-forming unit; *CFU*, colony-forming unit; *EPO*, erythropoietin; *IL*, interleukin; *MSC*, myeloid stem cell; *PSC*, pluripotent stem cell; *TNF*, tumor necrosis factor; *TPO*, thrombopoietin. (From Sieff CA, Nathan DG, Clark SC. The anatomy and physiology of hematopoiesis. In: Orkin SH, Nathan DG, eds. *Hematology of Infancy and Childhood*. 5th ed. Philadelphia: WB Saunders; 1998:168.)

The bone marrow is the major storage organ for mature neutrophils and contains about seven times the intravascular pool of neutrophils. It contains 2.5-5 times as many cells of myeloid lineage as cells of erythroid lineage. Smaller numbers of megakaryocytes, plasma cells, histiocytes, lymphocytes, and stromal cells are also stored in the marrow.

Erythropoiesis (red blood cell [RBC] production) is controlled by erythropoietin, a glycoprotein that stimulates primitive pluripotential stem cells

to differentiate along the erythroid line. It is made by the juxtaglomerular apparatus of the kidney in response to local tissue hypoxia. The normally high hemoglobin level of the fetus is a result of fetal erythropoietin production in the liver in response to low partial pressure of oxygen (PO_2) in utero. Erythropoietin leads to production of the **erythroid colony-forming unit**. The earliest recognizable erythroid cell is the erythroblast, which forms eight or more daughter cells. The RBC nucleus becomes gradually pyknotic and eventually is extruded. The cell is then released from the marrow as a **reticulocyte** that maintains residual mitochondrial and protein synthetic capacity. These highly specialized RBC precursors are engaged primarily in the production of **globin chains, glycolytic enzymes, and heme**. Iron is taken up via transferrin receptors and incorporated into the heme ring, which combines with globin chains synthesized within the immature RBC. When the messenger RNA and mitochondria are gone from the RBC, heme or protein synthesis is no longer possible; however, the RBC continues to function for its normal life span of about 120 days.

Embryonic hemoglobins are produced during yolk sac erythropoiesis, then replaced by **fetal hemoglobin** (hemoglobin F, $\alpha_2\gamma_2$) during the hepatic phase. During the third trimester, gamma chain production gradually diminishes, replaced by beta chains, resulting in **hemoglobin A** ($\alpha_2\beta_2$). Some fetal factors (e.g., infant of a diabetic mother) delay onset of beta chain production, but premature birth does not. Just after birth, with rapid increases in oxygen saturation, erythropoietin production stops and thus erythropoiesis ceases. Fetal RBCs have a shorter survival time (60 days).

During the first few months of postnatal life, rapid growth, shortened RBC survival, and cessation of erythropoiesis cause a gradual decline in hemoglobin levels, with a nadir at 8-10 weeks of life. This so-called **physiological nadir** is accentuated in premature infants. Erythropoietin is produced in response to the decline in hemoglobin and decreased oxygen delivery. Erythropoiesis subsequently resumes with an increase in the reticulocyte count. The hemoglobin level gradually increases, accompanied by synthesis of increasing amounts of hemoglobin A. By 6 months of age in healthy infants, only trace gamma chain synthesis occurs.

Production of **neutrophil precursors** is controlled predominantly by two different colony-stimulating factors (see [Fig. 149.1](#)). The most immature neutrophil precursors are controlled by **granulocyte-macrophage colony-stimulating factor** (GM-CSF), produced by monocytes and lymphocytes. GM-

CSF increases the entry of primitive precursor cells into the myeloid line of differentiation. **Granulocyte colony-stimulating factor** (G-CSF) augments the production of more mature granulocyte precursors. GM-CSF and G-CSF, working in concert, can augment production of neutrophils, shorten the usual 10- to 14-day production time from stem cell to mature neutrophil, and stimulate functional activity. The rapid increase in neutrophil count that occurs with infection is caused by release of stored neutrophils from the bone marrow, under the control of GM-CSF. During maturation, a mitotic pool of neutrophil precursors exists—myeloblasts, promyelocytes, and myelocytes possessing primary granules. The postmitotic pool consists of metamyelocytes, bands, and mature polymorphonuclear leukocytes containing secondary or specific granules that define the cell type. Only bands and mature neutrophils are fully functional with regard to phagocytosis, chemotaxis, and bacterial killing. Neutrophils migrate from the bone marrow, circulate for 6-7 hours, and enter the tissues, where they become end-stage cells that do not recirculate. Eosinophil production is under the control of a related glycoprotein hormone, interleukin 3. Eosinophils, which play a role in host defense against parasites, also are capable of living in tissues for prolonged periods.

Megakaryocytes are giant, multinucleated cells derived from the primitive stem cell and are polyploid (16-32 times the normal DNA content) because of nuclear, but not cytoplasmic, cell division. Platelets form by invagination of the megakaryocytic cell membrane and bud off from the periphery. **Thrombopoietin** is the primary regulator of platelet production. Platelets adhere to damaged endothelium and subendothelial surfaces via specific receptors for the adhesive proteins, von Willebrand factor (VWF), and fibrinogen. Platelets also have specific granules that readily release their contents after stimulation and trigger the process of platelet aggregation. Platelets circulate for 7-10 days and have no nucleus.

Lymphocytes are particularly abundant in the bone marrow of young children. These are primarily B lymphocytes arising in the spleen and lymph nodes, but T lymphocytes also are present.

CHAPTER 150

Anemia

Etiology

The diagnosis of anemia is determined by comparison of the patient's **hemoglobin level** with age-specific and sex-specific normal values (see [Table 149.2](#)). The production of androgens at the onset of puberty in boys causes males to maintain a normal hemoglobin value approximately 1.5-2 g/dL higher than girls. The easiest quantitative definition of anemia is any hemoglobin or hematocrit value that is 2 standard deviations (SDs; 95% confidence limits) below the mean for age and gender. However, in certain pathological states, anemia may be present with a normal hemoglobin level (e.g., cyanotic cardiac or pulmonary disease or abnormally high hemoglobin affinity for oxygen). This is a physiological definition of anemia. Anemia is often a manifestation of another other primary process and may accentuate other organ dysfunction.

Anemias are classified based on the size and hemoglobin content of the cells ([Fig. 150.1](#)). **Hypochromic, microcytic anemia** is caused by an inadequate production of hemoglobin. The most common causes of this type of anemia are iron deficiency and thalassemia. Most **normocytic anemias** are associated with a systemic illness that impairs adequate marrow synthesis of red blood cells (RBCs). Vitamin B₁₂ and folic acid deficiencies lead to **macrocytic anemia**. **Hemolytic diseases** are mediated either by disorders intrinsic or extrinsic to the RBC that increase cell destruction. The most common RBC membrane disorders are **hereditary spherocytosis** and **hereditary elliptocytosis**. In both of these disorders, abnormalities of proteins within the cytoskeleton lead to abnormal RBC shape and function. Numerous RBC enzyme deficiencies may lead to hemolysis, but only two are common: **glucose-6-phosphate dehydrogenase (G6PD) deficiency** and **pyruvate kinase deficiency**. Immune-mediated hemolysis may be extravascular when RBCs coated with antibodies or complement are phagocytosed by the reticuloendothelial system. The hemolysis may be intravascular when antibody binding leads to complement fixation and lysis of RBCs.

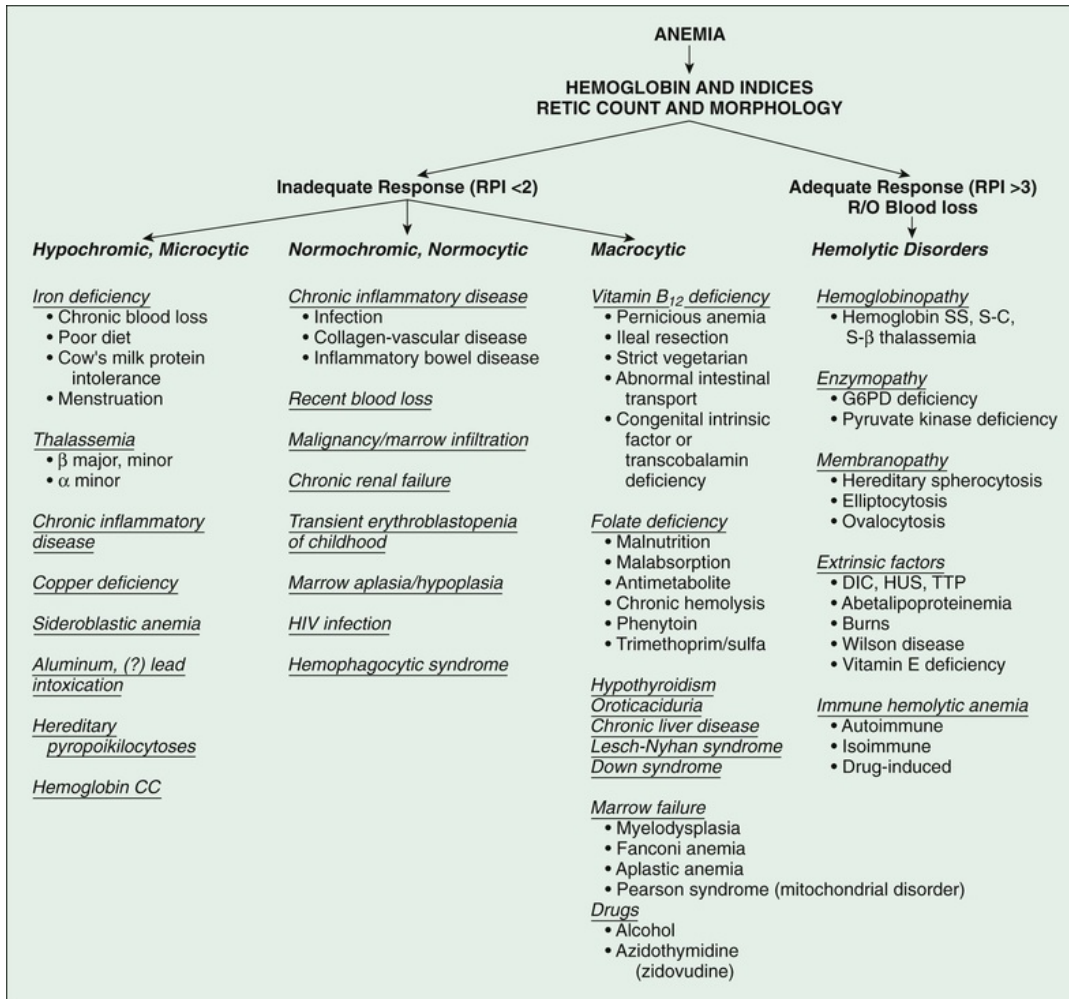

FIGURE 150.1 Use of the complete blood count, reticulocyte count, and blood smear in the diagnosis of anemia. *DIC*, Disseminated intravascular coagulation; *G6PD*, glucose-6-phosphate dehydrogenase; *HUS*, hemolytic uremic syndrome; *R/O*, rule out; *RPI*, reticulocyte production index; *TTP*, thrombotic thrombocytopenic purpura.

Clinical Manifestations

Decision-Making Algorithms

Heart Murmurs
 Jaundice
 Splenomegaly
 Edema
 Anemia

Acute onset of anemia can result in a poorly compensated state, manifested as an elevated heart rate, a systolic flow murmur, poor exercise tolerance, headache, excessive sleeping (especially in infants) or fatigue, irritability, poor feeding, and syncope. In contrast, chronic anemia often is exceptionally well tolerated in children because of their cardiovascular reserve. Usually, children with chronic anemia will have minimal tachycardia and a systolic flow murmur on examination. The urgency of diagnostic and therapeutic intervention, especially the use of packed RBC transfusion, should be dictated by the extent of cardiovascular or functional impairment more than the absolute level of hemoglobin.

The causes of anemia often can be suspected from a careful history adjusted for the patient's age (Tables 150.1 and 150.2). Anemia at any age demands a search for **blood loss**. A history of jaundice, pallor, previously affected siblings, drug ingestion by the mother, or excessive blood loss at the time of birth provides important clues to the diagnosis in newborns. A careful **dietary history** is crucial. A history of **jaundice, pallor, and/or splenomegaly** are often present with hemolytic anemia. Because of increased bilirubin production, **gallstones** (bilirubinate) are a common complication of chronic hemolysis. Systemic complaints suggest acute or chronic illnesses as probable causes of anemia. In later childhood and adolescence, the presence of constitutional symptoms, unusual diets, drug ingestion, or blood loss, especially from menstrual bleeding, often points to a diagnosis. **Congenital hemolytic disorders** (enzyme deficiencies and membrane problems) often present in the first 6 months of life and frequently are associated with neonatal jaundice, although these disorders often go undiagnosed. A careful **drug history** is essential for detecting problems that may be drug induced. Pure dietary iron deficiency is rare except in children's ages 1-3 years when cow's milk protein intolerance causes gastrointestinal blood loss and further complicates an already inadequate iron intake.

TABLE 150.1

Historical Clues in Evaluation of Anemia

VARIABLE	COMMENTS
Age	Iron deficiency rare in the absence of blood loss before 6 mo or in term infants or before doubling of birth weight in preterm infants Neonatal anemia with reticulocytosis suggests hemolysis or blood loss; with

	reticulocytopenia, suggests bone marrow failure Sickle cell anemia and β -thalassemia appear as fetal hemoglobin disappears (4-8 mo of age)
Family history and genetic considerations	X-linked: G6PD deficiency Autosomal dominant: spherocytosis Autosomal recessive: sickle cell anemia, Fanconi anemia Family member with history of cholecystectomy (for bilirubin stones) or splenectomy at an early age Ethnicity (thalassemia in persons of Mediterranean origin; G6PD deficiency in blacks, Greeks, and people of Middle Eastern origin) Race (β -thalassemia in persons of Mediterranean, African, or Asian descent; α -thalassemia in those of African and Asian descent; SC and SS in those of African descent)
Nutrition	Cow's milk diet: iron deficiency Strict vegetarian: vitamin B ₁₂ deficiency Goat's milk diet: folate deficiency Pica: plumbism, iron deficiency Cholestasis, malabsorption: vitamin E deficiency
Drugs	G6PD: oxidants (e.g., nitrofurantoin, antimalarials) Immune-mediated hemolysis (e.g., penicillin) Bone marrow suppression (e.g., chemotherapy) Phenytoin, increasing folate requirements
Diarrhea	Malabsorption of vitamin B ₁₂ or E or iron Inflammatory bowel disease and anemia of inflammation (chronic disease) with or without blood loss Milk protein intolerance–induced blood loss Intestinal resection: vitamin B ₁₂ deficiency
Infection	<i>Giardia lamblia</i> infection: iron malabsorption Intestinal bacterial overgrowth (blind loop): vitamin B ₁₂ deficiency Fish tapeworm: vitamin B ₁₂ deficiency Epstein-Barr virus, cytomegalovirus infection: bone marrow suppression, hemophagocytic syndromes <i>Mycoplasma</i> infection: hemolysis Parvovirus infection: bone marrow suppression HIV infection Chronic infection Endocarditis Malaria: hemolysis Hepatitis: aplastic anemia

G6PD, Glucose-6-phosphate dehydrogenase.

TABLE 150.2

Physical Findings in the Evaluation of Anemia

SYSTEM/STRUCTURE	OBSERVATION	SIGNIFICANCE
Skin	Hyperpigmentation	Fanconi anemia, dyskeratosis congenita
	Café-au-lait spots	Fanconi anemia
	Vitiligo	Vitamin B ₁₂ deficiency
	Partial oculocutaneous albinism	Chediak-Higashi syndrome

	Jaundice	Hemolysis
	Petechiae, purpura	Bone marrow infiltration, autoimmune hemolysis with autoimmune thrombocytopenia, hemolytic uremic syndrome, hemophagocytic syndromes
	Erythematous rash	Parvovirus or Epstein-Barr virus infection
	Butterfly rash	SLE antibodies
	Bruising	Bleeding disorder, nonaccidental trauma, scurvy
Head	Frontal bossing	Thalassemia major, severe iron deficiency, chronic subdural hematoma
	Microcephaly	Fanconi anemia
Eyes	Microphthalmia	Fanconi anemia
	Retinopathy	Hemoglobin SS, SC disease (see Table 150.7)
	Optic atrophy	Osteopetrosis
	Blocked lacrimal gland	Dyskeratosis congenita
	Kayser-Fleischer ring	Wilson disease
	Blue sclera	Iron deficiency, osteopetrosis
Ears	Deafness	
Mouth	Glossitis	Vitamin B ₁₂ deficiency, iron deficiency
	Angular stomatitis	Iron deficiency
	Cleft lip	Diamond-Blackfan syndrome
	Pigmentation	Peutz-Jeghers syndrome (intestinal blood loss)
	Telangiectasia	Osler-Weber-Rendu syndrome (blood loss)
	Leukoplakia	Dyskeratosis congenita
Chest	Shield chest or widespread nipples	Diamond-Blackfan syndrome
	Murmur	Endocarditis: prosthetic valve hemolysis; severe anemia
Abdomen	Hepatomegaly	Hemolysis, infiltrative tumor, chronic disease, hemangioma, cholecystitis, extramedullary hematopoiesis
	Splenomegaly	Hemolysis, sickle cell disease, (early) thalassemia, malaria, leukemia/lymphoma, Epstein-Barr virus, portal hypertension
	Nephromegaly	Fanconi anemia
	Absent kidney	Fanconi anemia
Extremities	Absent thumbs	Fanconi anemia
	Triphalangeal thumb	Diamond-Blackfan syndrome
	Spoon nails	Iron deficiency
	Beau line (nails)	Heavy metal intoxication, severe illness
	Mees line (nails)	Heavy metals, severe illness, sickle cell anemia
	Dystrophic nails	Dyskeratosis congenita

Rectal	Hemorrhoids	Portal hypertension
	Heme-positive stool	Gastrointestinal bleeding
Nerves	Irritable, apathy	Iron deficiency
	Peripheral neuropathy	Deficiency of vitamins B ₁ , B ₁₂ , and E; lead poisoning
	Dementia	Deficiency of vitamins B ₁₂ and E
	Ataxia, posterior column signs	Vitamin B ₁₂ deficiency
	Stroke	Sickle cell anemia, paroxysmal nocturnal hemoglobinuria
General	Small stature	Fanconi anemia, HIV infection, malnutrition

SLE, Systemic lupus erythematosus.

The physical examination may point to the potential causes (see [Table 150.2](#)). The **physiological stability** of the patient may be abnormal with acute blood loss and acute hemolysis, manifesting as tachycardia, blood pressure changes, and, most ominously, an altered state of consciousness. The presence of **jaundice** suggests hemolysis. **Petechiae** and **purpura** indicate a coagulopathy. **Hepatosplenomegaly** and **adenopathy** suggest infiltrative disorders. **Growth failure** or poor weight gain suggests anemia of inflammation (previously termed anemia of chronic disease). An essential element of the physical examination is the investigation of the stool for the presence of **occult blood**.

Laboratory Studies

A hemoglobin or hematocrit test indicates the severity of the anemia. After anemia has been substantiated, the work-up should include a complete blood count with differential, platelet count, indices, and reticulocyte count. Examination of the peripheral blood smear assesses the morphology of RBCs ([Fig. 150.2](#)), white blood cells (WBCs), and platelets. All cell lines should be scrutinized to determine whether anemia is the result of a process limited to the erythroid line or a process that affects other marrow elements. Using data obtained from the indices and reticulocyte count, the work-up can be organized on the basis of whether RBC production is adequate or inadequate and whether the cells are microcytic, normocytic, or macrocytic (see [Fig. 150.1](#)).

FIGURE 150.2 Morphological abnormalities of the red blood cell. **A**, Normal. **B**, Hypochromic microcytes (iron deficiency). **C**, Schistocytes (hemolytic uremic syndrome). **D**, Blister cells (glucose-6-phosphate dehydrogenase deficiency). **E**, Sickle cells (hemoglobin SS disease). **F**, Spherocytes (autoimmune hemolytic anemia). Arrows represent the cell discussed. (Courtesy B. Trost and J.P. Scott.)

An appropriate bone marrow response to anemia includes an elevated absolute reticulocyte number, suggesting increased RBC production. This implies either hemolysis or blood loss. Anemia with a normal reticulocyte number suggests decreased or ineffective production for the degree of anemia. Reticulocytopenia signifies either an acute onset of anemia such that the marrow has not had adequate time to respond; that reticulocytes are being destroyed in the marrow (antibody mediated); or that intrinsic bone marrow disease is present. The best indicators of the severity of hemolysis are the hemoglobin level and the elevation of the **reticulocyte count**. Biochemical evidence of hemolysis includes an increase in levels of bilirubin and lactate dehydrogenase and a decrease in haptoglobin.

Differential Diagnosis

Hypochromic, Microcytic Anemia

Iron Deficiency Anemia

Decision-Making Algorithm

Anemia

Etiology

Infants fed cow's milk when younger than 1 year of age, toddlers fed large volumes of cow's milk, and menstruating adolescent females who are not receiving supplemental iron are at high risk for iron deficiency. **Dietary** iron deficiency anemia is most common in bottle-fed toddlers who are receiving large volumes of cow's milk and eat minimal amounts of food high in iron content (see Chapters 28 and 31). Iron deficiency anemia also may be found in children with chronic inflammatory diseases, even without **chronic blood loss**.

Epidemiology

The prevalence of iron deficiency, the most common cause of anemia in the world, is approximately 9% in toddlers, 9-11% in adolescent females, and less than 1% in adolescent males. Iron deficiency anemia occurs in approximately one third of children who are iron deficient (Table 150.3). Children from low socioeconomic status in the United States may be at increased risk for iron deficiency because of poor dietary intake (see Chapter 31). Breast-fed infants are less likely to have iron deficiency than bottle-fed infants because, although there is less iron in breast milk, this iron is more efficiently absorbed. However, infants who continue to be exclusively breast fed in the second half of the first year of life are at risk for iron deficiency.

TABLE 150.3

Stages in Development of Iron Deficiency Anemia

HEMOGLOBIN (g/dL)	PERIPHERAL SMEAR	SERUM IRON ($\mu\text{g/dL}$)	BONE MARROW IRON	SERUM FERRITIN (ng/mL)
13+ (normal)	nc/nc	50-150	Fe ²⁺	Male: 40-340 Female: 40-150
10-12	nc/nc	↓	Fe ²⁺ absent, erythroid hyperplasia	<12
8-10	hypo/nc	↓	Fe ²⁺ absent, erythroid hyperplasia	<12
<8	hypo/micro*	↓	Fe ²⁺ absent, erythroid hyperplasia	<12

*Microcytosis, determined by a mean corpuscular volume (in fL) <2 standard deviations (SD) below the mean, must be adjusted for age (e.g., -2 SD at 3-6 months = 74; at 0.5-2 years = 70; at 2-6 years = 75; at 6-12 years = 77; and at 12-18 years = 78).

hypo/micro, Hypochromic, microcytic; *hypo/nc*, hypochromic, normocytic; *nc/nc*, normochromic, normocytic.

From Andreoli TE, Bennett JC, Carpenter CC, et al. *Cecil Essentials of Medicine*. 4th ed. Philadelphia: WB Saunders; 1997.

Clinical Manifestations

In addition to cardiovascular manifestations of anemia, central nervous system (CNS) abnormalities (**apathy, irritability, poor concentration**) have been linked to iron deficiency, presumably resulting from alterations of iron-containing enzymes (monoamine oxidase) and cytochromes. Poor muscle endurance, gastrointestinal dysfunction, and impaired WBC and T-cell function have been associated with iron deficiency. Iron deficiency in infancy may be associated with later **cognitive deficits** and poor school performance.

Treatment

In an otherwise healthy child, a **therapeutic trial of oral iron** is the best diagnostic study for iron deficiency as long as the child is re-examined and a response is documented. The response to oral iron includes rapid subjective improvement, especially in neurological function (within 24-48 hours) and reticulocytosis (48-72 hours); increase in hemoglobin levels (4-30 days); and repletion of iron stores (in 1-3 months). The usual therapeutic dose of 4-6 mg/day of elemental iron induces an increase in hemoglobin of 0.25-0.4 g/dL per day (a 1%/day increase in hematocrit). If the hemoglobin level fails to increase within 2 weeks after institution of iron treatment, careful re-evaluation for ongoing blood loss, development of infection, poor compliance, malabsorption, or other causes of microcytic anemia is required ([Table 150.4](#); see [Fig. 150.1](#)).

TABLE 150.4

Differentiating Features of Microcytic Anemias*

TEST	IRON DEFICIENCY ANEMIA	THALASSEMIA MINOR [†]	ANEMIA OF INFLAMMATION [‡]
Serum iron	Low	Normal	Low

Serum iron-binding capacity	High	Normal	Low or normal
Serum ferritin	Low	Normal or high	Normal or high
Marrow iron stores	Low or absent	Normal or high	Normal or high
Marrow sideroblasts	Decreased or absent	Normal or increased	Normal or increased
Free erythrocyte protoporphyrin	High	Normal or slightly increased	High
Hemoglobin A ₂ or F	Normal	High β -thalassemia; normal α -thalassemia	Normal
Red blood cell distribution width [§]	High	Normal	Normal/†

[†]See [Table 150.3](#) for definition of microcytosis.

[†] α -Thalassemia minor can be diagnosed by the presence of Bart hemoglobin on newborn screening.

[‡]Usually normochromic; 25% of cases are microcytic.

[§]Red blood cell distribution width quantitates the degree of anisocytosis (different sizes) of red blood cells.

Prevention

Bottle-fed infants should receive an iron-containing formula until 12 months of age. Exclusively breast-fed infants older than 6 months of age should receive an iron supplement. The introduction of iron-enriched solid foods at 6 months of age, followed by a transition to a limited amount of cow's milk and increased solid foods at 1 year, can help prevent iron deficiency anemia. Adolescent females who are menstruating should have a diet enriched with iron-containing foods. A vitamin with iron may also be used.

Thalassemia Minor

Etiology and Epidemiology

α -Thalassemia and **β -thalassemia minor** are common causes of microcytosis, either with or without a mild hypochromic, microcytic anemia. They are prevalent in certain ethnic groups (Mediterranean, Southeast Asian, African Americans). Individuals of Asian descent are at risk of having three or four α genes deleted, resulting in hemoglobin disease (β_4 tetramers) or hydrops fetalis, which is largely Bart (γ_4 tetramers) hemoglobin ([Table 150.5](#) and [Fig. 150.3](#)).

TABLE 150.5

Thalassemia Syndromes

DISORDER	GENOTYPIC ABNORMALITY	CLINICAL PHENOTYPE
β-THALASSEMIA		
Thalassemia major (Cooley anemia)	Homozygous β ⁰ -thalassemia	Severe hemolysis, ineffective erythropoiesis, transfusion dependency, hepatosplenomegaly, iron overload
Thalassemia intermedia	Compound heterozygous β ⁰ - and β ⁺ -thalassemia	Moderate hemolysis, splenomegaly, moderately severe anemia, but not transfusion dependent; main life-threatening complication is iron overload
Thalassemia minor	Heterozygous β ⁰ - and β ⁺ -thalassemia	Microcytosis, mild anemia
α-THALASSEMIA		
Silent carrier	α-/αα	Normal complete blood count
α-Thalassemia trait	αα/- - (α-thalassemia 1, <i>cis</i> deletion) or α -/α - (α-thalassemia 2, <i>trans</i> deletion)	Mild microcytic anemia
Hemoglobin H	α -/- -	Microcytic anemia and mild hemolysis; not transfusion dependent*
Hydrops fetalis	- -/- -	Severe anemia, intrauterine anasarca from congestive heart failure; death in utero or at birth

*The Constant Spring variant may require chronic transfusion.

From Andreoli T, Carpenter C, Griggs R, et al. *Cecil Essentials of Medicine*. 7th ed. Philadelphia: Saunders: 2007.

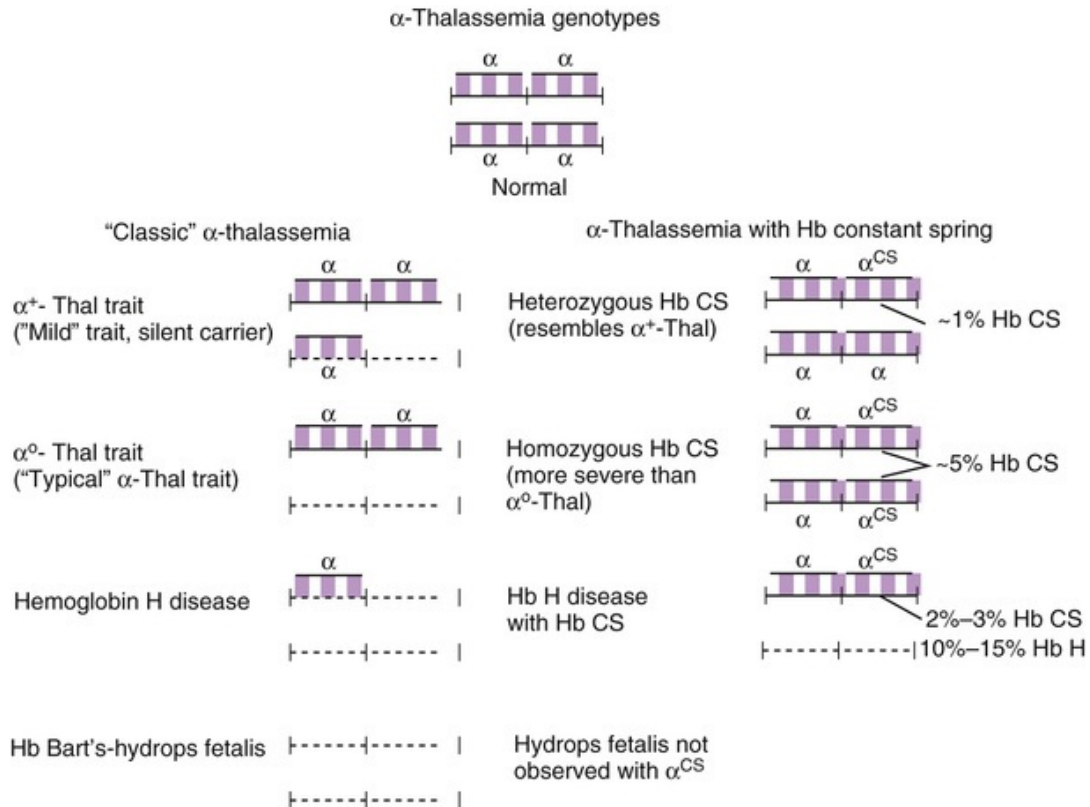

FIGURE 150.3 Genetic origins of the classic α -thalassemia syndromes due to gene deletions in the α -globin gene cluster. Hb Constant Spring (Hb CS) is an α -globin chain variant synthesized in such small amounts (1-2% of normal) that it has the phenotypic impact of a severe nondeletion α -thalassemia allele; however, the α^{CS} allele is always linked to a functioning α -globin gene, so it has never been associated with hydrops fetalis. (From Hoffman R, Benz EJ, Shattil SS, et al, eds. *Hematology: Basic Principles and Practice*. 5th ed. Philadelphia: Churchill Livingstone; 2008.)

Laboratory Testing

The thalassemia minor syndromes (i.e., α -thalassemia trait, β -thalassemia trait) are characterized by a mild hypochromic, microcytic anemia with a low absolute reticulocyte count (see [Table 150.5](#)). The RBC count is usually elevated. As a result, if the mean corpuscular volume (MCV) divided by the RBC count is less than 12.5 (Mentzer index), the diagnosis is suggestive of thalassemia trait. The blood smear reveals only microcytosis with α -thalassemia minor. Outside the neonatal period, when Bart hemoglobin is no longer detectable, the hemoglobin electrophoresis is usually normal in α -thalassemia minor (see [Fig. 150.3](#)). Blood smears of patients with β -thalassemia minor also reveal microcytic RBCs. In addition, target cells and basophilic stippled RBCs, caused by precipitation of alpha-chain tetramers, may also be present. The diagnosis of β -thalassemia

minor is based on an elevation of hemoglobin A₂ and F levels. Molecular testing is indicated for identification of more severe or unusual variants.

Treatment

No treatment is required for children with **thalassemia minor**. However, children with more severe forms of thalassemia, such as β -thalassemia intermedia or major or children with hemoglobin H disease (β_4 tetramers), especially the Constant Spring variant, require chronic transfusion therapy (see [Table 150.5](#)).

Lead Poisoning

Lead poisoning may be associated with a hypochromic, microcytic anemia because most patients have concomitant iron deficiency. The history of living in an older home (built before 1980) with chipped paint or lead dust should raise suspicion of lead poisoning, especially in a child with **pica**. The lead content of water should also be assessed due to the potential for lead containing pipes. **Basophilic stippling** on the blood smear is common. Lead intoxication rarely causes hemolytic anemia. Detection by routine screening, removal from exposure, chelation therapy, and correction of iron deficiency are crucial to the potential development of affected children.

Normocytic Anemia

Etiology and Treatment

Anemia is a common component of chronic inflammatory disease. Hepcidin, a protein made in the liver, plays a key role in iron homeostasis. Inflammation causes an increase in the production of hepcidin, interrupting the process of iron release by macrophages and the absorption of iron from the intestines leading to anemia. The **anemia of inflammation** may be normocytic or, less often, microcytic. This may pose a clinical challenge, when children with inflammatory disorders associated with blood loss (i.e., inflammatory bowel disease) exhibit a microcytic anemia. In these circumstances, only a bone marrow aspiration with staining of the sample for iron can differentiate the two entities clearly (see [Table 150.4](#)). Low ferritin levels indicate concurrent iron deficiency. A trial of iron therapy is not indicated without a specific diagnosis in children who appear to be systemically ill.

Bone marrow **infiltration by malignant cells** commonly leads to a normochromic, normocytic anemia. The mechanism by which neoplastic cells interfere with RBC and other marrow cell synthesis is multifactorial. The reticulocyte count is often low. Immature myeloid elements may be released into the peripheral blood because of the presence of the infiltrating tumor cells. An examination of the peripheral blood may reveal lymphoblasts; when solid tumors metastasize to the marrow, these cells are seldom seen in the peripheral blood. Teardrop cells may be seen in the peripheral blood. A bone marrow examination is frequently necessary in the face of normochromic, normocytic anemia.

Congenital hypoplastic anemia (Diamond-Blackfan syndrome), a lifelong disorder, usually presents in the first few months of life or at birth with severe anemia and mild macrocytosis or normocytic anemia. This RBC disorder is due to a deficiency of bone marrow RBC precursors (Table 150.6). More than a third of patients have short stature. Many patients (50-66%) respond to corticosteroid treatment but must receive therapy indefinitely. Patients who do not respond to corticosteroid treatment are transfusion dependent and are at risk of the multiple complications of long-term transfusion therapy, especially iron overload. These patients have a higher rate of developing leukemia or other hematological malignancies than the general population.

TABLE 150.6

Differentiation of Red Blood Cell Aplasias and Pancytopenia

DISORDER	AGE AT ONSET	CHARACTERISTICS	TREATMENT
CONGENITAL			
Diamond-Blackfan syndrome (congenital hypoplastic anemia)	Newborn-1 mo; 90% of patients are <1 yr of age	Pure red blood cell aplasia, autosomal recessive trait, elevated fetal hemoglobin, fetal i antigen present, macrocytic, short stature, webbed neck, cleft lip, triphalangeal thumb; late-onset leukemia, mutation analysis	Prednisone, transfusion, hematopoietic stem cell transplant
ACQUIRED			
Transient erythroblastopenia	6 mo-5 yr of age; 85% of patients are >1 yr of age	Pure red blood cell defect; no anomalies, fetal hemoglobin, or i antigen; spontaneous recovery, normal MCV	Expectant transfusion for symptomatic anemia
Idiopathic aplastic anemia (status post)	All ages	All cell lines involved; exposure to felbamate, chloramphenicol, radiation	Hematopoietic stem cell

hepatitis, drugs, unknown)			transplantation, antithymocyte globulin, cyclosporine, androgens
FAMILIAL			
Fanconi anemia	Usually before 10 yr of age; mean is 8 yr	All cell lines; microcephaly, absent thumbs, café-au-lait spots, cutaneous hyperpigmentation, short stature; chromosomal breaks, high MCV and hemoglobin F; horseshoe or absent kidney; leukemic transformation; autosomal recessive trait	Androgens, corticosteroids, hematopoietic stem cell transplantation
Paroxysmal nocturnal hemoglobinuria	After 5 yr	Initial hemolysis followed by aplastic anemia; increased complement-mediated hemolysis; thrombosis; iron deficiency; CD59 low	Iron, hematopoietic stem cell transplantation, androgens, steroids, eculizumab
Dyskeratosis congenita	Mean is 10 yr for skin; mean is 17 yr for anemia	Pancytopenia; hyperpigmentation, dystrophic nails, leukoplakia; X-linked recessive; lacrimal duct stenosis; high MCV and fetal hemoglobin	Androgens, splenectomy, hematopoietic stem cell transplantation
Familial hemophagocytic lymphohistiocytosis	Before 2 yr	Pancytopenia; fever, hepatosplenomegaly, hypertriglyceridemia, CSF pleocytosis	Transfusion; often lethal; VP-16, hematopoietic stem cell transplantation, IVIG, cyclosporine
INFECTIOUS			
Parvovirus	Any age	Any chronic hemolytic anemia, typically sickle cell; new-onset reticulocytopenia and severe anemia	Red blood cell transfusion
Epstein-Barr virus (EBV)	Any age; usually <5 yr of age	X-linked immunodeficiency syndrome, pancytopenia	Transfusion, bone marrow transplantation
Virus-associated hemophagocytic syndrome (CMV, HHV-6, EBV)	Any age	Pancytopenia; hemophagocytosis in marrow, fever, hepatosplenomegaly	Transfusion, antiviral therapy, IVIG

CMV, Cytomegalovirus; CSF, cerebrospinal fluid; HHV-6, human herpesvirus 6; IVIG, intravenous immunoglobulin; MCV, mean corpuscular volume; VP-16, etoposide.

In contrast to the congenital hypoplastic anemias, **transient erythroblastopenia of childhood**, a normocytic anemia caused by suppression of RBC synthesis, usually appears between 6 months and 5 years of age in an otherwise normal child (see [Table 150.6](#)). Viral infections are thought to be the trigger, although the mechanism leading to RBC aplasia is poorly understood. The onset is gradual, but anemia may become severe. Recovery is usually

spontaneous. Differentiation from Diamond-Blackfan syndrome, in which erythroid precursors also are absent or diminished in the bone marrow, may be challenging. Transfusion of packed RBCs may be necessary if the anemia becomes symptomatic before recovery.

Aplastic crises may complicate any chronic hemolytic anemia. Human parvovirus B19 (the cause of fifth disease) infects erythroid precursors and shuts down erythropoiesis. In children with chronic hemolytic anemia, these periods of severe reticulocytopenia can lead to an acute exacerbation of the anemia that may precipitate cardiovascular decompensation. Transient erythroid aplasia is without consequence in individuals with normal RBC survival. Recovery from parvovirus infection in hemolytic disease is spontaneous, but patients may need transfusion if the anemia is severe.

Macrocytic Anemia

See [Fig. 150.1](#).

Marrow Failure/Pancytopenia

Decision-Making Algorithm

Anemia

Etiology

Pancytopenia is a simultaneous quantitative decrease in formed elements of the blood—erythrocytes, leukocytes, and platelets. Patients more often exhibit symptoms of infection or bleeding than anemia because of the relatively short life span of WBCs and platelets compared with the life span of RBCs. Causes of pancytopenia include failure of production (implying intrinsic bone marrow disease), sequestration (hypersplenism), and increased peripheral destruction.

Differential Diagnosis

Features that suggest **bone marrow failure** and mandate an examination of bone marrow include a low reticulocyte count, teardrop forms of RBCs (implying marrow replacement, not just failure), presence of abnormal forms of leukocytes or myeloid elements less mature than band forms, small platelets, and an

elevated MCV in the face of a low reticulocyte count. Pancytopenia resulting from bone marrow failure is usually a gradual process, starting with one or two cell lines but later involving all three cell lines. Features suggesting **increased destruction** include reticulocytosis, jaundice, immature erythroid or myeloid elements on the blood smear, large platelets, and increased serum bilirubin and lactic dehydrogenase.

Aplastic Anemia

Decision-Making Algorithm

Anemia

Etiology and Epidemiology

In a child with aplastic anemia, pancytopenia evolves as the hematopoietic elements of the bone marrow disappear and the marrow is replaced by fat. In developed countries, aplastic anemia is most often idiopathic. The disorder may be induced by drugs such as chloramphenicol and felbamate or by toxins such as benzene. Aplastic anemia also may follow infections, particularly hepatitis and infectious mononucleosis (see [Table 150.6](#)). Immunosuppression of hematopoiesis is postulated to be an important mechanism in patients with postinfectious and idiopathic aplastic anemia.

Laboratory Studies

A **bone marrow biopsy** is crucial to determine cellularity or the extent of depletion of the hematopoietic elements.

Treatment

Survival rate is approximately 20% in severe aplastic anemia with supportive care alone, although the duration of survival may be years when vigorous blood product and antibiotic support is provided. For children with severe aplastic anemia—defined by an absolute reticulocyte count less than $50,000/\mu\text{L}$, absolute neutrophil count less than $500/\text{mm}^3$, platelet count less than $20,000/\text{mm}^3$, and bone marrow cellularity on biopsy specimen less than 25% of normal—the treatment of choice is **hematopoietic stem cell transplantation (HSCT)** from a

sibling with identical human leukocyte antigen (HLA) and compatible mixed lymphocytes. When HSCT occurs before the recipient is sensitized to blood products, survival rate is greater than 80%. The treatment of aplastic anemia without an HLA-matched donor for HSCT is evolving, with two major options: potent immunosuppressive therapy or unrelated or partially matched HSCT. Results of trials using immunosuppressive therapy with antithymocyte globulin, cyclosporine, and corticosteroids in combination with hematopoietic growth factors have been encouraging. Such therapy is often toxic, and relapses often occur when therapy is stopped.

Fanconi Anemia

Decision-Making Algorithms

Anemia
Petechiae/Purpura
Pancytopenia

Etiology and Epidemiology

Fanconi anemia is a constitutional form of aplastic anemia that usually presents in the latter half of the first decade of life and may evolve over years. A group of genetic defects in proteins involved in **DNA repair** have been identified in Fanconi anemia, which is inherited in an autosomal recessive manner. The diagnosis is based on demonstration of increased chromosomal breakage after exposure to agents that damage DNA. The repair mechanism for DNA damage is abnormal in all cells in Fanconi anemia, which may contribute to the increased risk of malignancies. Acute leukemia develops in 10% of cases. Other malignancies that can occur include solid tumors of the head and neck, gastrointestinal tumors, and gynecological tumors.

Clinical Manifestations

Patients with Fanconi anemia have numerous characteristic clinical findings (see [Table 150.6](#)).

Treatment

HSCT can cure the pancytopenia caused by bone marrow aplasia. Many patients with Fanconi anemia and approximately 20% of children with aplastic anemia seem to respond for a time to **androgenic therapy**, which induces masculinization and may cause liver injury and liver tumors. Androgenic therapy increases RBC synthesis and may diminish transfusion requirements. The effect on granulocytes, and especially the platelet count, is less impressive.

Other less common etiologies of familial bone marrow failure resulting in pancytopenia are outlined in [Table 150.6](#). These include dyskeratosis congenita and familial hemophagocytic lymphohistiocytosis.

Marrow Replacement

Marrow replacement may occur as a result of **leukemia**, **solid tumors** (especially neuroblastoma), **storage diseases**, **osteopetrosis** in infants, and **myelofibrosis**, which is rare in childhood. The mechanisms by which malignant cells impair marrow synthesis of normal hematopoietic elements are complex and incompletely understood. Bone marrow aspirate and biopsy are needed for precise diagnosis of the etiology of marrow synthetic failure.

Pancytopenia Resulting From Destruction of Cells

Pancytopenia resulting from destruction of cells may be caused by **intramedullary destruction** of hematopoietic elements (myeloproliferative disorders, deficiencies of folic acid and vitamin B₁₂) or by the **peripheral destruction** of mature cells. The usual site of peripheral destruction of blood cells is the spleen, although the liver and other parts of the reticuloendothelial system may contribute. **Hypersplenism** may be the result of anatomical causes (portal hypertension or splenic hypertrophy from thalassemia); infections (including malaria); storage diseases (Gaucher disease); or malignancy (lymphomas, histiocytosis). Splenectomy is indicated only when the pancytopenia is of clinical significance.

Alpha-Chain Hemoglobinopathies

Etiology.

Because alpha chains are needed for fetal erythropoiesis and production of hemoglobin F ($\alpha_2\gamma_2$), **alpha-chain hemoglobinopathies** are present in utero. Four alpha genes are present on the two number 16 chromosomes (see [Fig. 150.3](#) and [Table 150.5](#)). Single gene deletions produce no disorder (silent carrier state) but can be detected by measuring the rates of α and β synthesis or by using molecular biological techniques. Deletion of two genes produces **α -thalassemia minor** with mild or no anemia and microcytosis. In individuals of African origin, the gene deletions occur on different chromosomes (*trans*). Thus infants born to parents that both have α -thalassemia gene deletions in *trans* have a benign disorder. In the Asian population, deletions may occur on the same chromosome (*cis*). Thus infants born to parents who both have α -thalassemia gene deletions in *cis* may inherit two number 16 chromosomes lacking three or even four genes resulting in severe disease. Deletion of all four α genes leads to hydrops fetalis, severe intrauterine anemia, and death, unless intrauterine transfusions are administered. Deletion of three genes produces moderate hemolytic anemia with γ_4 tetramers (**Bart hemoglobin**) in the fetus and β_4 tetramers (hemoglobin H) in older children and adults (see [Table 150.5](#)).

Beta-Chain Hemoglobinopathies

Beta-chain hemoglobinopathies in the United States are more prevalent than alpha-chain disorders, possibly because these abnormalities are not symptomatic in utero. The major beta hemoglobinopathies include those that alter hemoglobin function, including **hemoglobins S, C, E, and D**, and those that alter beta-chain production, the **β -thalassemias**. Because each RBC has two copies of chromosome 11 and they express both β -globin genes, most disorders of beta chains are not clinically severe, unless both beta chains are abnormal. By convention, when describing β -thalassemia genes, β^0 indicates a thalassemic gene resulting in absent beta-chain synthesis, whereas β^+ indicates a thalassemic

gene that permits reduced but not absent synthesis of normal β chains. Disorders of the beta chain usually manifest themselves clinically between 4 and 12 months of age when fetal hemoglobin nadirs, unless they have been detected prenatally or by cord blood screening.

β -Thalassemia Major (Cooley Anemia)

Etiology and Epidemiology

β -Thalassemia major is caused by mutations that impair **beta-chain synthesis**. Because of unbalanced synthesis of alpha and beta chains, alpha chains precipitate within the cells, resulting in RBC destruction either in the bone marrow or in the spleen. β -Thalassemia major is seen most commonly in individuals of Mediterranean or Asian descent. The clinical severity of the illness varies on the basis of the molecular defect ([Table 150.5](#)).

Clinical Manifestations

Signs and symptoms of β -thalassemia major result from the combination of chronic hemolytic disease, decreased or absent production of normal hemoglobin A, and ineffective erythropoiesis. The anemia is severe and leads to growth failure and high-output heart failure. **Ineffective erythropoiesis** causes increased expenditure of energy and expansion of the bone marrow cavities of all bones, leading to osteopenia, pathological fractures, extramedullary erythropoiesis with resultant hepatosplenomegaly, and an increase in the rate of iron absorption.

Treatment

Treatment of β -thalassemia major is based on a **hypertransfusion program** that corrects the anemia and suppresses the patient's own ineffective erythropoiesis, limiting the stimulus for increased iron absorption. This suppression permits the bones to heal, decreases metabolic expenditures, increases growth, and limits dietary iron absorption. Splenectomy may reduce the transfusion volume, but it adds to the risk of serious infection. Chelation therapy with deferoxamine or deferasirox should start when laboratory evidence of iron overload (**hemochromatosis**) is present and before there are clinical signs of iron overload (nonimmune diabetes mellitus, cirrhosis, heart failure, bronzing of the skin, and multiple endocrine abnormalities). HSCT in childhood, before organ dysfunction induced by iron overload, has had a high success rate in β -thalassemia major and is the treatment of choice.

Sickle Cell Disease

Decision-Making Algorithms

Abdominal Pain
 Jaundice
 Hepatomegaly
 Splenomegaly
 Anemia
 Pancytopenia
 Fever Without a Source
 Irritable Infant

Etiology and Epidemiology

The common sickle cell syndromes are **hemoglobin SS disease**, **hemoglobin S-C disease**, **hemoglobin S-β⁰-thalassemia**, **hemoglobin S-β⁺-thalassemia**, and rare variants (Table 150.7). The specific hemoglobin phenotype must be identified because the clinical complications differ in frequency, type, and severity. As a result of a single **amino acid substitution** (valine for glutamic acid at the β6 position), sickle hemoglobin crystallizes and forms a gel in the deoxygenated state. When reoxygenated, the sickle hemoglobin is normally soluble. The so-called reversible sickle cell is capable of entering the microcirculation. As the oxygen is extracted and saturation declines, sickling may occur, occluding the microvasculature. The surrounding tissue undergoes infarction, inducing pain and dysfunction. This sickling phenomenon is exacerbated by hypoxia, acidosis, fever, hypothermia, and dehydration.

TABLE 150.7

Comparison of Sickle Cell Syndromes

GENOTYPE	CLINICAL CONDITION	PERCENT HEMOGLOBIN					OTHER FINDING(S)
		Hb A	Hb S	Hb A ₂	Hb F	Hb C	
SA	Sickle cell trait	55-60	40-45	2-3	–	–	Usually asymptomatic
SS	Sickle cell anemia	0	85-95	2-3	5-15	–	Clinically severe anemia; Hb F heterogeneous in

							distribution
S-β ⁰ thalassemia	Sickle cell-β ⁰ thalassemia	0	70-80	3-5	10-20	–	Moderately severe anemia; splenomegaly in 50%; smear: hypochromic, microcytic anemia
S-β ⁺ thalassemia	Sickle cell-β ⁺ thalassemia	10-20	60-75	3-5	10-20	–	Hb F distributed heterogeneously; mild microcytic anemia
SC	Hb SC disease	0	45-50	–	–	45-50	Moderately severe anemia; splenomegaly; retinopathy; target cells
S-HPFH	Sickle-hereditary persistence of Hb F	0	70-80	1-2	20-30	–	Often asymptomatic; Hb F is uniformly distributed

From Andreoli T, Carpenter C, Griggs R, et al. *Cecil Essentials of Medicine*. 7th ed. Philadelphia: Saunders; 2007.

Clinical Manifestations and Treatment

A child with sickle cell disease is vulnerable to **life-threatening infection** by 4 months of age due to splenic dysfunction. **Splenic dysfunction** is caused by sickling of the RBCs within the spleen, resulting in an inability to filter microorganisms from the bloodstream in most patients. Splenic dysfunction is followed, eventually, by **splenic infarction**, usually by 2-4 years of age. The loss of normal splenic function makes the patient susceptible to overwhelming infection by encapsulated organisms, especially *Streptococcus pneumoniae* and other pathogens (Table 150.8). The hallmark of infection is fever. A febrile patient with a sickle cell disease (temperature >38.5°C) must be evaluated immediately (see Chapter 96). Current precautions to prevent infections include prophylactic daily oral penicillin begun at diagnosis and vaccinations against pneumococcus, *Haemophilus influenzae* type b, meningococcus, hepatitis B virus, and influenza virus.

TABLE 150.8

Clinical Manifestations of Sickle Cell Anemia*

MANIFESTATION	COMMENTS
Anemia	Chronic, onset 3-4 mo of age; may require folate therapy for chronic hemolysis; hemoglobin usually 6-10 g/dL
Aplastic crisis	Parvovirus infection, reticulocytopenia; acute and reversible; may need transfusion
Sequestration crisis	Massive splenomegaly (may involve liver), shock; treat with transfusion

Hemolytic crisis	May be associated with G6PD deficiency
Dactylitis	Hand-foot swelling in early infancy
Pain	Microvascular painful vasoocclusive infarcts of muscle, bone, bone marrow, lung, intestines; chronic pain (nervous system sensitization)
Cerebrovascular accidents (overt and silent)	Large and small vessel occlusion → thrombosis/bleeding (stroke); requires chronic transfusion
Acute chest syndrome	Infection, asthma, atelectasis, infarction, fat emboli, severe hypoxemia, infiltrate, dyspnea, absent breath sounds; treated with transfusions, antibiotics, oxygen, bronchodilators
Chronic lung disease	Pulmonary fibrosis, restrictive lung disease, cor pulmonale, pulmonary hypertension
Priapism	Causes eventual impotence; treated with transfusion, oxygen, or corpora cavernosa-to-spongiosa shunt
Ocular	Retinopathy
Gallbladder disease	Bilirubin stones; cholecystitis
Renal	Hematuria, papillary necrosis, renal concentrating defect; nephropathy
Cardiomyopathy	Heart failure
Skeletal	Osteonecrosis (avascular) of femoral or humeral head
Leg ulceration	Seen in older patients
Infections	Functional asplenia, defects in properdin system; pneumococcal bacteremia, meningitis, and arthritis; deafness from meningitis; <i>Salmonella</i> and <i>Staphylococcus aureus</i> osteomyelitis; severe <i>Mycoplasma pneumoniae</i>
Growth failure, delayed puberty	May respond to nutritional supplements
Psychological problems	Narcotic addiction (rare), dependence unusual; chronic illness, chronic pain syndrome

Clinical manifestations with sickle cell trait are unusual but include renal papillary necrosis (hematuria), sudden death on exertion, intraocular hyphema extension, and sickling in unpressurized airplanes.

G6PD, Glucose-6-phosphate dehydrogenase.

The anemia of hemoglobin SS disease is usually a chronic, moderately severe, hemolytic anemia that is not routinely transfusion dependent. The severity depends in part on the patient's phenotype. Manifestations of chronic anemia include jaundice, pallor, variable splenomegaly in infancy, a cardiac flow murmur, and delayed growth and sexual maturation. Decisions about transfusion should be made on the basis of the patient's clinical condition, the hemoglobin level, and the reticulocyte count.

Sickle cell disease is complicated by sudden, occasionally severe and life-threatening events caused by the acute intravascular sickling of the RBCs, with resultant pain or organ dysfunction (i.e., **crisis**). In two different clinical situations, an acute, potentially life-threatening decline in the hemoglobin level may be superimposed on the chronic compensated anemia. **Splenic sequestration crisis** is a life-threatening, hyperacute drop in the hemoglobin

level (blood volume) secondary to splenic pooling of the patient's RBCs and sickling within the spleen. The spleen is moderately to markedly enlarged, and the reticulocyte count is elevated. In an **aplastic crisis**, parvovirus B19 infects RBC precursors in the bone marrow and induces transient RBC aplasia with reticulocytopenia and a rapid worsening of anemia because of the very short life span of sickle RBCs. Simple transfusion therapy is indicated for sequestration and aplastic crises when the anemia is symptomatic.

Vasooclusive painful events may occur in any organ of the body and manifest as pain and/or significant dysfunction (see [Table 150.8](#)). The **acute chest syndrome** is a vasooclusive crisis within the lungs with evidence of a new infiltrate on chest radiograph. It is often associated with infection and infarction. The patient may first complain of chest pain but within a few hours develops cough, increasing respiratory and heart rates, hypoxia, and progressive respiratory distress. Physical examination reveals areas of decreased breath sounds and dullness on chest percussion. Treatment involves early recognition and prevention of arterial hypoxemia. Oxygen, fluids, judicious use of analgesic medications, antibiotics, bronchodilators, and RBC transfusion (rarely exchange transfusion) are indicated as therapy for acute chest syndrome. *Incentive spirometry* may help reduce the incidence of acute chest crisis in patients presenting with pain in the chest or abdomen.

Acute painful events are the most common type of vasooclusive events. Pain usually localizes to the long bones of the arms or legs but may occur in smaller bones of the hands or feet in infancy (dactylitis) or in the abdomen. Painful events usually last 2-7 days. Repeated painful events within the femur may lead to avascular necrosis of the femoral head and chronic hip disease. Treatment of painful events includes administration of fluids, analgesia (usually opioids and nonsteroidal antiinflammatory drugs), and oxygen if the patient is hypoxic. Appropriate use of analgesics is imperative to control pain. Patients with sickle cell disease often require high doses of opioids due to tolerance to provide adequate pain control. The frequency of acute painful events increases with age. In addition, chronic daily pain irrespective of an acute vasooclusive event is associated with increasing age, occurring in 30% of adults and 23-40% of children. Chronic nervous system sensitization is likely a key driver of the chronic pain seen in patients with sickle cell disease.

Priapism occurs in males, usually between 6 and 20 years old. The child experiences a sudden, painful onset of a tumescent penis that will not relax. Therapeutic steps for priapism include the administration of oxygen, fluids,

analgesia, and transfusion when appropriate to achieve a hemoglobin S less than 30%. Urgent partial exchange transfusion is often required to lower the hemoglobin S.

Overt **stroke** occurs in approximately 8-10% of patients with SS disease. These events may present as the sudden onset of an altered state of consciousness, seizures, or focal paralysis. **Silent stroke**, which is defined as evidence of cerebral infarction on imaging studies but a normal neurological examination, is more common and occurs in approximately 20% of patients with SS disease. A significant change in school performance or behavior has been associated with silent stroke. Children with Hg SS disease older than 3 years should be screened for increased risk of stroke using transcranial Doppler (TCD). Chronic monthly transfusions are indicated in those with overt stroke and abnormal TCDs and should be considered for those with silent strokes.

Laboratory Diagnosis

The diagnosis of hemoglobinopathies is made by identifying the precise amount and type of hemoglobin using **hemoglobin electrophoresis**, **isoelectric focusing**, or **high-performance liquid chromatography**. Every member of an at-risk population should have a precise hemoglobin phenotype performed at birth (preferably) or during early infancy. All U.S. states perform newborn screening for sickle cell disease.

Treatment

Direct therapy of sickle cell disease is evolving. The mainstay of care is supportive measures. The use of chronic RBC transfusions to treat patients who have had a stroke has been very successful. Chronic RBC transfusions have also been used successfully for short time periods to prevent recurrent vasoocclusive events, including pain, acute chest syndrome, and priapism. **Hydroxyurea**, which increases hemoglobin F, decreases the number and severity of painful events, frequency of acute chest syndrome and need for transfusions in children as early as 1 year of age. Current published clinical care guidelines from the National Institutes of Health (NIH)/National Heart, Lung, and Blood Institute (NHLBI) for patients with sickle cell disease recommend hydroxyurea should be initiated in asymptomatic children with severe sickle cell disease (HbSS or HbS β^0 -thalassemia). **HSCT** using a matched sibling donor has cured many children with sickle cell disease. HSCT using alternative donors for children, without a suitable sibling match, is being studied.

Enzymopathies

Decision-Making Algorithms

Splenomegaly
Anemia

Etiology

G6PD deficiency is an abnormality in the **hexose monophosphate shunt pathway** of glycolysis that results in the depletion of reduced nicotinamide adenine dinucleotide phosphate (NADPH) and the inability to regenerate reduced glutathione. When a patient with G6PD is exposed to significant oxidant stress, hemoglobin is oxidized, forming precipitates of sulfhemoglobin (**Heinz bodies**), which are visible on specially stained preparations. The gene for G6PD deficiency is on the X chromosome.

The severity of hemolysis depends on the enzyme variant. In many G6PD variants the enzymes become unstable with aging of the RBC and cannot be replaced because the cell is anucleated. Older cells are most susceptible to oxidant-induced hemolysis. In other variants the enzyme is kinetically abnormal.

Epidemiology

The most common variants of G6PD deficiency have been found in areas where malaria is endemic. G6PD deficiency protects against parasitism of the erythrocyte. The most common variant with normal activity is termed **type B** and is defined by its electrophoretic mobility. The approximate gene frequencies in African Americans are 70% type B, 20% type A, and 10% type A-. Only the **A- variant**, termed the *African variant*, is unstable. Ten percent of black males are affected. A group of variants found in Sardinians, Sicilians, Greeks, Sephardic and Oriental Jews, and Arabs is termed the **Mediterranean variant** and is associated with chronic hemolysis and potentially life-threatening hemolytic disease. Because the gene for G6PD deficiency is carried on the X chromosome, clinical hemolysis is most common in males. Heterozygous females who have randomly inactivated a higher percentage of the normal gene may become symptomatic, as may homozygous females with the A- variant (0.5-1% of females of African descent).

Clinical Manifestations

G6PD deficiency has two common presentations. Individuals with the A-variant have normal hemoglobin values when well but develop an **acute episode of hemolysis** triggered by serious (bacterial) infection or ingestion of an oxidant drug. The RBC morphology during episodes of acute hemolysis is striking, appearing to have “bites” taken out of them (cookie cells). These are areas of absent hemoglobin that are produced by phagocytosis of Heinz bodies by splenic macrophages; as a result, the RBCs appear blistered. Clinically evident jaundice, dark urine resulting from bilirubin pigments, hemoglobinuria when hemolysis is intravascular, and decreased haptoglobin levels are common during hemolytic episodes. Early on, the hemolysis usually exceeds the ability of the bone marrow to compensate, so the reticulocyte count may be low for 3-4 days.

Laboratory Studies

The diagnosis of G6PD deficiency is based on decreased NADPH formation. However, G6PD levels during an acute, severe hemolytic episode may be normal because the most deficient cells have been destroyed and reticulocytes are enriched with G6PD. Repeating the test at a later time when the patient is in a steady-state condition, testing the mothers of boys with suspected G6PD deficiency, or performing electrophoresis to identify the precise variant present aids in diagnosis.

Treatment and Prevention

The treatment of G6PD deficiency is supportive. Transfusions are indicated when significant cardiovascular compromise is present. Maintaining hydration and urine alkalization protects the kidneys against damage from precipitated free hemoglobin. Hemolysis is prevented by avoidance of known oxidants, particularly long-acting sulfonamides, nitrofurantoin, primaquine, dimercaprol, and moth balls (naphthalene). Fava beans (favism) have triggered hemolysis, particularly in patients with the Mediterranean variant. Serious infection also is a potential precipitant of hemolysis in G6PD-deficient young children.

Pyruvate kinase deficiency is much less common than G6PD deficiency and represents a clinical spectrum of disorders caused by the functional deficiency of pyruvate kinase. Some individuals have a true deficiency state, and others have abnormal enzyme kinetics. The metabolic consequence of pyruvate kinase deficiency is adenosine triphosphate (ATP) depletion, impairing RBC survival. Pyruvate kinase deficiency is usually an autosomal disorder, and most children

who are affected (and are not products of consanguinity) are double heterozygotes for two abnormal enzymes. Hemolysis is not aggravated by oxidant stress due to the profound reticulocytosis in this condition. Aplastic crises are potentially life threatening. The spleen is the site for RBC removal in pyruvate kinase deficiency. Most patients have amelioration of the anemia and a reduction of transfusion requirements after splenectomy.

Membrane Disorders

Decision-Making Algorithms

Anemia
Pancytopenia

Etiology

The biochemical basis of **hereditary spherocytosis** and **hereditary elliptocytosis** are similar. Both conditions appear to have a defect in the protein lattice (spectrin, ankyrin, protein 4.2, band 3) that underlies the RBC lipid bilayer and provides stability of the membrane shape. In hereditary spherocytosis, pieces of membrane bud off as microvesicles because of abnormal vertical interaction of the cytoskeletal proteins and uncoupling of the lipid bilayer from the cytoskeleton. When the RBC loses membrane, cell shape changes from a biconcave disk to a spherocyte. The RBC is less deformable when passing through narrow passages in the spleen. Hereditary elliptocytosis is a disorder of spectrin dimer interactions that occurs primarily in individuals of African descent. The transmission of the two variants is usually autosomal dominant, but spontaneous mutations causing hereditary spherocytosis are common. **Hereditary pyropoikilocytosis** (unusual instability of the erythrocytes when they are exposed to heat at 45°C) is the result of a structural abnormality of spectrin.

Clinical Manifestations

Hereditary spherocytosis varies greatly in clinical severity, ranging from an asymptomatic, well-compensated, mild hemolytic anemia that may be discovered incidentally to a severe hemolytic anemia with growth failure,

splenomegaly, and chronic transfusion requirements in infancy necessitating early splenectomy. The most common variant of hereditary elliptocytosis is a clinically insignificant morphological abnormality without shortened RBC survival. The less common variant is associated with spherocytes, ovalocytes, and elliptocytes with a moderate, usually compensated, hemolysis. Far more significant hemolysis occurs in hereditary pyropoikilocytosis. The peripheral blood smear in hereditary pyropoikilocytosis often includes elliptocytes, spherocytes, fragmented RBCs, and striking microcytosis. Such patients may have bizarre blood smears in the newborn period with small, fragmented RBCs.

Laboratory Diagnosis

The clinical diagnosis of hereditary spherocytosis should be suspected in patients with even a few spherocytes found on the blood smear because the spleen preferentially removes spherocytes. An incubated **osmotic fragility test** confirms the presence of spherocytes and increases the likelihood of the diagnosis. The osmotic fragility test result is abnormal in any hemolytic disease in which spherocytes are present (e.g., in antibody-mediated hemolysis). Genetic studies (band 3 gene mutation) can also be done to confirm the diagnosis of hereditary spherocytosis.

Treatment

Splenectomy corrects the anemia and normalizes the RBC survival in patients with hereditary spherocytosis, but the morphological abnormalities persist. Splenectomy should be reserved for any child with severe hereditary spherocytosis and symptoms referable to chronic anemia or growth failure. Splenectomy should be deferred until age 5 years, if possible, to minimize the risk of overwhelming postsplenectomy sepsis and to maximize the antibody response to the polyvalent pneumococcal and meningococcal vaccine. In several reports, partial splenectomy seems to improve the hemolytic anemia and maintain splenic function in host defense.

Hemolytic Anemia Caused by Disorders Extrinsic to the Red Blood Cell

Etiology and Clinical Manifestations

Decision-Making Algorithm

Anemia

Isoimmune hemolysis is caused by active maternal immunization against fetal antigens that the mother's erythrocytes do not express (see [Chapter 62](#)). Examples are antibodies to the A, B, and Rh D antigens; other Rh antigens; and the Kell, Duffy, and other blood groups. Anti-A and anti-B hemolysis is caused by the placental transfer of naturally occurring maternal antibodies from mothers who lack A or B antigen (usually blood type O). Positive results of the direct antiglobulin (**Coombs**) test on the infant's RBCs ([Fig. 150.4](#)), the indirect antiglobulin test on the mother's serum, and the presence of spherocytes and immature erythroid precursors (erythroblastosis) on the infant's blood smear confirm this diagnosis. Isoimmune hemolytic disease varies in clinical severity. There may be no clinical manifestations or the infant may exhibit jaundice, severe anemia, and hydrops fetalis.

FIGURE 150.4 Coombs or direct antiglobulin test (DAT). In the DAT, so-called Coombs serum that recognizes human immunoglobulin (Ig) or complement (C) is used to detect the presence of antibody or C on the surface of the red blood cells (RBCs) by agglutination. **A**, An IgM antibody can bind two RBCs simultaneously because of its multiple antigen-binding sites. The great size of the IgM allows it to bridge the surface repulsive forces (zeta potential) between RBCs and cause agglutination. **B**, An IgG antibody is too small to bridge the zeta potential and cause agglutination. **C**, On the addition of Coombs serum, the zeta potential is bridged successfully, and RBCs agglutinate. (Modified from Ware RE, Rosse WF. Autoimmune hemolytic anemia. In: Orkin SH, Nathan DG, Look AT, Ginsburg D, eds. *Hematology of Infancy and Childhood*. 6th ed. Philadelphia: Saunders; 2003:530.)

Autoimmune hemolytic anemia is usually an acute, self-limited Coombs-positive process that develops after an infection (*Mycoplasma*, Epstein-Barr, or other viral infections) due to the production of autoantibodies that cause red cell

destruction. Autoimmune hemolytic anemia may also be the presenting symptom of a chronic autoimmune disease (systemic lupus erythematosus, lymphoproliferative disorders, or immunodeficiency). Drugs may induce a Coombs-positive hemolytic anemia by forming a hapten on the RBC membrane (penicillin) or by forming immune complexes (quinidine) that attach to the RBC membrane. Antibodies then activate complement-induced intravascular hemolysis. The third type of drug-induced immune hemolysis occurs during treatment with α -methyldopa and a few other drugs. In this type, prolonged drug exposure alters the RBC membrane, inducing neoantigen formation. Antibodies are produced that bind to the neoantigen; this produces a positive antiglobulin test result far more commonly than it actually induces hemolysis. In each of these conditions, the erythrocyte is an *innocent bystander*.

A second form of acquired hemolytic disease is caused by mechanical damage to the RBC membrane during circulation. In **thrombotic microangiopathy** the RBCs are trapped by fibrin strands in the circulation and physically broken by shear stress as they pass through these strands. Hemolytic uremic syndrome, disseminated intravascular coagulation (DIC), thrombotic thrombocytopenic purpura, malignant hypertension, toxemia, and hyperacute renal graft rejection can produce thrombotic microangiopathy. The platelets are usually large, indicating that they are young, but have a decreased survival even if the numbers are normal. Consumption of clotting factors is more prominent in DIC than in the other forms of thrombotic microangiopathy. The smear shows RBC fragments (schistocytes), microspherocytes, teardrop forms, and polychromasia. Other examples of mechanical injury to RBCs include damage by exposure to nonendothelialized surfaces (as in artificial heart valves) or as a result of high flow and shear rates in giant hemangiomas (**Kasabach-Merritt syndrome**).

Alterations in plasma lipids, especially cholesterol, may lead to damage to the RBC membrane and shorten RBC survival. Lipids in the plasma are in equilibrium with lipids in the RBC membrane. High cholesterol levels increase the membrane cholesterol and the total membrane surface without affecting the volume of the cell. This condition produces **spur cells** that may be seen in abetalipoproteinemia and liver diseases. Hemolysis occurs in the spleen, where poor RBC deformability results in erythrocyte destruction. **Circulating toxins** (e.g., snake venoms and heavy metals) that bind sulfhydryl groups may damage the RBC membrane and induce hemolysis. Irregularly spiculated RBCs (burr cells) are seen in renal failure. **Vitamin E deficiency** can also cause an acquired hemolytic anemia as a result of abnormal sensitivity of membrane lipids to

oxidant stress. Vitamin E deficiency may occur in premature infants who are not being supplemented with vitamin E or who have insufficient nutrition, in infants with severe malabsorption syndromes (including cystic fibrosis), and in infants with transfusional iron overload, which can lead to severe oxidant exposure.

Laboratory Diagnosis

The peripheral blood smear in autoimmune hemolytic anemia usually reveals spherocytes and occasionally nucleated RBCs. The reticulocyte count varies because some patients have relatively low reticulocyte counts as a result of autoantibodies that cross react with RBC precursors.

Treatment and Prognosis

Transfusion for the treatment of autoimmune hemolysis is challenging because crossmatching is difficult because the autoantibodies react with virtually all RBCs. In addition to **transfusion**, which may be lifesaving, management of autoimmune hemolytic anemia depends on antibody type. Management may involve administration of **corticosteroids** and, at times, **intravenous immunoglobulin**. Corticosteroids reduce the clearance of sensitized RBCs in the spleen. In drug-induced hemolysis, withdrawal of the drug usually leads to resolution of the hemolytic process. More than 80% of children with autoimmune hemolytic anemia recover spontaneously.

CHAPTER 151

Hemostatic Disorders

Normal Hemostasis

Hemostasis is the dynamic process of **coagulation** as it occurs in areas of vascular injury, involving the carefully modulated interaction of platelets, vascular wall, and procoagulant and anticoagulant proteins. After an injury to the vascular endothelium, subendothelial collagen induces a conformational change in von Willebrand factor (**VWF**), an adhesive protein to which platelets bind via their glycoprotein Ib receptor. After adhesion, platelets undergo activation and release numerous intracellular contents, including adenosine diphosphate (ADP).

These **activated platelets** subsequently induce aggregation of additional platelets. Simultaneously, tissue factor, collagen, and other matrix proteins in tissue activate the coagulation cascade, leading to the formation of the enzyme **thrombin** (Fig. 151.1). Thrombin causes further aggregation of platelets, a positive feedback activation of factors 5 and 8, the conversion of fibrinogen to fibrin, and the activation of factor 11. A **platelet plug** forms, and bleeding ceases, usually within 3-7 minutes. The generation of thrombin leads to formation of a permanent clot by the activation of factor 13, which cross links fibrin, forming a stable thrombus. Finally, contractile elements within the platelet mediate **clot retraction**. Thrombin also contributes to the eventual limitation of clot size by binding to the protein thrombomodulin on intact endothelial cells, converting protein C into activated protein C. Thrombin contributes to the eventual lysis of the thrombus by activating plasminogen to plasmin. All of the hemostatic processes are closely interwoven and occur on biological surfaces that mediate coagulation by bringing the critical players—platelets, endothelial cells, and subendothelium—into close proximity with pro- and anticoagulant proteins.

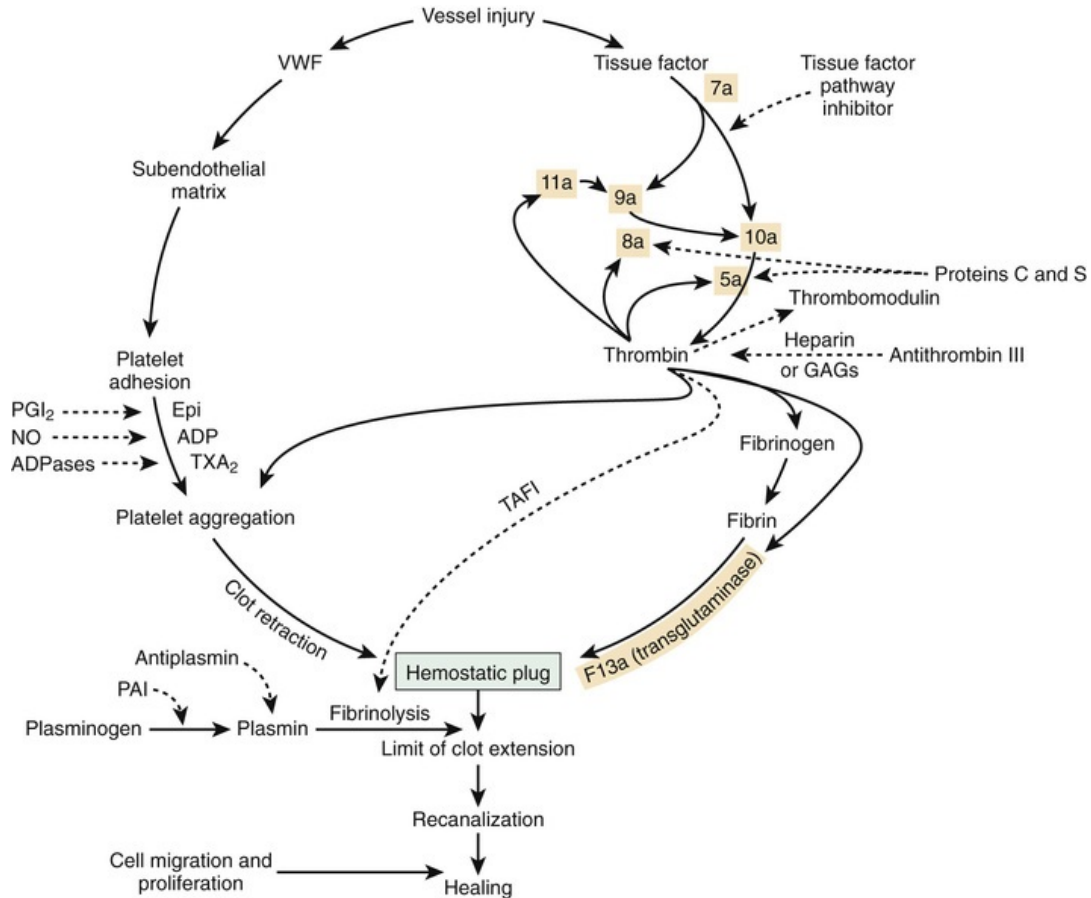

FIGURE 151.1 Diagram of the multiple interactions of the hemostatic mechanism. *Solid lines* indicate reactions that favor coagulation, and *dashed lines* indicate reactions that inhibit clotting. *Epi*, Epinephrine; *GAGs*, glycosaminoglycans; *NO*, nitric oxide; *PAI*, plasminogen activator inhibitor; *PGI₂*, prostaglandin I₂ (prostacyclin); *TAFI*, thrombin-activated fibrinolytic inhibitor; *TXA₂*, thromboxane A₂; *VWF*, von Willebrand factor.

(Modified from Scott JP, Montgomery RR. Hemorrhagic and thrombotic diseases. In: Kliegman RM, Behrman RE, Jenson HB, Stanton BF, eds. *Nelson Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders; 2007:2062.)

Many think of coagulation as having **intrinsic and extrinsic pathways**, but the reality is that these pathways are closely interactive and do not react independently (Fig. 151.2). For ease of use, all coagulation factors are denoted using Arabic rather than Roman numerals to prevent misreading factor VII (7) as factor VIII (8). In vivo, factor 7 autocatalyzes to form small amounts of factor 7a. When tissue is injured, **tissue factor** is released and causes a burst of factor 7a generation. Tissue factor, in combination with calcium and factor 7a, activates factor 9 and factor 10. The activation of factor 9 by factor 7a results in eventual generation of thrombin, which feeds back on factor 11, generating factor 11a and accelerating thrombin formation. This process explains why deficiency of factor

8 or factor 9 leads to severe bleeding disorders, whereas deficiency of factor 11 is usually mild, and deficiency of factor 12 is asymptomatic.

FIGURE 151.2 Simplified pathways of blood coagulation. The area inside the solid black line is the intrinsic pathway measured by the activated partial thromboplastin time (aPTT). The area inside the green line is the extrinsic pathway, measured by the prothrombin time (PT). The area encompassed by both lines is the common pathway. *AT-III*, Antithrombin III; *F*, factor; *HMWK*, high molecular weight kininogen; *P-C/S*, protein C/S; *PL*, phospholipid; *TFPI*, tissue factor pathway inhibitor. (Modified from Scott JP, Montgomery RR. Hemorrhagic and thrombotic diseases. In: Kliegman RM, Behrman RE, Jenson HB, Stanton BF, eds. *Nelson Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders; 2007:2061.)

A series of **inhibitory factors** serve to tightly regulate the activation of coagulation. **Antithrombin III** inactivates thrombin and factors 10a, 9a, and 11a. The **protein C and protein S** system inactivates activated factors 5 and 8, which are cofactors localized in the “tenase” and “prothrombinase” complexes. The **tissue factor pathway inhibitor**, an anticoagulant protein, limits activation of the coagulation cascade by factor 7a and factor 10a. **Fibrinolysis** is initiated by the action of tissue plasminogen activator on plasminogen, producing plasmin, the active enzyme that degrades fibrin into split products. Fibrinolysis eventually dissolves the clot and allows normal flow to resume. Deficiencies of anticoagulant proteins may predispose to thrombosis.

Developmental Hemostasis

In the fetus, fibrinogen, factor 5, factor 8, and platelets approach normal levels during the second trimester. Levels of other clotting factors and anticoagulant proteins increase gradually throughout gestation. The premature infant is simultaneously at increased risk of bleeding or clotting complications that are exacerbated by many of the medical interventions needed for care and monitoring, especially indwelling arterial or venous catheters. Most children attain normal levels of procoagulant and anticoagulant proteins by 1 year of age, although levels of protein C lag and normalize in adolescence.

Hemostatic Disorders

Etiology and Epidemiology

A detailed **family history** is crucial to the diagnosis of bleeding and thrombotic disorders. **Hemophilia** is X-linked, and almost all affected children are boys. **von Willebrand disease** usually is inherited in an autosomal dominant fashion. In the investigation of thrombotic disorders, a personal or family history of blood clots in the legs or lungs, early-onset stroke, or heart attack suggests a hereditary predisposition to thrombosis. The causes of bleeding may be hematological in origin or due to vascular, nonhematological causes ([Fig. 151.3](#)). Thrombotic disorders can be congenital or acquired ([Table 151.1](#)) and frequently present after an initial event (central catheter, trauma, malignancy, infection, pregnancy, or treatment with estrogens) provides a nidus for clot formation or a procoagulant stimulus.

Clinical Manifestations

Decision-Making Algorithms

Gastrointestinal Bleeding
Bleeding
Petechiae/Purpura

Patients with hemostatic disorders may have complaints of either bleeding or clotting. Age at onset of bleeding indicates whether the problem is congenital or acquired. The **sites of bleeding** (mucocutaneous or deep) and **degree of trauma** (spontaneous or significant) required to induce injury suggest the type and severity of the disorder. Certain medications (aspirin and valproic acid) are known to exacerbate preexisting bleeding disorders by interfering with platelet function.

The **physical examination** should characterize the presence of skin or mucous membrane bleeding and deeper sites of hemorrhage into the muscles and joints or internal bleeding sites. The term **petechia** refers to a nonblanching lesion less than 2 mm in size. **Purpura** is a group of adjoining petechiae, **ecchymoses** (bruises) are isolated lesions larger than petechiae, and **hematomas** are raised, palpable ecchymoses.

The physical examination should also search for manifestations of an underlying disease, lymphadenopathy, hepatosplenomegaly, vasculitic rash, or chronic hepatic or renal disease. **Deep venous thrombi** may cause warm, swollen (distended), tender, purplish discolored extremities or organs or no findings. **Arterial clots** cause acute, painful, pale, and poorly perfused extremities. Arterial thrombi of the internal organs present with signs and symptoms of infarction.

Laboratory Testing

Screening laboratory studies for bleeding patients include a **platelet count, prothrombin time, partial thromboplastin time, fibrinogen, and bleeding time** or other screening test of platelet function. Many laboratories have adopted the platelet function analyzer (PFA) to replace the bleeding time as a screening test for platelet function abnormalities and von Willebrand disease. The PFA has variable sensitivity and specificity for common bleeding disorders. No single laboratory test can screen for all bleeding disorders. The findings on screening tests for bleeding vary with the specific disorder ([Table 151.2](#)).

TABLE 151.2

Screening Tests for Bleeding Disorders

TEST	MECHANISM TESTED	NORMAL VALUES	DISORDER
Prothrombin time	Extrinsic and common pathway	<12 sec beyond neonate; 12-18 sec in term neonate	Defect in vitamin K–dependent factors; hemorrhagic disease of newborn, malabsorption, liver disease, DIC, oral anticoagulants, ingestion of rat poison
Activated partial thromboplastin time	Intrinsic and common pathway	70 sec in term neonate 25-40 sec beyond neonate	Hemophilia; von Willebrand disease, heparin; DIC; deficient factors 12 and 11; lupus anticoagulant
Thrombin time	Fibrinogen to fibrin conversion	12-17 sec in term neonate; 10-15 sec beyond neonate	Fibrin split products, DIC, hypofibrinogenemia, heparin, uremia
Bleeding time	Hemostasis, capillary and platelet function	3-7 min beyond neonate	Platelet dysfunction, thrombocytopenia, von Willebrand disease, aspirin
Platelet count	Platelet number	150,000-450,000/mL	Thrombocytopenia differential diagnosis (see Fig. 151.4)
PFA	Closure time		
Blood smear	Platelet number and size; RBC morphology	–	Large platelets suggest peripheral destruction; fragmented, bizarre RBC morphology suggests microangiopathic process (e.g., hemolytic uremic syndrome, hemangioma, DIC)

DIC, Disseminated intravascular coagulation; *PFA*, platelet function analyzer-100; *RBC*, red blood cell.

Differential Diagnosis

Disorders of Platelets

Decision-Making Algorithms

Bleeding
Petechiae/Purpura

Platelet counts less than $150,000/\text{mm}^3$ constitute **thrombocytopenia**. Mucocutaneous bleeding is the hallmark of platelet disorders, including thrombocytopenia. The risk of bleeding correlates imperfectly with the platelet count. Children with platelet counts greater than $80,000/\text{mm}^3$ are able to withstand all but the most extreme hemostatic challenges, such as surgery or major trauma. Children with platelet counts less than $20,000/\text{mm}^3$ are at risk for spontaneous bleeding. These generalizations are modified by factors such as the age of the platelets (young, large platelets usually function better than old ones) and the presence of inhibitors of platelet function, such as antibodies, drugs (especially aspirin), fibrin degradation products, and toxins formed in the presence of hepatic or renal disease. The size of platelets is routinely measured as the mean platelet volume (MPV). The etiology of thrombocytopenia ([Fig. 151.4](#)) may be organized into three mechanisms:

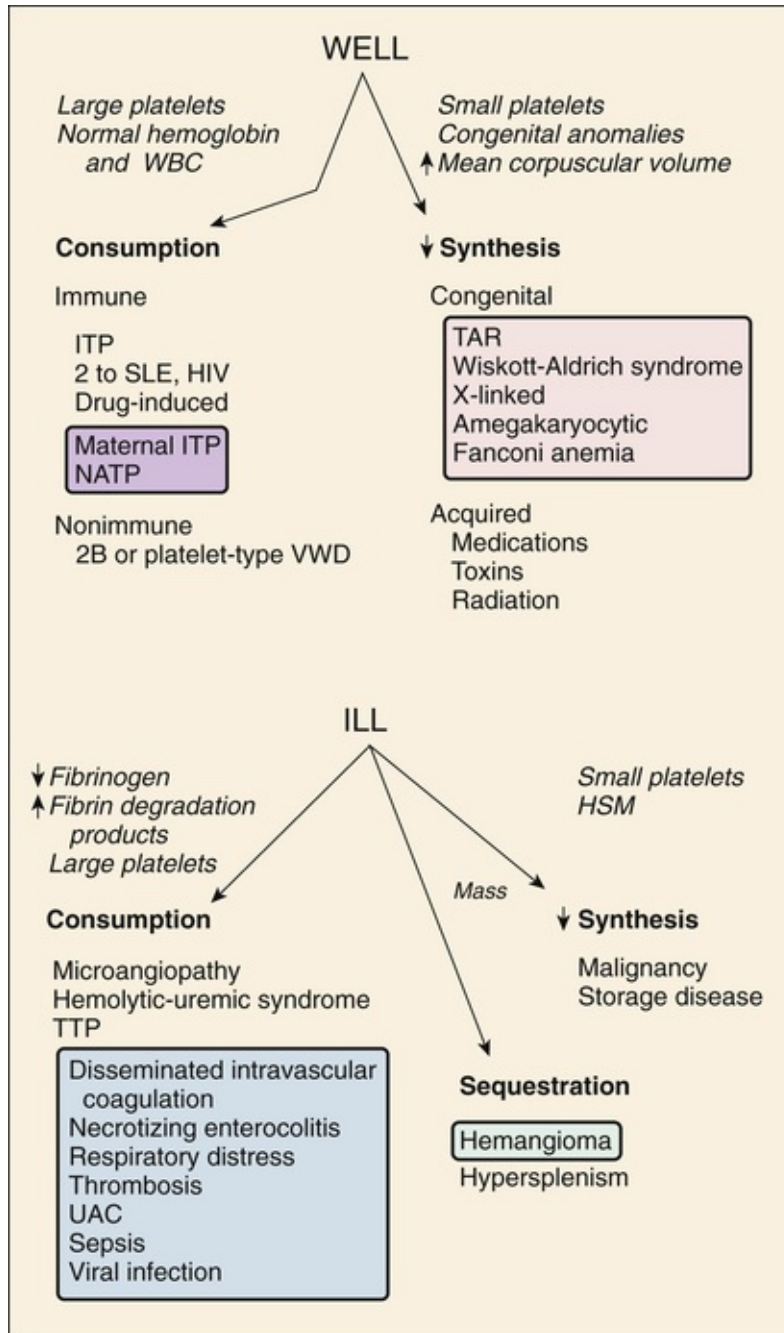

FIGURE 151.4 Differential diagnosis of childhood thrombocytopenic syndromes. The syndromes initially are separated by their clinical appearances. Clues leading to the diagnosis are presented in *italics*. The mechanisms and common disorders leading to these findings are shown in the *lower part of the figure*. Disorders that commonly affect neonates are listed in the *shaded boxes*. *HSM*, Hepatosplenomegaly; *ITP*, idiopathic immune thrombocytopenic purpura; *NATP*, neonatal alloimmune thrombocytopenic purpura; *SLE*, systemic lupus erythematosus; *TAR*, thrombocytopenia with absence of radius (syndrome); *TTP*, thrombotic thrombocytopenic purpura; *UAC*, umbilical artery catheter; *VWD*, von Willebrand disease; *WBC*, white blood cell. (From Scott JP. Bleeding and

1. Decreased platelet production
2. Increased destruction
3. Sequestration

Thrombocytopenia Resulting From Decreased Platelet Production

Primary disorders of megakaryopoiesis (platelet production) are rare in childhood, other than as part of an aplastic syndrome. **Thrombocytopenia with absent radii syndrome** is characterized by severe thrombocytopenia in association with orthopedic abnormalities, especially of the upper extremity. The thrombocytopenia usually improves over time. **Amegakaryocytic thrombocytopenia** presents at birth or shortly thereafter with findings of severe thrombocytopenia, but no other congenital anomalies. The marrow is devoid of megakaryocytes and usually progresses to aplasia of all hematopoietic cell lines.

Acquired thrombocytopenia as a result of decreased production is rarely an isolated finding. It is seen more often in the context of **pancytopenia resulting from bone marrow failure** caused by infiltrative or aplastic processes. Certain chemotherapeutic agents may affect megakaryocytes selectively more than other marrow elements. **Cyanotic congenital heart disease with polycythemia** often is associated with thrombocytopenia, but this is rarely severe or associated with significant clinical bleeding. Congenital (TORCH [toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex]) and acquired **viral infections** (human immunodeficiency virus [HIV], Epstein-Barr virus, and measles) and some **drugs** (anticonvulsants, antibiotics, cytotoxic agents, heparin, and quinidine) may induce thrombocytopenia. Postnatal infections and drug reactions usually cause transient thrombocytopenia, whereas congenital infections may produce prolonged suppression of bone marrow function.

Thrombocytopenia Resulting From Peripheral Destruction

Etiology

In a child who appears well, **immune-mediated mechanisms** are the most common cause of thrombocytopenia resulting from rapid peripheral destruction

of antibody-coated platelets by reticuloendothelial cells. **Neonatal alloimmune thrombocytopenic purpura** (NATP) occurs as a result of sensitization of the mother to antigens present on fetal platelets. Antibodies cross the placenta and attack the fetal platelet (see [Chapter 59](#)). Many platelet alloantigens have been identified and sequenced, permitting prenatal diagnosis of the condition in an at-risk fetus. Mothers with idiopathic thrombocytopenic purpura (**maternal ITP**) or with a history of ITP may have passive transfer of antiplatelet antibodies, with resultant neonatal thrombocytopenia (see [Chapter 59](#)). The maternal platelet count is sometimes a useful indicator of the probability that the infant will be affected.

Clinical Manifestations

The infant with NATP is at risk for **intracranial hemorrhage** in utero and during the immediate delivery process. In ITP, the greatest risk seems to be present during passage through the birth canal, during which molding of the head may induce intracranial hemorrhage. Fetal scalp sampling or percutaneous umbilical blood sampling may be performed to measure the fetal platelet count.

Treatment

Administration of intravenous immunoglobulin (IVIG) before delivery increases fetal platelet counts and may alleviate thrombocytopenia in infants with NATP and ITP. Delivery by cesarean section is recommended to prevent central nervous system (CNS) bleeding (see [Chapter 59](#)). Neonates with severe thrombocytopenia (platelet counts $<20,000/\text{mm}^3$) may be treated with IVIG or corticosteroids or both until thrombocytopenia remits. If necessary, infants with NATP may receive washed maternal platelets.

Idiopathic Thrombocytopenic Purpura

Etiology

Autoimmune thrombocytopenic purpura of childhood (childhood ITP) is a common disorder that usually follows an acute viral infection. Childhood ITP is caused by an antibody (IgG or IgM) that binds to the platelet membrane. The condition results in Fc receptor–mediated splenic destruction of antibody-coated platelets. Rarely, ITP may be the presenting symptom of an autoimmune disease, such as systemic lupus erythematosus (SLE).

Clinical Manifestations

Young children typically exhibit ITP 1-4 weeks after viral illness, with abrupt onset of petechiae, purpura, and epistaxis. The thrombocytopenia usually is severe. Significant adenopathy or hepatosplenomegaly is unusual, and the red blood cell (RBC) and white blood cell (WBC) counts are normal.

Diagnosis

The diagnosis of ITP usually is based on clinical presentation and the platelet count and does not often require a bone marrow examination. If atypical findings are noted, however, marrow examination is indicated to rule out an infiltrative disorder (leukemia) or an aplastic process (aplastic anemia). In ITP, an examination of the bone marrow reveals increased megakaryocytes and normal erythroid and myeloid elements.

Treatment and Prognosis

Therapy is seldom indicated for platelet counts greater than $30,000/\text{mm}^3$. Therapy does not affect the long-term outcome of ITP but is intended to increase the platelet count acutely. For moderate and severe clinical bleeding with severe thrombocytopenia (platelet count $<10,000/\text{mm}^3$), therapeutic options include **prednisone**, starting dose of 2 mg/kg per 24 hours for 2 weeks or IVIG, 1 g/kg per 24 hours for 1-2 days. All of these approaches seem to decrease the rate of clearance of sensitized platelets, rather than decreasing production of antibody. The optimal choice for therapy (if any) is controversial. Splenectomy is indicated in acute ITP only for life-threatening bleeding. Approximately 80% of children have a spontaneous resolution of ITP within 6 months after diagnosis. Serious bleeding, especially intracranial bleeding, occurs in fewer than 1% of patients with ITP. There is no evidence that early treatment prevents intracranial bleeding.

ITP that persists for 6-12 months is classified as **chronic ITP**. Repeated treatments with IVIG, IV anti-D, or high-dose pulse steroids are effective in delaying the need for splenectomy. Secondary causes of chronic ITP, especially SLE and HIV infection, should be ruled out. Splenectomy induces a remission in 70-80% of childhood chronic ITP cases. The risks of splenectomy (surgery, sepsis from encapsulated bacteria, pulmonary hypertension) must be weighed against the risk of severe bleeding.

Other Disorders

Decision-Making Algorithms

Petechiae/Purpura
Eosinophilia
Recurrent Infections

Wiskott-Aldrich syndrome is an X-linked disorder characterized by hypogammaglobinemia, eczema, and thrombocytopenia caused by a molecular defect in a cytoskeletal protein common to lymphocytes and platelets (see [Chapter 74](#)). Small platelets are seen on a peripheral blood smear. Nevertheless, thrombocytopenia often is improved by splenectomy. Hematopoietic stem cell transplantation cures the immunodeficiency and thrombocytopenia. Familial X-linked thrombocytopenia can be seen as a variant of Wiskott-Aldrich syndrome or a mutation in the *GATA1* gene. Autosomal macrothrombocytopenia is due to deletions in chromosomes 22q11 or mutations in 22q12.

Thrombotic microangiopathy causes thrombocytopenia, anemia secondary to intravascular RBC destruction, and, in some cases, depletion of clotting factors. Children with thrombotic microangiopathy usually are quite ill. In a child with disseminated intravascular coagulation (**DIC**), the deposition of fibrin strands within the vasculature and activation of thrombin and plasmin result in a wide-ranging hemostatic disorder with activation and clearance of platelets. **Hemolytic uremic syndrome** occurs as a result of exposure to a toxin that induces endothelial injury, fibrin deposition, and platelet activation and clearance (see [Chapter 164](#)). In **thrombotic thrombocytopenic purpura**, platelet consumption, precipitated by a congenital or acquired deficiency of a metalloproteinase that cleaves VWF, seems to be the primary process, with a modest deposition of fibrin and RBC destruction.

Disorders of Platelet Function

Etiology

Primary disorders of platelet function may involve receptors on platelet membranes for adhesive proteins. Deficiency of glycoprotein Ib complex (VWF receptor) causes **Bernard-Soulier syndrome**. A deficiency of glycoprotein IIb-IIIa (the fibrinogen receptor) causes **Glanzmann thrombasthenia**. Mild abnormalities of platelet aggregation and release, detectable by platelet

aggregometry, are far more common. Secondary disorders caused by toxins and drugs (uremia, valproic acid, aspirin, nonsteroidal antiinflammatory drugs, and infections) may cause a broad spectrum of platelet dysfunction.

Clinical Manifestations

Disorders of platelet function present with mucocutaneous bleeding and a prolonged bleeding time or long PFA closure time and may be primary or secondary. The bleeding time is an insensitive screen for mild and moderate platelet function disorders but is usually prolonged in severe platelet function disorders, such as Bernard-Soulier syndrome or Glanzmann thrombasthenia.

Disorders of Clotting Factors

Decision-Making Algorithm

Bleeding

Etiology

Hereditary deficiencies of most procoagulant proteins lead to bleeding. The genes for factor 8 and factor 9 are on the X chromosome, whereas virtually all the other clotting factors are coded on autosomal chromosomes. **Factor 8 and factor 9 deficiencies** are the most common severe inherited bleeding disorders. **von Willebrand disease** is the most common congenital bleeding disorder. Of the procoagulant proteins, low levels of the so-called contact factors (prekallikrein, high molecular weight kininogen, and Hageman factor [factor 12]) cause a prolonged activated partial thromboplastin time (aPTT) but are not associated with a predisposition to bleeding.

Hemophilia

Etiology

Hemophilia A (factor 8 deficiency) occurs in 1 in 5,000 males. **Hemophilia B** (factor 9 deficiency) occurs in approximately 1 in 25,000 males. Clinically the two disorders are indistinguishable other than by their therapy ([Table 151.3](#)). The lack of factor 8 or factor 9 delays the generation of thrombin, which is crucial to

forming a normal, functional fibrin clot and solidifying the platelet plug that has formed in areas of vascular injury. The severity of the disorder is determined by the degree of clotting factor deficiency.

TABLE 151.3

Comparison of Hemophilia A, Hemophilia B, and von Willebrand Disease

FEATURE	HEMOPHILIA A	HEMOPHILIA B	VON WILLEBRAND DISEASE
Inheritance	X-linked	X-linked	Autosomal dominant
Factor deficiency	Factor 8	Factor 9	VWF, factor 8
Bleeding site(s)	Muscle, joint, surgical	Muscle, joint, surgical	Mucous membranes, skin, surgical, menstrual
Prothrombin time	Normal	Normal	Normal
Activated partial thromboplastin time	Prolonged	Prolonged	Prolonged or normal

Platelet aggregation	Normal	Normal	Normal
Treatment	DDAVP* or recombinant factor 8	Recombinant factor 9	DDAVP* or VWF concentrate

*Desmopressin (DDAVP) for mild to moderate hemophilia A or type 1 von Willebrand disease.

PFA, Platelet function analyzer-100; VWF, von Willebrand factor.

Clinical Manifestations

Patients with less than 1% (severe hemophilia) factor 8 or factor 9 may have **spontaneous bleeding** or bleeding with minor trauma. Patients with 1-5% (moderate hemophilia) factor 8 or factor 9 usually require moderate trauma to induce bleeding episodes. In mild hemophilia (>5% factor 8 or factor 9), significant trauma is necessary to induce bleeding; spontaneous bleeding does not occur. Mild hemophilia may go undiagnosed for many years, whereas severe hemophilia manifests in infancy when the child reaches the toddler stage. In severe hemophilia, spontaneous bleeding occurs, usually in the muscles or joints

(hemarthroses).

Laboratory Studies

The diagnosis of hemophilia is based on a **prolonged aPTT**. In the aPTT, a surface-active agent activates the intrinsic system of coagulation, of which factors 8 and 9 are crucial components. In factor 8 or factor 9 deficiency, the aPTT is quite prolonged but should correct to normal when the patient's plasma is mixed 1 : 1 with normal plasma. When an abnormal aPTT is obtained, **specific factor assays** are needed to make a precise diagnosis (see [Table 151.2](#)) to determine the appropriate factor replacement therapy. Prenatal diagnosis and carrier diagnosis are possible using molecular techniques.

Treatment

Early, appropriate **replacement therapy** is the hallmark of excellent hemophilia care. Acute bleeding episodes are best treated in the home when the patient has attained the appropriate age and the parents have learned home treatment. Bleeding associated with surgery, trauma, or dental extraction often can be anticipated, and excessive bleeding can be prevented with appropriate replacement therapy. Prophylactic therapy starting in infancy has greatly diminished the likelihood of chronic arthropathy in children with hemophilia. For life-threatening bleeding, levels of 80-100% of normal factor 8 or factor 9 are necessary. For mild to moderate bleeding episodes (hemarthroses), a 40% level for factor 8 or a 30-40% level for factor 9 is appropriate. The dose can be calculated using the knowledge that 1 U/kg body weight of factor 8 increases the plasma level 2%, whereas 1.5 U/kg of recombinant factor 9 increases the plasma level 1%:

$$\text{Dose for factor 8} = \text{desired level (\%)} \times \text{weight (kg)} \times 0.5$$

or

$$\begin{aligned} \text{Dose for recombinant factor 9} \\ = \text{desired level (\%)} \times \text{weight (kg)} \times 1.5 \end{aligned}$$

Desmopressin acetate is a synthetic vasopressin analog with minimal vasopressor effect. Desmopressin triples or quadruples the initial factor 8 level

of a patient with mild or moderate (not severe) hemophilia A, but has no effect on factor 9 levels. When adequate hemostatic levels can be attained, desmopressin is the treatment of choice for individuals with mild and moderate hemophilia A. Aminocaproic acid is an inhibitor of fibrinolysis that may be useful for oral bleeding.

Patients treated with older factor 8 or 9 concentrates derived from large pools of plasma donors were at high risk for **hepatitis B, C, and D** and **HIV**. Recombinant factor 8 and factor 9 concentrates are safe from virally transmitted illnesses. Acquired immunodeficiency syndrome (AIDS) is the most common cause of death in older hemophilia patients (who received plasma-derived factors). Many older patients also have chronic hepatitis C.

Inhibitors are IgG antibodies directed against transfused factor 8 or factor 9 in congenitally deficient patients. Inhibitors arise in 15% of patients with severe factor 8 deficiency but are less common in patients with severe factor 9 deficiency. They may be high or low titer and show an anamnestic response to treatment. The treatment of bleeding patients with an inhibitor is difficult. For low titer inhibitors, options include continuous factor 8 infusions. For high titer inhibitors, it is usually necessary to administer a product that bypasses the inhibitor, preferably recombinant factor 7a. Activated prothrombin complex concentrates, used in the past to treat inhibitor patients, paradoxically increased the risks of thrombosis, resulting in fatal complications, such as myocardial infarction. For long-term treatment of inhibitor patients, induction of immune tolerance by repeated infusion of the deficient factor with or without immunosuppression may be beneficial.

Early institution of factor replacement and continuous prophylaxis beginning in early childhood should prevent the chronic joint disease associated with hemophilia.

von Willebrand Disease

Etiology

von Willebrand disease is a common disorder (1% of the population) caused by a deficiency of **VWF**, an adhesive protein that serves two functions: acting as a bridge between subendothelial collagen and platelets and binding and protecting circulating factor 8 from rapid clearance from circulation. von Willebrand disease usually is inherited as an autosomal dominant trait and, rarely, as an autosomal recessive trait. VWF may be either quantitatively deficient (partial =

type 1 or absolute = type 3) or qualitatively abnormal (type 2 = dysproteinemia). Approximately 80% of patients with von Willebrand disease have classic (type 1) disease (i.e., a mild to moderate deficiency of VWF). Several other subtypes are clinically important, each requiring different therapy.

Clinical Manifestations

Mucocutaneous bleeding, epistaxis, gingival bleeding, cutaneous bruising, and menorrhagia occur in patients with von Willebrand disease. In severe disease, factor 8 deficiency may be profound, and the patient may also have manifestations similar to hemophilia A (hemarthrosis). Findings in classic von Willebrand disease differ from findings in hemophilia A and B (see [Table 151.3](#)).

Laboratory Testing

VWF testing involves measurement of the amount of protein, usually measured immunologically as the **VWF antigen** (VWF:Ag). VWF activity (VWF:Act) is measured functionally in the **ristocetin cofactor assay** (VWFR:Co), which uses the antibiotic ristocetin to induce VWF to bind to platelets. VWF multimer testing is done to assess the protein structure and assists in the diagnosis of the qualitative disorders (type 2 = dysproteinemia).

Treatment

The treatment of von Willebrand disease depends on the severity of bleeding. **Desmopressin** is the treatment of choice for most bleeding episodes in patients with type 1 disease and some patients with type 2 disease. When high levels of VWF are needed but cannot be achieved satisfactorily with desmopressin, treatment with a virally attenuated, **VWF-containing concentrate** (Humate P) may be appropriate. The dosage can be calculated as for factor 8 in hemophilia. Cryoprecipitate should not be used because it is not virally attenuated. Hepatitis B vaccine should be given before the patient is exposed to plasma-derived products. As in all bleeding disorders, aspirin and nonsteroidal antiinflammatory drugs should be avoided.

Vitamin K Deficiency

For discussion of vitamin K deficiency, see Chapters 27 and 31.

Disseminated Intravascular Coagulation

Decision-Making Algorithms

Bleeding
Petechiae/Purpura

Etiology

DIC is a disorder in which widespread activation of the coagulation mechanism is usually associated with shock. Normal hemostasis is a balance between hemorrhage and thrombosis. In DIC, this balance is altered by the severe illness, so the patient has activation of coagulation (thrombosis) mediated by thrombin and fibrinolysis mediated by plasmin (bleeding). Coagulation factors—especially platelets, fibrinogen, and factors 2, 5, and 8—are consumed, as are the anticoagulant proteins, especially antithrombin, protein C, and plasminogen. Endothelial injury, tissue release of thromboplastic procoagulant factors, or, rarely, exogenous factors (snake venoms) directly activate the coagulation mechanism (Table 151.4).

TABLE 151.4

Causes of Disseminated Intravascular Coagulation

INFECTIOUS

HEREDITARY THROMBOTIC DISORDERS
Antithrombin III deficiency Homozygous protein C deficiency
NEONATAL PERIOD
Maternal toxemia Group B streptococcal infections Abruptio placentae Severe respiratory distress syndrome Necrotizing enterocolitis Congenital viral disease (e.g., cytomegalovirus infection or herpes) Erythroblastosis fetalis
MISCELLANEOUS CONDITIONS/DISORDERS
Severe acute graft rejection Acute hemolytic transfusion reaction Severe collagen vascular disease Kawasaki disease Heparin-induced thrombosis Infusion of “activated” prothrombin complex concentrates Hyperpyrexia/encephalopathy, hemorrhagic shock syndrome

From Scott JP. Bleeding and thrombosis. In: Kliegman RM, ed. *Practical Strategies in Pediatric Diagnosis and Therapy*. Philadelphia: WB Saunders; 1996.

Clinical Manifestations

The diagnosis of DIC usually is suspected clinically and is confirmed by laboratory findings of a **decline in platelets and fibrinogen** associated with elevated prothrombin time, partial thromboplastin time, and elevated levels of D-dimer, formed when fibrinogen is clotted and then degraded by plasmin ([Table 151.5](#)). In some patients, DIC may evolve more slowly and there may be a degree of compensation. In a severely ill patient, the sudden occurrence of bleeding from a venipuncture or incision site, gastrointestinal or pulmonary hemorrhage, petechiae, or ecchymosis or evidence of peripheral gangrene or thrombosis suggests the diagnosis of DIC.

TABLE 151.5

Differential Diagnosis of Coagulopathies That Can Be Confused With Dissem Coagulation

	PROTHROMBIN TIME	PARTIAL THROMBOPLASTIN TIME	FIBRINOGEN	PLATELETS
DIC	↑	↑	↓	↓
Liver failure	↑	↑	↓	Normal or ↓
Vitamin K deficiency	↑	↑	Normal	Normal
Sepsis without shock	↑	↑	Normal	Normal

DIC, Disseminated intravascular coagulation.

From Scott JP. Bleeding and thrombosis. In: Kliegman RM, edr. *Practical Strategies in Pediatric Diagnosis and Therapy*. Philadelphia: WB Saunders; 1996.

Treatment

The treatment of DIC is challenging. General guidelines include the following: treat the disorder inducing the DIC first; **support** the patient by correcting hypoxia, acidosis, and poor perfusion; and replace depleted blood-clotting factors, platelets, and anticoagulant proteins by transfusion.

Heparin may be used to treat significant arterial or venous thrombotic disease unless sites of life-threatening bleeding coexist.

Thrombosis

Etiology

A hereditary predisposition to **thrombosis** (see [Table 151.1](#)) may be caused by a deficiency of an anticoagulant protein (**protein C or S, antithrombin, or plasminogen**) ([Fig. 151.5](#)), by an abnormality of a procoagulant protein making it resistant to proteolysis by its respective inhibitor (**factor 5 Leiden**), by a mutation resulting in an increased level of a procoagulant protein (prothrombin 20210), or by damage to endothelial cells (**homocysteinemia**). Neonates with deficiency syndromes may be particularly vulnerable to thrombosis. Neonates with homozygous protein C deficiency present with purpura fulminans or thrombosis of the major arteries and veins or both. Many individuals with an inherited predisposition to thrombosis exhibit symptoms in adolescence or early adulthood. Protein C deficiency presenting in adulthood usually is inherited as

an autosomal dominant trait, whereas the homozygous form usually is autosomal recessive. Protein S and antithrombin III deficiencies are inherited as autosomal dominant traits. Factor 5 Leiden is the most common hereditary cause of a predisposition to thrombosis, appearing in 3-5% of whites. **Acquired antiphospholipid antibodies** (anticardiolipin and lupus anticoagulant) also predispose to thrombosis.

FIGURE 151.5 Formation of the hemostatic plug at the site of vascular injury. Three major physiological anticoagulant mechanisms—antithrombin III (AT III), protein C, and the fibrinolytic system—are activated to limit clot formation to the site of damage and to prevent generalized thrombosis. *T*, Thrombin. (From Schafer A. The hypercoagulable state. *Ann Intern Med.* 1985;102:814–828.)

Clinical Manifestations

Neonates and adolescents are the most likely pediatric patients to present with thromboembolic disease. Indwelling catheters, vasculitis, sepsis, immobilization, nephrotic syndrome, coagulopathy, trauma, infection, surgery, inflammatory bowel disease, oral contraceptive agents, pregnancy, and abortion all predispose to thrombosis. The manifestations of pulmonary emboli vary from no findings to chest pain, diminished breath sounds, a loud S_2 , cyanosis, tachypnea, and

hypoxemia.

Diagnostic and Imaging Studies

Venous thrombosis can be detected noninvasively by ultrasound Doppler flow compression studies. The gold standard for diagnosis is the venogram. An abnormal (*high probability*) ventilation-perfusion scan or detection of an intravascular thrombus on helical computed tomography is diagnostic of pulmonary emboli. There are no appropriate screening studies for thrombotic disorders. Diagnosis of a congenital or acquired predisposition to thrombosis requires a battery of specific assays.

Treatment

Therapy of thrombotic disorders depends on the underlying condition and usually involves standard or low molecular weight **heparin** followed by longer term anticoagulation with **warfarin**. New agents, including the direct thrombin inhibitors, are currently under active investigation in the pediatric population. Major vessel thrombosis, life-threatening thrombosis, or arterial thrombosis may necessitate treatment with **fibrinolytic agents** (recombinant tissue plasminogen activator). In newborns, inherited deficiency syndromes may present as emergencies and necessitate **replacement** with plasma, antithrombin III concentrates, or protein C concentrates.

CHAPTER 152

Blood Component Therapy

Transfusion of red blood cells (RBCs), platelets, plasma, cryoprecipitate, and granulocytes can be lifesaving or life-maintaining ([Table 152.1](#)). **Whole blood** is rarely indicated and is most useful to provide both oxygen-carrying capacity and functional procoagulant and anticoagulant factors. Otherwise, **packed RBCs** are used to treat anemia to increase oxygen-carrying capacity. RBC transfusions should not be used to treat asymptomatic nutritional deficiencies that can be corrected by administering the appropriate deficient nutrient (iron or folic acid).

TABLE 152.1

Commonly Used Transfusion Products

COMPONENT	CONTENT	INDICATION	DOSE	EXPECTED OUTCOME
Packed RBCs	250-300 mL/unit	↓ Oxygen-carrying RBCs	10-15 mL/kg	↑ Hb by 2-3 g/dL
Platelet concentrate from whole blood donation	$5-7 \times 10^{10}$ platelets/unit	Severe thrombocytopenia ± bleeding	1 unit/10 kg	↑ Platelet count by 50,000/ μ L
Platelet concentrate	3×10^{11} platelets/unit	Severe thrombocytopenia ± bleeding	1 unit/70 kg	↑ Platelet count by 30,000-50,000/ μ L
Fresh frozen plasma	1 unit of each clotting factor /mL	Multiple clotting factor deficiency	10-20 mL/kg	Improvement in significantly prolonged prothrombin and partial thromboplastin times
Cryoprecipitate	Fibrinogen, factor 8, VWF, factor 13	Hypofibrinogenemia, factor 13 deficiency	1 unit/5-10 kg	↑ Fibrinogen by 50-100 mg/dL
Recombinant factor concentrates	Units as labeled	Hemophilic bleeding or prophylaxis	F8: 20-50 units/kg F9: 40-120 units/kg	F8: ↑ 2%/unit/kg F9: ↑ 0.7 unit/kg
Recombinant factor VIIa (NovoSeven)	Micrograms (μ g)	Hemophilic bleeding in patient with inhibitor; also used for uncontrolled postoperative hemorrhage	30-90 μ g/kg/dose	Cessation of bleeding

Hgb, Hemoglobin; *RBCs*, red blood cells; *VWF*, von Willebrand factor.

Blood component therapy requires proper anticoagulation of the component unit, screening for infectious agents and blood group compatibility testing before administration. Typical **transfusion reactions** are listed in [Table 152.2](#). Transfusion may also result in circulatory overload, especially in the presence of cardiopulmonary deficiency. Filtering of blood products to remove white blood cells (WBCs) may prevent febrile reactions. Long-term complications of transfusions include graft-versus-host disease and **infectious diseases** such as **hepatitis B** (<1 : 250,000 units) and **C** (1 : 1,600,000 units), **human immunodeficiency virus** (<1 : 1,800,000 units), malaria, syphilis, babesiosis, brucellosis, and Chagas disease. Patients who are chronically transfused are more prone to iron overload and alloimmunization to RBCs and platelets.

TABLE 152.2

Evaluation of Transfusion Reactions

TYPE OF REACTION	CLINICAL SIGNS	MANAGEMENT
Acute hemolytic transfusion reaction (incidence of 1 : 250,000 to 1 : 1,000,000)	Acute shock, back pain, flushing, early fever, intravascular hemolysis, hemoglobinemia, hemoglobinuria (may be delayed 5-10 days and less severe if anamnestic response is present)	<ol style="list-style-type: none"> 1. Stop transfusion; return blood to bank with fresh sample of patient's blood 2. Hydrate intravenously*; support blood pressure, maintain high urine flow, alkalinize urine 3. Check for and correct electrolyte abnormalities (hyperkalemia)
Delayed hemolytic transfusion reaction (incidence of 1 : 100,000)	Onset 7-14 days after transfusion: pain, fever, jaundice, hemoglobinuria; fall in hemoglobin; reticulocytopenia	Transfuse only antigen-negative RBCs if needed;
Febrile nonhemolytic transfusion reaction (incidence of 1 : 100)	Fever during or within 4 hr after end of transfusion, chills, usually from passively transfused cytokines or recipient reaction to leukocytes Bacterial contamination can occur in 1 : 100,000 platelet transfusions	Antipyretics for symptomatic treatment or pretreatment for future transfusions; leukocyte reduction has decreased incidence of febrile reactions Blood culture if high suspicion for bacterial infection
Allergic transfusion reaction (incidence of 1 : 100)	Urticaria, pruritus, maculopapular rash, edema, respiratory distress, hypotension during or within 4 hr of transfusion; often because recipient has preformed antibodies against donor antigens, occasionally from passive infusion of antibodies from atopic donor	Diphenhydramine ± hydrocortisone for acute management For future transfusions consider: <ol style="list-style-type: none"> 1. Pretreatment with diphenhydramine ± hydrocortisone 2. Volume reduction to reduce donor plasma 3. Washing cellular products to remove all donor plasma (for severe reactions)

*Normal saline is the compatible intravenous fluid.

HLA, Human leukocyte antigen; RBCs, red blood cells; WBC, white blood cell.

Pearls for Practitioners

Chapter 149

Hematology Assessment

- Normal hematological values vary according to age.
- The physiological nadir occurs at 8-10 weeks of life; this nadir is accentuated in premature infants.
- The presence of petechiae, purpura, or deeper sites of bleeding, including generalized hemorrhage, indicates abnormalities of platelets, coagulation factors, or both.
- Organ system involvement or systemic illness point to a generalized illness as the cause for hematological abnormalities.

Chapter 150

Anemia

- Anemia is any hemoglobin or hematocrit value that is 2 standard deviations (SDs) below the mean for age and sex.
- Androgens at the onset of puberty results in male hemoglobin values about 1.5-2 g/dL higher than females.
- Anemias are classified based on red blood cell (RBC) size: microcytic, normocytic, or macrocytic.
- Key clinical findings in patients with hemolytic anemias are jaundice, pallor, and splenomegaly.
- An elevated reticulocyte count suggests increased red blood cell production.
- Anemia with a normal reticulocyte count suggests decreased or ineffective production.

Iron Deficiency Anemia

- Pure dietary iron deficiency is rare except in children 1-3 years of age; it is most common in bottle-fed toddlers receiving large amounts of cow's milk and lacking food high in iron.
- Menstruating adolescent females who are not receiving supplemental iron are at high risk for iron deficiency.
- In an otherwise healthy child, a therapeutic trial of oral iron is the best diagnostic study for iron deficiency as long as the child is re-examined and a response is documented reticulocytosis (48-72 hours); increase in hemoglobin levels (4-30 days); and repletion of iron stores (in 1-3 months).

Thalassemias

- α -thalassemia minor and β -thalassemia minor are common causes of microcytic anemia in otherwise healthy children of Mediterranean, Southeast Asian, or African American descent.

Lead Poisoning

- Lead poisoning may be associated with hypochromic, microcytic anemia since most patients have concomitant iron deficiency.

Normocytic Anemia

- Chronic inflammation can lead to normocytic anemia that is likely mediated through hepcidin.
- Malignancy can result in normocytic anemia; red blood cell aplasia (congenital and acquired) result in normocytic anemia.

Macrocytic Anemia

- Vitamin B₁₂ and folate deficiency should be evaluated for in the setting of macrocytic anemia.

Pancytopenia

- Pancytopenia is a simultaneous quantitative decrease in all formed elements of the blood.
- A low reticulocyte count, presence of abnormal forms of leukocytes or myeloid elements less mature than band forms, small platelets, and an elevated mean corpuscular volume in the face of a low reticulocyte count suggest bone marrow failure and require bone marrow examination.
- The etiology of aplastic anemia can be idiopathic, drug-induced, or postinfectious.
- Fanconi anemia, an autosomal recessive defect in DNA repair, leads to bone marrow failure, presents with multiple congenital anomalies, and can evolve into acute leukemia.

Hemoglobinopathies

- α -chain hemoglobinopathies present in utero since alpha chains are needed for fetal erythropoiesis.
- Four alpha genes are present on chromosome 16. A single gene deletion is a silent carrier, 2 gene deletions result in α -thalassemia minor (trait), 3 gene deletion results in hemoglobin H disease (moderate hemolytic anemia), 4 gene deletion results in hydrops fetalis with severe intrauterine anemia.
- β -chain hemoglobinopathies present between 4 and 12 months of age when fetal hemoglobin nadirs.

Sickle Cell Disease

- The common sickle cell syndromes are hemoglobin SS disease, hemoglobin SC disease, hemoglobin S- β^0 -thalassemia, and hemoglobin S- β^+ -thalassemia.
- A child with sickle cell disease is vulnerable to:
 - Life-threatening infection by 4 months of age due to

splenic dysfunction (a febrile patient with sickle cell disease must be evaluated immediately and empirically treated with antibiotics).

- Sudden, occasionally severe and life-threatening events caused by the acute intravascular sickling of the RBCs, with resultant pain or organ dysfunction.
- Acute painful events usually localized to the long bones of the arms or legs, but may occur in smaller bones of the hands or feet in infancy (dactylitis) or in the abdomen.
- Overt stroke occurs in approximately 8-10% of patients with hemoglobin SS or hemoglobin S- β^0 -thalassemia and is an indication for chronic transfusion.
- Hydroxyurea should be initiated in asymptomatic children with severe sickle cell disease (HbSS or HbS β^0 -thalassemia).

Enzymopathies

- The most common red blood cell enzyme disorders are glucose-6-phosphate dehydrogenase (G6PD) deficiency and pyruvate kinase deficiency.
- The gene for G6PD is on the X-chromosome.
- Patients with pyruvate kinase deficiency have depletion of adenosine triphosphate which impairs red blood cell survival.

Membrane Disorders

- The most common red blood cell membrane hemolytic disorders are hereditary spherocytosis and hereditary elliptocytosis.
- A positive osmotic fragility test supports the diagnosis of hereditary spherocytosis.

Hemolytic Anemia Caused by Disorders Extrinsic to the Red Blood Cell

- Isoimmune hemolysis is caused by active maternal immunization against fetal antigens (i.e., A, B, and Rh D antigens).
- Autoimmune hemolytic anemia is Coombs-positive due to the production of autoantibodies that cause red blood cell destruction, often following an infection.
- Treatment often requires red blood cell transfusion in addition to corticosteroids for some types.

Chapter 151

Hemostatic Disorders

Normal Hemostasis

- All of the hemostatic processes are closely interwoven and occur on biological surfaces that mediate coagulation by bringing platelets, endothelial cells, and subendothelium into close proximity with pro- and anticoagulant proteins.
- Deficiency of factor 8 or factor 9 leads to severe bleeding disorders, deficiency of factor 11 can be associated with mild bleeding, and deficiency of factor 12 is asymptomatic.
- Fibrinolysis is initiated by the action of tissue plasminogen activator on plasminogen, producing plasmin, the active enzyme that degrades fibrin into split products.

Developmental Hemostasis

- Most children attain normal levels of procoagulant and anticoagulant proteins by 1 year of age; levels of protein C lag and normalize in adolescence.

Hemostatic Disorders

- A detailed family history is crucial to the diagnosis of bleeding

and thrombotic disorders.

- No single laboratory test can screen for all bleeding disorders.

Platelet Disorders

- Platelet counts less than $150,000 /\text{mm}^3$ constitute thrombocytopenia. Mucocutaneous bleeding is the hallmark of platelet disorders. The risk of bleeding correlates imperfectly with the platelet count.
- The etiology of thrombocytopenia is organized into three mechanisms:
 - Decreased platelet production.
 - Increased platelet destruction: neonatal autoimmune thrombocytopenia, acute idiopathic thrombocytopenia purpura, and thrombotic microangiopathy.
 - Platelet sequestration.
- Disorders of platelet function present with mucocutaneous bleeding, prolonged bleeding time, or long PFA closure time and can be primary or secondary disorders.

Disorders of Clotting Factors

- Hemophilia A (factor 8 deficiency) and hemophilia B (factor 9 deficiency) are X-linked, severe bleeding disorders.
 - Clinical bleeding often occurs in the muscles and joints; the severity of bleeding is proportional to the patient's baseline level of factor 8 or 9.
 - Factor 8 or factor 9 recombinant replacement therapy is used to treat acute bleeds, for hemostasis for surgical procedures, and as prophylaxis in patients with severe hemophilia.
- von Willebrand disease is a congenital bleeding disorder that affects about 1% of the population.
 - Associated with mucocutaneous bleeding such as

epistaxis, gingival bleeding, cutaneous bruising, and menorrhagia.

- The treatment depends on the type and the severity of bleeding; it commonly includes desmopressin (DDAVP).

Disseminated Intravascular Coagulation

- Disseminated intravascular coagulation (DIC) is a disorder with widespread activation of coagulation (thrombosis) and fibrinolysis (bleeding).
 - Diagnosis usually is suspected clinically and is confirmed by laboratory findings.
 - General treatment guidelines include:
 - Treat the disorder inducing DIC first.
 - Support the patient by correcting hypoxia, acidosis, and poor perfusion.
 - Replace depleted blood-clotting factors, platelets, and anticoagulant proteins by transfusion.

Thrombosis

- Hereditary predisposition to thrombosis:
 - Protein C or S, antithrombin, or plasminogen deficiency.
 - Abnormality of a procoagulant protein (factor 5 Leiden).
 - Increased level of a procoagulant protein (prothrombin 20210).
 - Damage to endothelial cells (homocysteinemia).
- Acquired thrombosis due to indwelling catheters, vasculitis, sepsis, immobilization, nephrotic syndrome, coagulopathy, trauma, infection, surgery, inflammatory bowel disease, oral contraceptive agents, and pregnancy.
- Venous thromboses cause warm, swollen, tender, or purplish discolored extremities; arterial thromboses cause painful, pale and

poorly perfused extremities.

- Venous thrombosis can be detected noninvasively by ultrasound Doppler flow compression studies. The gold standard for diagnosis is the venogram.
- Therapy of thrombotic disorders usually involves standard or low molecular weight heparin followed by longer-term anticoagulation with warfarin.

Chapter 152

Blood Component Therapy

- Transfusion of red blood cells (RBCs), platelets, plasma, cryoprecipitate, and granulocytes can be lifesaving or life-maintaining.
- Packed red blood cells are used to treat anemia to increase oxygen-carrying capacity.
- Long-term complications of transfusions include:
 - Graft-versus-host disease.
 - Infectious diseases such as hepatitis B (<1 : 250,000 units) and C (1 : 1,600,000 units), human immunodeficiency virus (<1 : 1,800,000 units), malaria, syphilis, babesiosis, brucellosis, and Chagas disease.
- Patients who are chronically transfused are more prone to iron overload and alloimmunization to red blood cells and platelets.

CHAPTER 153

Oncology Assessment

Childhood cancer is rare. Although only about 1% of new cancer cases in the United States occur among children younger than 19 years of age, cancer is the leading cause of disease-related death in children age 1-14 years. Hematopoietic tumors (leukemia, lymphoma) are the most common childhood cancers, followed by brain/central nervous system (CNS) tumors and sarcomas of soft tissue and bone (Fig. 153.1). There is wide variability in the age-specific incidence of childhood cancers. Embryonal tumors, such as neuroblastoma and retinoblastoma, peak during the first 2 years of life; acute lymphoblastic leukemia (ALL) peaks during early childhood (ages 2-5 years); osteosarcoma peaks during adolescence; and Hodgkin disease peaks during late adolescence (Fig. 153.2). The overall incidence of cancer among white children is higher than that among other ethnic groups and is twice that of African American children in the United States.

*Includes osteosarcoma and Ewing sarcoma

FIGURE 153.1 Number of Childhood Cancer Diagnoses per Year. Total = 15,780, Age 0-19 years. (Courtesy CureSearch for Children's Cancer, <http://curesearch.org/Number-of-Diagnoses>; Source of data: American Cancer Society, Cancer Facts and Figures, 2014.)

FIGURE 153.2 Incidence of the most common types of cancer in children by age. The cumulative incidence is shown as a *dashed line*. (Courtesy Archie Bleyer, MD.)

History

Many signs and symptoms of childhood cancer are nonspecific. Although most

children with fever, fatigue, weight loss, or limp do not have cancer, each of these symptoms may be a manifestation of an underlying malignancy. Uncommonly, a child with cancer will have no symptoms at all. An abdominal mass may be palpated on routine examination, or a complete blood count (CBC) may be unexpectedly abnormal. Some children have a genetic susceptibility to cancer and should be screened appropriately ([Table 153.1](#)).

TABLE 153.1

Known Risk Factors for Selected Childhood Cancers

CANCER TYPE	RISK FACTOR	COMMENTS
Acute lymphoid leukemia	Ionizing radiation	Prenatal diagnostic x-ray exposure and therapeutic irradiation for cancer treatment increases risk.
	Race	White children have a twofold higher rate than black children in the United States.
	Genetic conditions	Down syndrome is associated with an estimated 10- to 20-fold increased risk. Neurofibromatosis 1, Bloom syndrome, and ataxia-telangiectasia, among others, are associated with an elevated risk.
Acute myeloid leukemias	Chemotherapy and radiation therapy	Alkylating agents and epipodophyllotoxins increase risk, as does receiving radiation therapy for other cancers.
	Genetic factors	Down syndrome and neurofibromatosis 1 are strongly associated. Familial monosomy 7 and several other genetic syndromes are also associated with increased risk.
Brain cancers	Ionizing radiation to the head	Radiation therapy for one brain tumor can lead to a secondary brain tumor.
	Genetic factors	Neurofibromatosis 1 is strongly associated with optic gliomas and, to a lesser extent, with other CNS tumors. Tuberous sclerosis and several other genetic syndromes are associated with increased risk.
Hodgkin disease	Family history	Monozygotic twins and siblings are at increased risk.
	Infections	Epstein-Barr virus is associated with increased risk.
Non-Hodgkin lymphoma	Immunodeficiency	Acquired and congenital immunodeficiency disorders and immunosuppressive therapy increase risk.
	Infections	Epstein-Barr virus is associated with increased risk in African countries.
Osteosarcoma	Ionizing radiation	Cancer radiation therapy and high radium exposure increase risk.
	Chemotherapy	Alkylating agents increase risk.
	Genetic factors	Increased risk is apparent with Li-Fraumeni syndrome and hereditary retinoblastoma.
Ewing sarcoma	Race	Incidence is about nine times higher in white children than in black children in the United States.
Neuroblastoma	Genetic factors	Chromosome 6p22 variants and mutations in the <i>ALK</i> and <i>PHOX</i> genes are

		associated with increased risk.
Retinoblastoma	Genetic factors	Mutations in the Rb gene on chromosome 14
Wilms tumor	Congenital anomalies	Aniridia, Beckwith-Wiedemann syndrome, and other congenital and genetic conditions are associated with increased risk.
Renal medullary carcinoma	Sickle cell trait	Etiology is unknown.
Rhabdomyosarcoma	Congenital anomalies and genetic conditions	Li-Fraumeni syndrome and neurofibromatosis 1 are associated with increased risk.
Hepatoblastoma	Prematurity Genetic factors	Etiology is unknown. Beckwith-Wiedemann syndrome, hemihypertrophy, Gardner syndrome, and familial adenomatous polyposis are associated with increased risk.
Hepatocellular carcinoma	Infections	Hepatitis B virus infection increases risk.
Malignant germ cell tumors	Cryptorchidism	Cryptorchidism is a risk factor for testicular germ cell tumors.

CNS, Central nervous system.

Modified from Scheurer ME, Lupo PL, and Bondy ML. Epidemiology of childhood cancer. In: Pizzo PA, Poplack DG, eds. *Principles and Practice of Pediatric Oncology*. 7th ed. Philadelphia: Wolters Kluwer; 2016:10.

It is important to explore quality, duration, location, severity, and precipitating events of the chief complaint. A prominent lymph node that does not resolve (with or without antibiotics) may warrant a biopsy. A limp that does not improve within weeks should prompt a CBC and a radiograph. Fever, night sweats, or weight loss should raise the concern for lymphoma. In addition, it is important to obtain the birth history, medical and surgical history, growth history, developmental history, family history, and social history. Even though family history in most patients does not predict an underlying predisposition syndrome, cancer-predisposing genes (such as *TP53*) are mutated in approximately 9% of children and adolescents with cancer.

Physical Examination

Growth parameters and vital signs are important to obtain in all patients. Pulse oximetry should be obtained if respiratory symptoms are present. The overall appearance of the patient should be noted, particularly general appearance, pain, cachexia, pallor, and respiratory distress. Palpable masses should be measured. Lymphadenopathy and organomegaly should be quantified, if present. A thorough examination of the skin may reveal rashes, bruises, and petechiae.

Careful neurological and ophthalmological examinations are crucial if headache or vomiting is present because the vast majority of patients with CNS tumors have abnormal neurological examinations.

Common Manifestations

Decision-Making Algorithms

Visual Impairment and Leukocoria
 Vomiting
 Hepatomegaly
 Splenomegaly
 Headaches
 Lymphadenopathy
 Anemia
 Petechiae/Purpura
 Pancytopenia
 Fever of Unknown Origin

The most common manifestations of childhood cancer are fatigue, anorexia, malaise, pain, fever, abnormal lump or mass, pallor, bruising, petechiae, bleeding, headache, vomiting, visual changes, weight loss, and night sweats (Table 153.2). Lymphadenopathy and organomegaly are common in leukemia, particularly with T-cell ALL or non-Hodgkin lymphoma. Patients with solid tumors usually have a palpable or measurable mass. Other signs and symptoms may include limp, cough, dyspnea, cranial nerve palsies, and papilledema. In general, malignant masses are firm, fixed, and nontender, whereas masses that are infectious or inflammatory in nature are relatively softer, mobile, and tender to palpation.

TABLE 153.2

Common Manifestations of Childhood Malignancies

SIGN/SYMPTOM	SIGNIFICANCE	EXAMPLE
HEMATOLOGICAL		

Pallor, anemia	Bone marrow infiltration	Leukemia, neuroblastoma
Petechiae, thrombocytopenia	Bone marrow infiltration	Leukemia, neuroblastoma
Fever, neutropenia	Bone marrow infiltration	Leukemia, neuroblastoma
SYSTEMIC		
Bone pain, limp, arthralgia	Primary bone tumor, metastasis to bone	Osteosarcoma, Ewing sarcoma, leukemia, neuroblastoma
Fever of unknown origin, weight loss, night sweats	Lymphoreticular malignancy	Hodgkin disease, non-Hodgkin lymphoma
Painless lymphadenopathy	Lymphoreticular malignancy, metastatic solid tumor	Leukemia, Hodgkin disease, non-Hodgkin lymphoma, Burkitt lymphoma, thyroid carcinoma
Cutaneous lesion	Primary or metastatic disease	Neuroblastoma, leukemia, Langerhans cell histiocytosis, melanoma
Abdominal mass	Abdominal/pelvic organ	Neuroblastoma, Wilms tumor, lymphoma, hepatoblastoma, germ cell tumor
Hypertension	Sympathetic nervous system tumor	Wilms tumor, neuroblastoma, pheochromocytoma
Diarrhea	Vasoactive intestinal polypeptide	Neuroblastoma
Soft tissue mass	Local or metastatic tumor	Ewing sarcoma, osteosarcoma, neuroblastoma, rhabdomyosarcoma, germ cell tumor, thyroid carcinoma
Diabetes insipidus, galactorrhea, poor growth	Neuroendocrine involvement of hypothalamus or pituitary gland	Germ cell tumor, adenoma, craniopharyngioma, prolactinoma, Langerhans cell histiocytosis
Emesis, visual disturbances, ataxia, headache, papilledema, cranial nerve palsies	Increased intrathecal pressure	Primary brain tumor; metastasis to the brain
OPHTHALMOLOGICAL		
Leukocoria	White pupil	Retinoblastoma
Periorbital ecchymosis	Metastasis	Neuroblastoma
Miosis, ptosis, heterochromia	Horner syndrome: compression of cervical sympathetic nerves	Neuroblastoma
Opsomyoclonus, ataxia	Neurotransmitters (?)	Neuroblastoma
	Autoimmunity (?)	
Exophthalmos, proptosis	Orbital tumor	Rhabdomyosarcoma, neuroblastoma, lymphoma
THORACIC		
Anterior mediastinal mass	Cough, stridor, pneumonia, tracheal-bronchial compression	Germ cell tumor, T-cell lymphoma/leukemia, Hodgkin disease, primary mediastinal large B-cell lymphoma
Posterior mediastinal mass	Vertebral or nerve root compression; dysphagia	Neuroblastoma, ganglioneuroblastoma, ganglioneuroma

Differential Diagnosis

Distinguishing a malignant process from another disease can be difficult. Ultimately, a tissue diagnosis (from bone marrow or solid tumor biopsy) with pathological confirmation is required to confirm a diagnosis of cancer. Infection commonly masquerades as a potential malignancy. In particular Epstein-Barr virus, cytomegalovirus, and mycobacterial infections can mimic leukemia or lymphoma by causing fever, lymphadenopathy, organomegaly, weight loss, and abnormal blood counts. Trauma may produce swelling that can mimic solid tumors. Idiopathic thrombocytopenic purpura and iron deficiency can produce thrombocytopenia and anemia, respectively. Immune deficiencies or irregularities (autoimmune hemolytic anemia or neutropenia) can also produce cytopenias. Juvenile idiopathic arthritis and other collagen vascular disease can cause musculoskeletal pain and anemia, mimicking leukemia. Benign tumors are relatively common in children, including mature germ cell tumors/hamartomas, hemangiomas or other vascular tumors, mesoblastic nephromas, and bone cysts.

Initial Diagnostic Evaluation

Screening Tests

A CBC with differential and review of the peripheral blood smear is the best screening test for many pediatric malignancies. Leukopenia (with or without neutropenia), anemia, or thrombocytopenia may be present in leukemia or any cancer that invades the bone marrow (e.g., neuroblastoma, rhabdomyosarcoma, and Ewing sarcoma). Leukemia may also produce leukocytosis, usually with blasts present on the peripheral blood smear. An isolated cytopenia (neutropenia, anemia, or thrombocytopenia) widens the differential diagnosis but still may be the only abnormal laboratory finding. Of note, a patient with leukemia may also have a normal CBC. Lactate dehydrogenase and uric acid are often elevated in fast-growing tumors (leukemia or lymphoma) and occasionally in sarcomas or neuroblastoma. In many cases, it is appropriate to assess electrolytes and renal and hepatic function in the screening process. Elevated blood pressure, if confirmed by repeat measurements, should prompt a urinalysis, as should the palpation of an abdominal mass. Serum (and/or cerebrospinal fluid) alpha-fetoprotein (AFP) and beta-human chorionic gonadotropin (β -HCG) are screening tests (and tumor markers) for germ cell tumors. Serum AFP is also a tumor marker for hepatoblastoma. Urine homovanillic acid (HVA) and

vanillylmandelic acid (VMA) are tumor markers for neuroblastoma.

Diagnostic Imaging

A chest x-ray (CXR; posteroanterior and lateral) is the best screening radiographic study for a patient with suspicious cervical lymphadenopathy, fever, and weight loss. Mediastinal masses and pleural effusions can often be detected on CXR. Abdominal signs or symptoms warrant an ultrasound or computed tomography (CT) scan. Persistent headaches or morning vomiting should prompt a CT or magnetic resonance imaging (MRI) scan of the head. If bone tumors are suspected, plain radiographs are indicated and will usually reveal the lesion(s), if present. Radiographs may be normal when a bony pelvic lesion is suspected; thus a CT or MRI should be obtained. Other imaging studies to delineate a mass and to search for suspected metastases are often indicated, but these decisions are usually best left to the pediatric oncology team with input from radiologists. [Table 153.3](#) shows the general use of diagnostic imaging following confirmation of a diagnosis of cancer to assess the primary tumor and metastases. Positron emission tomography (PET), with or without CT, has proved useful for staging and assessing response for lymphomas and sarcomas. Metaiodobenzylguanidine (mIBG) scans are useful for neuroblastoma.

TABLE 153.3

Minimum Work-Up Required for Common Pediatric Malignancies to Assess I and Potential Metastases*

MALIGNANCY	BMA/bx	CXR	CT Scan	MRI	BONE SCAN, PET SCAN, or PET-CT SCAN	CSF ANALYSIS	MARKERS
Leukemia	Yes	Yes	—	—	—	Yes	—

CHAPTER 154

Principles of Cancer Treatment

The overall goal of pediatric oncology is to cure all patients with minimal toxicity. Treatment for children with cancer is often multimodal and may involve surgery, radiation therapy, chemotherapy, and immunotherapy. Surgery and radiation are generally local treatment modalities (an exception is total body irradiation as part of a bone marrow or stem cell transplant), whereas chemotherapy and immunotherapy have both local and systemic effects.

Primary prevention strategies for most pediatric malignancies are unknown. Two exceptions are the use of hepatitis B vaccine to lower the rates of hepatocellular carcinoma and the use of human papillomavirus vaccine to reduce the risk of genitourinary and oropharyngeal cancers. Childhood malignancies are not associated with tobacco or alcohol use, dietary factors, or sun exposure. Treatment with certain chemotherapy agents and radiation therapy increases the

rate of second malignancies. Secondary prevention may be accomplished by screening the at-risk child (e.g., a child with Beckwith-Wiedemann syndrome or twin of a leukemia patient), but these opportunities are rare.

Oncological Emergencies

Adverse effects of tumors and treatments may result in oncological emergencies in children and adolescents (Table 154.1). Mediastinal masses from lymphoma can cause life-threatening airway obstruction. Tumors with a large tumor burden (e.g., lymphoma, leukemia) may affect renal function adversely from tubular deposition of uric acid crystals. Allopurinol or rasburicase can be administered before chemotherapy to minimize this effect.

TABLE 154.1

Oncological Emergencies

CONDITION	MANIFESTATIONS	ETIOLOGY	MALIGNANCY	TREATMENT
METABOLIC				
Hyperuricemia	Uric acid nephropathy, renal insufficiency or failure	Tumor lysis syndrome	Lymphoma, leukemia	Allopurinol; rasburicase
Hyperkalemia	Arrhythmias	Tumor lysis syndrome	Lymphoma, leukemia	Kayexalate; sodium bicarbonate; glucose plus insulin
Hyperphosphatemia	Hypocalcemic tetany; metastatic calcification, photophobia, pruritus	Tumor lysis syndrome	Lymphoma, leukemia	Hydration, dialysis, oral aluminum hydroxide, phosphate binders
Hypercalcemia	Anorexia, nausea, polyuria, pancreatitis, gastric ulcers; prolonged PR/shortened QT interval	Bone resorption; ectopic parathormone, vitamin D, or prostaglandins	Metastasis to bone, rhabdomyosarcoma	Hydration and furosemide; diuresis; corticosteroids; mithramycin; calcitonin; denosumab
HEMATOLOGICAL				
Anemia	Pallor, weakness, heart failure	Bone marrow suppression or infiltration; blood loss	Any with chemotherapy	Packed red blood cells transfusion
Thrombocytopenia	Petechiae, hemorrhage	Bone marrow suppression or infiltration	Any with chemotherapy	Platelet transfusion
Disseminated intravascular	Shock, hemorrhage	Sepsis, hypotension, tumor factors	Promyelocytic leukemia, others	Fresh frozen plasma, platelets, cryoprecipitate

coagulation				infection
Neutropenia	Infection	Bone marrow suppression or infiltration	Any with chemotherapy	If patient is febrile, administer spectrum antibiotic; filgrastim
Hyperleukocytosis (WBC $\geq 50,000/\text{mm}^3$)	Hemorrhage, thrombosis; pulmonary infiltrates, hypoxia; tumor lysis syndrome	Leukostasis; vascular occlusion	Leukemia	Hydration; chemotherapy
Graft-versus-host disease	Dermatitis, diarrhea, hepatitis	Immunosuppression and nonirradiated blood products; bone marrow transplantation	Any with immunosuppression	Corticosteroids; cyclosporine; methotrexate; tacrolimus; mycophenolate mofetil; antithymocyte globulin
SPACE-OCCUPYING LESIONS				
Spinal cord compression	Back pain, motor and sensory deficits	Invasion of spinal canal by primary tumor or metastases	Neuroblastoma, medulloblastoma	MRI for diagnosis; corticosteroids; radiation; laminectomy; chemotherapy
Increased intracranial pressure	Headache, confusion, coma, emesis, headache, hypertension, bradycardia, seizures, papilledema, hydrocephalus; cranial nerve III and VI palsies	Primary or metastatic brain tumor	Astrocytoma, medulloblastoma, others; neuroblastoma	CT or MRI for diagnosis; corticosteroids; ventriculostomy; radiation therapy; chemotherapy
Superior vena cava syndrome	Distended neck veins, plethora, edema of head and neck, cyanosis, proptosis; Horner syndrome	Superior mediastinal mass	Lymphoma	Chemotherapy; radiation
Tracheal compression	Respiratory distress	Mediastinal mass compressing trachea	Lymphoma	Radiation therapy; corticosteroids

CNS, Central nervous system; *CT*, computed tomography; *G-CSF*, granulocyte colony-stimulating factor; *MRI*, magnetic resonance imaging; *WBC*, white blood cell.

A common metabolic emergency is **tumor lysis syndrome**, often seen in treatment of leukemia and lymphoma. Large amounts of phosphate, potassium, and uric acid are released into the circulation from lysed cells. Overwhelming infection and spinal cord compression with neurological compromise are other oncological emergencies.

Surgery

Appropriate imaging (usually with computed tomography [CT] or magnetic resonance imaging [MRI]) for solid tumors presenting as a palpable mass or mass-related symptoms (pain, respiratory distress, intestinal obstruction) should be obtained and followed by resection (when possible) or biopsy (if complete resection is not feasible or indicated). Pediatric lymphomas are chemosensitive and rarely require complete surgical resection.

It is crucial to determine the amount of tissue required and the appropriate distribution of the tissue for testing so that all necessary studies are performed. A general oncological surgery principle is to resect not just the tumor but also, in most cases, a surrounding margin of normal tissue to ensure the entire tumor has been resected.

Chemotherapy

Because most pediatric solid tumors have a high risk for micrometastatic disease at the time of diagnosis, chemotherapy is used in almost all cases (Table 154.2). Exceptions include low-stage neuroblastoma and Wilms tumor (particularly in infants) and low-grade central nervous system (CNS) tumors. For patients with localized solid tumors, chemotherapy administered after removal of the primary tumor is referred to as **adjuvant therapy**. Chemotherapy administered while the primary tumor is still present is referred to as **neoadjuvant chemotherapy**. Neoadjuvant chemotherapy has a number of potential benefits, including an early attack on presumed micrometastatic disease, shrinkage of the primary tumor to facilitate local control, and additional time to plan for definitive surgery.

TABLE 154.2

Cancer Chemotherapy

DRUG	ACTION	INDICATION	ACUTE TOXICITY*
ANTIMETABOLITES			
Methotrexate	Folic acid antagonist; inhibits dihydrofolate reductase	ALL, lymphoma, medulloblastoma, osteosarcoma	Myelosuppression (nadir 7-10 days), mucositis, dermatitis, hepatitis, renal and CNS effects with high-dose administration; prevent with hydration and leucovorin, monitor levels
6-Mercaptopurine	Purine analog	ALL	Myelosuppression; hepatitis; mucositis; allopurinol increases toxicity
Cytosine	Pyrimidine analog;	ALL, AML, lymphoma	Myelosuppression, conjunctivitis, mucositis,

arabinoside (Ara-C)	inhibits DNA polymerase		neurotoxicity
ALKYLATING AGENTS			
Cyclophosphamide	Alkylates guanine; inhibits DNA synthesis	ALL, lymphoma, sarcoma, brain tumors	Myelosuppression; hemorrhagic cystitis
Ifosfamide	Similar to cyclophosphamide	Lymphoma, Wilms tumor, sarcoma, germ cell and testicular tumors	Similar to cyclophosphamide; neurotoxicity, cardiac toxicity
Carmustine (BCNU), lomustine (CCNU)	Carbamylation of DNA; inhibits DNA synthesis	CNS tumors, lymphoma, Hodgkin disease	Delayed myelosuppression (4-6 wk); pulmonary fibrosis, carcinogenic, stomatitis
Cisplatin	Inhibits DNA synthesis	Osteosarcoma, neuroblastoma, CNS tumors, germ cell tumors	Nephrotoxic; myelosuppression, ototoxicity, neurotoxicity, hemolytic uremic syndrome
Carboplatin	Inhibits DNA synthesis	Same as for cisplatin	Myelosuppression
TOPOISOMERASE INHIBITORS			
Doxorubicin and daunorubicin	Intercalation, DNA strand breaks	ALL, AML, osteosarcoma, Ewing sarcoma, lymphoma, neuroblastoma	Cardiomyopathy, red urine, tissue necrosis on extravasation, myelosuppression, conjunctivitis, radiation dermatitis, arrhythmia
Dactinomycin	Intercalation, DNA strand breaks	Wilms tumor, rhabdomyosarcoma, Ewing sarcoma	Tissue necrosis on extravasation, myelosuppression, hepatopathy with thrombocytopenia, stomatitis
Etoposide (VP-16)	DNA strand breaks	ALL, AML, lymphoma, germ cell tumor, sarcoma	Myelosuppression, secondary leukemia, allergic reaction
Topotecan	DNA strand breaks	Neuroblastoma, rhabdomyosarcoma	Myelosuppression, diarrhea, mucositis
TUBULIN INHIBITORS			
Vincristine	Inhibits microtubule formation	ALL, lymphoma, Wilms tumor, Hodgkin disease, Ewing sarcoma, neuroblastoma, rhabdomyosarcoma, brain tumors	Local cellulitis, peripheral neuropathy, constipation, ileus, jaw pain, inappropriate ADH secretion, seizures, ptosis, minimal myelosuppression
Vinblastine	Inhibits microtubule formation	Hodgkin disease, Langerhans cell histiocytosis	Local cellulitis, myelosuppression
ENZYME			
Asparaginase	Depletion of asparagine	ALL, AML	Allergic reaction; pancreatitis, hyperglycemia, platelet dysfunction and coagulopathy, encephalopathy, stroke, thrombosis
HORMONES			
Prednisone,	Direct lymphocyte	ALL; Hodgkin disease,	Cushing syndrome, cataracts, diabetes,

dexamethasone	cytotoxicity	lymphoma	hypertension, myopathy, osteoporosis, infection, peptic ulceration, irritability, psychosis, hunger, fluid retention
MONOCLONAL ANTIBODIES			
Rituximab	Anti-CD20	CD20+ B-cell leukemia, lymphoma	Fever, chills, allergy
Brentuximab	Anti-CD30	CD30+ lymphomas	Myelosuppression, peripheral neuropathy, fatigue, fever
Blinatumomab	Anti-CD19 and anti-CD3	CD19+ refractory B-lymphoblastic leukemia	Cytokine release syndrome, neurotoxicity
Dinutuximab	Anti-G _{D2}	High-risk neuroblastoma	Neuropathic pain, hypotension, hypoxia, fever, capillary leak syndrome, hypersensitivity reactions
SMALL MOLECULE PATHWAY INHIBITORS			
Imatinib	Inhibits BCR-ABL, VEGF, c-KIT kinases	Ph+ CML, ALL	Nausea, vomiting, fatigue, headache
Dasatinib	Inhibits BCR-ABL, c-KIT, and other kinases	Ph+ CML, ALL	Fluid retention, rash, nausea
MISCELLANEOUS			
Tretinoin (all-trans retinoic acid) and isotretinoin (cis-retinoic acid)	Promotes differentiation	Acute promyelocytic leukemia (ATRA); neuroblastoma (CRA)	Fever, respiratory distress, leukocytosis (ATRA); dry mouth, hair loss, pseudotumor cerebri (CRA)
Arsenic	Promotes differentiation, apoptosis	Acute promyelocytic leukemia	Transaminitis, nausea, vomiting, abdominal pain, QTc prolongation

Many drugs produce nausea and vomiting during administration; many cause alopecia with repeated doses.

ADH, Antidiuretic hormone; *ALL*, acute lymphoblastic leukemia; *AML*, acute myeloid leukemia; *ATRA*, all-trans retinoic acid; *CML*, chronic myeloid leukemia; *CNS*, central nervous system; *VEGF*, vascular endothelial growth factor.

Resistance to particular chemotherapeutic agents can develop relatively quickly. Thus combinations of chemotherapy drugs are used, as opposed to sequential single agents, to treat childhood cancer. The blood-brain barrier prevents the penetration of chemotherapeutic drugs into the CNS. Thus administration of the chemotherapeutic agent directly into the cerebrospinal fluid (by lumbar puncture) is used for leukemia and lymphoma. Radiation therapy also circumvents the blood-brain barrier.

Radiation Therapy

Radiation therapy is the process of delivering ionizing radiation to malignant cells to kill them directly or, more commonly, prevent them from dividing by interfering with DNA replication. Conventional radiation therapy uses photons, but atomic particles such as electrons, protons, and neutrons can also be used. Not all tumors are radiosensitive, and radiation therapy is not necessary in all tumors that are radiosensitive.

Other Therapies

Certain cancers have been treated with biological response modifiers, tyrosine kinase inhibitors, or monoclonal antibodies in addition to standard treatments. **Targeted therapies** specifically target the tumor cells, sparing normal host cells. Imatinib and dasatinib are tyrosine kinase inhibitors that target the effects of the t(9;22) translocation (*BCR-ABL*) of chronic myeloid leukemia and acute lymphoblastic leukemia. Rituximab is a monoclonal antibody directed against the cell surface antigen CD20 expressed in some lymphomas. Dinutuximab is an anti-G_{D2} monoclonal antibody used for neuroblastoma. Chimeric antigen receptor T-cell therapy and bi-specific T-cell engager therapy are immunotherapies that leverage the patient's own T cells to kill cancer cells.

Supportive care also plays an important role in pediatric oncology, including the use of appropriate antimicrobial agents, blood products, nutritional support, intensive care, and integrative therapies.

Adverse Effects

Because chemotherapy agents are cellular toxins, numerous adverse effects are associated with their use. Bone marrow suppression, immunosuppression, nausea, vomiting, and alopecia are general adverse effects of commonly used chemotherapy drugs. Each chemotherapy drug also has specific toxicities. Doxorubicin can cause cardiac damage; cisplatin can cause renal damage and ototoxicity; cyclophosphamide and ifosfamide can cause hemorrhagic cystitis; and vincristine can cause peripheral neuropathy. Radiation therapy produces many adverse effects such as mucositis, growth retardation, organ dysfunction, and the later development of secondary cancers. Significant therapy-related **late effects** may develop in pediatric cancer patients ([Table 154.3](#)).

TABLE 154.3

Long-Term Sequelae of Cancer Therapy

PROBLEM	ETIOLOGICAL AGENT(S)
Infertility	Alkylating agents; radiation
Second cancers	Genetic predisposition; radiation; alkylating agents, etoposide, topoisomerase II inhibitors
Sepsis	Splenectomy
Hepatotoxicity	Methotrexate, 6-mercaptopurine; radiation
Hepatic venoocclusive disease	High-dose, intensive chemotherapy (busulfan, cyclophosphamide) ± bone marrow transplant
Scoliosis	Radiation
Pulmonary (fibrosis)	Radiation; bleomycin, busulfan
Cardiomyopathy	Doxorubicin, daunorubicin; radiation
Leukoencephalopathy	Cranial radiation, methotrexate
Cognition/intelligence	Cranial radiation, methotrexate
Pituitary dysfunction (growth hormone deficiency, panhypopituitarism)	Cranial radiation
Psychosocial	Stress, anxiety, death of peers; conditioned responses to chemotherapy
Thyroid dysfunction	Radiation
Osteonecrosis	Corticosteroids

CHAPTER 155

Leukemia

Etiology

The etiology of childhood leukemia is unknown and is thought to be multifactorial with both genetics and environmental factors contributing to malignant transformation. In **chronic myeloid leukemia (CML)** and, less commonly, in **acute lymphoblastic leukemia (ALL)**, a translocation involving chromosomes 9 and 22 (Philadelphia [Ph] chromosome) creates a novel fusion gene called *BCR-ABL*. This results in the production of a constitutively activated tyrosine kinase that drives the development of CML and Ph-positive ALL. In addition, a number of genetic syndromes/diseases including Down syndrome

(Trisomy 21), Fanconi anemia, Bloom syndrome, ataxia-telangiectasia, Wiskott-Aldrich syndrome, neurofibromatosis type 1, and rare familial leukemia syndromes can predispose children to the development of acute leukemia. Siblings of children with leukemia are at an increased risk of developing leukemia with an approximately two- to fourfold risk above the general pediatric population (approximately 25% risk for monozygotic twins). Environmental factors that may increase the risk of leukemia include ionizing radiation and chemical exposures including certain chemotherapy agents (particularly the topoisomerase II inhibitors).

Epidemiology

ALL accounts for approximately 75%, acute myeloid leukemia (AML) accounts for approximately 20%, and CML accounts for less than 5% of leukemia cases in the pediatric population. Other chronic leukemias, including juvenile myelomonocytic leukemia, chronic myelomonocytic leukemia, and chronic lymphocytic leukemia, are rare in childhood. ALL is the most common childhood cancer, comprising 25% of cancer prior to the age of 15 years (40 per 1 million children under the age of 15 years) and 19% of cancer prior to the age of 20 years.

ALL is classified according to lymphoid lineage as either B cell or T cell. The incidence of B-lineage ALL peaks at 2-5 years of age and is slightly more common in boys than in girls. T-cell ALL is associated with male predominance and an older age of onset. In the United States, ALL is more common in whites than in African American children. The incidence of AML is relatively higher in the neonatal period, then drops and stabilizes until adolescence when there is a slight increase, which continues into adulthood (especially beyond 55 years of age). Males and females are equally affected by AML. Hispanic and African American children have a slightly higher incidence of AML than white children.

Clinical Manifestations

Decision-Making Algorithms

- Arthritis
- Extremity Pain
- Lymphadenopathy

Anemia Bleeding

Signs and symptoms of acute leukemia are related to the infiltration of leukemic cells into normal tissues, resulting in either bone marrow failure (anemia, neutropenia, thrombocytopenia) and/or specific tissue infiltration (lymph nodes, liver, spleen, brain, bone, skin, gingiva, testes). Common presenting symptoms are fever, pallor, petechiae and/or ecchymoses, lethargy, malaise, anorexia, and bone/joint pain. Physical examination frequently reveals lymphadenopathy and hepatosplenomegaly. The testes and central nervous system (CNS) are common extramedullary sites for ALL involvement; neurological symptoms or a painless enlargement of one or both testes may be seen. Patients with T-cell ALL often have high white blood cell (WBC) counts, an anterior mediastinal mass (mediastinal adenopathy and/or thymic infiltration), cervical lymphadenopathy, hepatosplenomegaly, and CNS involvement. In patients with AML, extramedullary soft tissue tumors may be found in various sites.

Laboratory and Imaging Studies

The diagnosis of acute leukemia is confirmed by findings of immature blast cells on the peripheral blood smear, bone marrow aspirate, or both. Most patients have abnormal blood counts; anemia and thrombocytopenia are common. The WBC count may be low, normal, or high; 15-20% of patients have a WBC count of $50,000/\text{mm}^3$ or higher (hyperleukocytosis) at presentation. Definitive diagnosis requires the evaluation of cell surface markers (immunophenotype) by flow cytometry. Cytogenetic analysis should be undertaken in all cases of acute leukemia because many reoccurring cytogenetic abnormalities have prognostic implications and are used, in combination with other risk factors, to assign therapy to optimize outcome. In B-lineage ALL, the t(12;21) translocation (previously called *TEL/AML*; now referred to as *ETV6/RUNX1*) is the most common (approximately 20% of all cases) and is associated with a favorable prognosis when combined with other low-risk features. The t(9;22) translocation occurs in 3% of cases and, historically, has a poor prognosis. However, much like in CML, the use of tyrosine kinase inhibitors in Ph-positive ALL has resulted in dramatic improvements in outcomes. The t(4;11) translocation (and

other translocations involving the MLL gene on chromosome 11) often occurs in infant ALL and patients with secondary AML (often in patients that have been exposed to topoisomerase II inhibitors). It is associated with a poor prognosis. Fluorescent in situ hybridization or polymerase chain reaction techniques are now used in most cases of leukemia because many chromosomal abnormalities are not apparent on routine karyotypes. DNA microarray techniques are becoming an important diagnostic and prognostic tool. Recently, a new high-risk subgroup called Philadelphia-like ALL has been identified using this technique. A lumbar puncture should always be performed at the time of diagnosis to evaluate the possibility of CNS involvement. A chest x-ray should be obtained in all patients to assess for an anterior mediastinal mass. Electrolytes (particularly potassium, phosphorous, and calcium), uric acid, and renal and hepatic function should be monitored in all patients to assess and treat patients at risk for tumor lysis syndrome.

Differential Diagnosis

The differential diagnosis of acute leukemia includes nonmalignant and malignant diseases. Infection is probably the most common mimicker of acute leukemia, particularly Epstein-Barr virus. Other infections (cytomegalovirus, other viruses, mycobacteria) may also produce signs and symptoms common to leukemia. Noninfectious considerations include aplastic anemia, histiocytosis, juvenile idiopathic arthritis, immune thrombocytopenic purpura, and congenital or acquired conditions that result in neutropenia or anemia. Several malignant diagnoses including neuroblastoma, rhabdomyosarcoma, and Ewing sarcoma can also mimic leukemia. Newborns with trisomy 21 may have a condition known as transient myeloproliferative disorder, which produces elevated WBC counts with peripheral blasts, anemia, and thrombocytopenia. It usually resolves with supportive care only, but these children have a significantly increased risk (30%) of developing acute leukemia (ALL or AML) within the next few months to years of life.

Treatment

Patients with B-lineage ALL generally receive three- or four-agent induction chemotherapy (patients with T-cell ALL receive a four-agent induction) based on their initial risk group assignment. Standard-risk patients receive vincristine,

corticosteroids, and pegylated asparaginase over 4 weeks; high-risk patients also receive an anthracycline (typically daunorubicin). Intrathecal therapy with cytarabine or methotrexate is given to treat existing or subclinical CNS leukemia. Following induction therapy, patients undergo an end-of-induction bone marrow evaluation to assess for remission (nearly all patients with ALL achieve a remission). The intensity of postinduction therapy relies on risk adaptation using a variety of prognostic tools (cytogenetics, rapidity and depth of remission using tests for minimal residual disease [MRD], etc.). ALL patients with CNS involvement detected at diagnosis often require more intensive treatment that can include an escalation in their intrathecal therapy as well as the use of cranial radiation therapy. Recently, the omission of cranial radiation therapy for all pediatric leukemia patients holds great promise. Patients with ALL receive chemotherapy for a total of 2-3 years. The treatment of AML is divided into three general types including (1) acute promyelocytic leukemia with a t(15;17) translocation (*PML-RARA*) that relies heavily on all-trans retinoic acid and arsenic trioxide; (2) myeloid leukemias of Down syndrome in which less intensive therapy is administered, and (3) AML that parallels the risk and biological features most commonly seen in adult AML. The latter results in the need for intensive therapy and, in select high-risk patients, the use of stem cell transplantation after completing upfront intensive chemotherapy. The majority of pediatric patients with AML require four cycles of intensive cytarabine-based chemotherapy for low- and intermediate-risk patients and stem cell transplant for high-risk patients. Much like ALL, risk adaptive therapy is based on cytogenetics and response to therapy. Additionally, the availability of a human leukocyte antigen (HLA)-matched donor (ideally an HLA-matched sibling) determines the use of stem cell transplantation in first remission. Unlike ALL, there is little evidence that low-dose continuation therapy is helpful in AML (with the exception of acute promyelocytic leukemia).

Complications

Major short-term complications associated with the treatment of leukemia result from bone marrow suppression caused by chemotherapy. Patients may have bleeding and significant anemia that necessitates transfusion of platelets and red blood cells. The development of neutropenia predisposes patients to a significant risk of both bacterial and fungal infections. Cell-mediated immunosuppression increases the risk of *Pneumocystis jiroveci* (*carinii*) pneumonia; hence,

prophylaxis, most commonly with oral trimethoprim-sulfamethoxazole, is recommended. Prophylaxis with antibiotics and antifungal agents is becoming more commonplace, particularly in patients with AML who are at high risk for treatment-related mortality (obese patients and adolescent/young adult patients). Long-term sequelae of therapy are less common than in previous treatment eras but continue to be a priority for prevention, recognition, and treatment. These sequelae include neurocognitive impairment, short stature, obesity, cardiac dysfunction, infertility, second malignant neoplasms, and psychosocial problems (Table 154.3).

Prognosis

Patients with ALL are classified into prognostic risk groups (B-lineage ALL currently separates patients into low, average, high, and very high risk) based on age, initial WBC count, genetic characteristics (cytogenetics), extramedullary involvement at diagnosis (testicular and/or CNS involvement), and response to induction therapy using MRD techniques. Risk stratification factors are evolving (Table 155.1). The overall cure rate for childhood B-lineage ALL is approaching 90%. Relapse of ALL occurs most commonly in the bone marrow but can involve other extramedullary sites, such as the CNS or testicles. Relapse therapy relies on several treatment options based on the timing and location of relapse as well as the patient's response to initial reinduction with chemotherapy. Thereafter a number of treatment options are employed including chemotherapy only, combination of chemotherapy with immunotherapy, immunotherapy alone, and stem cell transplantation. The current overall cure rate for childhood AML is approximately 65%. The prognosis for relapsed AML is poor, particularly in patients who have received a stem cell transplant.

TABLE 155.1

General Prognostic Factors in Acute Lymphoblastic Leukemia

FACTOR	FAVORABLE (LOWER RISK)	UNFAVORABLE (HIGHER RISK)
Age	1-9.99 years	<1 or ≥10 years
Gender	Female	Male
Race and ethnicity	Caucasian, Asian/Pacific Islanders	African American, Hispanic, Native American

Initial WBC count	<50,000/mm ³	≥50,000/mm ³
CNS disease at diagnosis	Absent	Present
Immunophenotype	B-lineage	T cell
Ploidy	Hyperdiploidy	Hypodiploidy
Genetics	t(12;21), trisomies of chromosomes 4 and 10	t(4;11), t(9;22), Ph-like, iamp21
Minimal residual disease after remission induction	Negative	Positive

CNS, Central nervous system; WBC, white blood cell.

CHAPTER 156

Lymphoma

Etiology

Lymphomas are malignancies of lymphoid tissues and are the third most common malignancy in childhood, behind leukemias and central nervous system (CNS) tumors. There are two major types of lymphoma: **Hodgkin lymphoma (HL)** and **non-Hodgkin lymphoma (NHL)**. The etiologies are multifactorial. Both congenital and acquired immunodeficiencies are more commonly associated with NHL, whereas the Epstein-Barr virus (EBV) has been associated with both HL and NHL.

Almost all cases of NHL in childhood are diffuse, highly malignant, and show little differentiation. NHL has three histological subtypes: small noncleaved cell (Burkitt lymphoma), lymphoblastic, and large cell. For simplicity, these may be regarded as B cell, T cell, and large cell (which may be of B-cell or T-cell origin; [Table 156.1](#)). Chromosomal translocations can result in unregulated/increased expression of an oncogene that drives malignant transformation. In Burkitt lymphoma, translocations occurring between chromosome 8 (*c-myc* oncogene) and the immunoglobulin gene locus (found on chromosomes 2, 14, or 22) lead to overexpression of *c-myc*, causing malignant transformation.

TABLE 156.1

Subtypes of Non-Hodgkin Lymphoma in Children

HISTOLOGICAL CATEGORY	IMMUNOPHENOTYPE	USUAL PRIMARY SITE	MOST COMMON TRANSLOCATION(S)
Small noncleaved (Burkitt lymphoma)	Mature B-cell (surface immunoglobulin present)	Abdomen (sporadic form) Head and neck (endemic form)	t(8;14)(q24;q32) t(2;8)(p11;q24) t(8;22)(q24;q11)
Lymphoblastic	T-cell (rarely pre-B-cell)	Neck and/or anterior mediastinum	Many
Large cell	T-cell, B-cell, or indeterminate	Lymph nodes, skin, soft tissue, bone	t(2;5)(p23;q35)

Epidemiology

The incidence of HL has a bimodal distribution with peaks in the adolescent/young adult years and again after age 50; it is rarely seen in children younger than 5 years of age. In children, boys are affected more commonly than girls; in adolescents, the gender ratio is approximately equal. The incidence of NHL increases with age. It is twice as common in whites as in African Americans and has a male predominance. NHL has been described in association with congenital or acquired immunodeficiency states and after organ or stem cell transplantation. Burkitt lymphoma is commonly divided into two forms: a sporadic form, commonly seen in North America, and an endemic form, with a strong association with EBV and commonly seen in Africa.

Clinical Manifestations

Decision-Making Algorithms

- Lymphadenopathy
- Neck Masses
- Abdominal Pain
- Fever

The most common clinical presentation of HL is painless, firm lymphadenopathy often confined to one or two contiguous lymph node areas (most commonly the supraclavicular and cervical nodes). Mediastinal lymphadenopathy, which produces cough or shortness of breath, is a frequent presenting symptom. The presence of one of three B symptoms has prognostic value: fever ($>38^{\circ}\text{C}$ for 3 consecutive days), drenching night sweats, and unintentional weight loss of 10% or more within 6 months of diagnosis.

The sporadic (North American) form of Burkitt lymphoma more commonly has an abdominal presentation (typically with pain), whereas the endemic (African) form frequently presents with tumors of the jaw. The anterior mediastinum and cervical nodes are the usual primary sites for T-cell lymphomas. These lymphomas may cause airway or superior vena cava obstruction, pleural effusion, or both.

The diagnosis of lymphoma is established by biopsy of an involved lymph node. Systemic symptoms such as fever and weight loss may be present, particularly in patients with anaplastic large cell lymphoma (ALCL), which can be insidious in onset. If the bone marrow contains 25% or greater blasts, the disease is classified as acute leukemia (either B-lineage acute lymphoblastic leukemia [ALL], T-cell ALL, or Burkitt leukemia). This distinction makes little prognostic or therapeutic difference as they all require aggressive, systemic therapy in addition to CNS-directed therapy.

Laboratory/Imaging Studies

Patients suspected of having lymphoma should have a complete blood count, erythrocyte sedimentation rate, and measurement of serum electrolytes (particularly potassium, phosphorous, and calcium), lactate dehydrogenase, and uric acid as well as a chest x-ray to assess for a mediastinal mass (Fig. 156.1). The diagnosis ultimately requires a pathological confirmation from tissue or fluid sampling (pleural or peritoneal fluid). For staging purposes, a bone marrow evaluation, positron emission tomography (PET) and, less commonly, a bone scan are indicated to assess extent of disease (staging). The pathological hallmark of HL is the identification of Reed-Sternberg cells. Histopathological subtypes in childhood HL are the same as those reported in adults. Nodular sclerosis (NS) is the most common subtype in adolescents/young adults, whereas mixed cellularity subtypes and nodular lymphocyte predominant are more common in younger children. Staging of HL is according to the Ann Arbor

system. About half of pediatric patients will have Stage II involvement at presentation (I 19%, II 49%, III 19%, IV 13%), and about 39% will have B symptoms.

FIGURE 156.1 Chest x-ray of a 15-year-old boy demonstrating a large superior anterior mediastinal mass (*large arrows*) compressing the trachea and deviating it to the right (*arrowheads*). Biopsy revealed non-Hodgkin lymphoma.

Differential Diagnosis

The differential diagnosis for lymphomas in children includes leukemia, rhabdomyosarcoma, nasopharyngeal carcinoma, germ cell tumors, and thymomas. Nonmalignant diagnoses include infectious mononucleosis (EBV infection), branchial cleft and thyroglossal duct cysts, cat scratch disease (*Bartonella henselae*), bacterial or viral lymphadenitis, mycobacterial infection, toxoplasmosis, and even tinea capitis, all of which can produce significant lymphadenopathy that can mimic lymphoma. Patients with acute abdominal pain from Burkitt lymphoma may be misdiagnosed as having appendicitis.

Treatment

Pediatric HL is highly curable even with advanced disease; overall survival rates now exceed 90%. Risk-adaptive therapy using stage, the presence of bulky disease, the presence or absence of B symptoms, serum albumin, and the response to upfront chemotherapy has been employed to reduce the need for radiation therapy and excess chemotherapy. Multiagent chemotherapy usually consists of drugs such as doxorubicin, vincristine, bleomycin, vinblastine, etoposide, prednisone, and cyclophosphamide. In general, four to six courses of chemotherapy are given. The use of anti-CD30 monoclonal therapy (Brentuximab vedotin) and the elimination of bleomycin are currently under investigation in pediatric HL. Response to therapy is often assessed after two cycles of upfront chemotherapy, relying on PET (to assess metabolic response) and computed tomography (CT; to assess bulk reduction) to determine the need for subsequent chemotherapy (slow response obligates more aggressive chemotherapy) and the need for radiation therapy. Of interest, patients with Stage I (single-node with complete resection) nodular lymphocyte predominant HL are cured with surgery alone 80% of the time.

Distant, noncontiguous metastases are common in childhood NHL. Systemic chemotherapy is mandatory and should be administered to all children with NHL, even those with clinically localized disease at diagnosis. B- and T-cell lymphoblastic lymphoma and ALCL are generally treated with aggressive multidrug regimens similar to the regimens used in ALL. Surgery and radiation therapy are not commonly used because the disease is rarely localized and is highly sensitive to chemotherapy. Burkitt lymphoma and diffuse large B-cell lymphomas are highly curable with cyclophosphamide, vincristine, prednisolone, and doxorubicin. Much like HL treatment, monoclonal antibody therapy is being added to the traditional chemotherapy backbone in Burkitt lymphoma (anti-CD20) and in ALCL (anti-CD30).

Complications

The short-term complications from the treatment of lymphoma are similar to other pediatric malignancies and commonly include immunosuppression, related sequelae from myelosuppression, nausea, vomiting, and alopecia. Late adverse effects include second malignant neoplasms (acute myeloid leukemia or myelodysplasia, thyroid malignancies, and breast cancer), hypothyroidism,

impaired soft tissue and bone growth, cardiac dysfunction, and pulmonary fibrosis.

Prognosis

Children and adolescents with HL are classified as low, intermediate, or high risk according to stage, nodal bulk, the presence of B symptoms, and the serum albumin at presentation. The prognosis is generally excellent with overall survival exceeding 90% for most patients (approaching 100% for low-risk patients). The overall 3-year survival rates for B-cell, T-cell, and large cell NHL are 70-90%.

CHAPTER 157

Central Nervous System Tumors

Etiology

Most central nervous system (CNS) tumors in children and adolescents are **primary tumors** that originate in the CNS and include gliomas (especially low-grade gliomas) and embryonic neoplasms (such as medulloblastoma and CNS primitive neuroectodermal tumors). In contrast, CNS tumors in adults are often high-grade astrocytomas or **secondary tumors** that are metastatic from other carcinomas. CNS tumors also may arise in patients previously treated with radiation therapy. CNS tumors are likely multifactorial in etiology. The classification of CNS tumors is complex and evolving, with the World Health Organization classification being the most complete and accurate system.

Epidemiology

CNS tumors are the most common solid tumors in children, second to leukemia in overall cancer incidence during childhood. However, due primarily to improved outcomes for leukemia, CNS tumors are now the leading cause of childhood cancer deaths. About 1,700 new cases occur each year in the United States; the rate is approximately 33 cases per 1 million children under 15 years

of age. The incidence peaks before age 10 years and then decreases until a second peak after age 70. For medulloblastoma and ependymoma, males are more affected than females; for other tumor types, no gender differences exist. In the first 2-3 years of life, whites are affected more than nonwhite children; otherwise incidence rates are essentially equal for whites and nonwhite children.

Children with certain inherited syndromes, such as neurofibromatosis (types 1 and 2), Li-Fraumeni syndrome, tuberous sclerosis, Turcot syndrome, and von Hippel-Lindau syndrome, have an increased risk for developing a CNS tumor. However, most CNS tumors arise in children with no known underlying disorder or risk factor.

Clinical Manifestations

Decision-Making Algorithms

Abnormal Head Size, Shape, and Fontanelles
Visual Impairment and Leukocoria
Strabismus
Vomiting
Headaches
Ataxia

Brain tumors can cause symptoms by impingement on normal tissue (usually cranial nerves) or by an increase in intracranial pressure caused either by obstruction of cerebrospinal fluid (CSF) flow or by a direct mass effect. Tumors that obstruct the flow of CSF quickly become symptomatic. Symptoms of **increased intracranial pressure** are lethargy, headache, and vomiting (particularly in the morning on awakening). Irritability, anorexia, poor school performance, and loss of developmental milestones all may be signs of slow-growing CNS tumors. In young children with open cranial sutures, an increase in head circumference may occur. Optic pathway tumors may lead to loss of visual acuity or visual field defects. Inability to abduct the eye as the result of sixth cranial nerve palsy is a common sign of increased intracranial pressure. Other cranial nerve deficits suggest involvement of the brainstem. Seizures occur in 20-50% of patients with supratentorial tumors; focal weakness or sensory

changes also may be seen. Pituitary involvement can produce neuroendocrine effects such as precocious puberty or diabetes insipidus. Cerebellar tumors are associated with ataxia and diminished coordination. A history and physical examination are fundamental for evaluation and should include a careful neurological assessment, including visual fields and a funduscopic examination.

Laboratory/Imaging Studies

If an intracranial lesion is suspected, **magnetic resonance imaging (MRI)** is currently the examination of choice (Fig. 157.1). Examination of CSF by cytocentrifuge histological testing is indicated to determine the presence of metastatic disease in primitive neuroectodermal tumors, germ cell tumors, and pineal region tumors. A lumbar puncture should not be performed before imaging has been obtained to evaluate for evidence of increased intracranial pressure. If a tumor is suspected to have metastatic potential (medulloblastoma), MRI of the entire spine should be obtained before surgery to assess for neuraxial dissemination. A postoperative MRI study of the brain should be obtained within 24-48 hours of surgery to assess the extent of resection. During follow-up, magnetic resonance spectroscopy can help distinguish recurrent tumor from radiation necrosis.

FIGURE 157.1 Magnetic resonance imaging scan of a 9-year-old boy showing a heterogeneously enhancing fourth ventricular mass (*arrow*). It was resected, and pathology revealed medulloblastoma.

Differential Diagnosis

The differential diagnosis of a CNS mass lesion includes malignant tumor, benign tumor, arteriovenous malformation, aneurysm, brain abscess, cysticercosis, granulomatous disease (tuberculosis, sarcoid), intracranial hemorrhage, pseudotumor cerebri, vasculitis, and, rarely, metastatic tumor.

Treatment

The therapy for children with CNS tumors is individualized and depends on the tumor type, location, size, and associated symptoms. High-dose **dexamethasone** is often administered immediately to reduce tumor-associated edema. Surgical objectives are complete excision, if possible, and maximal debulking if a complete excision is not possible. In children, radiation therapy is often combined with chemotherapy; in young children, radiation therapy may be delayed or avoided altogether. Proton radiation therapy is an emerging therapy that holds promise for decreased toxicity. Primitive neuroectodermal tumors

(including medulloblastoma) and germ cell tumors are sensitive to chemotherapy; gliomas are less sensitive to chemotherapy. Chemotherapy plays an especially important role in infants in whom the effects of high-dose CNS radiation may have devastating effects on growth and neurocognitive development.

Complications

Short-term adverse effects of therapy include nausea, vomiting, anorexia, fatigue, immunosuppression, and cushingoid features. Long-term adverse effects include neurocognitive deficits, endocrinological sequelae, decreased bone growth, ototoxicity, renal insufficiency, cataracts, infertility, and second malignant neoplasms. The neurocognitive deficits can be significant, particularly in infants and young children, and are the primary reason for the continued search for the lowest efficacious radiation therapy dose and the most conformal delivery methods for the radiation therapy boosts. **Posterior fossa syndrome** (also known as “cerebellar mutism”) occurs in up to 25% of patients after resection of a posterior fossa tumor and is characterized by an acute decrease in speech, behavioral changes (e.g., irritability, apathy, or both), diffuse cerebellar dysfunction, and other neurological abnormalities. It may begin within hours to days of surgery and is usually self-resolving within weeks to months, although some neurological complications may persist. **Somnolence syndrome**, which is characterized by excessive fatigue and sleepiness, may occur in the months after completion of radiation therapy and is self-limited.

Prognosis

Improvements in neurodiagnosis, neurosurgical techniques, chemotherapy regimens, and radiation therapy techniques have improved overall outcome. The 5-year overall survival rate associated with all childhood CNS tumors is approximately 50-60%, resulting in large measure from the high curability of cerebellar astrocytomas and the increasing cure rate for patients with medulloblastoma (Table 157.1). Intrinsic brainstem gliomas and glioblastoma multiforme have extremely poor prognoses.

TABLE 157.1

Location, Incidence, and Prognosis of Central Nervous System Tumors in

Children

LOCATION	INCIDENCE (%)	5-YEAR SURVIVAL (%)
Infratentorial (posterior fossa)	50-60	
Astrocytoma (cerebellum)	15	90
Medulloblastoma	15	50-80
Glioma (brainstem)	15	High grade: 0-5; low grade: 30
Ependymoma	5	50-60
Supratentorial (cerebral hemispheres)	35-45	
Astrocytoma	20	50-75
Glioblastoma multiforme	10	0-5
Ependymoma	5	50-75
Choroid plexus papilloma	2	95
Midline	10-15	
Craniopharyngioma	6	70-90
Germ cell tumors	3	65-95
Pineal	1	65-75
Optic nerve glioma	3	90

CHAPTER 158

Neuroblastoma

Etiology

Neuroblastoma is derived from **neural crest cells** that form the adrenal medulla and the sympathetic nervous system. The cause is unknown. Most cases occur in young children. Neuroblastoma may rarely (1-2% of cases) be hereditary. Mutations in the *ALK*, *PHOX2B*, and *TP53* genes have been associated with familial cases. In sporadic cases, several somatic genetic mutations have been identified, with *MYCN* amplification being the most common.

Epidemiology

Neuroblastoma is the most common extracranial solid tumor of childhood and

the most common malignancy in infancy. The median age at diagnosis is 17 months. There are approximately 800 new cases of neuroblastoma in the United States each year. The prevalence is estimated to be 1 in 7,000 live births.

Clinical Manifestations

Decision-Making Algorithms

- Abdominal Masses
- Neck Masses
- Abnormal Eye Movements
- Limp
- Pancytopenia

Neuroblastoma is remarkable for its broad spectrum of clinical behavior ranging from spontaneous regression to rapid progression with metastases resulting in death. Children with localized disease are often asymptomatic at diagnosis, whereas children with metastases often appear ill and have systemic complaints such as fever, weight loss, and pain. The most common presentation is abdominal pain or mass. The mass is often palpated in the abdomen or flank and is hard and nontender. Approximately 45% of tumors arise in the adrenal gland, and 25% arise in the retroperitoneal sympathetic ganglia. Other sites of origin are the paravertebral ganglia of the chest and neck. Paraspinal tumors may invade through the neural foramina and cause spinal cord compression. Horner syndrome is sometimes seen with neck or apical masses. Several **paraneoplastic syndromes**, including secretory diarrhea, profuse sweating, and **opsomyoclonus**, are associated with neuroblastoma.

Neuroblastoma may metastasize to multiple organs, including the liver, bone, bone marrow, and lymph nodes. Periorbital ecchymoses are a sign of orbital bone metastases. A unique category of neuroblastoma, **stage MS**, is defined in infants (<18 months old) with metastases limited to skin, liver, or bone marrow. It is associated with a favorable outcome.

Laboratory/Imaging Studies

A complete blood count and plain radiographs may help identify patients with neuroblastoma. Calcification within abdominal neuroblastoma tumors is often observed on plain radiographs of the abdomen. About 90% of neuroblastomas produce **catecholamines (vanillylmandelic acid; homovanillic acid)** that can be detected in the urine. Definitive diagnosis of neuroblastoma requires tissue biopsy for microscopic examination and genetic testing. A computed tomography (CT) scan of the chest, abdomen, and pelvis; a bone scan and/or metaiodobenzylguanidine scan; bilateral bone marrow aspiration and biopsies; and urinary catecholamines complete the evaluation.

Differential Diagnosis

The abdominal presentation of neuroblastoma must be differentiated from Wilms tumor, which also presents as an abdominal or flank mass. Ultrasound or CT examination usually differentiates the tumors prior to surgery. Periorbital ecchymoses from orbital metastases can be mistaken for child abuse. Because children with bone marrow involvement may have anemia, thrombocytopenia, or neutropenia, leukemia is often considered in the differential.

Treatment

Treatment of neuroblastoma is based on risk classification ([Table 158.1](#)), an evolving scheme based on emerging genetic discoveries, and treatment advances. Complete surgical excision is the initial treatment of choice for localized neuroblastoma. Children with very low- or low-risk tumors who undergo a gross total resection require no further therapy. Patients with intermediate-risk disease are usually treated with surgery and 4-8 cycles of chemotherapy. In patients with high-risk disease, combination chemotherapy is given after confirmation of the diagnosis. The most commonly used agents are vincristine, cyclophosphamide, topotecan, doxorubicin, cisplatin, and etoposide. Resection of the primary tumor is undertaken after several courses of chemotherapy. Patients then undergo **high-dose chemotherapy with autologous stem cell rescue**; recent data suggest two courses of high-dose therapy are better than one. Radiation therapy is then administered to the primary tumor bed and areas of metastatic disease. Finally, **cis-retinoic acid** (isotretinoin) and **Dinutuximab** (a form of immunotherapy directed against the G_{D2} antigen) are administered to treat minimal residual disease.

TABLE 158.1**International Neuroblastoma Risk Group Pretreatment Classification Scheme**

Complications

Spinal cord compression from neuroblastoma may cause an irreversible neurological deficit and is an oncological emergency. Children with opsomyoclonus syndrome may suffer from developmental delay. The aggressive

chemotherapy and radiation therapies currently used to treat high-risk neuroblastoma may result in complications such as ototoxicity, nephrotoxicity, growth problems, and second malignancies.

Prognosis

The prognosis is affected by age at diagnosis, stage (based on presence or absence of metastasis and image-defined risk factors), DNA ploidy, *MYCN* status, 11q aberration, and histopathology (grade of tumor differentiation). Currently, children with neuroblastoma can be divided into four groups: very low, low, intermediate, and high risk. Patients with favorable biology tend to be younger and often have localized disease. Older patients with metastatic disease most commonly have unfavorable biology; approximately 50% will ultimately relapse due to drug-resistant residual disease. Although neuroblastoma represents only 8% of cases of childhood cancer, it is responsible for 15% of cancer deaths in children.

CHAPTER 159

Wilms Tumor

Etiology and Epidemiology

Wilms tumor is thought to arise from primitive, metanephric blastema, the precursor of a normal kidney. Nephrogenic rests are foci of embryonal cells that are rarely (<1%) found in normal infant kidneys but commonly (25-40%) found in Wilms tumor-bearing kidneys. Although the cause of Wilms tumor is unknown, approximately 15-20% of sporadic tumors have *WT1* mutations or deletions. Over 70% of Wilms tumors demonstrate loss of imprinting or loss of heterozygosity at 11p15, leading to overexpression of *IGF2*, thought to play a key role in tumorigenesis. Certain syndromes including Beckwith-Wiedemann and WAGR (Wilms tumor, aniridia, genitourinary anomalies, and retardation; mutation involving 11p13 region) are at increased risk of developing the disease.

Wilms tumor is the most common malignant renal tumor of childhood, with approximately 500 new cases per year in the United States. Unilateral tumors

have a median age of diagnosis of 44 months versus bilateral tumors, which have a median age of diagnosis of 31 months. Bilateral presentations are commonly associated with hereditary forms of the disease.

Clinical Manifestations

Decision-Making Algorithms

Abdominal Pain
Abdominal Masses
Hematuria

Most children with Wilms tumor are brought to medical attention because they have an abdominal mass that is discovered by their parents. Although many children do not have complaints at the time that the mass is first noted, associated symptoms may include abdominal pain (often mistaken for constipation), fever, hypertension, and hematuria.

Laboratory/Imaging Studies

An abdominal ultrasound or computed tomography (CT) scan can usually distinguish an intrarenal mass from a mass arising from the adrenal gland (most commonly neuroblastoma) or other surrounding structures. Evaluation of the inferior vena cava is crucial because the tumor may extend from the kidney into the vena cava. The diagnostic work-up includes a complete blood count, urinalysis, liver and renal function studies, as well as a CT scan of the chest, abdomen, and pelvis to assess for metastatic involvement (pulmonary involvement is the most common metastatic site). The diagnosis is confirmed by histological examination of the tumor.

Differential Diagnosis

The differential diagnosis of Wilms tumor includes hydronephrosis and polycystic disease of the kidney; benign renal tumors, such as mesoblastic nephroma and hamartoma; and other malignant tumors, such as neuroblastoma,

renal cell carcinoma, lymphoma, and retroperitoneal rhabdomyosarcoma.

Treatment

The timing of nephrectomy for unilateral, resectable Wilms tumor remains divided between the North American approach and the European approach. Both approaches have a similar overall survival. The North American approach recommends an upfront nephrectomy (confirming tissue diagnosis) followed by adjuvant chemotherapy with or without radiation therapy, whereas the European approach is to make a diagnosis relying predominantly on imaging (sometimes a biopsy), provide upfront (neoadjuvant) chemotherapy, then nephrectomy of the involved kidney followed by adjuvant chemotherapy with or without radiation therapy. The Children's Oncology Group (North American approach) relies on stage, histology (favorable versus anaplastic/unfavorable), patient age, tumor weight, loss of heterozygosity of 1p and 16q, and imaging response of pulmonary nodules after initial chemotherapy to risk stratify patients. Most patients will receive a 2-3 drug chemotherapy regimen (vincristine, actinomycin, with or without doxorubicin) as well as radiation therapy for those with high-risk features. Patients designated with very-low-risk unilateral Wilms tumor can often be cured with nephrectomy only.

Bilateral Wilms tumor is present in about 5% of children on initial presentation. The treatment goal for patients with bilateral Wilms tumor is to balance the need to achieve a cure while retaining as much normal kidney function as possible.

Prognosis and Complications

The overall survival rate for Wilms tumor is 90%. Unfortunately, 25% of survivors will experience serious chronic health conditions. Survivors of Wilms tumor are at risk for cardiomyopathy, scoliosis, hypertension and prehypertension, renal and bladder insufficiency, pulmonary dysfunction, hepatic dysfunction, infertility, and second malignancies. Patients with bilateral Wilms tumor are sometimes left with renal insufficiency or failure. Female survivors may have complicated pregnancies and deliveries most commonly associated with flank radiation.

CHAPTER 160

Sarcomas

Sarcomas are divided into soft tissue sarcomas and bone cancers. Soft tissue sarcomas arise primarily from the connective tissues of the body, such as muscle tissue, fibrous tissue, and adipose tissue. **Rhabdomyosarcoma (RMS)**, the most common soft tissue sarcoma in children, is derived from mesenchymal cells of muscle lineage. Less common soft tissue sarcomas include fibrosarcoma, synovial sarcoma, and extraosseous Ewing sarcoma. The most common malignant bone cancers in children are **osteosarcoma** and **Ewing sarcoma**. Osteosarcomas derive from primitive bone-forming mesenchymal stem cells. Ewing sarcomas are thought to be of neural crest cell origin.

Etiology

The cause is unknown for most children diagnosed with sarcoma, although a few observations have been made regarding risks. Individuals with Li-Fraumeni syndrome (associated with a germline p53 mutation) and neurofibromatosis (associated with *NF1* mutations) have an increased risk of soft tissue sarcomas. There is a 500-fold increased risk for osteosarcoma for individuals with hereditary retinoblastoma. Prior treatment for childhood cancer with radiation therapy or chemotherapy (specifically alkylating agents), or both, increases the risk for osteosarcoma as a second malignancy.

Epidemiology

In the United States, 850-900 children and adolescents under 20 years of age are diagnosed with soft tissue sarcomas each year; approximately 350 are RMS. The incidence of RMS peaks in children 2-6 years old and again in adolescents. The early peak is associated with tumors in the genitourinary region, head, and neck; the later peak is associated with tumors in the extremities, trunk, and male genitourinary tract. Boys are affected 1.5 times more often than girls. Of the 650-700 U.S. children and adolescents under 20 years of age diagnosed with bone tumors each year, approximately two thirds have osteosarcoma and one third have Ewing sarcoma. Osteosarcoma most commonly affects adolescents;

the peak incidence occurs during the period of maximum growth velocity. The incidence of Ewing sarcoma peaks between ages 10 and 20 years but may occur at any age. Ewing sarcoma primarily affects whites; it rarely occurs in African American children or Asian children.

Clinical Manifestations

Decision-Making Algorithms

- Extremity Pain
- Limp
- Neck Masses
- Scrotal Swelling (Painless)
- Vaginal Discharge
- Lymphadenopathy

The clinical presentation of RMS varies, depending on the site of origin, subsequent mass effect, and presence of metastatic disease. Periorbital swelling, proptosis, and limitation of extraocular motion may be seen with an orbital tumor. Nasal mass, chronic otitis media, ear discharge, dysphagia, neck mass, and cranial nerve involvement may be noted with tumors in other head and neck sites. Urethral or vaginal masses, paratesticular swelling, hematuria, and urinary frequency or retention may be noted with tumors in the genitourinary tract. Trunk or extremity lesions tend to present as rapidly growing masses that may or may not be painful. If there is metastatic disease to bone or bone marrow, limb pain and evidence of marrow failure may be present.

Osteosarcoma is often located at the epiphysis or metaphysis of long bones that are associated with maximum growth velocity (distal femur, proximal tibia, proximal humerus), but any bone may be involved. It presents with pain and may be associated with a palpable mass. Because the pain and swelling often are initially thought to be related to trauma, radiographs of the affected region are frequently obtained; the radiographs usually reveal a lytic lesion, sometimes associated with calcification in the soft tissue surrounding the lesion. Although 75-80% of patients with osteosarcoma have apparently localized disease at diagnosis, most patients are believed to have micrometastatic disease as well.

Although Ewing sarcoma can occur in almost any bone in the body, the femur and pelvis are the most common sites. In addition to local pain and swelling, clinical manifestations may include constitutional symptoms such as fever, fatigue, and weight loss.

Laboratory/Imaging Studies

Tissue biopsy is needed for a definitive diagnosis of sarcoma. Selection of the biopsy site is important and has implications for future surgical resection and radiation therapy. Under light microscopy, RMS and Ewing sarcoma appear as small, round, blue cell tumors. Osteosarcomas are distinguishable by the presence of osteoid.

Immunohistochemical staining for muscle-specific proteins, such as actin and myosin, helps confirm the diagnosis of RMS. Two major histological variants exist for RMS: embryonal and alveolar. The **embryonal (ERMS; embryonal RMS)** histological variant is most common in younger children with head, neck, and genitourinary primary tumors. The **alveolar (ARMS; alveolar RMS)** histological variant occurs in older patients and is seen most commonly in trunk and extremity tumors. Alveolar RMS is often characterized by specific translocations: t(2;13) or t(1;13). Although histology is still used to determine risk group assignment/treatment, *FOXO1* fusion status is more predictive of outcome. The vast majority of ARMS are *PAX3-FOXO1* or *PAX7-FOXO1* translocation positive. Metastatic evaluation for patients with RMS should include positron emission tomography (PET) scan (when available), chest computed tomography (CT), and bilateral bone marrow aspiration/biopsy. A lumbar puncture is required in patients with a parameningeal primary site due to the risk of direct extension into the central nervous system (CNS).

The diagnosis of osteosarcoma is established with the presence of osteoid and immunohistochemical analysis of the biopsy material. The extent of the primary tumor should be delineated carefully with magnetic resonance imaging (MRI) before starting chemotherapy to determine surgical resection options. Osteosarcoma tends to metastasize to the lungs, most commonly, and rarely to other bones. Metastatic evaluation includes a chest CT scan and a bone scan (or PET scan).

The diagnosis of Ewing sarcoma is established with immunohistochemical analysis along with cytogenetic and molecular diagnostic studies of the biopsy material. Ewing sarcoma is characterized by a specific chromosomal

translocation, t(11;22), which is seen in 95% of tumors. MRI of the primary lesion should be performed to delineate extent of the lesion and any associated soft tissue mass. Metastatic evaluation involves a PET scan (when available), chest CT scan, and bilateral bone marrow aspiration/biopsy.

Differential Diagnosis

Patients with Ewing sarcoma may be misdiagnosed as having osteomyelitis; children with osteogenic sarcoma are often initially believed to have pain and swelling related to trauma. The differential diagnosis for RMS depends on the location of the tumor. Tumors of the trunk and extremities often present as a painless mass and may initially be thought to be benign tumors. Head and neck RMS may be misdiagnosed as allergies, orbital cellulitis, or chronic infection of ears or sinuses. The differential diagnosis for intraabdominal RMS includes other abdominal malignancies, such as Wilms tumor and neuroblastoma.

Treatment

Treatment of RMS is currently based on a staging system that incorporates a number of diagnostic features including primary site, histological subtype, *FOXO1* fusion status, stage (local, regional or metastatic involvement), and surgical grouping (the ability or inability to achieve a gross total resection prior to chemotherapy/radiation). The most common chemotherapy agents used in RMS are vincristine, dactinomycin, and cyclophosphamide. Other active agents include irinotecan, ifosfamide, and etoposide. The use of temsirolimus, temozolomide, and ganitumab (anti-IGF-1R monoclonal antibody) is currently under investigation. Radiation is administered to the primary tumor when surgical resection is incomplete or would be morbid. It may also be administered to involved regional nodal sites, and sometimes to distant metastatic sites.

The current treatment of osteosarcoma involves neoadjuvant chemotherapy, surgical resection of the primary tumor, followed by adjuvant chemotherapy. The most common chemotherapy agents used for osteosarcoma are high-dose methotrexate, doxorubicin, and cisplatin. Radiation therapy is ineffective for osteosarcoma, although it is sometimes used for palliative intent to treat pain. The treatment for Ewing sarcoma is similar to osteosarcoma and requires neoadjuvant chemotherapy, local control measures, followed by adjuvant chemotherapy. The most common chemotherapy agents used for Ewing sarcoma

are vincristine, doxorubicin, and cyclophosphamide in combination with ifosfamide and etoposide. The addition of topotecan in nonmetastatic patients and ganitumab in metastatic patients is currently under investigation. In contrast to osteosarcoma, Ewing sarcoma is radiation sensitive, and radiation therapy is administered to patients where the primary tumor cannot be safely resected as well as for metastatic sites.

Complications

In addition to potential late effects from the chemotherapy, children with sarcomas may have complications related to local control of the tumor. If the local disease is controlled with surgery, the long-term sequelae may include loss of limb or limitation of function. If local control is accomplished with radiation therapy, the late effects depend on the dose of radiation given, the extent of the radiated site, and the development of the child at the time of radiation therapy. Irradiating tissues interferes with growth and development, causes organ damage, and increases the risk of second malignant neoplasms.

Prognosis

For all children with sarcoma, presence or absence of metastatic disease at presentation is the most important prognostic factor. The outlook remains poor for patients who have distant metastases from Ewing sarcoma, RMS, or osteosarcoma. Patients with localized RMSs in favorable sites have an excellent prognosis when treated with surgery followed by chemotherapy. In patients with osteosarcoma, the amount of tumor necrosis after preoperative chemotherapy is prognostic. Patients who achieve >90% tumor necrosis after neoadjuvant chemotherapy have an overall survival rate of approximately 80% versus approximately 50% for patients who have <90% tumor necrosis. The overall cure rate for patients with localized osteosarcoma and Ewing sarcoma is approximately 60-70%. Patients who have lung metastasis at diagnosis have a cure rate of approximately 30%. Patients with metastases to other bones have a very poor prognosis (less than 20%).

Pearls for Practitioners

Chapter 153

Oncology Assessment

- The most common cancers in children and adolescents are leukemia, brain tumors, and lymphoma followed by sarcomas of soft tissue and bone.
 - Cancers that are seen almost exclusively in children, as opposed to adolescents and adults, include neuroblastoma, Wilms tumor, retinoblastoma, and hepatoblastoma.
- Many signs and symptoms of childhood cancer are nonspecific. Pain, fatigue, pallor, bruising/petechiae/bleeding, and a growing mass are all common on presentation.
- In general, malignant lymph nodes tend to be large, firm, fixed, and nontender; reactive lymph nodes tend to be small, soft, mobile, and tender.
- Almost all cancers require a biopsy of some type to make a

definitive diagnosis.

- A child with an abdominal mass should prompt consideration for neuroblastoma, Wilms tumor, and hepatoblastoma.
 - In general, toddlers and older children with neuroblastoma are ill, whereas children with Wilms tumor have few associated symptoms.
- Serum (and/or cerebrospinal fluid) alpha-fetoprotein (AFP) and beta-human chorionic gonadotropin (β -HCG) are tumor markers for germ cell tumors. AFP is a tumor marker for hepatoblastoma.
- Urine homovanillic acid (HVA) and vanillylmandelic acid (VMA) are tumor markers for neuroblastoma.
- The prognosis for children with cancer has improved dramatically in the past 60 years, with long-term survival improving from about 20% to 80%.
- Prognostic factors include age, histology, and the presence or absence of metastases. However, genetic factors (of both the cancer and the patient) and response to initial therapy are becoming more powerful determinants of survival.

Chapter 154

Principles of Cancer Treatment

- Treatment for children with cancer is usually multimodal and may involve surgery, radiation therapy, chemotherapy, and immunotherapy. Targeted therapies and immunotherapies are more commonly being used to treat pediatric cancers, often with dramatic results and manageable toxicities.
- Current primary prevention strategies for pediatric malignancy are uncommon but include use of the hepatitis B vaccine (hepatocellular carcinoma) and human papillomavirus vaccine (GU/oropharyngeal cancers).
- Adverse effects of treatment may lead to oncological

emergencies.

- Tumor lysis syndrome may be seen in patients with leukemia and lymphoma. It is best treated with hydration, allopurinol and/or rasburicase (to treat hyperuricemia), and treating the underlying cancer.
- Airway compression, spinal cord compression, and infection are other oncological emergencies.
- Many survivors of childhood cancer suffer from long-term side effects from the treatment.
 - As the prognosis for childhood cancer improves, clinical trials are shifting focus from improving survival to decreasing long-term side effects.

Chapter 155

Leukemia

- Children with cytopenias and/or leukocytosis should be considered for bone marrow aspiration to assess for acute leukemia.
- Acute lymphoblastic leukemia (ALL) accounts for approximately 75% of pediatric leukemia; acute myeloid leukemia (AML) accounts for approximately 20% and chronic myeloid leukemia (CML) accounts for less than 5%.
 - ALL is more common in whites, whereas AML has a slightly higher incidence in Hispanic and African American children.
- ALL is classified as B-cell or T-cell.
 - The incidence of B-cell ALL peaks at 2-5 years of age with a slight male predominance. T-cell ALL has a male predominance and presents at an older age.
- The diagnosis of acute leukemia is confirmed by findings of immature blast cells on a peripheral blood smear or bone marrow

aspirate.

- Cytogenetic analysis should be undertaken because cytogenetic abnormalities have prognostic indications and can be used to tailor treatment.
- Unlike adults, children with acute lymphoblastic leukemia generally have an excellent prognosis (90% survival). Children with acute myeloid leukemia have a more guarded prognosis (65% survival).

Chapter 156

Lymphoma

- Lymphomas are the third most common pediatric malignancy (following leukemia and central nervous system tumors).
- Hodgkin lymphoma peaks in the adolescent/young adult years (and again after age 50). It most commonly presents as painless, firm lymphadenopathy. Diagnosis is established by biopsy of an involved lymph node. It is highly curable, even with advanced disease.
- Non-Hodgkin lymphoma (NHL) incidence increases with age, is more common in whites, and has a male predominance. Distant, noncontiguous metastases are common in childhood NHL. Systemic chemotherapy is mandatory.

Chapter 157

Central Nervous System Tumors

- Most central nervous system (CNS) tumors in children and adolescents are primary tumors that originate in the CNS and include low-grade astrocytomas or embryonic neoplasms (such as medulloblastoma and CNS primitive neuroectodermal tumors).
- CNS tumors are the most common solid tumor in childhood and

are now the leading cause of childhood cancer deaths.

- Lethargy, headache, ataxia, and morning vomiting are common presenting symptoms of brain tumors; these symptoms should prompt consideration for imaging the brain (computed tomography [CT] and/or magnetic resonance imaging [MRI]).
- Treatment is individualized and may include surgery, chemotherapy, and/or radiation therapy. Radiation therapy is often delayed or avoided in young children.
- The 5-year survival is improving. It is now 50-60%, resulting, in large part, because of the curability of cerebellar astrocytomas and the increasing cure rate for medulloblastoma.

Chapter 158

Neuroblastoma

- Neuroblastoma is the most common malignancy in infancy.
 - Compared with toddlers and older children, infants with neuroblastoma are generally well, have less aggressive disease, and an excellent prognosis.
- The most common presentation of neuroblastoma is an abdominal mass or pain.
- Children with high-risk neuroblastoma have a guarded prognosis, even with aggressive treatment including chemotherapy, surgery, radiation therapy, retinoid acid, and immunotherapy.

Chapter 159

Wilms Tumor

- Wilms tumor is thought to arise from primitive, metanephric blastema.
 - Over 70% of Wilms tumors demonstrate loss of

imprinting or loss of heterozygosity at 11p15.

- The most common presentation is an abdominal mass.
- Treatment of Wilms tumor is nephrectomy and chemotherapy with or without radiation therapy.
- The overall survival rate is 90%, although 25% of survivors experience chronic health problems.

Chapter 160

Sarcomas

- There are two types of sarcomas: soft tissue sarcomas (rhabdomyosarcoma) or bone cancers (osteosarcoma, Ewing sarcoma).
- Sarcomas originating in the bone, such as osteosarcoma and Ewing sarcoma, usually present with a mass and/or pain.
- Prognostic factors for patients with sarcomas include the presence or absence of metastases, the extent of surgical resection, and the response to chemotherapy (usually measured by the amount of tumor necrosis).
 - Survival in patients with localized rhabdomyosarcoma is excellent following surgery and chemotherapy.
 - Patients with osteosarcoma with >90% tumor necrosis following chemotherapy have a >80% survival rate (50% survival if <90% tumor necrosis).
 - Overall survival for localized osteosarcoma or Ewing sarcoma is 60-70%.
 - Survival with lung metastases is ~30%.
 - Survival with metastases to other bones is <20%.

CHAPTER 161

Nephrology and Urology Assessment

The kidneys preserve homeostasis through (1) maintaining fluid and electrolyte balance; (2) excreting metabolic waste products through glomerular filtration and tubular secretion; (3) generating energy (gluconeogenesis); and (4) producing important endocrine hormones (renin, vitamin D metabolites, erythropoietin). Renal disorders, by disturbing homeostasis, can affect growth and development and cause a variety of clinical manifestations ([Table 161.1](#)). Renal disorders in children may be intrinsic renal diseases or derive from systemic conditions ([Table 161.2](#)).

TABLE 161.1

Common Manifestations of Renal Disease by Age

FINDING	SIGNIFICANCE
NEONATE	
Flank mass	Multicystic dysplasia, UT obstruction (hydronephrosis), polycystic disease, tumor
Hematuria	UTI, acute tubular/cortical necrosis, UT malformation, trauma, renal vein thrombosis
Anuria and oliguria	Renal agenesis, obstruction, acute tubular necrosis, vascular thrombosis
CHILD/ADOLESCENT	
Cola red-colored urine	Hemoglobinuria (hemolysis), myoglobinuria (rhabdomyolysis), pigmenturia (porphyria, urate, beets, drugs), hematuria (UTI, GN, Henoch-Schönlein purpura, hypercalciuria, stones)
Gross hematuria	UTI, GN, trauma, benign hematuria, nephrolithiasis, tumor
Edema	Nephrotic syndrome, GN, acute/chronic renal failure, cardiac/liver disease

Hypertension	Acute GN, acute/chronic renal failure, obstruction, cysts, dysplasia, coarctation of the aorta, renal artery stenosis
Polyuria	Diabetes mellitus, central and nephrogenic diabetes insipidus, obstruction, dysplasia, hypokalemia, hypercalcemia, psychogenic polydipsia, sickle disease/trait, polyuric renal failure, diuretic abuse
Oliguria	Dehydration, acute tubular necrosis, acute GN, interstitial nephritis, hemolytic uremic syndrome
Dysfunctional voiding/urgency	Neurogenic bladder, UTI, vaginitis, hypercalciuria, foreign body

GN, Glomerulonephritis; UT, Urinary tract; UTI, urinary tract infection.

TABLE 161.2

Primary and Systemic Causes of Renal Disease in Children

PRIMARY	SECONDARY (SYSTEMIC)
Minimal change nephrotic syndrome	Postinfectious glomerulonephritis
Focal segmental glomerulosclerosis	IgA nephropathy
Membranoproliferative glomerulonephritis	Henoch-Schönlein purpura-related nephritis Membranoproliferative glomerulonephritis (related to chronic infection, liver disease)
Membranous nephropathy	Hemolytic uremic syndrome Systemic lupus erythematosus Granulomatosis with polyangiitis and other vasculitides
Congenital nephrotic syndrome	Tubular toxins
Alport syndrome	Antibiotics
Intrinsic tubular disorders	Chemotherapeutic agents
Structural renal disorders	Hemoglobin/myoglobin
Congenital urinary tract abnormalities	Tubular disorders
Polycystic kidney disease	Cystinosis, oxalosis
Renal/urinary tract tumor	Galactosemia, hereditary fructose intolerance
	Stones
	Sickle disease/trait
	Trauma
	Extrarenal malignancy (leukemia, lymphoma)

Ig, Immunoglobulin.

History

Fetal urine production contributes to amniotic fluid volume, lung maturation, and somatic development. Congenital renal disorders may be associated with reduced (oligohydramnios) or increased amniotic fluid volume

(polyhydramnios). Pulmonary hypoplasia and fetal maldevelopment of the face and extremities may result from insufficient amniotic fluid (Potter syndrome; see [Chapters 58](#) and [60](#)).

Risk factors for renal disease (e.g., perinatal hypoxia-ischemia, acute tubular necrosis, renal vein thrombosis) can often be detected by a careful history. A detailed family history may identify hereditary renal conditions. Poor growth and/or feeding and abnormal fluid intake and/or output may indicate underlying renal dysfunction. Common manifestations of renal and urinary tract disorders are listed in [Table 161.1](#).

Physical Examination

Renal diseases in children may be initially asymptomatic and detected during routine visits. Abnormal growth, hypertension (HTN), dehydration, or edema may suggest underlying renal disease (see [Chapter 33](#)). Abnormal facial features may suggest syndromes associated with renal disorders (fetal alcohol syndrome, Down syndrome). Preauricular tags, external ear deformities, or ophthalmological abnormalities (keratoconus, aniridia, iridocyclitis, cataracts) can be associated with congenital renal defects. Abdominal examination may reveal renal masses or bladder distention due to urine-concentrating defect or urinary tract obstruction.

Renal Physiology

Normal renal function depends on intact **glomerular filtration** and **tubular function** (**proximal tubule** [PT], **loop of Henle**, and **distal tubule** [DT]) to produce **urine** ([Fig. 161.1](#)). Net glomerular pressure favors movement of fluid out of glomerular capillaries into Bowman's space. Intraglomerular pressure is regulated by afferent and, particularly, efferent arteriolar tone. **Renin** is generated by cells in the juxtaglomerular apparatus, located at the base of each glomerulus near the afferent/efferent arterioles and DT of that nephron. Renin is released in response to glomerular flow and perfusion.

FIGURE 161.1 Major transport functions of each nephron segment, including representative osmolalities in vasa recta, interstitium, and tubule at different levels within the kidney. *ADH*, Antidiuretic hormone; *Glu*, glucose; *OA*, organic acid. (From Andreoli TE, Carpenter CCJ, Plum F, et al., ed. *Cecil Essentials of Medicine*. Philadelphia: WB Saunders;1986.)

The PT conducts isosmotic reabsorption (see Fig. 161.1) to reclaim two thirds of filtered volume, sodium, and chloride. Glucose, amino acids, potassium, and phosphate are almost completely reabsorbed. Approximately 75% of filtered bicarbonate is reabsorbed in the PT. When filtered bicarbonate exceeds the PT threshold, it is spilled into the urine. The PT also secretes compounds such as organic acids, penicillins, and other drugs. The most potent vitamin D analog—1,25(OH)₂-cholecalciferol (**calcitriol**)—is produced by PT cells in response to parathyroid hormone and intracellular calcium/phosphorus concentrations.

The loop of Henle is the site of reabsorption of 25% of filtered sodium chloride (see Fig. 161.1). Active chloride transport drives the countercurrent multiplier and constructs the medullary interstitial hypertonic gradient required for urinary concentration.

The DT is composed of the **distal convoluted tubule** (DCT) and **collecting ducts (CD)**. The DCT is water impermeable and contributes to urine dilution by active sodium chloride absorption. The CD is the primary site of **antidiuretic hormone** (vasopressin) response, which leads to urine concentration. Sodium-potassium and sodium-hydrogen exchange in the CD is regulated by aldosterone. Active hydrogen ion secretion, responsible for final acidification of the urine, also occurs in the CD.

Renal **ammonia** production and intraluminal generation of ammonium (NH_4^+) facilitate urine hydrogen ion excretion. Urinary NH_4^+ is not easily measured but can be inferred by calculation of the **urinary anion gap**. The *gap* between measured anions and cations largely consists of NH_4^+ . Problems with renal acid excretion or ammonia production decrease the urinary anion gap. A urinary gap of approximately 1 mEq/kg body weight is typical in normal children.

Maximum **urinary concentrating capacity** in a preterm newborn (~400 mOsm/L) is less than in a full-term newborn (600-800 mOsm/L), which is less than in older children and adults (~1,200 mOsm/L). Neonates can dilute urine similar to adults (75-90 mOsm/L), but because **glomerular filtration rate** (GFR) is lower, the capacity to excrete a water load is less in infants. GFR reaches adult levels by 1-2 years of age. Tubular reabsorption of sodium, potassium, bicarbonate, and phosphate and excretion of hydrogen are all reduced in infants relative to adults. These functions mature independently and at different ages, so a neonate rapidly develops the ability to reabsorb sodium efficiently, but it takes 2 years for bicarbonate reabsorption to mature. **Erythropoietin** is secreted by interstitial cells in the renal medulla in response to low oxygen delivery and helps regulate bone marrow red blood cell production.

Common Manifestations

Decision-Making Algorithms

Dysuria
Enuresis
Red Urine and Hematuria

Renal disorders can be classified as **primary** or **secondary** (due to systemic

illnesses; see [Table 161.2](#)). Renal diseases may present with obvious signs (hematuria or edema), or with subtle signs detected on screening examinations (abdominal or flank mass, HTN, proteinuria). Fever, irritability, and vomiting may be presenting symptoms in neonates and infants with **urinary tract infections** (UTIs), whereas frequency and dysuria suggest UTI in older children. Chronic kidney disease is often associated with poor growth and feeding, but may be initially detected on screening examinations (HTN, hematuria). An abnormal urine stream may indicate posterior urethral valves other obstructive lesions or bladder disorders.

Diagnostic Studies

Laboratory Studies

GFR is measured most *accurately* by infusion of a substance that is *freely* filtered by the glomerulus but not metabolized, reabsorbed, or secreted in or by the tubules. GFR is calculated as follows:

$$\text{GFR} = [U]V/[P]$$

where $[U]$ is urine concentration, $[P]$ is serum concentration of a substance (mg/dL) used to measure clearance, and V is urine flow rate (mL/min).

By convention, GFR is corrected to body surface area of 1.73 m^2 to allow comparison between different-sized individuals. In a full-term newborn, an uncorrected GFR of 4-5 mL/min corrects to approximately 40 mL/min per 1.73 m^2 . GFR increases rapidly during the first 2 years of life until it achieves adult values (100-120 mL/min per 1.73 m^2). After that, GFR and body size increase proportionately, so $\text{GFR}/1.73 \text{ m}^2$ remains stable.

Plasma creatinine reflects muscle mass, increases with age, and is used to approximate GFR. Creatinine is also secreted by the PT, resulting in less accurate measurement of GFR with immature kidneys or with decreased renal function. **Blood urea nitrogen** is affected by renal function, but is also affected by hydration, nutrition, catabolism, and tissue breakdown. The correlation between creatinine and GFR can be used to estimate GFR. The revised Schwartz formula is the following:

$$\text{GFR} = \frac{0.413 \times \text{Ht}}{\text{Cr}_{\text{serum}}}$$

(height in cm; serum creatinine in mg/dL). This formula is most useful when body habitus and muscle mass are reasonably normal and when renal function is relatively stable. This formula is most accurate in GFR range of 15-75 mL/min per 1.73 m². Values greater than 75 are typically reported as greater than 75 rather than as a specific number. **Creatinine clearance** ($[U_{Cr}]V/[P_{Cr}]$) estimates GFR, but overestimates GFR when renal function is decreased.

Urinalysis is a useful screen for renal abnormalities. In addition to urine color and turbidity, **macroscopic urinalysis** uses a **urine dipstick** for pH and the presence of protein, glucose, ketones, blood, and leukocytes. Dilute urine may result in a false-negative result for protein; false-positive results may occur with extremely alkaline or concentrated urine or if there is a delay in reading the test. Dipsticks are exquisitely sensitive to presence of hemoglobin (or myoglobin); there are few false-negative test results but many false-positive results. **Glucose** is detected via glucose oxidase-peroxidase reaction, and leukocytes are detected via **leukocyte esterase** reaction. The **nitrite test** may detect bacteriuria if the bacteria can reduce nitrate to nitrite and have sufficient urine contact time. False-negative results occur with frequent voiding, low urine bacterial count, urinary tract obstruction, and infection with bacteria unable to generate nitrite. Gross hematuria or prolonged contact (uncircumcised boys) may result in a false-positive nitrite test. **Microscopic urinalysis** is used to confirm pyuria and hematuria and detect casts and crystals.

Proteinuria can be further defined by a **spot urine protein/creatinine** (U_{Pr}/Cr) in a single urine specimen. This unit-less value correlates very well with 24-hour urine protein excretion: spot U_{Pr}/Cr approximates 24-hour urine protein/m² per day (normal <0.20; nephrotic range >2.0 in children).

Imaging Studies

Ultrasound reliably assesses kidney size, determines degree of dilation, and differentiates cortex and medulla. The bladder also can be visualized. **Pulsed Doppler studies** assess arterial and venous blood flow and can provide the vascular resistive index in each kidney.

A **voiding cystourethrogram** involves filling of the bladder to detect vesicoureteral reflux and to evaluate the urethra. **Computed tomography** and

magnetic resonance imaging have mostly replaced the **intravenous pyelogram** to evaluate kidney structure and function. Radionuclide studies can define renal size, scars, and renal function/excretion.

CHAPTER 162

Nephrotic Syndrome and Proteinuria

Etiology and Epidemiology

Small amounts of protein are found in urine of healthy children ($<4 \text{ mg/m}^2$ per hour or $U_{\text{Pr/Cr}} < 0.2$). **Nephrotic proteinuria** in children is defined as protein $>40 \text{ mg/m}^2$ per hour or $U_{\text{Pr/Cr}} > 2.0$. Proteinuria between these levels is mildly to moderately elevated but not nephrotic.

Proteinuria may be **transient** or **persistent**, **asymptomatic** or **symptomatic**, and **orthostatic** (present in the upright position but not in the recumbent position) or **fixed** (present in all positions). Proteinuria may be **glomerular** (disruptions of the normal glomerular barrier to protein filtration) or **tubular** (increased filtration, impaired reabsorption, or secretion of proteins).

Nephrotic syndrome (NS) is characterized by persistent heavy **proteinuria** (mainly albuminuria; $>2 \text{ g/m}^2$ per 24 hour); **hypoproteinemia** (serum albumin $<3.0 \text{ g/dL}$); **hypercholesterolemia** ($>250 \text{ mg/dL}$); and **edema**. Age, race, and geography affect the incidence of NS. Certain human leukocyte antigen (HLA) types (HLA-DR7, HLA-B8, and HLA-B12) are associated with increased incidence of NS. Increased glomerular permeability is due to alterations in the normal glomerular cellular and basement membrane barrier that restrict serum protein filtration. The resultant massive proteinuria leads to decreased serum proteins, especially albumin. Plasma oncotic pressure is diminished, leading to fluid shifts from vascular to interstitial compartments and plasma volume contraction. Renal blood flow and glomerular filtration rate are not usually diminished. Edema results from reduction in effective circulating blood volume and increase in tubular sodium chloride reabsorption secondary to activation of the renin-angiotensin-aldosterone system. Hypoproteinemia stimulates hepatic lipoprotein synthesis and diminishes lipoprotein metabolism, leading to elevated serum lipids (cholesterol, triglycerides) and lipoproteins.

NS may be **primary** or **secondary** (Table 162.1). A child with apparent primary NS, prior to renal biopsy, is considered to have **idiopathic nephrotic syndrome**. **Minimal change nephrotic syndrome** (MCNS) is the most common histological form of primary NS in children. More than 80% of children less than 7 years of age with NS have MCNS. Children 7-16 years old with NS have a ~50% chance of having MCNS. Males are affected more frequently than females (2 : 1).

TABLE 162.1

Primary and Secondary Forms of Nephrotic Syndrome

PRIMARY	SECONDARY
Minimal change nephrotic syndrome Primary focal glomerulosclerosis Membranoproliferative glomerulonephritis Idiopathic membranous nephropathy	Systemic lupus erythematosus Henoch-Schönlein purpura, Granulomatosis with polyangiitis and other vasculitides Chronic infections (hepatitis B, hepatitis C, malaria, human immunodeficiency virus) Allergic reactions Diabetes Amyloidosis Malignancies Congestive heart failure, constrictive pericarditis Renal vein thrombosis

Focal segmental glomerulosclerosis (FSGS) accounts for ~10-20% of children with primary NS. It may present like MCNS or with less impressive proteinuria. FSGS may develop from MCNS or represent a separate entity. A circulating factor that increases glomerular permeability is found in some patients with FSGS. More than 35% of children with FSGS progress to renal failure.

Membranoproliferative glomerulonephritis (MPGN) is characterized by hypocomplementemia with signs of glomerular renal disease. MPGN represents 5-15% of children with primary NS, is typically persistent, and has a high likelihood of progression to renal failure over time.

Membranous nephropathy represents <5% of children with primary NS. It is seen most commonly in adolescents and children with systemic infections (hepatitis B, syphilis, malaria, and toxoplasmosis) or specific medications (gold, penicillamine).

Congenital NS presents during the first 2 months of life. There are two common types. The Finnish type is an autosomal recessive disorder most common in persons of Scandinavian descent and is due to a mutation in the

nephrin protein component in the glomerular filtration slit. The second type is a heterogeneous group of abnormalities, including diffuse mesangial sclerosis and conditions associated with drugs or infections. Prenatal onset is supported by elevated levels of maternal alpha-fetoprotein.

Secondary NS may result from many different causes in children and are listed in [Table 162.1](#).

Clinical Manifestations

Decision-Making Algorithms

Abdominal Pain
Red Urine and Hematuria
Proteinuria
Edema

The sudden onset of dependent pitting edema or ascites is the most common presentation for children with NS. Anorexia, malaise, and abdominal pain are often present. Blood pressure may be elevated in up to 25% of children on presentation; acute tubular necrosis and significant hypotension may occur with sudden decline in serum albumin and significant volume depletion. Diarrhea (intestinal edema) and respiratory distress (pulmonary edema or pleural effusion) may be present. Typical MCNS is characterized by *absence* of gross hematuria, renal insufficiency, hypertension (HTN), and hypocomplementemia.

Diagnostic Studies

Proteinuria of 1+ or higher on 2-3 random urine specimens suggests persistent proteinuria that should be further quantified. A $U_{Pr}/Cr > 0.2$ on a first morning specimen excludes orthostatic proteinuria. $U_{Pr}/Cr > 2.0$ indicates nephrotic range proteinuria.

In addition to a demonstration of proteinuria, hypercholesterolemia, and hypoalbuminemia, routine testing typically includes a serum C3 complement. A low serum C3 implies a lesion other than MCNS, and a renal biopsy is indicated before trial of corticosteroid therapy. Microscopic hematuria may be present in

up to 25% of cases of MCNS but does not predict response to steroids. Additional laboratory tests, including electrolytes, blood urea nitrogen, creatinine, total protein, and serum albumin level, are performed based on history and physical examination features. Renal ultrasound is often useful. Biopsy is performed when MCNS is not suspected.

Differential Diagnosis

Transient proteinuria can be seen after vigorous exercise, fever, dehydration, seizures, and adrenergic agonist therapy. Proteinuria usually is mild ($U_{Pr}/Cr < 1$), glomerular in origin, and always resolves within a few days. It does not indicate renal disease.

Postural (orthostatic) proteinuria is a benign condition defined by normal protein excretion while recumbent but significant proteinuria when upright. It is glomerular in origin, more common in adolescents and tall, thin individuals, and not associated with progressive renal disease. Many children with orthostatic proteinuria continue this process into adulthood.

Tubular proteinuria is characterized by preponderance of urine low molecular weight proteins and is seen with acute tubular necrosis, pyelonephritis, structural renal disorders, polycystic kidney disease, and tubular toxins such as antibiotics or chemotherapeutic agents. The combination of tubular proteinuria with tubular electrolyte wasting and glycosuria is termed **Fanconi syndrome**.

Glomerular proteinuria is characterized by a combination of urine large and small molecular weight proteins, variable levels of proteinuria, and often other evidence of glomerular disease (hematuria, red blood cell casts, HTN, and renal insufficiency). Causes of glomerular proteinuria include glomerular capillary disruption (hemolytic uremic syndrome, crescentic glomerulonephritis); glomerular capillary immune complex deposition (poststreptococcal glomerulonephritis and lupus nephritis); and altered glomerular capillary permeability (MCNS, congenital NS).

Treatment

Because greater than 80% of children less than 13 years of age with primary NS have steroid-responsive forms (chiefly MCNS), steroid therapy may be initiated without a renal biopsy if a child has typical features of NS. Typical therapy for

MCNS is prednisone, 2 mg/kg per day (60 mg/m² per 24 hour, maximum 60 mg/day), provided once a day or split into multiple doses. Over 90% of children who respond to steroids do so within 4 weeks. Responders should receive steroids for 12 weeks for best long-term results. A renal biopsy is indicated for nonresponders because steroid resistance decreases the chance that MCNS is the underlying disease. Frequent relapses or steroid resistance may necessitate additional immunosuppressive therapy.

Treatment responses in FSGS are highly variable. Approximately 35% respond to steroid therapy; others may respond to immunosuppressive therapy. MPGN and membranous glomerulonephritis often improve with chronic steroid or immunosuppressive therapy but do not reliably remit with standard NS steroid therapy. Aggressive medical therapy of familial congenital NS, with early nephrectomy, dialysis, and transplantation, is the only effective approach to this syndrome.

NS edema is treated by restricting salt intake. Severe edema may require use of loop diuretics. When these therapies do not alleviate severe edema, cautious parenteral administration of 25% albumin (0.5-1.0 g/kg intravenously over 1-2 hours) with an intravenous loop diuretic usually results in diuresis. The administered albumin is excreted rapidly, and thus salt restriction and diuretics must be continued. Significant pleural effusions may require drainage. Acute HTN is treated with β -blockers or calcium channel blockers. Persistent HTN usually responds to angiotensin-converting enzyme inhibitors.

Complications

An increased incidence of serious infections, particularly **bacteremia** and **peritonitis** (particularly *Streptococcus pneumoniae*, *Escherichia coli*, or *Klebsiella*), is due to urinary loss of immunoglobulins and complement. Side effects of steroids are most common in steroid-dependent and frequently relapsing patients. Hypovolemia may result from diarrhea or diuretic use. Loss of coagulation factors, antithrombin, and plasminogen may lead to a hypercoagulable state with a risk of **thromboembolism** (TE). Warfarin, Lovenox, low-dose aspirin, or dipyridamole may minimize risk of thrombosis in NS patients with a history of TE or high risk for TE. Hyperlipidemia promotes increased atherosclerotic vascular disease.

Prognosis

Most children with NS eventually go into remission. Nearly 80% of children with MCNS experience NS relapse, defined as heavy proteinuria that persists for 3 or more consecutive days. Transient proteinuria (up to 3 days) may occur with intercurrent infection in children with MCNS and is not considered a relapse. Steroid therapy is typically effective for true relapse. Steroid-responsive patients have little risk of chronic renal failure. Patients with FSGS may initially respond to steroids but later develop resistance. Many children with FSGS progress to end-stage kidney failure (see [Chapter 165](#)). Recurrence of FSGS occurs in ~30% of children who undergo renal transplantation.

CHAPTER 163

Glomerulonephritis and Hematuria

Etiology and Epidemiology

A child with **gross hematuria** may have a serious disease and requires prompt evaluation. **Microscopic hematuria**, defined as >3-5 red blood cells (RBCs) per high-power field on freshly voided and centrifuged urine, can be benign. Isolated asymptomatic microscopic hematuria is found in up to 4% of healthy children. In most cases this is a transient finding. Hematuria may originate from glomerular, tubulointerstitial, or lower urinary tract disorders ([Table 163.1](#)).

TABLE 163.1

Differential Diagnosis of Red Urine/Hematuria

FACTITIOUS HEMATURIA

- Nonpathological (urate crystals in infants, ingested foods, medications, dyes)
- Pathological (hemoglobinuria from hemolytic anemia, myoglobinuria from rhabdomyolysis)

GLOMERULAR

- Immunological injury (GN—e.g., PSGN, IgA nephropathy, MPGN, systemic diseases)
- Structural disorder (Alport syndrome, thin basement membrane disease)
- Toxin-mediated injury (HUS)

TUBULOINTERSTITIAL/PARENCHYMAL

- Inflammation (interstitial nephritis, pyelonephritis)
- Vascular (sickle cell trait/disease, Nutcracker syndrome)
- Structural (cyst rupture, Wilms tumor, urinary tract obstruction, renal trauma)

LOWER URINARY TRACT

Inflammation (cystitis, hemorrhagic cystitis, urethritis)
Injury (trauma, kidney stone)
Hypercalciuria

GN, Glomerulonephritis; *HUS*, hemolytic uremic syndrome; *Ig*, immunoglobulin; *MPGN*, membranoproliferative glomerulonephritis; *PSGN*, poststreptococcal glomerulonephritis.

Immune-mediated inflammation causes most **glomerulonephritis** (GN). Poststreptococcal glomerulonephritis (PSGN) is the most common form of acute GN, and immunoglobulin (Ig)A nephropathy is the most common chronic GN, but many other types of GN can occur. The most common identifiable lower urinary tract causes of hematuria include urinary tract infection (UTI), kidney stones, and hypercalciuria.

Clinical Manifestations

Decision-Making Algorithms

Red Urine and Hematuria
Proteinuria
Edema
Hypertension

Children with **acute GN** commonly present with hematuria (gross or microscopic) and other cardinal features of glomerular injury (proteinuria, hypertension, edema, oliguria, renal insufficiency). **PSGN** occurs most frequently in children 2-12 years of age and is more common in boys. Manifestations of PSGN are typical of acute GN and develop 5-21 days (average 10 days) after streptococcal pharyngitis infections and 4-6 weeks after impetigo. **Acute postinfectious GN** presents similar to PSGN following infections with other bacterial and viral pathogens. PSGN can develop even in the child treated with antibiotics for the infection. Special attention must be paid to the blood pressure as hypertension may be severe enough to cause heart failure, seizures, and/or encephalopathy.

The presentation of **IgA nephropathy** is more variable and may take the form of acute GN, asymptomatic microscopic hematuria, or recurrent gross hematuria concurrent with an upper respiratory infection (rather than several days later, as

with PSGN). Children with hematuria secondary to systemic disorders such as Henoch-Schönlein purpura nephritis, lupus nephritis, and vasculitis-associated GN typically present with other systemic features of the respective disease.

A special form of GN is **rapidly progressive glomerulonephritis (RPGN)** that presents with typical features of acute GN where renal insufficiency progresses more quickly and severely. Renal biopsy shows glomerular epithelial cell proliferation with crescents. RPGN may be idiopathic or secondary to any type of GN. Early recognition of RPGN is crucial to prevent progression to end-stage renal disease (ESRD) that occurs without prompt treatment.

Alport syndrome is typically caused by X-linked chromosome mutations, but has also been associated with mutations of genes for type IV collagen, both leading to abnormal glomerular basement membrane (GBM). The disease may present with either asymptomatic microscopic or gross hematuria. Males typically develop progressive renal failure and sensorineural hearing loss during adolescence and young adulthood. Females typically have a more benign course but usually have at least microscopic hematuria. **Thin basement membrane disease** (benign familial hematuria) is caused by mutations leading to isolated GBM thinning; these mutations are often autosomal dominant with hematuria frequently noted in first-degree relatives. As opposed to Alport syndrome, thin basement membrane disease is typically not progressive and usually has an excellent prognosis.

The presentation of nonglomerular causes of hematuria is more variable and related to the underlying etiology. Hematuria due to tubular disorders is usually microscopic and may be associated with proteinuria, glycosuria, and polyuria. These children typically do not have hypertension and develop renal insufficiency only with more severe disease. Painless gross hematuria may be seen with strenuous exercise, sickle cell trait/disease, or Wilms tumor. Hematuria may be associated with pain when due to bleeding from renal cysts or Nutcracker syndrome (renal vein compression). Gross hematuria following trauma may signify more severe renal or lower urinary tract injury. **UTI** is typically associated with dysuria and urinary frequency. **Urolithiasis** may be associated with asymptomatic hematuria or with flank or abdominal pain. **Hypercalciuria** can cause both gross and microscopic hematuria and may be associated with urinary tract symptoms such as dysuria and urinary frequency or may be asymptomatic.

Diagnostic Studies

All patients with hematuria should have a careful history and physical (including blood pressure) along with urinalysis including microscopic examination to identify RBCs. Glomerular hematuria is suggested by brownish (tea- or cola-colored) urine and presence of RBC casts and/or dysmorphic RBCs on urine microscopy. A urine color that is more bright red without RBC casts or dysmorphic RBCs is more suggestive of lower urinary tract source. However, there may be overlap of these findings.

A suggested algorithm for the evaluation of hematuria is given in [Fig. 163.1](#). Gross hematuria and microscopic hematuria with associated concerning findings should have additional laboratory evaluation. Presence of low C3 complement narrows the differential diagnosis to PSGN, membranoproliferative GN, and lupus nephritis. Children with isolated, asymptomatic microscopic hematuria may be observed with repeat urinalyses. If hematuria is persistent, additional evaluation may then be appropriate.

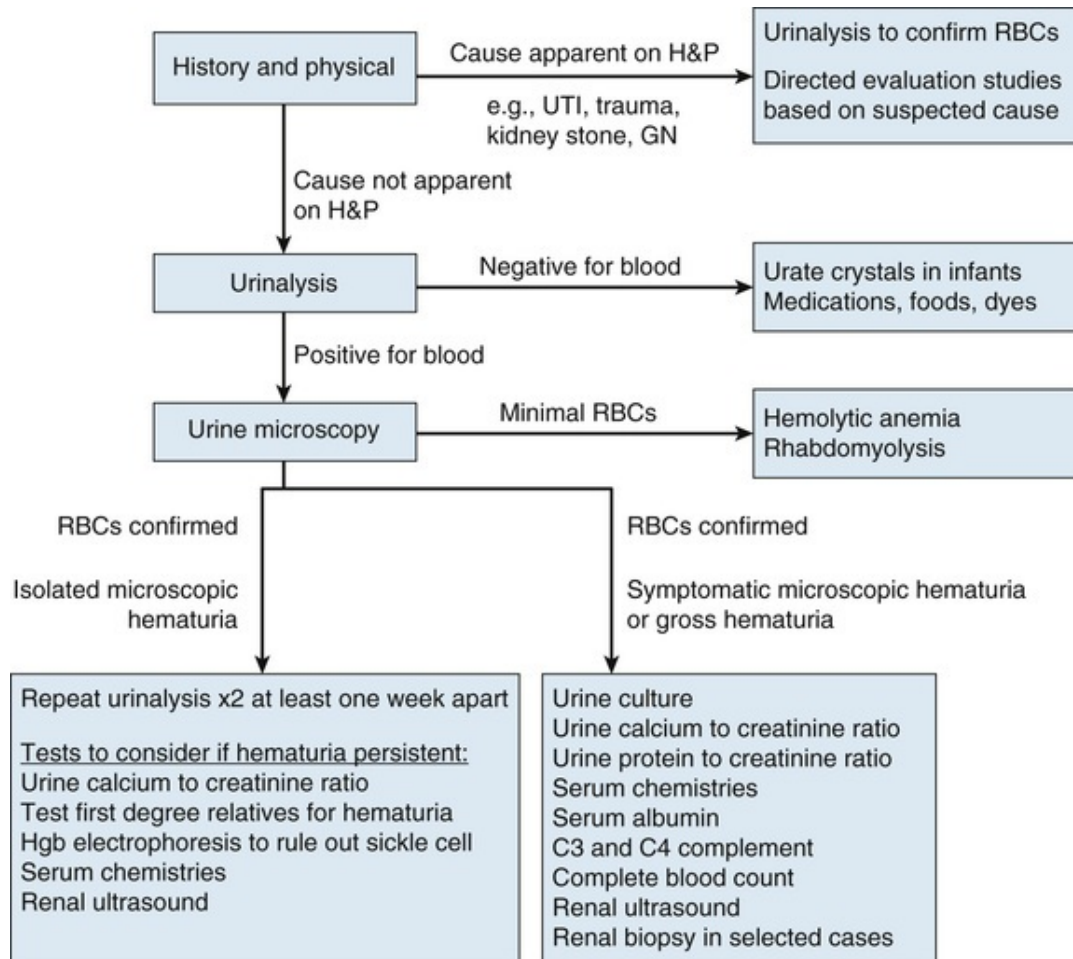

FIGURE 163.1 Suggested algorithm for evaluation of red urine/hematuria. *GN*, Glomerulonephritis; *Hgb*, hemoglobin; *H&P*, history and physical; *RBCs*, red blood cells; *UTI*, urinary tract infection.

Therapy

Therapy for PSGN is supportive and involves dietary sodium restriction, diuretics, and antihypertensive agents as needed. Although treating the streptococcal infection does not prevent PSGN, antibiotic treatment is still warranted with active streptococcal infection. Therapies for children with other forms of GN depend on underlying cause and severity. In some cases, antiinflammatory therapy involving corticosteroids and/or other immunosuppressive agents may be warranted. Treatment with angiotensin-converting enzyme inhibitors may reduce proteinuria and glomerular hyperperfusion, but should be used with caution in the setting of acute kidney injury.

Prognosis and Prevention

PSGN usually has a benign outcome. In typical cases, the gross hematuria, proteinuria, and edema decline quickly (5-10 days). Microscopic hematuria may persist for months or even years; greater than 95% of children recover completely with no long-term sequelae.

Children with IgA nephropathy and other forms of chronic GN have greater risk of progression to ESRD. The prognosis for renal recovery in chronic GN and in RPGN is variable and related to the underlying disorder and disease severity. The presence of persistent, heavy proteinuria, hypertension, decreased kidney function, and severe glomerular lesions on biopsy is associated with poor outcomes.

Children with idiopathic isolated, asymptomatic microscopic hematuria or suspected thin basement membrane disease typically have an excellent renal prognosis. Long-term follow-up, including yearly urinalysis (to rule out proteinuria) and blood pressure measurement, is required to exclude progressive forms of renal disease.

CHAPTER 164

Hemolytic Uremic Syndrome

Etiology and Epidemiology

Hemolytic uremic syndrome (HUS) is characterized by the triad of **microangiopathic hemolytic anemia, thrombocytopenia, and renal injury** and is an important cause of acute kidney injury in children. HUS typically occurs in children less than 5 years of age, but can occur in older children. The most common type of HUS is associated with a prodromal diarrheal illness (**D + HUS**). Contamination of meat, fruit, vegetables, or water with verotoxin (VT)-producing *Escherichia coli* (most commonly *E. coli* O157:H7) is responsible for many outbreaks. VT may be produced by other *E. coli* strains as well as other bacteria such as *Shigella*. VT causes hemorrhagic enterocolitis of variable severity and results in HUS in ~5-15% of affected children.

HUS presenting without a prodrome of diarrhea (**atypical HUS**) may occur at

any age. The clinical course is usually more severe than D + HUS. Atypical HUS can be secondary to infection (*Streptococcus pneumoniae*, human immunodeficiency virus), genetic and acquired defects in complement regulation, medications, malignancy, systemic lupus erythematosus, and pregnancy.

Clinical Manifestations

Decision-Making Algorithms

Diarrhea
Petechiae/Purpura

Classic D + HUS begins with enterocolitis, often with bloody stools, followed in 7-10 days by weakness, lethargy, and oliguria/anuria. Physical examination reveals irritability, pallor, and petechiae. Dehydration is frequent; however, some children have volume overload. Hypertension may be due to volume overload and/or renal injury. Central nervous system (CNS) involvement, including seizures, occurs in up to 25% of cases. Other potential organ involvement includes pancreatitis, cardiac dysfunction, and colonic perforation.

Children without evidence of diarrheal prodrome may have a similar microangiopathic syndrome, identified as **thrombotic thrombocytopenic purpura** (TTP). Children with TTP typically have predominant CNS symptoms but may also have significant renal disease. Recurrent episodes are common. Because CNS involvement is also seen in HUS, TTP can be difficult to distinguish from HUS in some cases. Deficiencies of ADAMTS13, a von Willebrand factor-cleaving protease, have been identified in children affected with TTP.

Diagnostic Studies

Common laboratory findings in HUS are listed in [Table 164.1](#). Peripheral blood smear reveals evidence of microangiopathic hemolysis. Coombs test is negative. Diarrhea and presence of toxin-producing *E. coli* may have resolved by the time HUS is diagnosed.

TABLE 164.1

Common Laboratory Findings With Hemolytic Uremic Syndrome

EVIDENCE OF MICROANGIOPATHIC HEMOLYTIC ANEMIA Anemia Thrombocytopenia Presence of schistocytes, helmet cells, and burr cells on peripheral blood smear Increased LDH Decreased haptoglobin Increased indirect bilirubin Increased AST Elevated reticulocyte count
EVIDENCE OF RENAL INJURY Elevated creatinine Presence of hematuria, proteinuria, pyuria, casts on urinalysis
OTHER POTENTIAL FINDINGS Leukocytosis Positive stool culture for <i>E. coli</i> O157:H7 Positive stool test for shiga-toxin Elevated amylase/lipase

AST, Aspartate aminotransferase; *E. coli*, *Escherichia coli*; LDH, lactate dehydrogenase.

Treatment and Prognosis

Therapy for HUS is supportive and includes volume repletion, hypertension control, and managing complications of renal insufficiency, including dialysis when indicated. Red blood cell transfusions are provided as needed. Platelet transfusions should be avoided because they may add to the thrombotic microangiopathy and are indicated only by active hemorrhage or prior to a procedure. Antibiotics and antidiarrheal agents may increase risk of developing HUS. Early hydration during the diarrheal phase may lessen the severity of renal insufficiency. Most children (>95%) with D + HUS survive the acute phase and recover normal renal function, although some may have evidence of long-term renal and other morbidity.

CHAPTER 165

Acute and Chronic Renal Failure

Acute Kidney Injury

Etiology

Acute kidney injury (AKI), formerly termed *acute renal failure*, refers to an abrupt decrease in glomerular filtration rate (GFR) and tubular function. This may lead to decreased excretion of waste products (e.g., urea) and disturbance in fluid and electrolyte homeostasis. Early recognition and management of AKI are crucial.

AKI may be **oliguric** (<1 mL/kg/hr in neonates and infants, <0.5 mL/kg/hr in children) or **nonoliguric**, which is more difficult to recognize. Although urine output in nonoliguric AKI is normal or polyuric, electrolyte disturbances and uremia may become significant. Major causes of AKI may be divided into **prerenal** (renal hypoperfusion), **intrinsic renal** (tubular, glomerular, or vascular injury), and **postrenal** (urinary tract obstruction) categories ([Table 165.1](#)). In many cases, the cause of AKI is multifactorial.

TABLE 165.1

Causes of Acute Kidney Injury

PRERENAL
Dehydration
Hemorrhage
Septic shock
Burns
Heart failure
Cirrhosis
POSTRENAL (OBSTRUCTION)
Urethral obstruction (stricture, posterior urethral valves)
Ureteral obstruction
Ureterocele
Extrinsic tumor compressing bladder outlet
Neurogenic bladder (myelomeningocele, spinal cord injury)
INTRINSIC
Acute tubular necrosis
Nephrotoxins (medications, contrast, myoglobin)
Infection (sepsis)
Interstitial nephritis

Glomerular injury (primary glomerulonephritis, vasculitis, hemolytic uremic syndrome)
Vascular (renal vein thrombosis, arterial emboli, malignant hypertension)

Prerenal azotemia is most commonly due to **dehydration**, but may be secondary to other mechanisms of glomerular hypoperfusion. Tubular injury encompasses the most common causes of intrinsic AKI in children. Tubular injury may occur from hypoxia-ischemia (**acute tubular necrosis**), infection (**sepsis**), **nephrotoxic agents** (medications, contrast, myoglobin), and inflammation (**interstitial nephritis**). Postrenal AKI may be due to either structural or functional **urinary tract obstruction**.

Clinical Manifestations

Decision-Making Algorithm

Hypertension

History, physical examination, and basic studies usually allow proper classification of the child with AKI (Table 165.2). Prerenal azotemia is characterized by history of precipitating factors and oliguria. Intrinsic tubular injury is associated with precipitating factors, but urine output may be low, normal, or high, depending on the severity of the injury. Glomerular and vascular disorders may present with hematuria, edema, hypertension, and oliguria. The urine output with postrenal AKI may be low or normal and may be associated with flank masses or a distended bladder on examination. Depending on the underlying cause and severity of illness, AKI can be associated with signs of dehydration or volume overload.

TABLE 165.2

Laboratory and Clinical Evaluation of Acute Kidney Injury

LABORATORY/CLINICAL FEATURE	PRERENAL		RENAL		POSTRENAL
	CHILD	NEONATE	CHILD	NEONATE	
Urine output	Low		Low, normal, or high		Low or normal
Urinalysis	Normal		RBCs, WBCs, protein, casts		Variable
Urine Na ⁺ (mEq/L)	<15	<20-30	>40	>50	Variable, may b

					>40
FE _{Na} * (%)	<1	<2.5	>2	>2.5	Variable, may b
Urine osmolality (mOsm/L)	>500	>350	~300	~300	Variable, may b <300
Renal ultrasound	Normal		Increased echogenicity, decreased corticomedullary differentiation		Hydronephrosis

*FE_{Na} (%) = [(urine sodium/plasma sodium) ÷ (urine creatinine/plasma creatinine)] × 100.

FE_{Na}, Fractional excretion of sodium; *RBCs*, red blood cells; *WBCs*, white blood cells.

Diagnostic Studies

A **urinalysis** (UA) should be obtained in all children with AKI. In prerenal azotemia, UA is unremarkable with high specific gravity reflecting appropriate renal retention of water associated with renal hypoperfusion. However, neonates are not able to concentrate urine as well. With intrinsic tubular injury and postrenal AKI, UA may show mild hematuria and/or proteinuria with specific gravity 1.015 or less. With glomerular and vascular injury, hematuria and proteinuria are usually moderate to severe. In oliguric states, differentiation between prerenal azotemia and acute tubular necrosis may be aided by determining urine osmolality and fractional excretion of sodium (see [Table 165.2](#)). **Renal ultrasound** is often helpful in defining AKI category (see [Table 165.2](#)). Renal biopsy is indicated only in select cases.

Common electrolyte abnormalities seen with AKI include hyperkalemia, metabolic acidosis, hypocalcemia, and hyperphosphatemia. These labs may need to be monitored frequently, depending on initial results and clinical course. A complete blood count should be obtained as anemia is frequently observed. Other studies may be obtained as clinically indicated.

Treatment

In some cases the underlying disorder can be treated. Examples include volume repletion in dehydration, stopping an offending nephrotoxic medication, and relieving urinary tract obstruction. In all cases efforts should be made to limit additional renal injury (e.g., ensuring adequate renal perfusion and avoiding nephrotoxic medications). Medication dosages should be adjusted for decreased renal function as appropriate.

Fluid therapy depends on volume status and urine output. If hypovolemia is present, intravascular volume should be expanded by intravenous saline administration. If hypervolemia is present, 1-2 mg/kg of furosemide and fluid restriction may be attempted. If euvolemia is present, total fluid input should be adjusted to meet the urine output, which may be higher or lower than normal. Assessment of intake and output should be augmented with serial body weight measurements.

AKI treatment particularly involves management of potential complications. Electrolyte disorders are treated as appropriate. Potassium intake and medications that increase potassium should be restricted. If hyperkalemia is present, intravenous calcium will lower the risk of arrhythmia while measures are initiated to shift potassium into cells (bicarbonate, β -agonists, insulin/dextrose) and hasten removal (diuretics, sodium-potassium exchange resins, dialysis). Preferred treatment of hypocalcemia involves oral calcium supplementation and calcitriol; intravenous (IV) calcium is reserved for severe cases. Hypertension may be treated with diuretics, calcium channel blockers, and vasodilators. Angiotensin-converting enzyme (ACE) inhibitors are usually avoided in the setting of AKI.

Major indications for **acute dialysis** are listed in [Table 165.3](#). Medical therapy may be attempted before initiating renal replacement therapy. There is no set blood urea nitrogen or creatinine level at which dialysis is started in AKI. Renal replacement options in children include peritoneal dialysis, hemodialysis, and continuous renal replacement therapy. The mode is selected based on individual factors.

TABLE 165.3

Indications for Renal Replacement Therapy

<p>ACUTE AND/OR CHRONIC DIALYSIS</p> <ul style="list-style-type: none"> Volume overload Metabolic acidosis Electrolyte abnormalities Uremia <p>ACUTE DIALYSIS</p> <ul style="list-style-type: none"> Certain ingestions Hyperammonemia <p>CHRONIC DIALYSIS</p> <ul style="list-style-type: none"> Poor growth Stage 5 chronic kidney disease (end-stage renal disease)

Prognosis

Recovery from AKI depends on etiology, severity, availability of specific treatments, and other patient aspects. Nonoliguric AKI usually recovers well, whereas outcomes with oliguric AKI are more variable. Even with seemingly good recovery, a history of AKI places the child at increased risk for future renal complications, including chronic kidney disease (CKD).

Chronic Kidney Disease

Etiology and Epidemiology

Congenital anomalies of the kidney and urinary tract (CAKUT) are the most common causes of CKD that present between birth and 10 years of age. After age 10, acquired renal diseases, such as focal segmental glomerulosclerosis and glomerulonephritis (GN), are more common causes of CKD. Risk of progression to end-stage renal disease (ESRD) is related to the underlying cause and severity of CKD. During puberty, renal function may deteriorate if the damaged kidneys are not able to grow and adapt to increased demands. CKD is staged to facilitate appropriate evaluation and monitoring (Table 165.4). GFR can be estimated in children using the Schwartz formula (see Chapter 161). Most complications of CKD do not manifest until at least stage 3 CKD. In stage 4 CKD, complications become more numerous and severe. Children with stage 5 CKD (ESRD) are typically treated with either dialysis or renal transplantation.

TABLE 165.4

Classification of the Stages of Chronic Kidney Disease

STAGE	GFR (mL/min/1.73 m ²)*	DESCRIPTION
1	>90	Minimal kidney damage
2	60-89	Kidney damage with mild reduction of GFR
3	30-59	Moderate reduction of GFR
4	15-29	Severe reduction of GFR
5	<15 (or dialysis)	End-stage renal disease

*GFR ranges apply for children 2 years of age and older.

GFR, Glomerular filtration rate.

Clinical Manifestations

The clinical presentation of a child with CKD is related to both underlying cause and complications of CKD. A child with CAKUT may have polyuria, polydipsia, and recurrent urinary tract infections. A child with glomerular disease may have hematuria, proteinuria, edema, and hypertension. Common complications of CKD in children are listed in [Table 165.5](#). Most of these complications are multifactorial in etiology. For example, factors associated with **growth failure** include poor nutrition, **CKD-mineral bone disorder (CKD-MBD)**, metabolic acidosis, hormonal abnormalities, and resistance to growth hormone. **Anemia** results primarily from a failure to produce adequate **erythropoietin** and iron deficiency. CKD-MBD is usually due to **secondary hyperparathyroidism** as a result of diminished renal 1,25-dihydroxyvitamin D production, hypocalcemia, and hyperphosphatemia (from decreased renal excretion). If prolonged and/or severe, CKD-MBD may lead to rickets and bone deformities. **Hypertension** and **left ventricular hypertrophy** are common cardiovascular complications. Delayed puberty results from altered gonadotropin secretion and regulation. Learning and school performance may also be impaired in CKD.

TABLE 165.5

Common Complications and Treatments of Chronic Kidney Disease

COMPLICATION	TREATMENT
1. Poor growth	Increased caloric intake, treat acidosis, treat CKD-MBD, recombinant GH
2. Anemia	Erythropoietin, iron supplementation
3. CKD-Mineral Bone Disorder/secondary hyperparathyroidism	1,25-Dihydroxyvitamin D supplementation, calcium supplementation, dietary phosphorous restriction, phosphate binders
4. Cardiovascular	
4a. Hypertension	Antihypertensive medications
4b. Left ventricular hypertrophy	Volume control
5. Electrolyte abnormalities	
5a. Hyperkalemia	Low K diet, furosemide, sodium polystyrene sulfonate
5b. Hyponatremia	Sodium supplementation
5c. Metabolic acidosis	Alkali replacement

CKD, Chronic kidney disease; *CKD-MBD*, chronic kidney disease—mineral bone disorder; *GH*, growth hormone; *K*, potassium.

Treatment

The management of children with advanced CKD requires a multidisciplinary team of pediatric practitioners. Adequate nutrition should be provided even if this requires dietary supplements and tube feedings. In infants, a low-solute formula may be indicated. Unless a child is oliguric, fluid restriction is not necessary. Many children with CAKUT require supplemental salt due to urine sodium wasting. Conversely, children with GN tend to retain sodium and may become hypertensive or edematous if given excess salt. Common treatment considerations for other CKD complications are given in [Table 165.5](#).

Measures can be taken to preserve kidney function or slow progression of CKD. Hypertension and proteinuria can be treated with ACE inhibitors or angiotensin receptor blockers. Potentially nephrotoxic medications should be avoided when feasible. Medication adjustment for reduced kidney function is important. Protein intake is typically not restricted in pediatric CKD.

The optimal treatment of ESRD is **renal transplantation**. Both deceased and living donors can be used for renal transplantation. Living donors are preferred when available. **Maintenance dialysis** is effective for a child awaiting renal transplantation or when renal transplantation is not possible. Indications for chronic dialysis are given in [Table 165.3](#). **Peritoneal dialysis** is done at home by the family. **Hemodialysis** is typically done three times a week at a dialysis facility.

Prognosis

Children with mild CKD (stages 1 and 2) may do well but need to be monitored for progressive loss of kidney function. Children with stages 3 and 4 CKD have a high likelihood of progressing to ESRD at some point, although the timing can vary. Children with kidney transplants generally do well, but have to take immunosuppressive medications associated with a variety of side effects, including infections, nephrotoxicity, cardiovascular complications, and increased risk for certain malignancies. Unfortunately, most transplanted kidneys fail over time but can last for >10-20 years. Children on maintenance dialysis have the highest morbidity and mortality, especially with longer time spent on dialysis.

Thus the primary goal is to provide a kidney transplant for children with ESRD.

CHAPTER 166

Hypertension

Definition

In children, hypertension (HTN) is defined as blood pressure (BP) greater than 95th percentile for age, gender, and height measured on at least three different occasions. The context of BP measurement (e.g., cuff size, pain, anxiety) is important. Staging of HTN is listed in [Table 166.1](#). Hypertensive emergency is defined as severe BP elevation associated with target organ damage (encephalopathy, heart failure).

TABLE 166.1

Classification of Blood Pressure

BLOOD PRESSURE CATEGORY	BLOOD PRESSURE PERCENTILE (%)
Normal	<90th
Prehypertension	90th-95th*
Stage 1 hypertension	95th to (99th + 5 mm Hg)
Stage 2 hypertension	>99th + 5 mm Hg

*If 90th % is greater than 120/80, use 120/80 as the lower limit.

Etiology

Pediatric HTN has many causes ([Table 166.2](#)) that are either **primary** (essential) or **secondary**. **Essential HTN** is the most common cause of HTN in younger children and adolescents. Obese children are more likely to develop essential HTN. Secondary HTN should be suspected with younger age and more severely elevated BP. **Renal disease** is the most common cause of secondary HTN in children.

TABLE 166.2

Causes of Hypertension

PRIMARY HYPERTENSION

Essential hypertension

Metabolic syndrome

RENAL CAUSES

Congenital anomalies (renal dysplasia, obstructive uropathy)

Structural disorders (Wilms tumor, polycystic kidney disease)

Glomerulonephritis

Acquired injury (renal scarring, acute tubular necrosis)

ENDOCRINE CAUSES

Catecholamine-secreting tumors (pheochromocytoma, neuroblastoma)

Hypercortisolism (Cushing syndrome)

Hyperaldosteronism

Hyperthyroidism

NEUROLOGICAL CAUSES

Increased sympathetic activity (stress, anxiety, pain)

Dysautonomia

Increased intracranial pressure

VASCULAR CAUSES

Coarctation of the aorta

Renal artery embolism (from umbilical artery catheter)

Renal vein thrombosis

Renal artery stenosis

Vasculitis

OTHER CAUSES

Obstructive sleep apnea

Medications, illicit drugs

Clinical Manifestations

Decision-Making Algorithms

Red Urine and Hematuria
Hypertension

Headaches
Obesity
Alkalemia

Most children with HTN have no symptoms. Signs and symptoms associated with severe HTN include encephalopathy (headache, vomiting, seizures), heart failure, stroke, and retinopathy (blurred vision, flame hemorrhage, and cotton wool spots on retinal exam). Neonatal history (low birth weight or use of umbilical artery catheter); family history of HTN, stroke, or heart disease; and dietary history (excessive salt or caffeine, drugs) are important. Additional findings that may suggest specific causes include abdominal bruit (renal artery stenosis); diminished leg pressure and weak femoral pulse (coarctation of aorta); café-au-lait spots (neurofibromatosis-associated renal artery stenosis); flank mass (hydronephrosis, Wilms tumor); tachycardia with flushing and diaphoresis (pheochromocytoma); and truncal obesity, acne, striae, and buffalo hump (Cushing syndrome). Signs of underlying kidney disease may be present.

Diagnostic Studies

In addition to history and physical examination, evaluation of children with confirmed HTN includes:

1. Baseline etiological assessment (urinalysis, electrolytes, blood urea nitrogen, creatinine, and renal ultrasound)
2. Focused studies based on clinical suspicion (e.g., plasma metanephrines, thyroid studies, vascular imaging)
3. Assessment for target organ damage (echocardiogram for left ventricular hypertrophy)
4. Assessment of other cardiovascular risk factors (lipids, fasting glucose, uric acid)

Treatment

Therapeutic lifestyle changes (diet, exercise) should be initiated for asymptomatic stage 1 HTN without target organ damage or systemic disease. Medication should be started for stage 2 or symptomatic HTN and stage 1 HTN

that fails to respond to lifestyle changes over 6-12 months. Calcium channel blockers or angiotensin-converting enzyme inhibitors are the most frequently chosen first-line options in children. Angiotensin receptor blockers, β -blockers, or diuretics are also effective first-line antihypertensive agents. More than one agent may be needed. Hypertensive emergency requires prompt hospitalization and may require parenteral antihypertensive treatment with nicardipine, labetalol, esmolol, or sodium nitroprusside.

Prognosis

Prognosis depends on underlying etiology and BP control. Essential HTN is usually not associated with morbidity at presentation. Left untreated, however, even asymptomatic stage 1 HTN may increase risk for cardiovascular, central nervous system, and renal morbidity in adults.

CHAPTER 167

Vesicoureteral Reflux

Etiology and Epidemiology

Vesicoureteral reflux (VUR) is retrograde flow of urine from the bladder up the ureter or even into the kidney. Most VUR results from congenital incompetence of the ureterovesical (UV) junction, a structure that matures through early childhood. In a significant minority of children, structural UV abnormalities exist that never resolve. VUR may be familial; 30-40% of siblings of a child with VUR also have VUR. VUR may also be secondary to distal bladder obstruction or other urinary tract anomalies.

VUR exposes the kidney to increased hydrodynamic pressure during voiding and increases likelihood of renal infection due to incomplete emptying of the ureter and bladder (see [Chapter 114](#)). **Reflux nephropathy** refers to development and progression of renal scarring. This is a particular risk if VUR is associated with urinary tract infection (UTI) or obstruction. Although a single UTI may result in renal scarring, the incidence is higher in children with recurrent UTIs. Renal dysplasia is associated with congenital VUR. Because of

increasing use of maternal-fetal ultrasonography, a number of newborns are now identified with VUR before UTI has occurred, creating opportunities for early intervention and prevention strategies. **Duplication of the ureters**, with or without associated ureterocele, may obstruct the upper collecting system. Often, the ureter draining the lower pole of a duplicated renal unit has VUR. **Neurogenic bladder** is accompanied by VUR in up to 50% of affected children. VUR may also be due to increased intravesicular pressure when the bladder outlet is obstructed from inflammation of the bladder (cystitis) or by acquired bladder obstruction.

Clinical Manifestations

VUR is most often identified during radiological evaluation following a UTI (see [Chapter 114](#)). The younger the patient with UTI, the more likely VUR is present. No clinical signs reliably differentiate children with UTI with and without VUR.

Diagnostic Studies

An imaging study can be performed after initiation of UTI treatment with no need to wait days or weeks before performing the test. **Renal ultrasound (RUS)** is the best study to evaluate the urinary tract in children. A **voiding cystourethrogram (VCUG)** or **radionuclide cystogram (NCG)** is performed to detect urethral/bladder abnormalities and/or VUR. Recent American Academy of Pediatrics guidelines for infants with a first UTI between 2 and 24 months of age recommend a VCUG if a RUS reveals hydronephrosis, scarring, or other findings suggestive of either high-grade VUR or obstructive uropathy and in other atypical or complex clinical circumstances. VCUG should also be performed if there is a recurrence of a febrile UTI. Although VCUG provides additional anatomical detail, a NCG may detect more children with mild VUR and involves less radiation. An international grading system is useful to describe reflux ([Fig. 167.1](#)). Incidence of renal scarring in patients with low-grade VUR is low (15%) and increases with grade IV or V reflux (65%). Grade I or II VUR is likely to resolve without surgical intervention, but VUR resolves in <50% grade IV or V. **Nuclear renal scanning** best identifies renal scars.

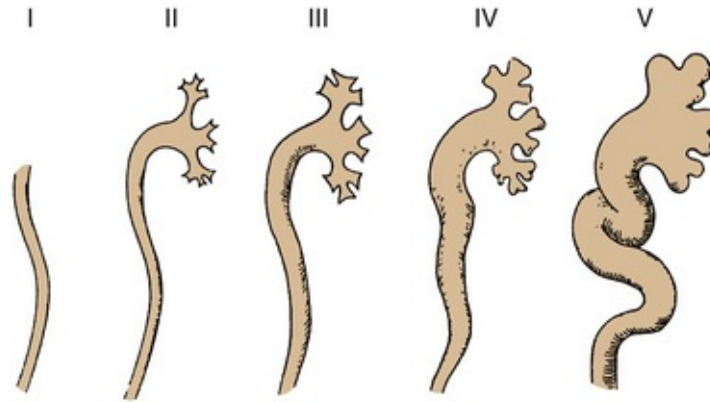

FIGURE 167.1 International classification of vesicoureteral reflux. Grade I: into a nondilated ureter; grade II: into the pelvis and calyces without dilation; grade III: mild to moderate dilation of the ureter, renal pelvis, and calyces with minimal blunting of the fornices; grade IV: moderate ureteral tortuosity and dilation of the pelvis and calyces; grade V: gross dilation of the ureter, pelvis, and calyces; loss of papillary impressions; and ureteral tortuosity. (From Wein A, Kavoussi L, Novick A, et al. *Campbell-Walsh Urology*. 9th ed. Philadelphia: Saunders; 2007.)

Treatment

Controversy remains about whether long-term prophylactic antibiotic therapy (trimethoprim-sulfamethoxazole or nitrofurantoin) is indicated in mild to moderate VUR. It is optional in this population and may be particularly useful in children with high-grade VUR and/or recurrent symptomatic UTI. **Complications** of reflux nephropathy are hypertension and chronic kidney disease (CKD). CKD is typically heralded by mild proteinuria and involves development of focal and segmental glomerulosclerosis as well as interstitial scarring. Indications for surgical repair of VUR are controversial, and options now include instillation of dextranomer/hyaluronic acid copolymer into the bladder wall (Deflux procedure), which appears to be a very successful, minimally invasive correction of mild to moderate VUR.

CHAPTER 168

Congenital and Developmental Abnormalities of the Urinary Tract

Etiology and Epidemiology

Anomalies of the urinary tract (UT) occur in up to 4% of infants. **Bilateral renal agenesis** occurs in 1 in 4,000 births. Renal agenesis is a component of **Potter syndrome** (flat facies, clubfoot, and pulmonary hypoplasia). Any intrauterine UT disorder that results in little fetal urine and therefore little amniotic fluid can lead to Potter syndrome. **Unilateral renal agenesis** occurs in 1 in 3,000 births and is more common in infants of diabetic mothers and African Americans. It is accompanied by normal or minimally reduced renal function. This condition can also be found with vesicoureteral reflux (VUR) and other anomalies of the genital tract, ear, skeletal system, and cardiovascular system. Unilateral renal agenesis can be a component of Turner syndrome, Poland syndrome, or VACTERL association (vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula, renal agenesis and dysplasia, and limb defects).

Renal hypoplasia/dysplasia refers to kidneys that are congenitally small, malformed, or both. Many affected children progress to chronic kidney disease (CKD) over time because of reduced nephron number. The kidneys are often unable to fully reabsorb sodium and water, and these children often require salt and water supplementation to optimize growth.

Multicystic renal dysplasia (MCD) is due to abnormal nephron development and occurs in 1 in 4,000 births. There is minimal or no functioning renal tissue in the affected kidney; bilateral disease is lethal. There is an association with VUR in the contralateral kidney. MCD often spontaneously involutes over the first few years of life and is rarely associated with hypertension (HTN) or recurrent urinary tract infection (UTI).

Polycystic kidney diseases (PKDs) are a group of genetic disorders affecting the kidneys and other tissues. PKD may be primary (autosomal recessive or autosomal dominant) or associated with other syndromes. Autosomal recessive PKD occurs in 1 in 10,000-40,000 children and is due to genetic defects in fibrocystin. Autosomal dominant PKD, due to defects in polycystin 1 or 2, occurs in 1 in 1,000 individuals, making it the most common inherited kidney disease. Although there is some overlap clinically, the two conditions differ morphologically. Both may appear in infancy or in older children. Renal cysts also are observed in other inherited disorders, such as von Hippel–Lindau syndrome, tuberous sclerosis, and Bardet-Biedl syndrome.

Urinary tract obstruction can occur at any anatomical level of the genitourinary system (Table 168.1). Early in gestation, severe obstruction results in renal dysplasia. Ureteral obstruction later in fetal life or after birth results in dilation of the ureter and collecting system, often with subsequent renal parenchymal alterations. An obstructed UT is susceptible to infections, which may worsen renal injury. **Posterior urethral valves** are the most common cause of **bladder outlet obstruction** in males, present in 1 in 50,000 boys. Parents may note a poor urine stream in affected children. The valves are sail-shaped membranes that arise from the verumontanum and attach to the urethral wall. The prostatic urethra becomes dilated, VUR may be present, and hypertrophied detrusor muscle develops. Renal dilation varies in severity. Renal dysplasia is often present. Severe obstruction may be associated with oligohydramnios, resulting in lethal pulmonary hypoplasia. Intrauterine renal pelvis rupture produces **urinary ascites**, a common cause of ascites in the newborn period.

TABLE 168.1

Site and Etiology of Urinary Tract Obstruction

SITE	ETIOLOGICAL CONDITION/DISORDER
Infundibula/pelvis	Congenital, calculi, infection, trauma/hemorrhage, tumor
Ureteropelvic junction	Congenital stenosis,* calculi, trauma/hemorrhage
Ureter	Obstructive megaureter,* ectopic ureter, ureterocele, calculi,* inflammatory bowel disease
	Retroperitoneal tumor (lymphoma), retroperitoneal fibrosis, chronic granulomatous disease
Bladder	Neurogenic dysfunction,* tumor (rhabdomyosarcoma), diverticula, ectopic ureter
Urethra	Posterior valves,* diverticula, strictures, atresia, ectopic ureter, foreign body, phimosis,* priapism

*Relatively common.

Clinical Manifestations

Decision-Making Algorithms

Red Urine and Hematuria
Hyponatremia

Bilateral renal agenesis results in insufficient lung development and Potter syndrome. Respiratory distress is severe, pneumothoraces can occur, and severe pulmonary hypoplasia is fatal. Unilateral renal agenesis may be asymptomatic because the nonaffected kidney undergoes compensatory growth and provides normal renal function.

Autosomal recessive PKD is characterized by marked bilateral renal enlargement. Interstitial fibrosis and tubular atrophy progress over time. Kidney failure usually occurs in early childhood. **Hepatic fibrosis** is present and may lead to portal HTN. Bile duct ectasia and biliary dysgenesis occur. Many affected infants display flank masses, hepatomegaly, pneumothorax, proteinuria, and/or hematuria.

Autosomal dominant PKD typically presents in middle adulthood but may present in infancy or childhood. Infants may have a clinical picture similar to autosomal recessive PKD, but older children typically show a pattern similar to that of adults, with large isolated cysts developing over time. The defect may occur anywhere along the nephron unit. Hepatic cysts are often present, and pancreatic, splenic, and ovarian cysts can also develop. **Cerebral aneurysms** may develop, and risk of cerebral hemorrhage depends on size, blood pressure, and family history of intracranial hemorrhage.

UT obstruction may be silent but is usually discovered during prenatal ultrasound or with UTI or flank mass in early childhood. In a newborn, the most common type of abdominal mass is renal (most commonly **ureteropelvic junction obstruction**).

Diagnostic Imaging

Renal ultrasound (RUS) and **radionuclide renography** (usually with diuretic administered) are the standard tests for diagnosis of UT obstruction. RUS can identify renal agenesis, hypoplasia, dysplasia, cysts, and/or UT dilation. Obstruction may be suggested, but a dilated UT may also result from VUR, ureteral hypoplasia, or neurogenic bladder. A **voiding cystourethrogram (VCUG)** is usually part of the evaluation. Many boys with posterior urethral valves are identified by prenatal ultrasound. Postnatally, the diagnosis and extent of renal damage are established by RUS and VCUG.

Treatment

Infants and children with bilateral dysplasia often require additional sodium and water due to renal wasting. With MCD, surgical kidney removal is rarely indicated unless severe HTN or recurrent UTI occurs.

Treatment of HTN can prolong maintenance of renal function. General therapy of CKD (see [Chapter 165](#)) can improve growth and development.

UT obstruction often requires drainage or surgical correction. Treatment of posterior urethral valve consists of either primary valve ablation or diversion (usually via vesicostomy) if ablation is not possible. Ectopic ureters are frequently obstructed; when this happens, surgical intervention is required.

Children with neurogenic bladder are prone to UTI and renal impairment from poor urine emptying. Clean intermittent catheterization or a urinary diversion can minimize these complications.

CHAPTER 169

Other Urinary Tract and Genital Disorders*

Urinary Tract Stones

Etiology

Urinary tract calculi are called **nephrolithiasis** or **urolithiasis**. Primary bladder stones can be seen with recurrent urinary tract infections (UTIs), neurogenic bladder or bladder surgery (sutures serve as a nidus), and intestinal bladder augmentation. Renal stones can result from obstructive abnormalities or an underlying metabolic predisposition. In industrialized societies, most stones (>90%) in children arise in the urinary tract (UT) and become symptomatic with passage or if lodged (commonly at the ureteropelvic junction or the ureterovesical junction). Metabolic causes include idiopathic familial hypercalciuria (IHC), hyperoxaluria, uric acid disorders, distal renal tubular acidosis, cystinuria, hypercalcemic hypercalciuria, and primary hyperparathyroidism. Some children with UT abnormalities and stones have a concomitant metabolic predisposition.

Clinical Manifestations

Decision-Making Algorithm

Red Urine and Hematuria

Acute obstruction of urine flow is the cause of renal colic, a severe sharp intermittent pain in the flank or lower abdomen often radiating to the groin. Vomiting, distress, and inability to relieve pain with position changes are characteristic. In younger children, fussiness and vomiting may be the only symptoms. Hematuria may be gross or microscopic and typically clears rapidly with passage of gravel or stone material.

Diagnostic Studies

Renal ultrasound may identify stones in the kidney but can easily miss UT stones. Computed tomography (CT), particularly a helical CT, can identify stones throughout the UT, but stones can be obscured by oral or intravenous contrast material. Etiological diagnosis is facilitated when stone material can be obtained and sent for analysis. Spot or 24-hour urine studies for mineral and electrolyte determinations, obtained on a typical diet for the child, are important to characterize any underlying metabolic predisposition and are valuable even when a stone is available for analysis.

Treatment

Acute treatment of urinary calculi consists of hydration and analgesia. Chronic treatment for all types of metabolic stones involves vigorous fluid intake, usually twice the maintenance volume. Infection-related stones require treatment of infection and, often, removal of the stone as well as correction of any predisposing anatomical abnormality. Specific metabolic conditions require specific treatments; for IHC, normal calcium intake with low sodium and low oxalate intake is prescribed. For some children with IHC, potassium citrate or thiazides are required to minimize stone recurrence. Tamsulosin has been increasingly used with success in older children with distal ureteral stones to promote passage. Lithotripsy or surgery by a pediatric urologist may be required

for children with large, infected, or obstructing stones.

Voiding Dysfunction

Etiology

Voiding difficulties are frequent in preschool age children due to delay in maturation of bladder and micturition pathways. Normal micturition and continence rely on structural UT integrity, neurological maturation, and coordination between somatic and autonomic nervous system units, including central nervous system, spinal cord pathways, bladder/urinary sphincter pathways, and the autonomic system. Daytime continence is usually achieved before nighttime continence. Most children are dry, day and night, by 4-5 years of age. Nocturnal enuresis is the involuntary loss of urine during sleep. Children with primary enuresis have never had a prolonged (usually >3 months) span of nighttime continence. Up to 10% of 5-year-old children have primary enuresis with 15% spontaneous resolution per year. Boys are affected more than girls with increased incidence in families (40% at 6 years of age if one affected parent, 70% if two affected parents). Secondary enuresis involves loss of nighttime control after an extended period of dryness and generally requires evaluation to uncover the cause.

Clinical Manifestations

Dysfunctional voiding (DV) may manifest as incontinence, frequency, urgency, hesitancy, dysuria, lower abdominal pain, or recurrent UTI. Symptoms may vary over time and be associated with obvious neurological problems (spinal cord injury, encephalitis), constipation, and/or behavioral problems. DV symptoms may vary, depending on recent UTI or changes in family or school life/stressors. The majority of children with DV are anatomically, neurologically, and psychologically normal.

Diagnostic Studies

Evaluation for DV may be performed at any age, but isolated urinary incontinence in an otherwise normal child is not usually evaluated until 5 years of age. Urinalysis and urine culture should be done to exclude occult infection and renal disease. Children with daytime incontinence should undergo

renal/bladder ultrasound to exclude structural abnormalities. Urodynamic evaluation is typically reserved for children with suspicion of neurogenic bladder or known neurological etiology.

Treatment

For children with recurrent UTI, prophylactic antibiotics may be useful. Timed voiding and anticholinergic medications are used to treat bladder hyperactivity and sensory defects. More complicated treatment regimens include biofeedback, α -blockers, and intermittent catheterization. For children with simple primary enuresis, the bed-wetting alarm provides safe and effective resolution of the problem for greater than 70% of affected children; medical therapy with anticholinergics, imipramine, or desmopressin may also be useful in selected children.

Disorders of the Penis

Etiology

Hypospadias occurs in ~1 in 500 newborn infants. In this condition, the urethral folds fail to fuse completely over the urethral groove, leaving the urethral meatus located ventrally and proximally to its normal position. The ventral foreskin is also lacking, and the dorsal portion gives the appearance of a hood. Severe hypospadias with undescended testes is a form of ambiguous genitalia. Etiologies include congenital adrenal hyperplasia with masculinization of females or androgen insensitivity. UT anomalies are uncommon in association with hypospadias. Hypospadias may occur alone, but in severe cases can be associated with a **chordee** (a fixed ventral curvature of the penile shaft). Rarely, when the urethra opens onto the perineum, the chordee is extreme, and the scrotum is bifid and sometimes extends to the dorsal base of the penis.

In 90% of uncircumcised males, the foreskin should be retractable by adolescence. Before this age, the prepuce may normally be tight and does not need treatment. After this age, the inability to retract the prepuce is termed **phimosis**. The condition may be congenital or the result of inflammation. **Paraphimosis** occurs when the prepuce has been retracted behind the coronal sulcus, cannot resume its normal position, and causes swelling of the glans or pain.

Clinical Manifestations and Treatment

The meatal opening in **hypospadias** may be located anteriorly (on the glans, coronal, or distal third of the shaft); on the middle third of the shaft; or posteriorly (near the scrotum). Testes are undescended in 10% of boys with hypospadias. Inguinal hernias are common. Males with hypospadias should not be circumcised, particularly if the meatus is proximal to the glans, as the foreskin may be necessary for later repair. Most pediatric urologists repair hypospadias before the patient is 18 months old.

Phimosis is rarely symptomatic. Parents should be reassured that loosening of the prepuce usually occurs during puberty. Treatment, if needed, is topical steroids. If the narrowing is severe, gentle stretching may be useful. Circumcision is reserved for the most severe cases. **Paraphimosis** with venous stasis and edema leads to severe pain. When paraphimosis is discovered early, reduction of the foreskin may be possible with lubrication. In some cases, emergent circumcision is needed.

Disorders and Abnormalities of the Scrotum and Its Contents

Etiology

Undescended testes (cryptorchidism) are found in ~1% of boys after 1 year of age. It is more common in full-term newborns (3.4%) than in older children. In neonates, cryptorchidism is more common with shorter gestation (20% in 2,000-2,500-g infants and 100% in <900-g infants). Cryptorchidism is bilateral in 30% of cases. Spontaneous testicular descent does not tend to occur after 1 year of age, but failure to find one or both testes in the scrotum does not indicate undescended testicles. **Retractile testes**, **absent testes**, and **ectopic testes** may resemble cryptorchidism in presentation.

Clinical Manifestations

Decision-Making Algorithms

Scrotal Pain
Scrotal Swelling (Painless)

A history of maternal drug use (steroids) and family history are important in the evaluation of a child for apparent cryptorchidism. Whether the testis was ever noted in the scrotum should be asked. The true undescended testis is found along the normal embryological path of descent, usually in the presence of a patent processus vaginalis. An undescended testis is often associated with an inguinal hernia; it is also subject to **torsion**. There is a high incidence of infertility in adulthood. When bilateral and untreated, infertility is uniform. There is increased malignancy risk (five times the normal rate) with undescended testis, usually presenting between the ages of 20 and 30. The risk is greater in untreated males or those with surgical correction during or after puberty.

Retractile testes are normal testes that retract into the inguinal canal from an exaggerated cremasteric reflex. The diagnosis of retractile testes is likely if testes are palpable in the newborn period but not at later examination. Frequently parents describe seeing their son's testes in his scrotum when he is in the bath and seeing one or both “disappear” when he gets cold.

Complications

Decision-Making Algorithm

Scrotal Pain

Torsion of the testis is an emergency requiring prompt diagnosis and treatment to save the affected testis. Torsion accounts for 40% of cases of acute scrotal pain and swelling and is the major cause of the acute scrotum in boys less than 6 years of age. It is thought to arise from abnormal fixation of the testis to the scrotum. On examination, the testicle is swollen and tender, and the cremasteric reflex is absent. The absence of blood flow on nuclear scan or Doppler ultrasound is consistent with torsion.

The differential diagnosis of testicular pain includes trauma, an incarcerated hernia, and torsion of the testicular epididymal appendix. Torsion of the appendix testis is associated with point tenderness over the lesion and minimal

swelling. In adolescents, the differential diagnosis of testicular torsion also must include **epididymitis**, the most common cause of acute scrotal pain and swelling in older adolescents. Diagnosis is aided by an antecedent history of sexual activity or UTI. Testicular torsion must be considered as the principal diagnosis when severe acute testicular pain is present.

Treatment

The undescended testis is usually histologically normal at birth. Atrophy and dysplasia are found after the first year of life. Some boys have congenital dysplasia in the contralateral descended testis. Surgical correction at an early age results in greater chance of adult fertility. Administration of human chorionic gonadotropin causes testosterone release from functioning testes and may result in descent of retractile testes.

Orchidopexy is usually done in the second year of life. Most extraabdominal testes can be brought into the scrotum with correction of the associated hernia. If the testis is not palpable, ultrasound or magnetic resonance imaging may determine its location. The closer the testis is to the internal inguinal ring, the better the chance of successful orchidopexy.

Surgical correction of testicular torsion is called *detorsion and fixation of the testis*. If performed within 6 hours of torsion, there is >90% chance of testicular salvage. The contralateral testis usually is fixed to the scrotum to prevent possible torsion. If torsion of the appendix is found, the necrotic tissue is removed.

Pearls for Practitioners

Chapter 161

Nephrology and Urology Assessment

- Fetal urine production contributes to amniotic fluid volume, lung maturation, and somatic development; reduced (oligohydramnios) or increased amniotic fluid volume (polyhydramnios) may be a sign of a congenital renal disorder.
- Glomerular filtration rate (GFR) is normally low in newborns infants (~25 mL/min/1.73 m²), and it takes up to 2 years of age to develop adult levels of GFR (100-120 mL/min/1.73 m²).
- The proximal tubule (PT) is responsible for most water and electrolyte reabsorption; this nephron portion consumes >90 % of renal O₂ and suffers most severe injury with anoxic-ischemic kidney injury (acute tubular necrosis); the inability of PT to maximally reabsorb bicarbonate leads to proximal renal tubular acidosis.
- The distal tubule collecting duct (CD) is the primary site of antidiuretic hormone (vasopressin) response, which leads to urine concentration; CD sodium-potassium and sodium-hydrogen exchange CD is regulated by aldosterone; abnormalities in CD active hydrogen ion secretion lead to distal and/or hyperkalemic renal tubular acidosis.
- The revised Schwartz formula [GFR = 0.413 × Ht (cm)/serum

Cr (mg/dL)] is used to estimate GFR in children.

Chapter 162

Nephrotic Syndrome and Proteinuria

- Urine protein is best quantified by a spot urine Pr/Cr, with normal <0.2 and heavy (nephrotic range) proteinuria >2.0 ; U Pr/Cr $0.2-2.0$ indicates mild to moderate proteinuria.
- Nephrotic syndrome (NS) is characterized by persistent heavy proteinuria (mainly albuminuria; $>2 \text{ g/m}^2/24 \text{ hr}$); hypoproteinemia (serum albumin $<3.0 \text{ g/dL}$); hypercholesterolemia ($>250 \text{ mg/dL}$); and edema.
- Primary forms of NS include minimal change nephrotic syndrome (MCNS—most common form of childhood NS; $>80\%$ of those with NS <7 years old having MCNS), focal glomerulosclerosis (FSGS), membranoproliferative glomerulonephritis (MPGN), and membranous glomerulonephritis.
- For the child with likely MCNS (presentation between 2 and 12 years of age, no signs of systemic disorder, minimal hematuria, normal GFR, and normal C_3), a corticosteroid trial is warranted.
- Complications of childhood NS include poor growth, hypertension, episodes of acute kidney injury (AKI), serious bacterial infections, episodes of thrombi and thromboemboli, and accelerated atherosclerotic disease.

Chapter 163

Glomerulonephritis and Hematuria

- Glomerulonephritis (GN) in children presents with some, but not necessarily all, of the cardinal features of GN: hematuria, proteinuria, decreased renal function, hypertension, oliguria

and/or edema; poststreptococcal GN is most common form of acute GN while immunoglobulin (Ig)A nephropathy is most common form of chronic GN in children.

- Hypocomplementemia (low C_3) characterizes acute post-streptococcal, postinfectious GN, MPGN, and lupus nephritis; all other causes of GN have normal C_3 .

Chapter 164

Hemolytic Uremic Syndrome

- Hemolytic uremic syndrome (HUS) is characterized by triad of microangiopathic hemolytic anemia, thrombocytopenia, and renal injury and is an important cause of AKI in children, typically occurring in children <5 years of age; the most common type of HUS is associated with a prodromal diarrheal illness (D + HUS) due to contamination of meat, fruit, vegetables, or water with verotoxin (VT)-producing *Escherichia coli* (most commonly *E. coli* O157:H7).
- HUS is a self-limited disorder that can be asymptomatic or involve full renal failure requiring dialysis; 95% of patients recover, although 20% of these patients have chronic sequelae such as hypertension or chronic kidney disease; atypical HUS secondary to certain pneumococcal infections or complement abnormalities can be recurrent and more severe than D + HUS.

Chapter 165

Acute and Chronic Renal Failure

- AKI is an abrupt decrease in GFR and tubular function that may lead to decreased excretion of waste products and disturbance in fluid and electrolyte homeostasis; AKI may be oliguric (<1 mL/kg/hr in neonates and infants, <0.5 mL/kg/hr in children)

or nonoliguric, and can be classified as prerenal (renal hypoperfusion), intrinsic renal (tubular, glomerular, or vascular injury), or postrenal (urinary tract obstruction).

- Indications for acute dialysis in children include volume overload, metabolic acidosis, electrolyte abnormalities, severe uremia, certain ingestions and metabolic disorders (e.g., hyperammonemia); indications for chronic dialysis include all of the above as well as poor growth due to CKD and CKD Stage 5 due to its significant risks of serious complications.
- Complications of CKD in children include poor growth, anemia, CKD-mineral bone disorder (bone deformities, fractures), cardiovascular issues (hypertension, left ventricular hypertrophy), and electrolyte disturbances (Na, K, HCO₃, Ca, P).

Chapter 166

Hypertension

- Hypertension in children (preadolescent and adolescent) is most frequently essential (primary) with secondary forms less common; the most common secondary cause in children is due to renal disease.
- In addition to history and physical examination, evaluation of children with confirmed HTN includes (1) baseline studies (urinalysis, electrolytes, blood urea nitrogen, creatinine, and renal ultrasound); (2) focused studies based on clinical suspicion (e.g., plasma metanephrines, thyroid studies, vascular imaging); (3) assessment for target organ damage (echocardiogram); and assessment of cardiovascular risk factors (lipids, fasting glucose, uric acid).

Chapter 167

Vesicoureteral Reflux

- Vesicoureteral reflux (VUR) results from congenital incompetence of the ureterovesical (UV) junction, a structure that often, but not always, matures through early childhood; VUR may be familial (seen in 30-40% of siblings of child) or may be secondary to distal bladder obstruction or other urinary tract anomalies.
- Reflux nephropathy refers to development and progression of renal scarring with VUR; it is more common when VUR is associated with UTI or obstruction; although a single UTI may result in renal scarring, the incidence is higher in children with recurrent UTIs; renal dysplasia is also associated with congenital VUR.

Chapter 168

Congenital and Developmental Abnormalities of the Urinary Tract

- Anomalies of the urinary tract (UT) occur in up to 4% of infants and include bilateral and unilateral renal agenesis, renal hypoplasia/dysplasia, multicystic renal dysplasia, polycystic kidney diseases (PKD—autosomal recessive PKD, autosomal dominant PKD and PKD associated with syndromes), and UT obstruction disorders (posterior urethral valves, ureterocele), which vary greatly in severity and are often diagnosed through prenatal ultrasound examinations.

Chapter 169

Other Urinary Tract and Genital Disorders

- In childhood nephrolithiasis, primary bladder stones are seen with recurrent urinary tract infections (UTIs), neurogenic bladder or bladder surgery (sutures as nidus), and intestinal bladder

augmentation while renal stones result from obstruction or an underlying metabolic predisposition; metabolic causes include idiopathic familial hypercalciuria (IHC), hyperoxaluria, uric acid disorders, distal renal tubular acidosis, cystinuria, hypercalcemic hypercalciuria, and primary hyperparathyroidism.

- In children daytime continence is usually achieved before nighttime; most children are dry, day and night, by 4-5 years of age; nocturnal enuresis is involuntary loss of urine during sleep; primary enuresis = never had >3 month span of nighttime continence (up to 10% of 5-year-olds; 15% spontaneous resolution/year; boys > girls; increased incidence in families); secondary enuresis involves loss of nighttime control after period of dryness and requires evaluation for cause.
- Dysfunctional voiding (DV) may manifest as incontinence, frequency, urgency, hesitancy, dysuria, lower abdominal pain, or recurrent UTI; most children with DV are anatomically, neurologically, and psychologically normal; for children with recurrent UTI, prophylactic antibiotics may be useful; for children with simple primary enuresis, the bed-wetting alarm provides safe and effective resolution for >70% of affected children; medical therapy with anticholinergics, imipramine, or desmopressin may also be useful in selected children.

CHAPTER 170

Endocrinology Assessment

The endocrine system regulates vital body functions by means of hormonal messengers. **Hormones** are defined as circulating messengers, with action at a distance from the organ (**gland**) of origin of the hormone. Hormones can be regulated by nerve cells; endocrine agents can serve as neural messengers. There is also a relationship between the endocrine system and the immune system; autoantibodies may cause an organ to produce an excess or deficiency of a hormone. Manifestations of an endocrine disorder are related to the response of the peripheral tissue to a hormone excess or deficiency.

Hormone action also may be **paracrine** (acting on adjacent neighboring cells to the cell of origin of the hormone) or **autocrine** (acting on the cell of origin of the hormone itself); agents acting in these ways are called *factors* rather than hormones (Fig. 170.1). Hormones generally are regulated in a feedback loop so that the production of a hormone is linked to its effect or its circulating concentration. Endocrine disorders generally manifest from one of four ways:

FIGURE 170.1 Schematic representation of mechanisms of action of hormones and growth factors. Although traditional hormones are formed in

endocrine glands and transported to distant sites of action through the bloodstream (endocrine mechanism), peptide growth factors may be produced locally by the target cells themselves (autocrine modality of action) or by neighboring cells (paracrine action). (From Wilson JD, Foster DW, eds. *Williams Textbook of Endocrinology*. 8th ed. Philadelphia: WB Saunders; 1992:1007.)

1. By **excess hormone**: In Cushing syndrome, there is an excess of glucocorticoid present; if the excess is secondary to autonomous glucocorticoid secretion by the adrenal gland, the trophic hormone adrenocorticotrophic hormone (ACTH) is suppressed.
2. By **deficient hormone**: In glucocorticoid deficiency, the level of cortisol is inadequate; if the deficiency is at the adrenal gland, the trophic hormone is elevated (ACTH).
3. By an abnormal **response of end-organ** to hormone: In pseudohypoparathyroidism, defects in the gene (*GNAS1*) encoding the alpha subunit of the stimulatory G protein (Gsa) is manifested by elevated parathyroid hormone (PTH) levels in the face of deficient PTH function (PTH resistance).
4. By **gland enlargement** that may have effects as a result of size rather than function: With a large nonfunctioning pituitary adenoma, abnormal visual fields and other neurological signs and symptoms result even though no hormone is produced by the tumor.

Peptide hormones act through specific cell membrane receptors; when the hormone is attached to the receptor, the complex triggers various intracellular second messengers that cause the biological effects. Peptide hormone receptor number and avidity may be regulated by hormones. **Steroid hormones** exert their effects by attachment to intranuclear receptors, and the hormone-receptor complex translocates to the nucleus, where it binds with DNA and leads to further gene activation.

The interpretation of serum hormone levels must be related to their controlling factors. For example, a given value of parathyroid hormone may be normal in a eucalcemic patient but inadequate in a hypocalcemic patient with partial hypoparathyroidism or excessive in a hypercalcemic patient with hyperparathyroidism.

Hypothalamic-Pituitary Axis

The **hypothalamus** controls many endocrine systems, either directly or through the pituitary gland. Higher central nervous system (CNS) centers control the hypothalamus. Hypothalamic releasing or inhibiting factors travel through capillaries of the pituitary portal system to control the anterior pituitary gland, regulating the hormones specific for the factor (Fig. 170.2). The pituitary hormones enter the peripheral circulation and exert their effects on target glands, which produce other hormones that feed back to suppress their controlling hypothalamic and pituitary hormones. Insulin-like growth factor-1 (IGF-1), growth hormone (GH), cortisol, sex steroids, and thyroxine (T_4) all feedback on the hypothalamic-pituitary system. Prolactin is the only pituitary hormone that is suppressed by a hypothalamic factor, dopamine. The hypothalamus is also the location of vasopressin-secreting axons that either terminate in the posterior pituitary gland and exert their effect via vasopressin secretion from this area or terminate in the mediobasal hypothalamus, from which they can exert effects on water balance, even in the absence of the posterior pituitary gland.

FIGURE 170.2 Hormonal influences of the hypothalamus and pituitary gland. Solid line represents stimulatory influence; dotted line represents inhibitory influence. *ACTH*, Adrenocorticotropin hormone; *CRH*, corticotropin-releasing hormone or CRF; *FSH*, follicle-stimulating hormone; *GH*, growth hormone; *GHRH*, GH-releasing hormone or GRF; *GnRH*, gonadotropin-releasing hormone or luteinizing hormone releasing factor, LRF or LHRH; *LH*, luteinizing hormone; *SRIF*, somatotropin release-inhibiting factor, somatostatin or SS; *TRH*, thyrotropin-releasing hormone or TRF; *TSH*, thyroid-stimulating hormone; *T₃*, triiodothyronine; *T₄*, thyroxine.

The **assessment** of pituitary function may be determined by measuring some of the specific pituitary hormone in the basal state; other assessments require the measurement after stimulation. Indirect assessment of pituitary function can be obtained by measuring serum concentrations of the target gland hormones ([Table 170.1](#)). Several tests of pituitary function are listed in [Table 170.2](#).

TABLE 170.1

Diagnostic Evaluation for Hypopituitarism

MANIFESTATION	CAUSE	TESTS*
Growth failure, hypothyroidism, or both	GH deficiency, TRH/TSH deficiency, or both	Provocative GH tests, free T ₄ , bone age, IGF-1, IGF-BP3
Hypoglycemia	GH deficiency, ACTH insufficiency, or both	Provocative GH tests, test of ACTH secretion, IGF-1, IGFBP3
Micropenis, pubertal delay or arrest	Hypogonadotropic hypogonadism with or without GH deficiency	Sex steroids (E ₂ , testosterone), basal LH and FSH (analyzed by ultrasensitive assays) or after LHRH administration, provocative GH tests, IGF-1, IGFBP3
Polyuria, polydipsia	ADH deficiency	Urine analysis (specific gravity), serum electrolytes, urine and serum osmolality, water deprivation test

*Each patient with hypopituitarism should have CNS MRI as part of evaluation to determine the etiology of the condition.

ACTH, Adrenocorticotropic hormone; *ADH*, Antidiuretic hormone; *CNS*, central nervous system; *E₂*, estradiol; *FSH*, follicle-stimulating hormone; *GH*, growth hormone; *GnRH*, gonadotropin-releasing hormone; *IGF-1*, insulin-like growth factor-1; *IGF-BP3*, insulin-like growth factor-binding protein 3; *LH*, luteinizing hormone; *LHRH*, luteinizing hormone releasing hormone; *MRI*, magnetic resonance imaging; *TRH*, thyrotropin-releasing hormone; *TSH*, thyroid-stimulating hormone; *T₄*, thyroxine.

TABLE 170.2

Anterior Pituitary Hormone Function Testing

RANDOM HORMONE MEASUREMENTS	PROVOCATIVE OR OTHER TESTS	TARGET HORMONE MEASUREMENT
GH (not useful as a random determination except in newborns, and in GH resistance or in pituitary gigantism)	Arginine (a weak stimulus) L-Dopa (useful clinically) Insulin-induced hypoglycemia (a dangerous but accurate test)	IGF-1, IGF-BP3 (affected by malnutrition as well as GH excess)
	Clonidine (useful clinically) GHRH	
	12- to 24-hr integrated GH levels (of questionable utility)	
ACTH (early morning sample useful only if in high-normal range)	Cortisol after insulin-induced hypoglycemia (a dangerous but accurate test)	8 A.M. cortisol
		24-hr urinary free cortisol
	ACTH stimulation test (may differentiate ACTH deficiency from primary adrenal insufficiency)	

TSH* LH, FSH*	TRH (not commonly performed) GnRH (difficult to interpret in prepubertal subjects)	FT ₄ Testosterone/estradiol
Prolactin (elevated in hypothalamic disease and decreased in pituitary disease)	TRH (not commonly performed)	None

*New supersensitive assays allow determination of abnormally low values found in hypopituitarism.

ACTH, Adrenocorticotropic hormone; *CRH*, corticotropin-releasing hormone; *FSH*, follicle-stimulating hormone; *FT₄*, free thyroxine; *GH*, growth hormone; *GnRH*, gonadotropin-releasing hormone; *GHRH*, growth hormone-releasing hormone; *IGF-1*, insulin-like growth factor-1; *IGF-BP3*, insulin-like growth factor-binding protein 3; *L-dopa*, L-dihydroxyphenylalanine; *LH*, luteinizing hormone; *TRH*, thyrotropin-releasing hormone; *TSH*, thyroid-stimulating hormone.

Disorders of the Hypothalamic-Pituitary Axis

Decision-Making Algorithms

Visual Impairment and Leukocoria
Amenorrhea
Pubertal Delay
Polyuria

Hypothalamic deficiency leads to a decrease in most pituitary hormone secretions but may lead to an increase in prolactin secretion. Destructive lesions of the pituitary gland or hypothalamus are more common in childhood than increased pituitary secretion of various hormones. A **craniopharyngioma**, a tumor of the Rathke pouch, may descend into the sella turcica, causing erosion of the bone and destruction of pituitary and hypothalamic tissue. **Acquired hypopituitarism** also may result from pituitary infections; from infiltration (Langerhans cell histiocytosis [histiocytosis X], lymphoma, and sarcoidosis); after radiation therapy or trauma to the CNS; and as a consequence of autoimmunity against the pituitary gland.

Congenital hypopituitarism can be caused by the absence of hypothalamic-releasing factors. Without hypothalamic stimulation, the pituitary gland does not release its hormones. Congenital defects associated with hypopituitarism range from **holoprosencephaly** (cyclopia, cebocephaly, orbital hypotelorism) to cleft palate (6% of cases of cleft palate are associated with GH deficiency). **Optic**

nerve hypoplasia, formerly known as septooptic dysplasia, may result in significant visual impairment with pendular (“roving”) nystagmus (inability to focus on a target) in addition to varying degrees of hypopituitarism. The magnetic resonance imaging (MRI) findings of congenital hypopituitarism may include an ectopic posterior pituitary gland *bright spot*, the appearance of a *pituitary stalk transection*, and/or small pituitary gland.

CHAPTER 171

Diabetes Mellitus

Diabetes mellitus (DM) is characterized by hyperglycemia and glycosuria and is an end-point of a few disease processes ([Table 171.1](#)). The most common type occurring in childhood is type 1 DM (T1D), which is caused by autoimmune destruction of the insulin-producing β cells (islets) of the pancreas, leading to permanent insulin deficiency. Type 2 DM (T2D) results from insulin resistance and relative insulin deficiency usually in the context of exogenous obesity. The incidence of T1D and T2D in the United States is increasing. Less common types of diabetes result from genetic defects of the insulin receptor or inherited abnormalities in sensing of ambient glucose concentration by pancreatic β cells (see [Table 171.1](#)).

TABLE 171.1

Classification of Diabetes Mellitus in Children and Adolescents

TYPE	COMMENT
TYPE 1 (INSULIN-DEPENDENT)	
Transient neonatal	Manifests immediately after birth; lasts 1-3 mo
Permanent neonatal	Other pancreatic defects possible
Classic type 1	Glycosuria, ketonuria, hyperglycemia, islet cell positive; genetic component
TYPE 2 (NON-INSULIN-DEPENDENT)	
Secondary	Cystic fibrosis, hemochromatosis, drugs (L-asparaginase, tacrolimus)
Adult type (classic)	Associated with obesity, insulin resistance; genetic component
OTHER	
Gestational diabetes	Abnormal glucose tolerance during pregnancy only, which reverts to normal postpartum;

Maturity-onset diabetes of youth Mitochondrial diabetes	increased risk for later onset of diabetes Autosomal dominant, onset before age of 25 years; not associated with obesity or autoimmunity Single-gene mutations include hepatocyte nuclear factors 1 β ,1 α , 4 α ; glucokinase; insulin promoter factor 1 Associated with deafness and other neurological defects, maternal transmission—mtDNA point mutations
--	---

Definition

A **diagnosis** of DM is made based on four glucose abnormalities that may need to be confirmed by repeat testing: (1) Fasting serum glucose concentration ≥ 126 mg/dL, (2) a random venous plasma glucose ≥ 200 mg/dL with symptoms of hyperglycemia, (3) an abnormal oral glucose tolerance test (OGTT) with a 2-hour postprandial serum glucose concentration ≥ 200 mg/dL, and (4) a HgbA1c $\geq 6.5\%$.

A patient is considered to have **impaired fasting glucose** if fasting serum glucose concentration is 100-125 mg/dL or **impaired glucose tolerance** if 2-hour plasma glucose following an OGTT is 140-199 mg/dL. Sporadic hyperglycemia can occur in children, usually in the setting of an intercurrent illness. When the hyperglycemic episode is clearly related to an illness or other physiological stress, the probability of incipient diabetes is small ($<5\%$).

Type 1 Diabetes Mellitus

Etiology

T1D results from the autoimmune destruction of insulin-producing β cells (islets) of the pancreas. In addition to the presence of diabetes susceptibility genes, an unknown environmental insult presumably triggers the autoimmune process. A variety of studies have produced conflicting data regarding a host of environmental factors. These include cow's milk feeding at an early age, viral infectious agents (coxsackie virus, cytomegalovirus, mumps, rubella), vitamin D deficiency, and perinatal factors. T1D is thought to be primarily a T cell-mediated disease.

Antibodies to islet cell antigens may be seen months to years before the onset of β cell dysfunction (Fig. 171.1). These include islet cell antibodies, insulin autoantibodies, antibodies to tyrosine phosphatase IA-2, antibodies to glutamic acid decarboxylase, and others. The risk for diabetes increases with the number of antibodies detected in the serum. In individuals with only one detectable

antibody, the risk is only 10-15% while in individuals with three or more antibodies the risk is 55-90%. When 80-90% of the β cell mass has been destroyed, the remaining β cell mass is insufficient to maintain euglycemia and clinical manifestations of diabetes result (see Fig. 171.1).

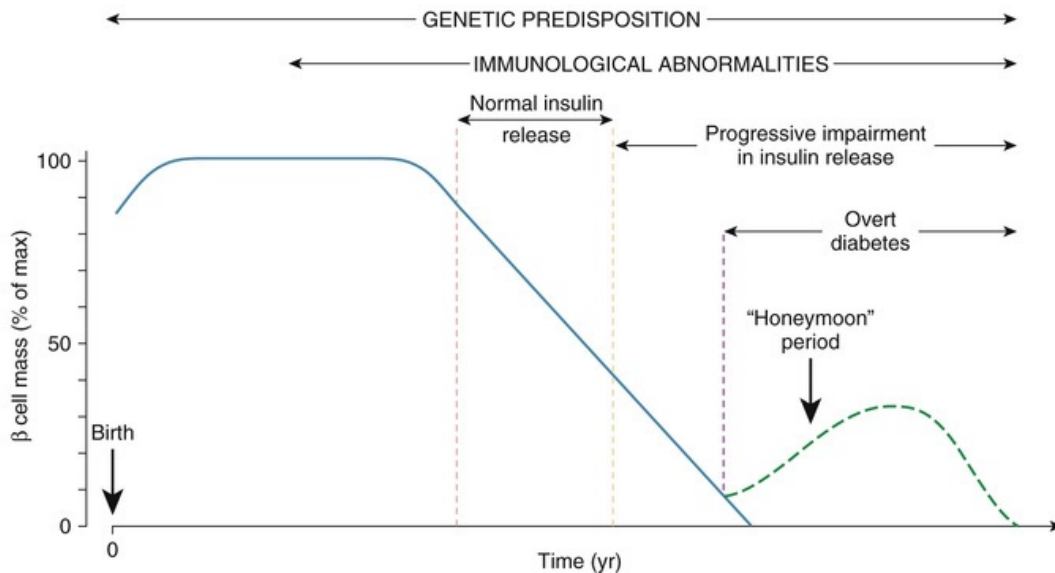

FIGURE 171.1 Schematic representation of the autoimmune evolution of diabetes in genetically predisposed individuals.

Epidemiology

The annual incidence of T1D is increasing steadily but with significant geographic differences. In the United States, the annual incidence is approximately 20 in 100,000. The annual incidence in children ranges from a high of 40 in 100,000 among Scandinavian populations to less than 1 in 100,000 in China. The prevalence of T1D in the United States is highest in non-Hispanic whites followed by African Americans, Hispanics, and American Indians.

Genetic determinants play a role in the susceptibility to T1D, although the mode of inheritance is complex and multigenic. Siblings or offspring of patients with diabetes have a risk of 2-8% for the development of diabetes; an identical twin has a 30-50% risk. The human leukocyte antigen (HLA) region on chromosome 6 provides the strongest determinant of susceptibility, accounting for approximately 40% of familial inheritance of T1D. Specific class II DR and DQ HLA alleles (HLA DR3 and HLA DR4) increase the risk of developing T1D,

whereas other specific HLA alleles exert a protective effect. More than 90% of children with T1D possess HLA DR3 alleles, HLA DR4 alleles, or both. The insulin gene region variable number tandem repeat on chromosome 11 is also linked to T1D susceptibility. There is evidence for association, beyond HLA, of more than 100 other loci with T1D. Genetic factors do not fully account for susceptibility to T1D; environmental factors also play a role.

Clinical Manifestations

Decision-Making Algorithms

Polyuria
Failure to Thrive

Hyperglycemia results when insulin secretory capacity becomes inadequate to enhance peripheral glucose uptake and to suppress hepatic and renal glucose production. Insulin deficiency usually first causes postprandial hyperglycemia and then fasting hyperglycemia. Ketogenesis is a sign of more complete insulin deficiency. Lack of suppression of gluconeogenesis and glycogenolysis further exacerbates hyperglycemia, while fatty acid oxidation generates the ketone bodies: β -hydroxybutyrate, acetoacetate, and acetone. Protein stores in muscle and fat stores in adipose tissue are metabolized to provide substrates for gluconeogenesis and fatty acid oxidation.

Glycosuria occurs when the serum glucose concentration exceeds the renal threshold for glucose reabsorption (from 160 to 190 mg/dL). Glycosuria causes an osmotic diuresis (including obligate loss of sodium, potassium, and other electrolytes) leading to dehydration. Polydipsia occurs as the patient attempts to compensate for the excess fluid losses. Weight loss results from the persistent catabolic state and the loss of calories through glycosuria and ketonuria. The classic presentation of T1D includes polyuria, polydipsia, polyphagia, and weight loss.

Diabetic Ketoacidosis

If the clinical features of new-onset T1D are not detected, **diabetic ketoacidosis**

(DKA) will occur. DKA may also occur in patients with known T1D if insulin injections are omitted or during an intercurrent illness when greater insulin requirements are unmet in the presence of elevated concentrations of the counter-regulatory and stress hormones (glucagon, growth hormone [GH], cortisol, and catecholamines). DKA can be considered to be present if (1) the arterial pH is below 7.3, (2) the serum bicarbonate level is below 15 mEq/L, and (3) ketones are elevated in serum or urine.

Pathophysiology

In the absence of adequate insulin secretion, persistent partial hepatic oxidation of fatty acids to ketone bodies occurs. Two of these three ketone bodies are organic acids and lead to metabolic acidosis with an elevated anion gap. Lactic acid may contribute to the acidosis when severe dehydration results in decreased tissue perfusion. Hyperglycemia causes an osmotic diuresis that is initially compensated for by increased fluid intake. As the hyperglycemia and diuresis worsen, most patients are unable to maintain the large fluid intake and dehydration occurs. Vomiting and increased insensible water losses caused by tachypnea can worsen the dehydration. Electrolyte abnormalities occur through a loss of electrolytes in the urine and transmembrane alterations resulting from acidosis. As hydrogen ions accumulate as a result of ketoacidosis, intracellular potassium is exchanged for hydrogen ions. Serum concentrations of potassium increase initially with acidosis then decrease as serum potassium is cleared by the kidney. Depending on the duration of ketoacidosis, serum potassium concentrations at diagnosis may be increased, normal, or decreased, but intracellular potassium concentrations are depleted. A decreased serum potassium concentration is an ominous sign of total body potassium depletion. Phosphate depletion also can occur as a result of the increased renal phosphate excretion required for elimination of excess hydrogen ions. Sodium depletion is also common in ketoacidosis resulting from renal losses of sodium caused by osmotic diuresis and from gastrointestinal losses from vomiting ([Fig. 171.2](#)).

FIGURE 171.2 Pathophysiology of diabetic ketoacidosis.

Clinical Presentation

Decision-Making Algorithms

Abdominal Pain
 Polyuria
 Acidemia
 Hyponatremia

Patients with DKA present initially with polyuria, polydipsia, nausea, and vomiting. Abdominal pain occurs frequently and can mimic an acute abdomen. The abdomen may be tender from vomiting or distended secondary to a paralytic ileus. The presence of polyuria, despite a state of clinical dehydration, indicates osmotic diuresis and differentiates patients with DKA from patients with gastroenteritis or other gastrointestinal disorders. Respiratory compensation for acidosis results in tachypnea with deep (**Küssmaul**) respirations. The *fruity* odor of acetone frequently can be detected on the patient's breath. An altered mental

status can occur, ranging from disorientation to coma.

Laboratory studies reveal hyperglycemia (serum glucose concentrations ranging from 200 mg/dL to >1,000 mg/dL). Arterial pH is below 7.30, and the serum bicarbonate concentration is less than 15 mEq/L. Serum sodium concentrations may be elevated, normal, or low, depending on the balance of sodium and free water losses. The measured serum sodium concentration is artificially low, however, because of hyperglycemia. Hyperlipidemia also contributes to the decrease in measured serum sodium. The level of blood urea nitrogen (BUN) can be elevated with prerenal azotemia secondary to dehydration. The white blood cell count is usually elevated and can be left-shifted without implying the presence of infection. Fever is unusual and should prompt a search for infectious sources that may have triggered the episode of DKA.

Treatment

Decision-Making Algorithms

Altered Mental Status
Acidemia
Hypokalemia

Therapy for patients with DKA involves careful replacement of fluid deficits, correction of acidosis and hyperglycemia via insulin administration, correction of electrolyte imbalances, and monitoring for complications of treatment. The optimal approach to management of DKA must strike a balance between adequate correction of fluid losses and avoidance of rapid shifts in osmolality and fluid balance. The most serious complication of DKA and its treatment is **cerebral edema** and cerebral herniation.

A patient with severe DKA is assumed to be approximately 10% dehydrated. If a recent weight measurement is available, the precise extent of dehydration can be calculated. An initial intravenous (IV) fluid bolus of a glucose-free isotonic solution (normal saline, lactated Ringer solution) at 10-20 mL/kg should be given to restore intravascular volume and renal perfusion. The remaining fluid deficit after the initial bolus should be added to maintenance fluid

requirements, and the total should be replaced slowly over 36-48 hours. Ongoing losses resulting from osmotic diuresis usually do not need to be replaced unless urine output is large or signs of poor perfusion are present. Osmotic diuresis is usually minimal when the serum glucose concentration decreases to less than 300 mg/dL. To avoid rapid shifts in serum osmolality, 0.9% sodium chloride can be used as the replacement fluid for the initial 4-6 hours, followed by 0.45% sodium chloride.

Hyperglycemia

Fast-acting soluble insulin should be administered as a continuous IV infusion (0.1 U/kg/hr). Serum glucose concentrations should decrease at a rate no faster than 100 mg/dL/hr. When serum glucose concentrations decrease to less than 250-300 mg/dL, glucose should be added to the IV fluids. If serum glucose concentrations decrease to less than 200 mg/dL before correction of acidosis, the glucose concentration of the IV fluids should be increased, but the insulin infusion should not be decreased by more than half, and it should never be discontinued before resolution of acidosis.

Acidosis

Insulin therapy decreases the production of free fatty acids and protein catabolism and enhances glucose usage in target tissues. These processes correct acidosis. Bicarbonate therapy should be avoided. Potential adverse effects of bicarbonate administration include paradoxical increases in central nervous system (CNS) acidosis caused by increased diffusion of carbon dioxide across the blood-brain barrier, potential tissue hypoxia caused by shifts in the oxyhemoglobin dissociation curve, abrupt osmotic changes, and increased risk of the development of cerebral edema.

As acidosis is corrected, urine ketone concentrations may appear to rise. β -Hydroxybutyrate, which is not detected in urine ketone assays, is converted with treatment to what the assay most detects, acetoacetate. Hence minute-to-minute urine ketone concentrations are not a required index of the adequacy of therapy.

Electrolyte Imbalances

Regardless of the serum potassium concentration at presentation, total body potassium depletion is likely. Serum potassium concentrations can decrease rapidly as insulin and then glucose therapy improves acidosis, and potassium is

exchanged for intracellular hydrogen ions. When adequate urine output is shown, potassium should be added to the IV fluids. Potassium replacement should be given as 50% potassium chloride and 50% potassium phosphate at a concentration of 20-40 mEq/L. This combination provides phosphate for replacement of deficits, but avoids excess phosphate administration, which may precipitate hypocalcemia. If the serum potassium level is greater than 6 mEq/L, potassium should not be added to IV fluids until the potassium level decreases.

Monitoring

Initial laboratory measurements should include serum glucose, sodium, potassium, chloride, bicarbonate, BUN, creatinine, calcium, phosphate, and magnesium concentrations; arterial or venous pH; and a urinalysis. Serum glucose measurement should be repeated every hour during therapy; electrolyte concentrations should be repeated every 2-3 hours. Calcium, phosphate, and magnesium concentrations should be measured every 4-6 hours during therapy. Neurological and mental status should be assessed at frequent intervals. Any complaints of headache or deterioration of mental status should prompt rapid evaluation for possible **cerebral edema**. Indicative symptoms include a decreased sensorium, sudden severe headache, vomiting, change in vital signs (bradycardia, hypertension, apnea), a dilated pupil, ophthalmoplegia, or seizure.

Complications

Clinically apparent **cerebral edema** occurs in 1-5% of cases of DKA. Cerebral edema is the most serious complication of DKA, with a mortality rate of 20-80%. The pathogenesis of cerebral edema likely involves osmolar shift resulting in fluid accumulation in the intracellular compartment and cell swelling. Subclinical cerebral edema is common in patients with DKA, but the factors that exacerbate this process leading to symptomatic brain swelling and possible cerebral herniation are not clearly defined. Cerebral edema typically occurs 6-12 hours after therapy for DKA is begun, often following a period of apparent clinical improvement. Factors that correlate with increased risk for cerebral edema include higher initial BUN concentration, lower initial PCO_2 , failure of the serum sodium concentration to increase as glucose concentration decreases during treatment, and treatment with bicarbonate.

Signs of advanced cerebral edema include obtundation, papilledema, pupillary dilation or inequality, hypertension, bradycardia, and apnea. **Treatment** involves

the rapid use of IV mannitol, endotracheal intubation, and ventilation and may require the use of a subdural bolt. Other complications of DKA are intracranial thrombosis or infarction, acute kidney injury with acute renal failure caused by severe dehydration, pancreatitis, arrhythmias caused by electrolyte abnormalities, pulmonary edema, and bowel ischemia. Peripheral edema occurs commonly 24-48 hours after therapy is initiated and may be related to residual elevations in antidiuretic hormone and aldosterone.

Transition to Outpatient Management

When the acidosis has been corrected and the patient tolerates oral feedings, the IV insulin infusion can be discontinued and a regimen of subcutaneous (SC) insulin injections can be initiated. The first SC insulin dose should be given 30-45 minutes before discontinuation of the IV insulin infusion. Further adjustment of the insulin dose should be made over the following 2-3 days. A patient already diagnosed with T1D may be restarted on the prior doses if they were adequate. For a patient with new-onset T1D, typical starting total daily doses are approximately 0.5-0.7 U/kg/24 hr for prepubertal patients and approximately 0.7-1 U/kg/24 hr for adolescents, using any number of the available insulin combinations. The best and most common choice for making the transition to SC insulin is to begin by giving injections of fast-acting (bolus) insulin (lispro, aspart, or glulisine insulin) with each meal and long-acting (basal) insulin (glargine or detemir) at bedtime. This regimen of multiple daily injections provides the most flexibility but requires the patient to administer many injections per day and to count carbohydrates in food. An alternative is a fixed mixed split dosing regimen (neutral protamine Hagedorn [NPH] and fast-acting insulin) with two daily injections.

Externally worn pumps that provide a continuous SC infusion of fast-acting insulin are available, although not usually used at the very onset of T1D. Insulin pumps provide fast-acting insulin in small basal amounts continuously every hour and will provide bolus insulin when instructed. Insulin pumps may be used by all age groups who are highly motivated to achieve tight control. The absence of SC depot insulin (glargine or detemir) can increase the risk of DKA.

Serum glucose concentrations should be assessed before each meal, at bedtime, and periodically at 2-3 A.M. to provide information for adjustment of the regimen. Patients and their families should begin learning the principles of diabetes care as soon as possible. Demonstration of the ability to administer

insulin injections and test glucose concentrations using a glucose meter is necessary before discharge, as is knowledge of hypoglycemia management. Meal planning is crucial to control glucose in T1D. Nutrition services must be part of the care delivered to the families from diagnosis.

Honeymoon Period

In some patients with new onset of T1D, the β cell mass has not been completely destroyed. The remaining functional β cells seem to recover function with insulin treatment. When this occurs, exogenous insulin requirements decrease. This is a period of stable blood glucose control, often with nearly normal glucose concentrations. This phase of the disease, known as the honeymoon period, usually starts in the first weeks of therapy, often continues for 3-6 months, and can last 2 years.

Outpatient Type 1 Diabetes Mellitus Management

Management of T1D in children requires a comprehensive approach with attention to medical, nutritional, and psychosocial issues. Therapeutic strategies should be flexible with the individual needs of each patient and the family taken into account. Optimal care involves a team of diabetes professionals, including a physician, a diabetes nurse educator, a dietitian, and a social worker or psychologist.

Goals

The Diabetes Control and Complications Trial established that intensive insulin therapy, with the goal of maintaining blood glucose concentrations as close to normal as possible, can delay the onset and slow the progression of complications of diabetes (retinopathy, nephropathy, neuropathy). Attaining this goal using intensive insulin therapy can increase the risk of hypoglycemia. The adverse effects of hypoglycemia in young children may be significant because the immature CNS may be more susceptible to glycopenia. Although the risk for diabetic complications increases with duration of diabetes, there is controversy as to whether the increase of risk is slower in the prepubertal years than in adolescence and adulthood.

Given the benefits of stable, near normal blood glucose concentrations, a goal

of HgbA1c <7.5% is set for children of all ages. Preprandial blood glucose target concentrations are 90-130 mg/dL and concentrations before bedtime and overnight of 90-150 mg/dL. Goals of therapy need to take into account other individual characteristics, such as a past history of severe hypoglycemia and the abilities of the patient and family.

Insulin Regimens

Many types of insulin differ in duration of action and time to peak effect (Table 171.2). These insulins can be used in various combinations, depending on the needs and goals of the individual patient. The most commonly used regimen is that of multiple injections of fast-acting insulin given with meals in combination with long-acting basal insulin given at bedtime. This regimen provides flexibility but requires administration of many injections per day and will require assistance for young children. After the total daily dose of insulin is determined, 30-50% is given as long-acting insulin, and the remainder is given as fast-acting insulin, divided according to the need for corrections of high glucose levels and for meals. To correct for hyperglycemia, one can determine the insulin sensitivity using the 1,800/1,500 rule: dividing 1,800 (or 1,500) by the total daily dose of insulin to determine how many milligrams per deciliter of glucose will decrease with one unit of insulin. The insulin:carbohydrate ratio is used to calculate insulin for the carbohydrate content of food; 500 divided by the total daily dose determines the number of grams of carbohydrate that requires one unit of insulin.

TABLE 171.2

Representative Profiles of Insulin

INSULIN	ONSET	PEAK ACTION	DURATION
VERY SHORT ACTING			
Lispro, aspart, glulisine	5-15 min	30-90 min	3-5 hr
SHORT ACTING			
Regular	30-60 min	2-3 hr	5-8 hr
INTERMEDIATE ACTING			
Neutral protamine Hagedorn (NPH) (isophane)	2-4 hr	4-10 hr	10-16 hr
LONG ACTING			
Glargine	2-4 hr	None	20-24 hr

Detemir	2-4 hr	6-14 hr	16-20 hr
Degludec	2-4 hr	None	24+ hr

Data from Wolfsdorf JI, ed. *Intensive Diabetes Management*. 4th ed. Alexandria, VA: American Diabetes Associations; 2009.

Insulin pumps that provide a continuous SC infusion of short-acting insulin also are available and are being used by children and adolescents who are highly motivated to achieve tight control.

Lispro, aspart, and glulisine insulin are synthetic human insulin analogs in which amino acid alterations result in fast absorption and onset of action (see [Table 171.2](#)). Because of the short duration of action, these are used in combination with long-acting insulin. Glargine and detemir are insulin analogs with increased solubility at acidic pH and decreased solubility at physiological pH. They have a duration of greater than 24 hours and act as a basal insulin.

Newly diagnosed patients in the honeymoon period may require 0.4-0.6 U/kg/24 hr. Prepubertal patients with diabetes longer than 1-2 years typically require 0.5-1 U/kg/24 hr. During middle adolescence when elevated GH concentrations produce relative insulin resistance, insulin requirements increase by 40-50%, and doses of 1-2 U/kg/24 hr are typical.

Nutrition

Balancing the daily meal plan with the dosages of insulin is crucial for maintaining serum glucose concentrations within the target range and avoiding hypoglycemia or hyperglycemia. The content and schedule of meals vary according to the type of insulin regimen used. It is recommended that carbohydrates contribute 50-65% of the total calories, protein 12-20%, and fat <30%. Saturated fat should contribute <10% of the total caloric intake, and cholesterol intake should be less than 300 mg/24 hr. High-fiber content is recommended.

Patients using multiple daily injections or the insulin pump can maintain a more flexible meal schedule with regard to the timing of meals and the carbohydrate content. These patients give an injection of insulin before or immediately after each meal with the total dose calculated according to the carbohydrate content of the meal. Further adjustments in the dose can be made based on the measured serum glucose concentration and plans for activity during the day. Children using a twice-a-day combination of intermediate-acting and fast-acting insulins need to maintain a relatively consistent meal schedule so that carbohydrate absorption and insulin action peaks correspond. A typical meal

schedule for a patient using this type of regimen involves three meals and three snacks daily. The total carbohydrate content of the meals and snacks should be kept constant.

Blood Glucose Testing

Blood glucose should be routinely monitored before each meal and at bedtime. Hypoglycemia during the night or excessive variability in the morning glucose concentrations should prompt additional testing at 2 or 3 A.M. to ensure that there is no consistent hypoglycemia or hyperglycemia. During periods of illness or when blood glucose concentrations are higher than 300 mg/dL, urine ketones also should be tested. Continuous glucose monitors, which provide minute-to-minute blood glucose concentration information, can be useful in following trends of blood glucose concentrations, but should not be used in calculations of mealtime insulin doses.

Long-Term Glycemic Control

Measurements of **glycohemoglobin** or **hemoglobin A_{1c} (HgbA1c)** reflect the average blood glucose concentration over the preceding 3 months and provide a means for assessing long-term glycemic control. HgbA1c should be measured four times a year, and the results should be used for counseling of patients. The American Diabetes Association has set HgbA1c targets for children at <7.5%. Measurements of HgbA1c are inaccurate in patients with hemoglobinopathies. Glycosylated albumin or fructosamine can be used in these cases.

Complications

Patients with T1D for more than 3-5 years should receive an annual ophthalmological examination for retinopathy. Urine should be collected annually for assessment of microalbuminuria, which suggests early renal dysfunction and indicates a high risk of progression to nephropathy. Treatment with angiotensin-converting enzyme inhibitors may halt the progression of microalbuminuria. In children with T1D, annual cholesterol measurements and periodic assessment of blood pressure are recommended. Early detection of hypertension and hypercholesterolemia with appropriate intervention can help limit future risk of coronary disease.

Other Disorders

Chronic autoimmune lymphocytic thyroiditis is particularly common and can result in hypothyroidism. Because symptoms can be subtle, thyroid function tests should be performed annually. Other disorders that occur with increased frequency in children with T1D include celiac disease, immunoglobulin A deficiency, Addison disease, and peptic ulcer disease.

Special Problems: Hypoglycemia

Hypoglycemia occurs commonly in patients with T1D. For patients in adequate or better control, it is expected to occur on average once or twice a week. Severe episodes of hypoglycemia, resulting in seizures or coma or requiring assistance from another person, occur in 10-25% of these patients per year.

Hypoglycemia in patients with T1D results from a relative excess of insulin in relation to the serum glucose concentration. This excess can be caused by alterations in the dose, timing, or absorption of insulin; alterations of carbohydrate intake; or changes in insulin sensitivity resulting from activity. Defective counter-regulatory responses also contribute to hypoglycemia. Abnormal glucagon responses to falling serum glucose concentrations develop within the first few years of the disease, and abnormalities in epinephrine release occur after a longer duration.

Lack of awareness of hypoglycemia occurs in approximately 25% of patients with diabetes. Recent episodes of hypoglycemia may play a role in the pathophysiology of *hypoglycemia unawareness*; after an episode of hypoglycemia, autonomic responses to subsequent episodes are reduced. A return of symptoms of hypoglycemia can be exhibited in these patients after 2-3 weeks of strict avoidance of hypoglycemic episodes.

Symptoms of hypoglycemia include symptoms resulting from neuroglycopenia (headache, visual changes, confusion, irritability, or seizures) and symptoms resulting from the catecholamine response (tremors, tachycardia, diaphoresis, or anxiety). Mild episodes can be treated with administration of rapidly absorbed oral glucose (glucose gel or tablets or fruit juices). More severe episodes that result in seizures or loss of consciousness at home should be treated with glucagon injections. IV glucose should be given in hospital settings.

Prognosis

Long-term complications of T1D include retinopathy, nephropathy, neuropathy, and macrovascular disease. Evidence of organ damage caused by hyperglycemia is rare in patients with diabetes of less than 5-10 years' duration; clinically apparent disease rarely occurs before 10-15 years' duration. Diabetic retinopathy is the leading cause of blindness in the United States. Nephropathy eventually occurs in 30-40% and accounts for approximately 30% of all new adult cases of end-stage renal disease. Neuropathy occurs in 30-40% of postpubertal patients with T1D and leads to sensory, motor, or autonomic deficits. Macrovascular disease results in an increased risk of myocardial infarction and stroke among individuals with diabetes.

Intensive control of diabetes, using frequent blood glucose testing, continuous glucose monitoring, and multiple daily injections of insulin or an insulin pump, can reduce the development or progression of diabetic complications, including a 76% reduction of risk for retinopathy, a 39% reduction in microalbuminuria, and a 60% reduction in clinical neuropathy. For pubertal and adult patients, the benefits of intensive therapy likely outweigh the increased risk for hypoglycemia. For younger patients, in whom the risks for hypoglycemia are greater and the benefits of tight glucose control may be lower, a less intensive regimen may be appropriate.

Type 2 Diabetes Mellitus

Pathophysiology

T2D can occur as the result of various pathophysiological processes; however, the most common form results from peripheral insulin resistance and compensatory hyperinsulinemia, followed by failure of the pancreas to maintain adequate insulin secretion (see [Table 171.1](#)).

Epidemiology

The prevalence of T2D in children is increasing in parallel with childhood obesity and is highest in children of ethnic groups with a high prevalence of T2D in adults, including Native Americans, Hispanic Americans, and African Americans. Obesity, the metabolic syndrome, ethnicity, and a family history of T2D are risk factors. Autoantibodies to the pancreas are present among some clinically assumed to have T2D, compounding the difficulty in differentiating T1D from T2D at the time of diagnosis.

Clinical Manifestations and Differential Diagnosis

Fasting and postprandial glucose levels for diagnosis of T2D are the same as those for T1D. The diagnosis of T2D may be suspected on the basis of polyuria and polydipsia in a background of the metabolic syndrome. Differentiating T2D from T1D in children on only clinical grounds can be challenging. The possibility of T2D should be considered in patients who are obese, have a strong family history of T2D, have other characteristics of the metabolic syndrome, or have absence of antibodies to β cell antigens at the time of diagnosis of diabetes. **Acanthosis nigricans**, a dermatological manifestation of hyperinsulinism and insulin resistance, presents as hyperkeratotic pigmentation in the nape of the neck and in flexural areas and is noted as a sign in the metabolic syndrome. Although ketoacidosis occurs far more commonly in T1D, it also can occur in patients with T2D under conditions of physiological stress and cannot be used as an absolute differentiating factor. T2D can be confirmed by the evaluation of insulin or C-peptide responses to stimulation with oral carbohydrate and in the absence of islet cell autoreactivity.

Therapy

T2D is the result of a combination of insulin resistance, relative insulin deficiency, and a secretory β cell defect. Asymptomatic patients with mildly elevated glucose values (slightly >126 mg/dL for fasting or slightly >200 mg/dL for random glucose) may be managed initially with lifestyle modifications, including nutrition therapy (dietary adjustments) and increased exercise. Exercise has been shown to decrease insulin resistance. In most children with new-onset, uncomplicated T2D, oral agents are usually the first line of therapy. Only metformin, an insulin secretagogue, is approved by the U.S. Food and Drug Administration for use in children. A rare side effect of metformin is lactic acidosis, occurring mainly in patients with compromised renal function. The most common side effect is gastrointestinal upset. If ketonuria or ketoacidosis occurs, insulin treatment is necessary to first achieve adequate glycemic control, but may be discontinued within weeks with continuation of oral medications. Insulin therapy may be required if adequate glycemic control is not achieved with lifestyle modifications and metformin.

Because T2D may have a long preclinical course, early diagnosis is possible

in subjects at risk who have the **metabolic syndrome**. Significant lifestyle modifications, such as improved eating habits and increased exercise, have a role in preventing or decreasing the morbidity of T2D. Finally, it is critical to monitor and manage the other components of metabolic syndrome, such as advanced pubertal development, hypertension, hyperlipidemia, and polycystic ovary syndrome in females.

Maturity-Onset Diabetes of Youth (MODY)

MODY comprises a group of dominantly inherited forms of relatively mild diabetes. Insulin resistance does not occur in these patients; instead, the primary abnormality is an insufficient insulin secretory response to glycemic stimulation. Treatment depends on the type and can include the use of sulfonylureas.

CHAPTER 172

Hypoglycemia

Hypoglycemia in infancy and childhood can result from a large variety of hormonal and metabolic defects ([Table 172.1](#)). Hypoglycemia occurs most frequently in the early neonatal period, often as a result of transient neonatal hyperinsulinemia in infants of diabetic mothers or as a result of inadequate energy stores to meet the disproportionately large metabolic needs of premature or small for gestational age newborns. Hypoglycemia during the first few days of life in an otherwise normal newborn is less frequent and warrants concern (see [Chapter 6](#)). After the initial 2-3 days of life, hypoglycemia is far less common and is more frequently the result of endocrine or metabolic disorders (although sepsis must always be ruled out).

TABLE 172.1

Classification of Hypoglycemia in Infants and Children

Definition

Clinical hypoglycemia is defined as a plasma glucose (PG) concentration low enough to cause symptoms and/or signs of impaired brain function. Brain glucose utilization is reduced at a PG concentration of approximately 55-65 mg/dL. **Autonomic system** (neurogenic) symptoms are perceived at a PG concentration <55 mg/dL. Cognitive function is impaired (**neuroglycopenia**) at a PG concentration <50 mg/dL (Table 172.2).

TABLE 172.2

Symptoms and Signs of Hypoglycemia

FEATURES ASSOCIATED WITH EPINEPHRINE RELEASE*	FEATURES ASSOCIATED WITH CEREBRAL GLYCOPENIA

Perspiration	Headache
Palpitation (tachycardia)	Mental confusion
Pallor	Somnolence
Paresthesia	Dysarthria
Trembling	Personality changes
Anxiety	Inability to concentrate
Weakness	Staring
Nausea	Hunger
Vomiting	Convulsions
	Ataxia
	Coma
	Diplopia
	Stroke

These features and perceptions of the features may be blunted if the patient is receiving β -blocking agents.

Clinical Manifestations

Decision-Making Algorithms

Hypotonia and Weakness
 Altered Mental Status
 Irritable Infant

The symptoms and signs of hypoglycemia result from direct depression of the central nervous system owing to lack of energy substrate and the counter-regulatory adrenergic response to low glucose via catecholamine secretion designed to correct hypoglycemia (see [Table 172.2](#)). Compared with older children, infants do not usually show adrenergic symptoms. The signs and symptoms of hypoglycemia in infants are relatively nonspecific and include jitteriness, feeding difficulties, pallor, hypotonia, hypothermia, episodes of apnea and bradycardia, depressed levels of consciousness, and seizures. In older children, signs and symptoms include confusion, irritability, headaches, visual changes, tremors, pallor, sweating, tachycardia, weakness, seizures, and coma.

Failure to recognize and treat severe, prolonged hypoglycemia can result in

serious long-term morbidity, including intellectual disability and nonhypoglycemic seizures. Younger infants and patients with more severe or prolonged hypoglycemia are at greatest risk for adverse outcomes.

Pathophysiology

Hormonal Signal

Normal regulation of serum glucose concentrations requires appropriate interaction of a number of hormonal signals and metabolic pathways (Fig. 172.1). In a normal individual, a decrease in serum glucose concentrations leads to a suppression of insulin secretion and increased secretion of the counter-regulatory hormones (growth hormone [GH], cortisol, glucagon, and epinephrine; see Fig. 172.1). This hormonal signal promotes the release of amino acids (particularly alanine) from muscle to fuel gluconeogenesis and the release of triglyceride from adipose tissue stores to provide free fatty acids (FFAs) for hepatic ketogenesis. FFAs and ketones serve as alternate fuels for muscle. This hormonal signal also stimulates the breakdown of hepatic glycogen and promotes gluconeogenesis. Failure of any of the components of this hormonal signal can lead to hypoglycemia.

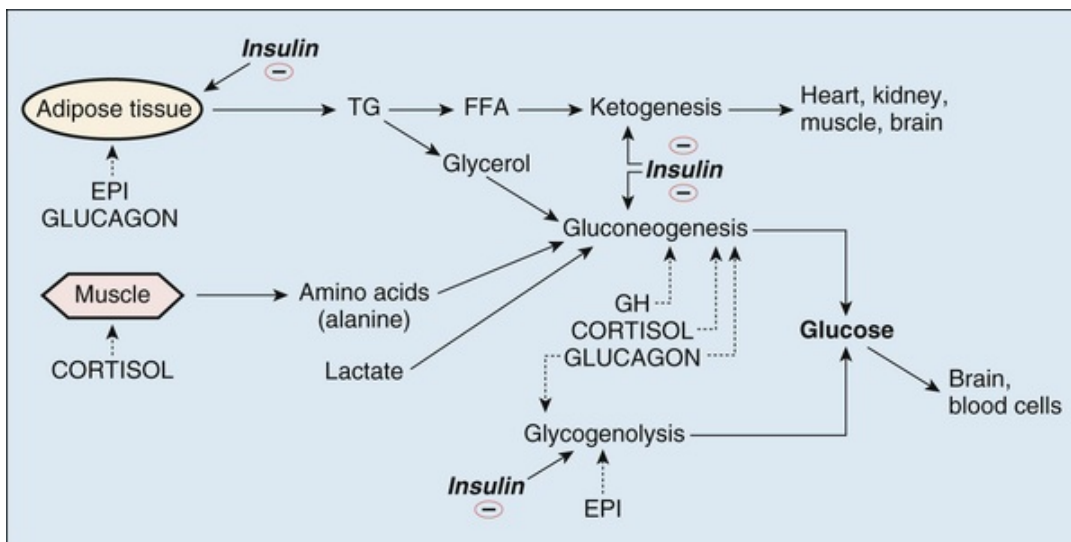

FIGURE 172.1 Regulation of serum glucose.

represents inhibitions. *EPI*, Epinephrine; *FFA*, free fatty acid; *GH*, growth hormone; *TG*, triglyceride.

Hyperinsulinemia

Decision-Making Algorithm

Obesity

A lack of suppression of insulin secretion in response to low serum glucose concentrations can occur in infants but is uncommon beyond the neonatal period. This situation arises most frequently in infants of diabetic mothers who were exposed to high concentrations of maternally derived glucose in utero, resulting in fetal islet cell hyperplasia. The hyperinsulinemic state is transient, usually lasting hours to days.

Hyperinsulinism that persists beyond a few days of age can result from distinct genetic disorders affecting glucose-regulated insulin release, or **congenital hyperinsulinism**. In these infants, hyperplasia of the pancreatic islet cells develops in the absence of excess stimulation by maternal diabetes. There are currently 11 genes associated with monogenic forms of hyperinsulinism (*ABCC8*, *KCNJ11*, *GLUD1*, *GCK*, *HADH1*, *UCP2*, *MCT1*, *HNF4A*, *HNF1A*, *HK1*, *PGM1*), as well as several syndromic genetic forms of HI (e.g., Beckwith-Wiedemann, Kabuki, and Turner syndromes). The most common causes for congenital hyperinsulinism involve inactivating K_{ATP} channel mutations and account for approximately 60% of all identifiable mutations. Hyperinsulinism also can occur in **Beckwith-Wiedemann syndrome** (a condition characterized by neonatal somatic gigantism, macrosomia, macroglossia, omphalocele, visceromegaly, and earlobe creases).

Regardless of the cause, neonates with hyperinsulinism are characteristically large for gestational age (see [Chapter 60](#)). Hypoglycemia is severe and frequently occurs within 1-3 hours of a feeding. Glucose requirements are increased, often two to three times the normal basal glucose requirement of 6-8 mg/kg/min. The *diagnosis* of hyperinsulinism in children is determined by evaluating markers of inappropriate insulin effects (e.g., suppressed ketogenesis) because plasma insulin concentrations are frequently not clearly elevated.

Diagnosis is most reliably based on a closely monitored provocative fasting test that includes (1) frequent sampling of plasma concentrations of glucose, insulin, β -hydroxybutyrate, and FFAs and (2) terminating the test when glucose concentrations decline toward 50 mg/dL with a determination of the glycemic response to glucagon. The absence of serum and urine ketones at the time of hypoglycemia is an important diagnostic feature, distinguishing hyperinsulinism from defects in counter-regulatory hormone secretion.

Treatment initially involves the infusion of intravenous (IV) glucose at high rates and of diazoxide to suppress insulin secretion. If diazoxide therapy is unsuccessful, long-acting somatostatin analogs can be tried. Often medical therapy for persistent hyperinsulinemic hypoglycemia of the newborn is unsuccessful, and subtotal (90%) pancreatectomy is required to prevent long-term neurological sequelae of hypoglycemia.

Factitious Hyperinsulinemia

In rare cases, insulin or a hypoglycemic medication is administered by a parent or caregiver to a child as a form of child abuse, which is a condition referred to as **Munchausen syndrome by proxy**. This *diagnosis* should be suspected if extremely high insulin concentrations are detected ($>100 \mu\text{U/mL}$). C-peptide concentrations are low or undetectable, which confirms that the insulin is from an exogenous source.

Defects in Counter-Regulatory Hormones

Abnormalities in the secretion of counter-regulatory hormones that produce hypoglycemia usually involve GH, cortisol, or both. Deficiencies in glucagon and epinephrine secretion are rare. GH and cortisol deficiency occur as a result of hypopituitarism. Hypopituitarism results from congenital hypoplasia or aplasia of the pituitary or, more commonly, from deficiency of hypothalamic releasing factors (see [Chapter 173](#)). Clues to this diagnosis in infants include the presence of hypoglycemia in association with midline facial or neurological defects (e.g., cleft lip and palate or absence of the corpus callosum), pendular (roving) nystagmus (indicating visual impairment from possible abnormalities in the development of the optic nerves, which can occur in optic nerve hypoplasia), and the presence of microphallus and cryptorchidism in boys (indicating abnormalities in gonadotropin secretion). Jaundice and hepatomegaly also can occur, simulating neonatal hepatitis. Despite the presence of GH deficiency,

these infants are usually of normal size at birth.

Deficient cortisol secretion also can occur in primary adrenal insufficiency, resulting from a variety of causes. In infants it often results from congenital adrenal hyperplasia, most frequently as a result of 21-hydroxylase deficiency (see [Chapters 177](#) and [178](#)). In older children, primary adrenal insufficiency is seen most frequently in **Addison disease** and other disorders (see [Chapter 178](#)).

Confirmation of GH or cortisol deficiency as the cause of hypoglycemia requires the detection of low serum GH and cortisol concentrations during an episode of hypoglycemia or after other stimulatory testing. In contrast to hyperinsulinism, serum and urine ketones are positive at the time of hypoglycemia and FFAs are elevated. Treatment involves supplementation of the deficient hormones in physiological doses.

Energy Stores

Sufficient energy stores in the form of glycogen, adipose tissue, and muscle are necessary to respond appropriately to hypoglycemia. Deficiencies in these stores are a common cause of hypoglycemia in neonates who are small for gestational age or premature (see [Chapter 60](#)). Beyond the early neonatal period, energy stores are usually sufficient to meet the metabolic requirements except in malnourished children.

Idiopathic Ketotic Hypoglycemia

A common cause of new-onset hypoglycemia is idiopathic ketotic hypoglycemia, usually seen in children between 18 months and remits by 8 years of age. Patients have symptoms of hypoglycemia after a period of prolonged fasting, often in the setting of an intercurrent illness with decreased feeding. Children with this disorder are often thin and small and may have a history of being small for gestational age. Defective mobilization of alanine from muscle to fuel gluconeogenesis is thought to be the cause, although the condition may derive mostly from having lower fuel reserves. Because there are no specific diagnostic tests for this disorder, ketotic hypoglycemia is a *diagnosis of exclusion*.

Treatment involves avoidance of fasting and frequent feedings of a high-protein, high-carbohydrate diet. Patients may require hospitalization for IV glucose infusion if they cannot maintain adequate oral intake during a period of

illness.

Disrupted Metabolic Response Pathways

Maintenance of normal serum glucose concentrations in the fasting state requires glucose production via glycogenolysis and gluconeogenesis and the production of alternative energy sources (FFAs and ketones) via lipolysis and fatty acid oxidation.

Glycogenolysis

Some glycogen storage diseases (GSDs) occur in a variety of subtypes that differ in severity (see [Chapter 52](#)). Among the subtypes that result in hypoglycemia, the most severe form is glucose-6-phosphatase deficiency, which is characterized by severe hypoglycemia, massive hepatomegaly, growth retardation, and lactic acidosis. In contrast, deficiencies in the glycogen phosphorylase enzymes may cause isolated hepatomegaly with or without hypoglycemia.

The *diagnosis* of GSD is suggested by a finding of hepatomegaly without splenomegaly (although GSD type 0 is not associated with hepatomegaly). Confirmation of the diagnosis requires specific biochemical studies of leukocytes or liver biopsy specimens. *Treatment* for the most common types involves frequent high-carbohydrate feedings during the day and continuous feedings at night via nasogastric tube. Feedings of uncooked cornstarch overnight are sufficient to maintain serum glucose concentrations in some patients.

Gluconeogenesis

Defects in gluconeogenesis are uncommon and include fructose-1,6-diphosphatase deficiency and phosphoenolpyruvate carboxykinase deficiency. Affected patients exhibit fasting hypoglycemia, hepatomegaly, lactic acidosis, and hyperuricemia. Ketosis occurs, and FFA and alanine concentrations are high. *Treatment* involves frequent high-carbohydrate, low-protein feedings (see [Chapter 52](#)).

Fatty Acid Oxidation

Fatty acid oxidation disorders of ketogenesis include the fatty acid acyl-

coenzyme A (CoA) dehydrogenase deficiencies; long-chain, medium-chain, and short-chain acyl-CoA dehydrogenase deficiencies; and hereditary carnitine deficiency (see [Chapter 55](#)). Of these disorders, medium-chain acyl-CoA dehydrogenase deficiency is the most common; it occurs in 1 in 4,000-17,000 live births, depending on the population. Patients often are well in infancy and have the first episode of hypoglycemia at 2 years of age or older. Mild hepatomegaly may be present along with mild hyperammonemia, hyperuricemia, and mild elevations in hepatic transaminases. Episodes of nonketotic hypoglycemia usually occur with prolonged fasting or during episodes of intercurrent illness. *Treatment* involves avoidance of fasting.

Other Metabolic Disorders

Many metabolic disorders can lead to hypoglycemia, including galactosemia, hereditary fructose intolerance, and disorders of organic acid metabolism (see [Table 172.1](#)). Hypoglycemia in these disorders is usually a reflection of global hepatic dysfunction secondary to the buildup of hepatotoxic intermediates. Many of these disorders present with low concentrations of ketone bodies because ketogenesis also is affected. The finding of non-glucose-reducing substances in the urine after ingestion of offending substances suggests a diagnosis of galactosemia or hereditary fructose intolerance. *Treatment* requires dietary restriction of the specific offending substances.

Medications and Intoxication

Hypoglycemia can occur as an adverse effect of numerous medications (see [Table 172.1](#)). Ethanol ingestion also can cause hypoglycemia, especially in younger children, because the metabolism of ethanol results in the depletion of cofactors necessary for gluconeogenesis.

Diagnosis

Although the list of causes of hypoglycemia is long and complex, establishing the *etiology* in a particular patient is important. Frequently it is difficult to make an accurate diagnosis until one can obtain a *critical sample* of blood and urine at the time of the hypoglycemic episode. In a child with unexplained hypoglycemia, a serum sample should be obtained before treatment for the

measurement of glucose and insulin, GH, cortisol, FFAs, and β -hydroxybutyrate and acetoacetate. Measurement of serum lactate levels also should be considered. A urine specimen should be obtained for measuring ketones and reducing substances. *Hypoglycemia without ketonuria suggests hyperinsulinism or a defect in fatty acid oxidation.* The results of this initial testing can establish whether endocrine causes are responsible and, if not, provide initial information regarding which types of metabolic disorders are most likely.

Emergency Management

Acute care of a patient with hypoglycemia consists of rapid administration of IV glucose (2 mL/kg of 10% dextrose in water). After the initial bolus, an infusion of IV glucose should provide approximately 1.5 times the normal hepatic glucose production rate (8-12 mg/kg/min in infants, 6-8 mg/kg/min in children). This infusion allows for suppression of the catabolic state and prevents further decompensation in patients with certain metabolic disorders. If adrenal insufficiency is suspected, stress doses of glucocorticoids should be administered.

CHAPTER 173

Short Stature

Growth

Normal growth is the final common pathway of many factors, including endocrine, environmental, nutritional, and genetic influences (see [Chapter 5](#)). A normal linear growth pattern is good evidence of overall health and can be considered a *bioassay* for the well-being of the whole child. The effects of certain hormones on growth and ultimate height are listed in [Table 173.1](#). Just as various factors influence stature, stature itself influences psychological, social, and potentially economic well-being. Parental concern about the psychosocial consequences of abnormal stature often causes a family to seek medical attention.

TABLE 173.1**Hormonal Effects on Growth**

HORMONE	BONE AGE	GROWTH RATE	ADULT HEIGHT*
Androgen excess	Advanced	Increased	Diminished
Androgen deficiency	Normal or delayed	Normal or decreased	Increased slightly or normal
Thyroxine excess	Advanced	Increased	Normal or diminished
Thyroxine deficiency	Retarded	Decreased	Diminished
Growth hormone excess	Normal or advanced	Increased	Excessive
Growth hormone deficiency	Retarded	Decreased	Diminished
Cortisol excess	Retarded	Decreased	Diminished
Cortisol deficiency	Normal	Normal	Normal

*Effect in most patients with treatment.

Growth Hormone Physiology

Growth hormone (GH) secretion is pulsatile, stimulated by hypothalamic GH-releasing factor (GRF), and inhibited by GH release inhibitory factor (somatostatin, somatotropin release-inhibiting factor [SRIF]), which interact with their individual receptors on the pituitary somatotrope in a noncompetitive manner. GH is also stimulated by a number of factors (e.g., ghrelin, sex steroid hormones, clonidine, hypoglycemia, etc.). GH circulates bound to a GH-binding protein (GHBP); GHBP abundance reflects the abundance of GH receptors. GH has direct effects on tissue and also causes production and secretion of insulin-like growth factor-1 (IGF-1) in many tissues. GH stimulates IGF-1 production in the liver along with production of the acid-labile subunit and the IGF-binding protein (IGF-BP3); this forms the complex that delivers IGF-1 to tissue.

IGF-1 acts primarily as a paracrine and autocrine agent and is most closely associated with postnatal growth. When IGF-1 attaches to its membrane-bound receptor, second messengers are stimulated to change the physiology of the cell and produce growth effects. IGF-1 production is influenced by disease states such as malnutrition, chronic renal and liver disease, hypothyroidism, or obesity.

IGF-BP3 is measurable in clinical assays and is less influenced by nutrition and age than is IGF-1; measuring IGF-1 and IGF-BP3 is useful in evaluating GH

adequacy, particularly in infancy and early childhood.

Measurement of Growth

The correct measurement of an infant's length requires one adult to hold the infant's head still and another adult to extend the feet with the soles perpendicular to the lower legs. A caliper-like device, such as an infantometer, or the movable plates on an infant scale are used so that the exact distance between the two calipers or plates can be determined. Marking the position of the head and feet of an infant lying on a sheet of paper on the examining table leads to inaccuracies and may miss true disorders of growth or create false concerns about a disorder of growth in a normal child. Accurate measurements of height (standing), or length (lying down), and weight should be plotted on the Centers for Disease Control and Prevention growth charts for the timely diagnosis of growth disorders (<http://www.cdc.gov/growthcharts/>).

After 2 years of age, the height of a child should be measured in the standing position. Children measured in the standing position should be barefoot against a hard surface. A Harpenden stadiometer or equivalent device is optimal for the measurement of stature. A decrease of roughly 1.25 cm in height measurement may occur when the child is measured in the standing position rather than in the lying position, leading to the inappropriate referral of many children who appear to be *not growing* to a subspecialist.

Measurement of the **arm span** is essential when the diagnoses of Marfan or Klinefelter syndrome, short-limbed dwarfism, or other dysmorphic conditions are considered. Arm span is measured as the distance between the tips of the fingers when the patient holds both arms outstretched horizontally while standing against a solid surface. The **upper-to-lower segment ratio** is the ratio of the upper segment (determined by subtraction of the measurement from the symphysis pubis to the floor [known as the lower segment] from the total height) to the lower segment. This ratio changes with age. A normal term infant has an upper-to-lower ratio of 1.7 : 1, a 1-year-old has a ratio of 1.4 : 1, and a 10-year-old has a ratio of 1 : 1. Conditions of hypogonadism, not commonly discerned or suspected until after the normal age for onset of puberty, lead to greatly decreased upper-to-lower ratio in an adult, whereas long-lasting and untreated hypothyroidism leads to a high upper-to-lower ratio in the child.

Endocrine Evaluation of Growth Hormone

Secretion

Decision-Making Algorithm

Short Stature

GH is a 191–amino acid protein secreted by the pituitary gland under the control of GRF and SRIF (see [Fig. 170.2](#)). GH secretion is enhanced by α -adrenergic stimulation, hypoglycemia, starvation, exercise, early stages of sleep, and stress and inhibited by β -adrenergic stimulation and hyperglycemia. Because concentrations of GH are low throughout the day, except for brief secretory peaks in the middle of the night or early morning, the daytime ascertainment of GH deficiency or sufficiency on the basis of a single determination of a random GH concentration is impossible. Adequacy of GH secretion may be determined by a stimulation test to measure peak GH secretion. A normal response is a vigorous secretory peak after stimulation; the lack of such a peak is consistent with GH deficiency. However, there is a high false-positive rate (on any day, about 10% or more of normal children may not reach the normal GH peak after even two stimulatory tests). Indirect measurements of GH secretion, such as serum concentrations of IGF-1 and IGF-BP3, are considered better screens for GH deficiency.

The factors responsible for postnatal growth are not the same as the factors that mediate fetal growth. **Thyroid hormone** is essential for normal postnatal growth, although a thyroid hormone-deficient fetus achieves a normal birth length; similarly, a GH-deficient fetus has a normal birth length, although in IGF-1 deficiency resulting from GH resistance (**Laron dwarfism**), fetuses are shorter than control subjects. Adequate thyroid hormone is necessary to allow the secretion of GH. Hypothyroid patients may appear falsely to be GH deficient; with thyroid hormone repletion, GH secretion normalizes. Gonadal steroids are important in the pubertal growth spurt. The effects of other hormones on growth are noted in [Table 173.1](#).

Abnormalities of Growth

Short Stature of Nonendocrine Causes

Decision-Making Algorithm

Short Stature

Short stature is defined as subnormal height relative to other children of the same gender and age, taking family heights into consideration. It can be caused by numerous conditions (Table 173.2). The Centers for Disease Control and Prevention growth charts use the 3rd percentile of the growth curve as the demarcation of the lower limit. **Growth failure** denotes a slow growth rate regardless of stature. Ultimately a slow growth rate leads to short stature, but a disease process is detected sooner if the decreased growth rate is noted before the stature becomes short. Plotted on a growth chart, growth failure appears as a curve that crosses percentiles downward and is associated with a height velocity below the 5th percentile of height velocity for age (Fig. 173.1). A corrected midparental, or genetic target, height helps determine whether the child is growing well for the family (see Chapter 6). To determine a range of normal height for the family under consideration, the corrected midparental height is bracketed by 2 standard deviations (SDs), which, for the United States, is approximately 10 cm (4 in.). The presence of a height 3.5 SDs below the mean, a height velocity below the 5th percentile for age, or a height below the target height corrected for midparental height requires a diagnostic evaluation.

TABLE 173.2

Causes of Short Stature

VARIATIONS OF NORMAL

*Only if caloric intake is severely diminished.

AIDS, Acquired immunodeficiency syndrome; *CNS*, central nervous system; *GH*, growth hormone; *IGF*, insulin-like growth factor.

Modified from Styne DM. Growth disorder. In: Fitzgerald PA, ed. *Handbook of Clinical Endocrinology*. Norwalk, CT: Appleton & Lange; 1986.

FIGURE 173.1 Patterns of linear growth. Normal growth percentiles (5th, 50th, and 95th) are shown along with typical growth curves for (A) constitutional delay of growth and adolescence (short stature with normal growth rate for bone age, delayed pubertal growth spurt, and eventual achievement of normal adult stature); (B) familial short stature (short stature in childhood and as an adult); and (C) acquired pathological growth failure (e.g., acquired untreated primary hypothyroidism) (see [Chapter 5](#)).

Nutrition is the most important factor affecting growth on a worldwide basis (see [Chapter 28](#)). Failure to thrive may develop in the infant as a result of **maternal deprivation** (nutritional deficiency or aberrant psychosocial interaction) or as a result of organic illness (anorexia, nutrient losses through a form of malabsorption, or hypermetabolism caused by hyperthyroidism or other causes; see [Chapter 21](#)). Psychological difficulties also can affect growth, as in **psychosocial** or **deprivation dwarfism**, in which the child develops functional temporary GH deficiency and poor growth as a result of psychological abuse; when placed in a different, healthier psychosocial environment, GH physiology normalizes, and growth occurs.

The common condition known as **constitutional delay** in growth or puberty or both is considered a variation of normal growth, caused by a reduced tempo, or cadence, of physiological development (see [Fig. 173.1](#)). Usually a family

member had delayed growth or puberty but achieved a normal final height. The bone age is delayed, but the growth rate remains mostly within the lower limits of normal. Constitutional delay usually leads to a delay in secondary sexual development. **Genetic or familial short stature** (Table 173.3) refers to the stature of a child of short parents, who is expected to reach a lower than average height and yet normal for these parents. If the parents were malnourished as children, grew up in a zone of war, or suffered famine, the heights of the parents are less predictive.

TABLE 173.3

Differential Diagnosis and Therapy of Short Stature

DIAGNOSTIC FEATURE	HYPOPITUITARISM GH DEFICIENCY*	CONSTITUTIONAL DELAY	FAMILIAL SHORT STATURE	DEPRIVED DWARF
Family history positive	Rare	Frequent	Always	No
Gender	Both	Males more often affected than females	Both	Both
Facies	Immature or with midline defect (e.g., cleft palate or optic hypoplasias)	Immature	Normal	Normal
Sexual development	Delayed	Delayed	Normal	May be delayed
Bone age	Delayed	Delayed	Normal	Usually delayed or arrested linear growth
Dentition	Delayed	Normal; delay usual	Normal	Variable
Hypoglycemia	Variable	No	No	No
Karyotype	Normal	Normal	Normal	Normal
Free T ₄	Low (with TRH deficiency) or normal	Normal	Normal	Normal or low
Stimulated GH	Low	Normal for bone age	Normal	Possibly low in patient with normal bone age
Insulin-like growth factor-1	Low	Normal or low for chronological age	Normal	Low

Therapy	Replace deficiencies	Reassurance; sex steroids to initiate secondary sexual development in selected patients	None	Change or in environment
---------	----------------------	---	------	--------------------------

*Possibly with GnRH, CRH, or TRH deficiency.

CRH, Corticotropin-releasing hormone; *GH*, growth hormone; *GnRH*, gonadotropin-releasing hormone; *TRH*, thyrotropin-releasing hormone; *T₄*, thyroxine.

Phenotypic features suggesting an underlying chromosomal disorder can occur in many syndromes. These syndromes can be suspected by attending to arm spans and upper-to-lower segment ratios. Genetic syndromes often combine obesity and decreased height, whereas otherwise normal obese children are usually taller than average and have advanced skeletal development and physical maturation (see [Table 173.2](#)). The **Prader-Willi syndrome** includes fetal and infantile hypotonia, small hands and feet, postnatal acquired obesity with an insatiable appetite, developmental delay, hypogonadism, almond-shaped eyes, and abnormalities on the snRNP (small nuclear ribonucleic particle) portion of the 15th chromosome at 15q11-q13. Most cases have deletion of the paternal sequence, but about 20-25% have uniparental disomy, in which both chromosomes 15 derive from the mother. **Laurence-Moon-Bardet-Biedl syndrome** is characterized by retinitis pigmentosa, hypogonadism, and developmental delay with an autosomal dominant inheritance pattern. Laurence-Moon syndrome is associated with spastic paraplegia; Bardet-Biedl syndrome is associated with obesity and polydactyly. **Pseudohypoparathyroidism** leads to short stature and developmental delay with short fourth and fifth digits (Albright hereditary osteodystrophy phenotype), resistance to parathyroid hormone and resultant hypocalcemia, and elevated levels of serum phosphorus. **Turner syndrome** is characterized by a karyotype of 45,XO or by a mosaic karyotype and clinically presents with short stature, shield chest, wide-spaced nipples, wide-carrying angle of the upper extremities, high-arched palate, gonadal failure, kidney dysplasias with normal function, and aortic arch abnormalities. Affected girls are often susceptible to autoimmune disorders.

Decision-Making Algorithms

Hypotonia and Weakness
Short Stature
Pubertal Delay
Obesity
Hypocalcemia

Short Stature Caused by Growth Hormone Deficiency

Etiology and Epidemiology

Decision-Making Algorithm

Short Stature

Classic congenital or **idiopathic GH deficiency** occurs in about 1 in 4,000 children. Idiopathic GH deficiency, of unidentified specific etiology, is the most common cause of both congenital and acquired GH deficiency. Less often, GH deficiency is caused by anatomical defects of the pituitary gland, such as pituitary aplasia or other midline defects, with variable degrees of deficiency of other pituitary functions. Hereditary forms of GH deficiency that affect pituitary differentiation are the result of heterogeneous defects of the gene for GH, GRF, or GH receptor. *Classic GH deficiency* refers to very reduced to absent secretion of GH; numerous short children may have intermediate forms of decreased GH secretion. Acquired GH deficiency causing late-onset growth failure suggests the possibility of a **tumor** of the hypothalamus or pituitary causing compression of the area (see [Tables 173.2](#) and [173.3](#)).

Clinical Manifestations

Infants with congenital GH deficiency achieve a normal or near-normal birth length and weight at term, but the growth rate slows after birth, most noticeably after age 2-3 years. These children become progressively shorter for age and tend to have an elevated weight-to-height ratio. Careful measurements in the first year of life may suggest the diagnosis, but most patients elude diagnosis until

several years of age. A patient with classic GH deficiency has the appearance of a **cherub (a chubby, immature appearance)**, with a high-pitched voice resulting from an immature larynx. Unless severe hypoglycemia occurs or dysraphism (midline defects) of the head includes a central nervous system (CNS) defect that affects mentation, the patient has normal intellectual growth and age-appropriate speech. Male neonates with isolated GH deficiency with or without gonadotropin deficiency may have a micropallus (a stretched penile length of <2 cm [normal is 3-5 cm]) and fasting hypoglycemia. Patients who lack the adrenocorticotropic hormone (ACTH, stimulates cortisol) in addition to GH may have more profound hypoglycemia because cortisol also stimulates gluconeogenesis.

A very rare cause of growth failure is GH resistance or GH insensitivity, caused by abnormal number or function of GH receptors or by a postreceptor defect. Patients with the autosomal recessive **Laron syndrome**, involving mutations of the GH receptor, have a prominent forehead, hypoplastic nasal bridge, delayed dentition, sparse hair, blue sclerae, delayed bone maturation and osteoporosis, progressive adiposity, hypercholesterolemia, and low blood glucose. They have elevated serum GH concentrations, although serum IGF-1 and IGF-BP3 concentrations are low. Malnutrition, medications (corticosteroids), or severe liver disease may cause **acquired GH resistance** because serum GH is elevated and IGF-1 is decreased.

Diagnosis

If family or other medical history does not provide a likely diagnosis, screening tests should include a metabolic panel to evaluate kidney and liver function, a complete blood count (CBC) to rule out anemia, a celiac panel to rule out celiac disease, erythrocyte sedimentation rate (ESR), thyroid function testing, and IGF-1, IGF-BP-3 for children under age 3 years. A urine study should be performed to assess renal function and evaluate for renal tubular acidosis. In a girl, a karyotype to rule out **Turner syndrome** should be considered. A bone age will establish skeletal maturation.

If chronic disease or familial short stature are ruled out and routine laboratory testing is normal ([Table 173.4](#)), two GH stimulatory tests are commonly performed (see [Table 170.2](#)). GH testing should be offered to a patient who is short (<5 th percentile and usually >3.5 SDs below the mean), growing poorly (<5 th percentile growth rate for age), or whose height projection, based on bone age, is considerably below the target height when corrected for family height.

TABLE 173.4**Growth Failure: Screening Tests**

TEST	RATIONALE
CBC	<i>Anemia</i> : nutritional, chronic disease, malignancy
	<i>Leukopenia</i> : bone marrow failure syndromes
	<i>Thrombocytopenia</i> : malignancy, infection
ESR, CRP	Inflammation of infection, inflammatory diseases, malignancy
Metabolic panel (electrolytes, liver enzymes, BUN)	Signs of acute or chronic hepatic, renal, adrenal dysfunction; hydration and acid-base status
Carotene, folate, and prothrombin time; celiac antibody panel	Assess malabsorption; detect celiac disease
Urinalysis with pH	Signs of renal dysfunction, hydration, water and salt homeostasis; renal tubular acidosis
Karyotype	Determines Turner (XO) or other syndromes
Cranial imaging (MRI)	Assesses hypothalamic-pituitary tumors (craniopharyngioma, glioma, germinoma) or congenital midline defects
Bone age	Compare with height age and evaluate height potential
IGF-1, IGF-BP3	Reflects growth hormone status or nutrition
Free thyroxine	Detects MPHD or isolated hypothyroidism
Prolactin	Elevated in hypothalamic dysfunction or destruction, suppressed in pituitary disease

BUN, Blood urea nitrogen; *CBC*, complete blood count; *CRP*, C-reactive protein; *ESR*, erythrocyte sedimentation rate; *IGF-1*, insulin-like growth factor-1; *IGF-BP3*, insulin-like growth factor-binding protein 3; *MRI*, magnetic resonance imaging; *MPHD*, multiple pituitary hormone deficiency.

Classic GH-deficient patients do not show an increase in serum GH levels after stimulation. Some patients release GH in response to secretagogue testing but cannot release GH spontaneously during the day or night. Tests for GH secretion are insensitive, not very specific, and fairly variable. In equivocal cases, an operational definition of GH deficiency might be that patients grow significantly faster when administered a normal dose of GH than before treatment.

Treatment

GH deficiency is treated with biosynthetic recombinant DNA-derived GH. Dosage is titrated to the growth rate, weight of the patient, and IGF-1 levels. Treatment with GH carries the low risk of an increased incidence of slipped capital femoral epiphysis, especially in rapidly growing adolescents, and of

pseudotumor cerebri. Patients who have GH deficiency due to treatment for malignancy may be at higher risk for a secondary malignancy with GH therapy. Risks and benefits must be weighed with the family and treatment team.

Administration of GH to patients with normal GH responsiveness to secretagogues is controversial, but, as noted earlier, diagnostic tests are imperfect; if the patient is growing extremely slowly without alternative explanation, GH therapy is sometimes used. GH is effective in increasing the growth rate and final height in Turner syndrome and in chronic renal failure; GH also is used for treatment of short stature and muscle weakness of Prader-Willi syndrome. Other indications include children born small for gestational age who have not exhibited catch-up growth by 2 years of age and the long-term treatment of idiopathic short stature with height 2.25 SDs or less below the mean. Psychological support of children with severe short stature is important. Although there is controversy, marital status, satisfaction with life, and vocational achievement may be decreased in children of short stature who are not given supportive measures.

CHAPTER 174

Disorders of Puberty

Physiology

The staging of pubertal changes and the sequence of events are discussed in [Chapter 67](#). The onset of puberty is marked by pubarche and gonadarche. **Pubarche** results from adrenal maturation or adrenarche and is marked with the appearance of pubic hair; other features include oiliness of hair and skin, acne, axillary hair, and body odor. **Gonadarche** is characterized by increasing secretion of gonadal sex steroids as a result of the maturation of the hypothalamic-pituitary-gonadal axis. These sex steroids differ by gender, consisting of testosterone from the testes and estradiol and progesterone from the ovaries. In males physical signs are pubic hair, axillary hair, facial hair, increased muscularity, deeper voice, increased penile size, and increased testicular volume. In females the physical signs are breast development, development of the female body habitus, increased size of the uterus, and menarche with regular menstrual

cycles. The third component is the growth spurt of puberty.

Hypothalamic gonadotropin-releasing hormone (GnRH), produced by cells in the arcuate nucleus, is secreted from the median eminence of the hypothalamus into the pituitary portal system and reaches the membrane receptors on the pituitary gonadotropes to cause the production and release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) into the circulation. Mutations in genes encoding neurokinin B and neurokinin B receptor can alter the timing of puberty. Neurokinin B might play a role in regulating the secretion of kisspeptin, a compound responsible for the release of GnRH and, indirectly, release of LH and FSH. The hypothalamic-pituitary-gonadal axis is active in the fetus and newborn but is suppressed in the childhood years until activity increases again at the onset of puberty.

In females FSH stimulates the ovarian production of estrogen and, later in puberty, causes the formation and support of corpus luteum. In males LH stimulates the production of testosterone from the Leydig cells; later in puberty, FSH stimulates the development and support of the seminiferous tubules. The gonads also produce the protein inhibin. Both sex steroids and inhibin suppress the secretion of gonadotropins. The interplay of the products of the gonads and GnRH modulates the serum concentrations of gonadotropins. GnRH is released in episodic pulses that vary during development and during the menstrual period. These pulses ensure that gonadotropins are released in a pulsatile manner. With the onset of puberty, the amplitude of the pulses of gonadotropins and, in turn, the sex steroids increases, first at night and then throughout the day. Adrenarche generally occurs several years earlier than gonadarche and is heralded by increasing circulating dehydroepiandrosterone (DHEA) or androstenedione. Serum DHEA increases years before the appearance of its effects.

The typical developmental sequence in girls is **thelarche** (due to gonadarche), followed closely by **pubarche** (due to adrenarche), and finally **menarche** 2-3 years later. In boys the first typical event is scrotal thinning followed by the enlargement of testes and by the appearance of pubic hair (long diameter of the testis >2.5 cm, volume >4 mL). Most of the enlargement of testes during puberty is the result of seminiferous tubule maturation.

Delayed Puberty

Decision-Making Algorithm

Pubertal Delay

Puberty is delayed when there is no sign of pubertal development by age 13 years in girls and 14 years in boys living in the United States (Tables 174.1 and 174.2).

TABLE 174.1

Classification of Delayed Puberty and Sexual Infantilism

CONSTITUTIONAL DELAY IN GROWTH AND PUBERTY
HYPOGONADOTROPIC HYPOGONADISM
CNS disorders
Tumors (craniopharyngioma, germinoma, glioma, prolactinoma)
Congenital malformations
Radiation therapy
Other causes
Isolated gonadotropin deficiency
Kallmann syndrome (anosmia-hyposmia)
Other disorders
Idiopathic and genetic forms of multiple pituitary hormone deficiencies
Miscellaneous disorders
Prader-Willi syndrome
Laurence-Moon-Bardet-Biedl syndrome
Functional gonadotropin deficiency
• Chronic systemic disease and malnutrition
• Hypothyroidism
• Cushing disease
• Diabetes mellitus
• Hyperprolactinemia
• Anorexia nervosa
• Psychogenic amenorrhea
Impaired puberty and delayed menarche in female athletes and ballet dancers (exercise amenorrhea)
HYPERGONADOTROPIC HYPOGONADISM
Klinefelter syndrome (syndrome of seminiferous tubular dysgenesis) and its variants
Other forms of primary testicular failure
Anorchia and cryptorchidism
Syndrome of gonadal dysgenesis and its variants (Turner syndrome)
Other forms of primary ovarian failure
XX and XY gonadal dysgenesis

Familial and sporadic XX gonadal dysgenesis and its variants
Familial and sporadic XY gonadal dysgenesis and its variants
Noonan syndrome
Galactosemia

CNS, Central nervous system.

Constitutional Delay in Growth and Adolescence

Patients with constitutional delay have delayed onset of pubertal development and significant bone age delay (2 standard deviations below the mean, which is equal to a 1.5- to 2-year delay as a teenager). Usually height gain is below, although fairly parallel to, the normal percentiles on the growth curve. The prepubertal nadir, or deceleration before their pubertal growth spurt, is prolonged or protracted. A family history of delayed puberty in a parent or sibling is reassuring. Spontaneous puberty usually begins in these patients by the time the bone age reaches 12 years in boys and 11 years in girls. Other causes of delayed puberty must be eliminated before a diagnosis of constitutional delay in puberty is made. Observation and reassurance are appropriate. Adult height normal for the genetic potential is generally attained. In some cases, boys may be treated with low-dose testosterone for a few months if the bone age is at least 11-12 years. Treatment is not required for longer than 4-8 months because endogenous hormone production usually ensues. Boys who do not initiate endogenous hormone production should be evaluated for other causes of hypogonadism. Estrogen treatment has been used in girls with constitutional delay, but there are no clear studies showing the added benefits. Young women with delayed puberty may need to be evaluated for primary amenorrhea.

Hypogonadotropic Hypogonadism

As a cause of delayed or absent puberty, hypogonadotropic hypogonadism may be difficult to distinguish from constitutional delay (see [Tables 174.1](#) and [174.2](#)). Hypogonadotropic hypogonadism precludes spontaneous entry into gonadarche; adrenarche usually occurs to some degree. Throughout childhood and in early puberty, patients with hypogonadotropic hypogonadism have normal proportions and growth. When these patients reach adulthood, *eunuchoid* proportions may ensue because their long bones grow for longer than normal, producing an upper-to-lower ratio below the lower limit of normal of 0.9 and an arm span greater than their height.

Isolated Gonadotropin Deficiency

Decision-Making Algorithms

Pubertal Delay
Obesity

Disorders that can cause hypogonadism include congenital hypopituitarism, such as midline defects, tumors, infiltrative disease (hemochromatosis), and many syndromes, including Laurence-Moon-Bardet-Biedl, Prader-Willi, and Kallmann syndromes. If there is an inability to release gonadotropins but no other pituitary abnormality, the patient has isolated gonadotropin deficiency (almost universally a result of absent GnRH). Patients grow normally until the time of the pubertal growth spurt, when they fail to experience the accelerated growth characteristic of the normal growth spurt. There are a number of additional genetic mutations associated with hypogonadism that are very rare (*GnRH1*, *DAX1*, *TAC3*, *FGF8*, and others).

Kallmann syndrome combines isolated gonadotropin deficiency with disorders of olfaction. There is genetic heterogeneity; some patients have a decreased sense of smell, others have abnormal reproduction, and some have both. Most cases are sporadic, but a number of patients may have mutations in the *KAL1* gene at Xp 22.3 (X chromosome), *KAL2* gene (8p11.2), or *KAL3* gene (20p13). The mutation causes the GnRH neurons to remain ineffectually located in the primitive nasal area, rather than migrating to the correct location at the medial basal hypothalamus. Olfactory bulbs and olfactory sulci are often absent on magnetic resonance imaging (MRI). Other symptoms include disorders of the hand, with one hand copying the movements of the other hand, shortened fourth metacarpal bone, and an absent kidney.

Abnormalities of the Central Nervous System

Decision-Making Algorithms

Amenorrhea
Pubertal Delay

Central nervous system (CNS) tumors, including pituitary adenoma, glioma, prolactinoma, or craniopharyngioma, are important causes of gonadotropin deficiency. Craniopharyngiomas have a peak incidence in the teenage years and may cause any type of anterior or posterior hormone deficiency. Craniopharyngiomas usually calcify, eroding the sella turcica when they expand. They may impinge on the optic chiasm, leading to bitemporal hemianopsia and optic atrophy. Other tumors that may affect pubertal development include astrocytomas and gliomas.

Idiopathic hypopituitarism is the congenital absence of various combinations of pituitary hormones. Genes associated with this include *HESX1*, *PROP1*, *POU1F1(PIT1)*, *LHX3*, *LHX4*, *TBX19*, *SOX2*, and *SOX3*. Although this disorder may occur in family constellations, in X-linked or autosomal recessive patterns, sporadic types of congenital idiopathic hypopituitarism are more common. Congenital hypopituitarism may manifest in a male with growth hormone (GH) deficiency and associated gonadotropin deficiency with a microphallus or with hypoglycemia with seizures, especially if adrenocorticotrophic hormone and GH deficiency occurs as well.

Syndromes of Hypogonadotropic Hypogonadism

Decision-Making Algorithms

Amenorrhea
Pubertal Delay

Decreased gonadotropin function occurs when voluntary dieting, malnutrition, or chronic disease results in weight loss to less than 80% of ideal weight. **Anorexia nervosa** is characterized by striking weight loss and psychiatric disorders (see [Chapter 70](#)). Primary or secondary amenorrhea frequently is found in affected girls, and pubertal development is absent or minimal, depending on the level of weight loss and the age at onset. Regaining weight to the ideal level may not immediately reverse the condition. Increased physical activity, even

without weight loss, can lead to decreased menstrual frequency and gonadotropin deficiency in **athletic amenorrhea**; when physical activity is interrupted, menstrual function may return. Chronic or systemic illness (e.g., cystic fibrosis, diabetes mellitus, inflammatory bowel disease, or hematological diseases) can lead to pubertal delay or to amenorrhea from hypothalamic dysfunction. **Hypothyroidism** inhibits the onset of puberty and delays menstrual periods. Conversely, severe primary hypothyroidism may lead to precocious puberty.

Hypergonadotropic Hypogonadism

Decision-Making Algorithms

Pubertal Delay
Gynecomastia

Hypergonadotropic hypogonadism is characterized by elevated gonadotropins and low sex steroid levels resulting from primary gonadal failure. This permanent condition is almost always diagnosed following the lack of entry into gonadarche and is not suspected throughout childhood. Gonadotropins do not increase to greater than normal until shortly before or around the normal time of puberty.

Ovarian failure is diagnosed by elevated gonadotropins. **Turner syndrome** is a common cause of ovarian failure and short stature. The karyotype is classically 45,XO, but other abnormalities of the X chromosome, or mosaicism, are possible. The incidence of Turner syndrome is 1 in 2,000-1 in 3,000 births. The features of a girl with Turner syndrome need not be evident on physical examination or by history. The diagnosis must be considered in any girl who is short without a contributory history. Patients with other types of gonadal dysgenesis, or galactosemia, as well as patients who have undergone radiation therapy or chemotherapy for malignancy may develop ovarian failure.

Klinefelter syndrome (seminiferous tubular dysgenesis) is the most common cause of **testicular failure**. The karyotype is 47,XXY, but variants with more X chromosomes are possible. The incidence is approximately 1 in 500-1 in 1,000 in males. Testosterone levels may be close to normal, at least until mid-puberty,

because Leydig cell function may be spared; however, seminiferous tubular function characteristically is lost, causing infertility. Commonly LH levels may be normal to elevated, whereas FSH levels are usually more unequivocally elevated. The age of onset of puberty is usually normal, but secondary sexual changes may not progress because of inadequate Leydig cell function.

Primary Amenorrhea

Decision-Making Algorithms

Amenorrhea
Pubertal Delay

In addition to other diagnoses mentioned, other conditions need to be considered when evaluating girls with lack of menses. The Mayer-Rokitansky-Kuster-Hauser (MRKH) syndrome of congenital absence of the uterus occurs in 1 in 4,000-5,000 female births. Anatomical obstruction by imperforate hymen or vaginal septum also presents with normal secondary sexual development without menstruation. The complete syndrome of **androgen insensitivity** includes normal feminization, absence of pubic or axillary hair, and primary amenorrhea. In this syndrome, all müllerian structures, including ovaries, uterus, fallopian tubes, and upper third of the vagina, are lacking; the karyotype is 46,XY, and patients have intraabdominal testes.

Evaluation

When no secondary sexual development is present after the upper age limits of normal pubertal development, serum gonadotropin levels should be obtained to determine whether the patient has a hypogonadotropic or hypergonadotropic hypogonadism (see [Table 174.2](#)). Based on gonadotropin measurements only, the differentiation between constitutional delay in growth and hypogonadotropic hypogonadism is difficult; the gonadotropin levels are low in both conditions. Sometimes observation for months or years is necessary before the diagnosis is confirmed. Ultrasound of the pelvic structures in females would be helpful in the work-up of delayed puberty.

Treatment

If a permanent condition is apparent, replacement with sex steroids is indicated. Females are given titrated doses of transdermal estradiol, low-dose oral ethinyl estradiol, or conjugated estrogens until breakthrough bleeding occurs, at which time cycling is started with a dose for 25 days; on days 20-25, a progestational agent, such as medroxyprogesterone acetate (5 mg), is added to mimic the normal increases in gonadal hormones and to induce a normal menstrual period. Alternatively, combined estrogen and progesterone agents (oral contraceptives) may be used after breakthrough bleeding occurs. In males, testosterone enanthate or cypionate (50-100 mg monthly with a progressive increase to 100-200 mg) is given intramuscularly once every 4 weeks. This starting regimen is appropriate for patients with hypogonadotropic or hypergonadotropic hypogonadism, and doses are increased gradually to adult levels, often increasing the frequency of injections as needed. Alternatively, patients are transitioned to daily topical testosterone agents to keep levels more consistent. Oral agents are not used for fear of hepatotoxicity. Patients with apparent constitutional delay in puberty who have, by definition, passed the upper limits of normal onset of puberty may be given a 3- to 6-month course of low-dose, sex-appropriate gonadal steroids to see whether spontaneous puberty occurs. This course of therapy might be repeated once without undue advancement of bone age.

All patients with any form of delayed puberty are at risk for decreased bone density; adequate calcium intake is essential. Patients with hypogonadotropic hypogonadism may be able to achieve fertility by the administration of gonadotropin therapy or pulsatile hypothalamic-releasing hormone therapy administered by a programmable pump on an appropriate schedule.

In subjects with **Turner syndrome**, the goals of therapy include promoting growth with exogenous human GH supplementation and induction of the secondary sexual characteristics and of menses with low-dose cyclic estrogen/progesterone replacement therapy. Patients with Turner syndrome have had successful pregnancies after in vitro fertilization with a donor ovum and endocrine support.

Sexual Precocity

Decision-Making Algorithms

Precocious Puberty in the Male Precocious Puberty in the Female

Classification

Sexual precocity (**precocious puberty**) is classically defined as secondary sexual development occurring before the age of 9 years in boys or 8 years in girls (Tables 174.3 and 174.4). During the past 15-20 years, studies from the United States and Europe reported earlier breast development in girls, as compared to historical data. Studies clearly suggest an earlier age at puberty onset in American girls in the 1980s to 1990s compared to the 1930s and 1940s. However, age at menarche occurred at the same time or slightly earlier. Thus the time span from breast development to menarche seemed to have increased. The findings could reflect that exogenous or lifestyle factors may influence the typical sequence of pubertal events.

TABLE 174.3

Classification of Sexual Precocity

TRUE PRECOCIOUS PUBERTY OR COMPLETE ISOSEXUAL PRECOCITY

Idiopathic true precocious puberty

 CNS tumors

 Hamartomas (ectopic GnRH pulse generator)

 Other tumors

Other CNS disorders

True precocious puberty after late treatment of congenital virilizing adrenal hyperplasia

INCOMPLETE ISOSEXUAL PRECOCITY (GnRH-INDEPENDENT SEXUAL PRECOCITY)

Males

Chorionic gonadotropin-secreting tumors (hCG-dependent sexual precocity)

CNS tumors (e.g., germinoma, chorioepithelioma, teratoma)

Tumors in locations outside of the CNS (hepatoblastoma)

LH-secreting pituitary adenoma

Increased androgen secretion by adrenal or testis

Congenital adrenal hyperplasia (21-hydroxylase deficiency, 11-hydroxylase deficiency)

Virilizing adrenal neoplasm

Leydig cell adenoma

Familial male-limited precocious puberty

Females

Estrogen-secreting ovarian or adrenal neoplasms

Ovarian cysts

Males and females

McCune-Albright syndrome

Primary hypothyroidism

Peutz-Jeghers syndrome

Iatrogenic sexual precocity

VARIATIONS OF PUBERTAL DEVELOPMENT

Premature thelarche

Premature menarche

Premature adrenarche

Adolescent gynecomastia

CONTRASEXUAL PRECOCITY

Males (feminization)

Adrenal neoplasm

Increased extraglandular conversion of circulating steroids to estrogen

Females (virilization)

(Congenital adrenal hyperplasia, P-450_{c21} deficiency, P-450_{c11} deficiency, 3β-Hydroxysteroid dehydrogenase deficiency)

Virilizing adrenal neoplasms

Virilizing ovarian neoplasms (e.g., arrhenoblastomas)

CNS, Central nervous system; *CT*, computed tomography; *DHEAS*, dehydroepiandrosterone sulfate; *GnRH*, gonadotropin-releasing hormone; *hCG*, human chorionic gonadotropin; *LH*, luteinizing hormone; *MRI*, magnetic resonance imaging.

Modified from Grumbach MM, Styne DM. Puberty. In: Wilson JD, Foster DW, eds. *Williams Textbook of Endocrinology*. 9th ed. Philadelphia: WB Saunders; 1997.

Central precocious puberty, resulting in gonadarche, emanates from premature activation of the hypothalamic-pituitary-gonadal axis (GnRH-dependent). **Peripheral precocious puberty**, gonadarche or adrenarche, does not involve the hypothalamic-pituitary-gonadal axis (GnRH-independent).

Central Precocious Puberty (GnRH-Dependent Precocious Puberty)

In central precocious puberty, every endocrine and physical aspect of pubertal development is normal but too early; this includes tall stature, advanced bone age consistent with somatic age, increased sex steroid and pulsatile gonadotropin secretion, and increased response of LH to GnRH. The clinical course of central precocious puberty may wax and wane. Benign precocious puberty is the presumptive diagnosis in individuals who begin puberty early on a **constitutional** or **familial** basis. If no cause can be determined, the diagnosis is idiopathic precocious puberty, which occurs much more often in girls than in boys. Obese girls have earlier adrenarche, and sometimes menarche as well, than appropriate-weight girls. Compared with girls, boys with precocious puberty have a higher incidence of CNS disorders, such as tumors and hamartomas, precipitating the precocious puberty.

Almost any condition that affects the CNS, including hydrocephalus, meningitis, encephalitis, suprasellar cysts, head trauma, epilepsy, mental retardation, and irradiation, can precipitate central precocious puberty and must be considered before central precocious puberty is diagnosed. **Hamartomas** are nonmalignant tumors of the tuber cinereum with a characteristic appearance on computed tomography (CT) or MRI; biopsy is rarely required. The mass of GnRH neurons secrete GnRH and cause precocious puberty. Although hamartomas are not true neoplasms, they may require neurosurgical attention. The resulting precocious puberty is responsive to medical therapy with GnRH agonists, and surgery is rarely indicated.

GnRH-Independent Precocious Puberty

Decision-Making Algorithm

Precocious Puberty in the Female

The most common cause of GnRH-independent precocious puberty, **McCune-Albright syndrome**, is more frequent in girls than boys and includes precocious gonadarche, a bone disorder with polyostotic fibrous dysplasia and hyperpigmented cutaneous macules (café-au-lait spots). The precocious gonadarche results from ovarian hyperfunction and sometimes cyst formation, leading to episodic estrogen secretion. This disorder results from a postconception somatic mutation in the G protein intracellular signaling system (specifically G_{sa} , which leads to unregulated constitutive activation of adenylate cyclase, and of cAMP in the absence of trophic hormone stimulation), in the affected cells in ovary, bone, and skin; other endocrine organs may also autonomously hyperfunction for the same reason. Hyperthyroidism, hyperadrenalism, or acromegaly may occur. **Adrenal carcinomas** usually secrete adrenal androgens, such as DHEA; **adrenal adenomas** may virilize a child as a result of the production of androgen or may feminize a child as a result of the production of estrogen.

Boys may have precocious gonadarche on the basis of a rare entity called **familial male-limited precocious puberty**. This condition, with germ cell maturation caused by an X-limited dominant defect, produces constitutive activation of the LH receptor that leads to continuous production and secretion of testosterone without requiring LH or human chorionic gonadotropin (hCG).

hCG-secreting tumors stimulate LH receptors and increase testosterone secretion. These tumors may be found in various places, including the pineal gland (dysgerminomas) or the liver (hepatoblastoma).

Germinomas are noncalcifying hypothalamic or pineal tumors that frequently produce hCG, which may cause sexual precocity in prepubertal boys (hCG cross reacts with the LH receptor because of the similarity of structure between LH and hCG). **Optic** or **hypothalamic gliomas** (with or without neurofibromatosis), astrocytomas, and ependymomas may cause precocious puberty by disrupting the negative restraint of the areas of the CNS that normally inhibit pubertal development throughout childhood. These tumors may require radiotherapy, which contributes to a significant risk for hypopituitarism.

Ovarian cysts may occur once or may be recurrent. High serum estrogen values may mimic ovarian tumors. **Congenital adrenal hyperplasia (CAH)** is a cause of virilization in girls (see [Chapter 177](#)).

Evaluation of Sexual Precocity

The first step in evaluating sexual precocity is to determine which characteristics of normal puberty are apparent (see [Chapter 67](#)) and whether estrogen effects, androgen effects, or both are present (see [Table 174.4](#)). In girls the estrogen effect manifests as breast development, uterine increase, and, eventually, menarche. Both boys and girls manifest the androgen effect as adult body odor, pubic and axillary hair, and facial skin oiliness and acne. In boys it is also important to note whether the testes are enlarged more than 2.5 cm in length (4 mL volume), which implies gonadarche. If the testes are not enlarged but virilization is progressing, the source of the androgens may be the adrenal glands or exogenous sources.

Laboratory evaluation includes determination of adrenal androgen and sex steroid levels (testosterone, estradiol, DHEAS [dehydroepiandrosterone sulfate]) and baseline gonadotropin concentrations. The inherent nature of gonadotropin secretion is characterized by low secretory rates throughout childhood and pulsatile secretion in adolescents and adults. If baseline gonadotropin values are elevated into the normal pubertal range, central precocious puberty is likely. If baseline gonadotropins are low, however, no immediate conclusion may be drawn as to GnRH-dependent versus GnRH-independent precocious puberty. This distinction often requires the assessment of gonadotropin responsiveness to GnRH stimulation. A prepubertal GnRH response is FSH predominant, whereas a pubertal response is more LH predominant. Thyroid hormone determination also is useful because severe primary hypothyroidism can cause incomplete precocious puberty. If there is a suggestion of a CNS anomaly or a tumor (CNS, hepatic, adrenal, ovarian, or testicular), MRI of the brain and pituitary with and without contrast is indicated. MRI of the is recommended in patients with the diagnosis of central precocious puberty; however, the yield is generally low in girls over age 6. Boys as well as young girls have a higher risk of CNS lesions as a cause of precocious puberty.

Treatment

Long-acting, superactive analogs of GnRH (leuprolide depot, histrelin depot) are the treatment of choice for central precocious puberty. They suppress gonadotropin secretion by downregulating GnRH receptors in the pituitary gonadotropes ([Table 174.5](#)), causing gonadal secretion to revert to the

prepubertal state. Boys with GnRH-independent premature Leydig cell and germ cell maturation do not respond to GnRH analogs but require treatment with an inhibitor of testosterone synthesis (e.g., ketoconazole), an antiandrogen (e.g., spironolactone), or an aromatase inhibitor (e.g., testolactone or letrozole). Patients with precocious puberty from a hormone-secreting tumor require surgical removal, if possible. The precocious puberty of the McCune-Albright syndrome is GnRH independent and unresponsive to therapy with GnRH analog. Therapy is provided with testolactone and antiandrogens or antiestrogen, such as tamoxifen or aromatase inhibitor such as letrozole.

TABLE 174.5

Pharmacological Therapy of Sexual Precocity

DISORDER	TREATMENT	ACTION AND RATIONALE
GnRH-dependent true or central precocious puberty	GnRH agonists	Desensitization of gonadotropes; blocks action of endogenous GnRH
GnRH-independent incomplete sexual precocity Girls		
Autonomous ovarian cysts	Medroxyprogesterone acetate	Inhibition of ovarian steroidogenesis; regression of cyst (inhibition of FSH release)
McCune-Albright syndrome	Medroxyprogesterone acetate*	Inhibition of ovarian steroidogenesis; regression of cyst (inhibition of FSH release)
Boys	Testolactone*	Inhibition of P-450 aromatase; blocks estrogen synthesis
Familial GnRH-independent sexual precocity with premature Leydig cell maturation	Ketoconazole* Spironolactone* or flutamide <i>and</i> testolactone Medroxyprogesterone acetate*	Inhibition of P-450 _{c17} (mainly 17,20-lyase activity) Antiandrogen inhibition of aromatase; blocks estrogen synthesis Inhibition of testicular steroidogenesis

*If true precocious puberty develops, a GnRH agonist can be added.

FSH, Follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone.

Modified from Grumbach MM, Kaplan SL. Recent advances in the diagnosis and management of sexual precocity. *Acta Paediatr Jpn.* 1988;30(Suppl):155.

Variations in Pubertal Development

Isolated Premature Thelarche (Premature Breast Development)

Decision-Making Algorithm

Precocious Puberty in the Female

Benign **premature thelarche** is the isolated appearance of unilateral or bilateral breast tissue in girls, usually at ages 6 months to 3 years. There are no other signs of puberty and no evidence of excessive estrogen effect (vaginal bleeding, thickening of the vaginal secretions, increased height velocity, or bone age acceleration). Ingestion or dermal application of estrogen-containing compounds must be excluded. Laboratory investigations are not usually necessary, but a pelvic ultrasound study rarely may be indicated to exclude ovarian disease. Girls with this condition should be re-evaluated at intervals of 6-12 months to ensure that apparent premature thelarche is not the beginning of progression into precocious puberty. The prognosis is excellent; if no progression occurs, no treatment other than reassurance is necessary.

Gynecomastia

Decision-Making Algorithm

Gynecomastia

In males breast tissue is termed *gynecomastia*, and it may occur to some degree in 45-75% of normal pubertal boys (see [Chapter 67](#)). Androgens normally are converted to estrogen by aromatization; in early puberty, only modest amounts of androgens are produced, and the estrogen effect can overwhelm the androgen effects at this stage. Later in pubertal development, the androgen production is so great that there is little effect from the estrogen produced by aromatization. Gynecomastia also can suggest the possibility of **Klinefelter syndrome** as puberty progresses. Prepubertal gynecomastia suggests

an unusual source of estrogen either from exogenous sources (oral or dermal estrogen administration is possible from contamination of food or ointments) or from endogenous sources (from abnormal function of adrenal gland or ovary or from increased peripheral aromatization).

Isolated Premature Adrenarche (Pubarche)

Decision-Making Algorithms

Amenorrhea

Precocious Puberty in the Male

Precocious Puberty in the Female

The isolated appearance of pubic hair before age 6-7 years in girls or before age 9 years in boys is termed **premature pubarche**, usually resulting from adrenarche. It is relatively common. If the pubic hair is associated with any other feature of virilization (clitoral or penile enlargement or advanced bone age) or other signs (acne, rapid growth, or voice change), a detailed investigation for a pathological cause of virilization is indicated. Measurements of serum testosterone, 17-hydroxyprogesterone, and DHEAS are indicated to investigate the possibility of CAH. Ultrasound studies may reveal a hyperplastic adrenal gland or a virilizing adrenal or ovarian tumor. Most patients with isolated pubic hair do not have progressive virilization and simply have premature adrenarche (*pubarche*) resulting from premature activation of DHEA secretion from the adrenal gland. The skeletal maturation, as assessed by bone age, may be slightly advanced and the height slightly increased, but testosterone concentrations are normal. DHEA levels usually are high for prepubertal age but are consistent with Tanner (sexuality maturity rating) stages II and III. In girls, there have been studies linking premature adrenarche to the development of irregular menses or polycystic ovarian syndrome (PCOS) later in adolescence.

CHAPTER 175

Thyroid Disease

Thyroid Physiology and Development

Thyrotropin-releasing hormone (TRH), a tripeptide synthesized in the hypothalamus, stimulates the release of pituitary thyroid-stimulating hormone (TSH). Pituitary TSH is a glycoprotein that stimulates the synthesis and release of thyroid hormones by the thyroid gland. Thyroid function develops in three stages. At the end of the first trimester, the gland descends from the floor of the primitive oral cavity to its definitive position in the anterior lower neck. The hypothalamic-pituitary-thyroid axis becomes functional in the second trimester. Peripheral metabolism of thyroid hormones matures in the third trimester.

Thyroxine (T_4), triiodothyronine (T_3), and TSH do not cross the placenta in significant amounts. Concentrations in fetal serum reflect primarily fetal secretion and metabolism. Maternal thyroid antibodies, iodides (including radioactive iodides), and medications given to mothers to treat hyperthyroidism (methimazole and propylthiouracil) cross the placenta and affect fetal thyroid function. An infant born prematurely or with intrauterine growth restriction may have an interruption of the normal maturational process and appear to have hypothyroidism by standard tests (and newborn screen).

The thyroid gland concentrates iodine and binds it to tyrosine molecules to produce either monoiodotyrosine or diiodotyrosine, with subsequent coupling of two tyrosines, T_4 or T_3 . The major fraction of circulating T_3 (approximately 2/3) is derived from peripheral deiodination of T_4 to T_3 , but some is produced by the gland itself. The conversion of T_4 to T_3 requires the removal of one iodine from the outer ring of tyrosine; removing an iodine from the inner ring results in reverse T_3 , which has little biological effect. Preferential conversion of T_4 to reverse T_3 rather than T_3 occurs in utero and in all forms of severe illness, including respiratory distress syndrome, fevers, anorexia, and starvation. Conversion from T_4 to T_3 increases immediately after birth and throughout life. T_4 and T_3 are noncovalently bound to a specific serum carrier protein, **thyroxine-binding globulin**, and to a lesser extent, albumin. Only small (<0.02%) fractions of T_4 and T_3 are not bound; free T_4 (as it is converted to free T_3) and free T_3 are biologically active. Free T_3 exerts metabolic effects and negative feedback on TSH release ([Fig. 175.1](#)).

FIGURE 175.1 Interrelationships of the hypothalamic-pituitary-thyroid axis. Thyroid-stimulating hormone (*TSH*) from the pituitary gland stimulates the secretion of thyroxine (*T₄*) and triiodothyronine (*T₃*) from the thyroid gland. These act at the pituitary gland level to control secretion of *TSH* by a negative feedback mechanism. In addition, *T₄* is metabolized to the potent *T₃* within the pituitary gland by a deiodinase. Secretion of *TSH* is stimulated by thyrotropin-releasing hormone (*TRH*) from the hypothalamus and inhibited by somatostatin. Thyroid hormone acts at the hypothalamus to stimulate secretion of somatostatin (somatostatin acts as a negative signal to the pituitary secretion of *TSH*). *CRH*, Corticotropin-releasing hormone; *OB-R*, leptin receptor. (From Melmed S, Polonsky K, Kronenberg H, Larsen R, eds. *Williams Textbook of Endocrinology*. 10th ed. Philadelphia: Saunders; 2003:101.)

Serum *TSH* increases just after birth but soon decreases to lower values considered normal for later life. *T₄* secretion increases after birth as a result of

the peak in TSH and because of maturation of thyroid metabolism. It is important to refer to age-adjusted normative data to interpret thyroid function tests properly, whether relative to making diagnoses of hyperthyroidism or hypothyroidism or when adjusting therapy. Free T₄ is the test of choice because it eliminates the effects of variation in protein binding, which can be substantial.

Table 175.1 summarizes laboratory test results in various types of thyroid abnormalities. In usual circumstances, plasma concentrations of TSH above the normal range indicate primary hypothyroidism and concentrations below the normal range most often indicate the presence of hyperthyroidism. Thyroid scans with 99m-pertechnetate or 123-I-iodine are occasionally indicated in the evaluation of pediatric thyroid disease. They can be useful in identifying thyroid agenesis or ectopic thyroid tissue.

TABLE 175.1

Laboratory Test Results in Various Types of Thyroid Function Abnormalities in Children*

ABNORMALITY	SERUM		SERUM TSH	SERUM TBG
	TOTAL T ₄	FREE T ₄		
Primary hypothyroidism	↓	↓	↑	N
Hypothalamic (TRH) tertiary hypothyroidism	↓	↓	↓	N
Pituitary (TSH) secondary hypothyroidism	↓	↓	↓	N
TBG deficiency	↓	N	N	↓
TBG excess	↑	N	N	↑

TSH may be slightly elevated.

↓, Decreased; ↑, increased; N, Normal; T₄, thyroxine; TBG, thyroxine-binding globulin; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

Thyroid Disorders

Hypothyroidism

Decision-Making Algorithms

Short Stature
 Pubertal Delay
 Precocious Puberty in the Male
 Precocious Puberty in the Female

Hypothyroidism is diagnosed by a decreased serum free T₄ and may be the result of diseases of the thyroid gland (primary hypothyroidism), abnormalities of the pituitary gland (secondary), or abnormalities of the hypothalamus (tertiary). Hypothyroidism is congenital or acquired and may or may not be associated with a goiter (Table 175.2).

TABLE 175.2

Causes of Hypothyroidism in Infancy and Childhood

AGE GROUP	MANIFESTATION	CAUSE
Newborn	No goiter	Thyroid gland dysgenesis or ectopic location Exposure to iodides TSH deficiency TRH deficiency
	± Goiter	Inborn defect in hormone synthesis* or effect Maternal goitrogen ingestion, including propylthiouracil, methimazole, iodides Severe iodide deficiency (endemic)
Child	No goiter	Thyroid gland dysgenesis Cystinosis Hypothalamic-pituitary insufficiency Surgical after thyrotoxicosis or other thyroid surgery
	Goiter	Hashimoto thyroiditis: chronic lymphocytic thyroiditis Inborn defect in hormone synthesis or effect Goitrogenic drugs, infiltrative (sarcoid, lymphoma)

*Impaired iodide transport, defective thyroglobulin iodination, defective iodotyrosine dehalogenase, or defective thyroglobulin or its coupling to iodotyrosine.

TRH, Thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

Congenital Hypothyroidism

Congenital hypothyroidism occurs in approximately 1 in 2,000-4,000 live births and is caused by dysgenesis (agenesis, aplasia, ectopia) or, less often, dyshormonogenesis (e.g., enzyme defects). Thyroid tissue usually is not palpable

in these sporadic nongoitrous conditions. Dyshormonogenesis, disorders of intrathyroid metabolism, or goitrous congenital hypothyroidism occurs in about 1 in 30,000 live births. A goiter reflects an inborn error of metabolism in the pathway of iodide incorporation or thyroid hormone biosynthesis or reflects the transplacental passage of antithyroid drugs given to the mother. Routine neonatal screening programs to measure cord blood or heel-stick TSH values occur in every state in the United States. An immediate confirmatory serum sample should be obtained from any infant having a positive result on a **screening test**. A low free T_4 and high TSH confirm the finding.

Isolated secondary or tertiary hypothyroidism occurs in 1 in 100,000 live births; the free T_4 is normal to low, as is the TSH. When tertiary or secondary hypothyroidism is detected, assessment of other pituitary hormones and investigation of pituitary-hypothalamic anatomy via magnetic resonance imaging are indicated. Although not a hypothyroid condition, **congenital thyroxine-binding globulin deficiency** occurs in about 1 in 10,000 live births and is associated with low serum total T_4 concentration, normal TSH, and normal serum free T_4 . This is a euthyroid condition and does not require treatment with thyroid hormone because it is merely a binding protein abnormality. It is commonly X-linked dominant.

Clinical manifestations of congenital hypothyroidism in the immediate newborn period usually are subtle but become more evident weeks or months after birth. By then it is too late to ensure that there is not a detriment to the infant's cognitive development. Newborn screening is crucial to make an early diagnosis and initiate thyroid replacement therapy by younger than 1 month of age. Findings at various stages after birth include hypothermia, acrocyanosis, respiratory distress, large fontanel, abdominal distention, lethargy and poor feeding, prolonged jaundice, edema, umbilical hernia, mottled skin, constipation, large tongue, dry skin, and hoarse cry. Thyroid hormones are crucial for maturation and differentiation of tissues, such as bone and brain (most thyroid-dependent brain maturation occurs in the first 2-3 years after birth; [Table 175.3](#)).

TABLE 175.3

Symptoms and Signs of Hypothyroidism

ECTODERMAL
Poor growth

Dull facies: thick lips, large tongue, depressed nasal bridge, periorbital edema

Dry scaly skin

Sparse brittle hair

Diminished sweating

Carotenemia

Vitiligo

CIRCULATORY

Sinus bradycardia/heart block

Cold extremities

Cold intolerance

Pallor

ECG changes: low-voltage QRS complex

NEUROMUSCULAR

Muscle weakness

Hypotonia: constipation, potbelly

Umbilical hernia

Myxedema coma (carbon dioxide narcosis, hypothermia)

Pseudohypertrophy of muscles

Myalgia

Physical and mental lethargy

Developmental delay

Delayed relaxation of reflexes

Paresthesias (nerve entrapment: carpal tunnel syndrome)

Cerebellar ataxia

SKELETAL

Delayed bone age

Epiphyseal dysgenesis, increased upper-to-lower segment ratio

METABOLIC

Myxedema

Serous effusions (pleural, pericardial, ascites)

Hoarse voice (cry)

Weight gain

Menstrual irregularity

Arthralgia

Elevated CK

Macrocytosis (anemia)

Hypercholesterolemia

Hyperprolactinemia

Precocious puberty in severe cases

CK, Creatine kinase; ECG, electrocardiographic.

When **treatment** (with levothyroxine) is initiated within 1 month or less after birth, the prognosis for normal intellectual development is excellent. State screening programs usually allow for therapy within 1-2 weeks of birth. If therapy is instituted after 6 months when the signs of severe hypothyroidism are present, the likelihood of normal intellectual function is markedly decreased. Growth improves after thyroid replacement even in late diagnosed cases. The dose of levothyroxine changes with age; 10-15 $\mu\text{g}/\text{kg}$ of levothyroxine is used for a newborn, but about 3 $\mu\text{g}/\text{kg}$ is used later in childhood. In neonatal hypothyroidism, the goal is to bring the serum free T_4 rapidly into the upper half of the range of normal. Suppression of TSH is not seen and not necessary in all cases because such suppression may lead to excessive doses of levothyroxine.

Acquired Hypothyroidism

The **etiology** of acquired hypothyroidism is presented in [Table 175.2](#). The clinical manifestations may be subtle. Hypothyroidism should be suspected in any child who has a decline in growth velocity, especially if **not** associated with weight loss (see [Table 175.3](#)). The most common cause of acquired hypothyroidism in older children in the United States is lymphocytic autoimmune thyroiditis (**Hashimoto thyroiditis**). In many areas of the world, iodine deficiency is the etiology of endemic goiter (**endemic cretinism**). The failure of the thyroid gland may be heralded by an increase of TSH before T_4 levels decrease. In contrast to untreated congenital hypothyroidism, acquired hypothyroidism is not a cause of permanent developmental delay.

Hashimoto Thyroiditis

Also known as autoimmune or *lymphocytic thyroiditis*, Hashimoto thyroiditis is a common cause of goiter and acquired thyroid disease in older children and adolescents. A family history of thyroid disease is present in 25-35% of patients. The *etiology* is an autoimmune process targeted against the thyroid gland with lymphocytic infiltration and lymphoid follicle and germinal center formation preceding fibrosis and atrophy.

Clinical manifestations include a firm, nontender euthyroid, hypothyroid, or, rarely, hyperthyroid (hashitoxicosis) diffuse goiter with a pebble-like surface. See [Table 175.3](#) for signs and symptoms, which can be diverse. Onset typically occurs after 6 years of age with a peak incidence in adolescence with a female

predominance. Associated autoimmune diseases include celiac disease, type 1 diabetes mellitus, adrenal insufficiency, and hypoparathyroidism. **Autoimmune polyglandular syndrome type I** consists of hypoparathyroidism, Addison disease, mucocutaneous candidiasis, and hypothyroidism. **Autoimmune polyglandular syndrome type II** consists of Addison disease, type 1 diabetes mellitus, and frequently hypothyroidism. Trisomy 21 and Turner syndrome are predisposed to the development of autoimmune thyroiditis.

The **diagnosis** may be confirmed by serum antithyroid peroxidase (previously antimicrosomal) and antithyroglobulin antibodies. Neither biopsy nor thyroid scan is indicated in Hashimoto thyroiditis, although a thyroid scan with reduced uptake may differentiate hashitoxicosis from Graves disease.

Treatment with thyroid hormone sufficient to normalize TSH and free T_4 is indicated for hypothyroidism in Hashimoto thyroiditis. Patients without manifestation of hypothyroidism require thyroid function testing (serum TSH and free T_4) every 6-12 months to detect the later development of hypothyroidism. Goiter with a normal TSH usually is not an indication for treatment.

Hyperthyroidism

Decision-Making Algorithm

Neck Masses

Graves Disease

Most children with hyperthyroidism have Graves disease, the autonomous functioning of the thyroid caused by autoantibodies (thyroid-stimulating immunoglobulins [TSIs]) stimulating the thyroid. The resulting excessive synthesis, release, and peripheral metabolism of thyroid hormones produce the clinical features. Hashimoto thyroiditis and thyrotoxicosis are on a continuum of autoimmune diseases; there is overlap in their immunological findings.

Antithyroid peroxidase and antithyroglobulin antibodies may be present in thyrotoxicosis, although the values are usually lower than in Hashimoto thyroiditis. Exceptionally high titers of antibodies may indicate the thyrotoxic phase of Hashimoto thyroiditis with the subsequent evolution toward permanent

hypothyroidism. In Graves disease, serum free T₄, free T₃, or both levels are elevated, whereas TSH is suppressed. Rare causes of hyperthyroidism include McCune-Albright syndrome, thyroid nodule (often an adenoma), TSH hypersecretion, subacute thyroiditis, and iodine or thyroid hormone ingestion.

Clinical Manifestations

Graves disease presents as hyperthyroidism (Table 175.4) and is about five times more common in girls than in boys with a peak incidence in adolescence. Personality changes, mood instability, and poor school performance are common initial problems. Tremor, anxiety, inability to concentrate, and weight loss may be insidious and confused with a psychological disorder until thyroid function tests reveal the elevated serum free T₄ level. In rare cases, serum free T₄ may be near-normal, whereas serum T₃ is selectively elevated (T₃ toxicosis). A firm homogeneous goiter is usually present. Many patients complain of neck fullness. Thyroid gland enlargement is best visualized with the neck only slightly extended and with the examiner lateral to the patient. Palpation of the thyroid gland is best performed with the examiner's hands around the neck from the back. The patient swallows so that the examiner can feel and examine the size, consistency, nodularity, and motion of the gland. The examiner should watch the patient swallow to note any discernible enlargement or asymmetry of the thyroid lobes. Auscultation may reveal a bruit over the gland that needs to be differentiated from a carotid bruit.

TABLE 175.4

Clinical Manifestations of Hyperthyroidism

ASSOCIATED CHANGE	SIGN/SYMPTOM
Increased catecholamine effects	Nervousness
	Palpitations
	Tachycardia
	Atrial arrhythmias
	Systolic hypertension
	Tremor
	Brisk reflexes
Hypermetabolism	Increased sweating

	Shiny, smooth skin
	Heat intolerance
	Fatigue
	Weight loss—increased appetite
	Increased bowel movement (loose stools)
	Hyperkinesia
Myopathy	Weakness
	Periodic paralysis
	Cardiac failure—dyspnea
Miscellaneous	Proptosis, stare, exophthalmos, lid lag, ophthalmopathy
	Hair loss
	Inability to concentrate
	Personality change (emotional lability)
	Goiter
	Thyroid bruit
	Onycholysis
	Painful gland*
	Acute thyroid storm (hyperpyrexia, tachycardia, coma, high-output heart failure, shock)

*Unusual except in subacute thyroiditis with hyperthyroid phase.

Treatment

Three treatment choices are available: pharmacological, radioactive iodine, and surgical.

Drugs

Medical therapy to block thyroid hormone synthesis consists of methimazole (0.4-0.6 mg/kg/day once or twice daily) or propylthiouracil (5-7 mg/kg/day divided every 8 hours). Both medications are equally effective; however, propylthiouracil is no longer a first-line therapy secondary to concerns of severe liver injury and acute liver failure. A β blocker, such as propranolol or atenolol, is started if symptoms are severe to control cardiac manifestations and is tapered as the methimazole takes effect. Antithyroid medication is usually continued for 1-2 years because the remission rate is approximately 25% per year. In patients complying with the treatment regimen, the 2-year course of treatment can be repeated. Medication should suppress thyroid function to normal without the need to add thyroid hormone replacement to normalize serum free T_4 .

Complications of methimazole are muscle pain, rash, granulocytopenia, and jaundice. The granulocytopenia is an idiosyncratic complication of rapid onset, which is observed only in the early months after institution of antithyroid medication and requires monitoring the complete blood count. If a suppressed white blood cell count is observed, antithyroid therapy must be discontinued. This potentially lethal rare complication affects 3 in 10,000 users a year. After resolution, the other of the two antithyroid medications can be started because there is usually less than a 50% chance of a similar reaction from the other medication. Iodine administration, which may suppress thyroid function but becomes ineffective in a few weeks, is sometimes used as a preparation for surgery, but never for long-term therapy.

Radioiodine

Radioiodine (^{131}I) is slower in exerting therapeutic effects, may require repeated dosing, and is likely to cause permanent hypothyroidism. Hypothyroidism is the desired outcome because it is easier and safer to treat than continued hyperthyroidism. Although studies reveal no long-term consequences, concern remains about possible sequelae in children. This method of treatment is entering the mainstream for children and adolescents. Radioiodine given to a pregnant teenager renders the fetus hypothyroid and is contraindicated.

Surgery

Surgical treatment consists of partial or complete thyroidectomy. Risks associated with thyroidectomy include the use of anesthesia and the possibility that the thyroid removal will be excessive, causing hypothyroidism, or that it will be inadequate, resulting in persistent hyperthyroidism. In addition, keloid formation, recurrent laryngeal nerve palsy, and hypoparathyroidism (transient postoperative or permanent) may occur. Thyroid storm caused by the release of large amounts of preformed hormone is a serious but rare complication. Even with optimal immediate postoperative results, patients may become hypothyroid within 10 years.

Thyroid Storm

Thyroid storm (see [Table 175.4](#)) is a rare medical emergency consisting of tachycardia, disorientation, elevated blood pressure, and hyperthermia. Treatment includes reducing the hyperthermia with a cooling blanket and administering a β blocker to control the tachycardia, hypertension, and

autonomic hyperfunction symptoms. Iodine may be given to block thyroid hormone release after an antithyroid medication is started. Hydrocortisone may be indicated for relative adrenal insufficiency and therapy for heart failure includes diuretics and digoxin.

Congenital Hyperthyroidism

This disorder results from transplacental passage of maternal TSIs and may be masked for several days until the short-lived effects of transplacental maternal antithyroid medication wear off (assuming the mother was receiving such medication), at which time the effects of TSIs are observed. Irritability, tachycardia (often with signs of cardiac failure simulating *cardiomyopathy*), polycythemia, craniosynostosis, bone age advancement, poor feeding, and failure to thrive are the clinical hallmarks. This condition may be anticipated if the mother is known to be thyrotoxic or has an elevated TSI during third trimester of pregnancy. Cure of hyperthyroidism before pregnancy (surgery or radioiodine treatment) limits or curtails T_4 production but not the underlying immune disturbance producing TSIs; thus the infant still may be affected, at least transiently.

Treatment for a severely affected neonate includes methimazole and, as needed, a β blocker to help decrease symptoms. Because the half-life of the immunoglobulin is several weeks, spontaneous resolution of neonatal thyrotoxicosis resulting from transplacental passage of TSIs usually occurs by 2-3 months of age. Observation without treatment is indicated in patients who are minimally affected.

Nodules/Tumors of the Thyroid

About 2% of children develop solitary thyroid nodules, most of which are benign. Evaluation of a nodule includes thyroid function tests, neck ultrasound, and, if needed, fine-needle aspiration (FNA). Ultrasound guidance may be needed for aspiration of small nodules or those not palpable. Nodules found to be benign on FNA may be monitored through clinical exam and ultrasound.

Carcinoma of the thyroid is rare in children (1% of all pediatric cancers in the 5- to 9-year-old age group and up to 7% of cancers in the 15- to 19-year-old age group). Papillary and follicular carcinomas represent 90% of childhood thyroid cancers. A history of therapeutic head or neck irradiation or radiation exposure from nuclear accidents predisposes a child to thyroid cancer. Carcinoma usually

presents as a firm to hard, painless, nonfunctional solitary nodule and may spread to adjacent lymph nodes. Rapid growth, hoarseness (recurrent laryngeal nerve involvement), and lung metastasis may be present. If the nodule is solid on ultrasound, is *cold* on radioiodine scanning, and feels hard, the likelihood of a carcinoma is high. Excisional biopsy usually is performed, but FNA biopsy also may be diagnostic.

Treatment includes total thyroidectomy, selective regional node dissection, and radioablation with ^{131}I for residual or recurrent disease. The **prognosis** is usually good if the disease is diagnosed early.

Medullary carcinoma of the thyroid may be asymptomatic except for a mass. Diagnosis is based on the presence of elevated calcitonin levels, either in the basal state or after pentagastrin stimulation (difficult to obtain) and histological examination. This tumor most often occurs with multiple endocrine neoplasia 2a or 2b (MEN), possibly in a familial pattern. In some families, the presence of mutations of the *RET* protooncogene is predictive of the development of medullary carcinoma of the thyroid. The location of the mutation can help determine when removal of the thyroid is warranted. Genetic screening of other members of the family is indicated after a proband is recognized. Prophylactic thyroidectomy is indicated for the family members with the same allele.

CHAPTER 176

Disorders of Parathyroid Bone and Mineral Endocrinology

Parathyroid Hormone and Vitamin D

Calcium and phosphate are regulated mainly by diet and three hormones: parathyroid hormone (PTH), vitamin D, and calcitonin. PTH is secreted in response to a decrease in serum ionized calcium level. PTH attaches to its membrane receptor then acts via adenylate cyclase to mobilize calcium from bone into the serum and to enhance fractional reabsorption of calcium by the kidney while inducing phosphate excretion; all increase the serum calcium

concentration and decrease serum phosphate. Lack of PTH effect is heralded by low serum calcium in the presence of elevated phosphate for age. PTH stimulates vitamin D secretion by increasing renal 1α -hydroxylase activity and acts indirectly to elevate serum calcium concentration by stimulating the production of 1,25-dihydroxyvitamin D from 25-hydroxyvitamin D. Calcitonin increases the deposition of calcium into bone; in normal states the effect is subtle, but calcitonin may be used temporarily to suppress extremely elevated serum calcium values.

1,25-Dihydroxyvitamin D enhances calcium absorption from the gastrointestinal tract, increasing serum calcium levels and bone mineralization. Vitamin D is derived from exposure of the skin to ultraviolet rays (usually via the sun) or from oral ingestion. It is modified first to 25-hydroxyvitamin D in the liver and then 1α -hydroxylated to the metabolically active form (1,25-dihydroxyvitamin D) in the kidney. The serum concentration of 25-hydroxyvitamin D is a better reflection of vitamin D sufficiency than the measurement of 1,25-hydroxyvitamin D (see [Chapter 31](#)).

Hypocalcemia

Decision-Making Algorithm

Hypocalcemia

The **clinical manifestations** of hypocalcemia result from increased neuromuscular irritability and include muscle cramps, carpopedal spasm (tetany), weakness, paresthesia, laryngospasm, and seizure-like activity. Tetany can be detected by the *Chvostek sign* (facial spasms produced by lightly tapping over the facial nerve just in front of the ear) or by the *Trousseau sign* (carpal spasms exhibited when arterial blood flow to the hand is occluded for 3-5 minutes with a blood pressure cuff inflated to 15 mm Hg above systolic blood pressure). Total serum calcium concentration is usually measured, although a determination of serum ionized calcium, the biologically active form, is preferable. Albumin is the major reservoir of protein-bound calcium. Disorders that alter plasma pH or serum albumin concentration must be considered when circulating calcium concentrations are being evaluated. The fraction of ionized

calcium is inversely related to plasma pH; **alkalosis** can precipitate hypocalcemia by lowering ionized calcium without changing total serum calcium. Alkalosis may result from hyperpnea caused by anxiety or from hyperventilation related to physical exertion. Hypoproteinemia may lead to a false suggestion of hypocalcemia because the serum total calcium level is low even though the ionized Ca^{2+} remains normal. It is best to measure serum ionized calcium if hypocalcemia or hypercalcemia is suspected.

Primary hypoparathyroidism causes hypocalcemia but does not cause rickets. The etiology of primary hypoparathyroidism includes the following:

1. Congenital malformation (e.g., DiGeorge syndrome or other complex syndromes) resulting from developmental abnormalities of the third and fourth branchial arches (see [Chapters 143](#) and [144](#))
2. Surgical procedures, such as thyroidectomy or parathyroidectomy, in which parathyroid tissue is removed either deliberately or as a complication of surgery for another goal
3. Autoimmunity, which may destroy the parathyroid gland

Pseudohypoparathyroidism (all with hypocalcemia and hyperphosphatemia) may occur in one of four forms as follows:

1. *Type Ia*: an abnormality of the G_{sa} protein linking the PTH receptor to adenylate cyclase; biologically active PTH is secreted in great quantities, but does not stimulate its receptor
2. *Type Ib*: normal phenotype, normal G_{sa} with abnormalities in the production of adenylate cyclase
3. *Type Ic*: abnormal phenotype, normal production of adenylate cyclase, but a distal defect eliminates the effects of PTH
4. *Type II*: normal phenotype, normal production of adenylate cyclase, with a postreceptor defect, close to type Ib

Pseudohypoparathyroidism is an autosomal dominant condition that may present at birth or later. Pseudohypoparathyroidism is associated with **Albright hereditary osteodystrophy**, whose clinical manifestations include short stature, stocky body habitus, round facies, short fourth and fifth metacarpals, calcification of the basal ganglia, subcutaneous calcification, and developmental delay. Albright hereditary osteodystrophy may be inherited separately so that a

patient may have a normal appearance with hypocalcemia or may have the Albright hereditary osteodystrophy phenotype with normal serum calcium, phosphate, PTH, and response to PTH.

Transient neonatal hypocalcemia. During the first 3 days after birth, serum calcium concentrations normally decline in response to withdrawal of the maternal calcium supply via the placenta. Sluggish PTH response in a neonate may result in a transient hypocalcemia. Hypocalcemia caused by decreased PTH release is found in infants of mothers with hyperparathyroidism and hypercalcemia; the latter suppresses fetal PTH release, causing **transient hypoparathyroidism** in the neonatal period.

Normal serum magnesium concentrations are required for normal parathyroid gland function and action. **Hypomagnesemia** may cause a secondary hypoparathyroidism, which responds poorly to therapies other than magnesium replacement.

The **etiology** of hypocalcemia usually can be discerned by combining features of the clinical presentation with determinations of serum ionized calcium, phosphate, alkaline phosphatase, PTH (preferably at a time when the calcium is low), magnesium, and albumin. If the PTH concentration is not appropriately elevated in relation to the low serum calcium, hypoparathyroidism (transient, primary, or caused by hypomagnesemia) is present. Vitamin D stores can be estimated by measuring serum 25-hydroxyvitamin D. Renal function is assessed by a serum creatinine measurement or determination of creatinine clearance (Table 176.1).

TABLE 176.1

Important Physiological Changes in Bone and Mineral Diseases

CONDITION	CALCIUM	PHOSPHATE	PARATHYROID HORMONE	25(OH)D

Immobilization	↑	↑	↓	NI

25(OH)D, 25-Hydroxyvitamin D; NI, normal; sl, slight; ↑, high; ↓, low.

Treatment of severe tetany or seizures resulting from hypocalcemia consists of intravenous calcium gluconate (1-2 mL/kg of a 10% solution) given slowly over 10 minutes while cardiac status is monitored by electrocardiogram for bradycardia, which can be fatal. Long-term treatment of hypoparathyroidism involves administering vitamin D, preferably as 1,25-dihydroxyvitamin D and calcium. Therapy is adjusted to keep the serum calcium in the lower half of the normal range to avoid episodes of hypercalcemia that might produce nephrocalcinosis and to avoid pancreatitis.

Rickets

Decision-Making Algorithm

Hypocalcemia

Rickets is defined as decreased or defective bone mineralization in growing children; **osteomalacia** is the same condition in adults. The proportion of osteoid (the organic portion of bone) is excessive. As a result, the bone becomes soft and the metaphyses of the long bones widen. In older infants, poor linear growth, bowing of the legs on weight bearing (which can be painful), thickening at the wrists and knees, and prominence of the costochondral junctions (rachitic rosary) of the rib cage occur. At this stage, x-ray findings are diagnostic.

In **nutritional vitamin D deficiency** calcium is not absorbed adequately from the intestine (see [Chapter 31](#)). Poor vitamin D intake or avoidance of sunlight in infants (exacerbated by those exclusively breastfed) may contribute to the development of rickets. Fat malabsorption resulting from hepatobiliary disease (biliary atresia, neonatal hepatitis) or other causes (cystic fibrosis) also may produce vitamin D deficiency because vitamin D is a fat-soluble vitamin. Defects in vitamin D metabolism by the kidney (renal failure, autosomal recessive deficiency of 1α -hydroxylation, **vitamin D-dependent rickets**) or liver (defect in 25-hydroxylation) also can cause rickets.

In **familial hypophosphatemic rickets**, the major defect is failure of the kidney to adequately reabsorb filtered phosphate so that serum phosphate decreases and urinary phosphate is high. The *diagnosis* of this X-linked disease usually is made within the first few years of life and is typically more severe in

males.

The **etiology** of rickets usually can be determined by an assessment of the mineral and vitamin D status (25-hydroxyvitamin D <8 ng/mL suggests nutritional vitamin D deficiency) (see [Table 176.1](#)). Further testing of mineral balance or measurement of other vitamin D metabolites may be required.

Several forms of vitamin D can be used for **treatment** of the different rachitic conditions, but their potencies vary widely. Required dosages depend on the condition being treated (see [Chapter 31](#)). Rickets may also be treated with 1,25-hydroxyvitamin D and supplemental calcium. In hypophosphatemic rickets, phosphate supplementation (not calcium) must accompany vitamin D therapy, which is given to suppress secondary hyperparathyroidism. Adequate therapy restores normal skeletal growth and produces resolution of the radiographic signs of rickets. Nutritional rickets is treated with vitamin D given as a single large weekly dose or multiple smaller replacement doses. Surgery may be required to straighten legs in untreated patients with long-standing disease.

CHAPTER 177

Disorders of Sexual Development

Normal Sexual Development

The successive sequence of chromosomal sex, gonadal sex, and phenotypic sex leads to gender identity of the individual. Genes usually determine the morphology of internal organs and of gonads (gonadal sex); this directs the appearance of the external genitalia that form the secondary sex characteristics (phenotypic sex); self-perception of the individual (gender identity) and the perception of the individual by others (gender role) follow. In most children, these features blend and conform, but, in some patients, one or more features may not follow this sequence, leading to the disorder of sexual development (DSD; see [Chapter 23](#)).

The internal and external genitalia are formed between 6 and 13 weeks of gestation. Fetal gonad and external genitalia are bipotential and have the capacity to support development of a normal male or female phenotype ([Fig. 177.1](#)). In the presence of a gene called *SRY* for sex-determining region on the Y

chromosome, the primitive fetal gonad differentiates into a testis (Fig. 177.2). The Leydig cells of the testis secrete testosterone, which has direct effects (stimulating development of the wolffian ducts) but also is locally converted to dihydrotestosterone (DHT) by the 5α -reductase enzyme. DHT causes enlargement, rugation, and fusion of the labioscrotal folds into a scrotum; fusion of the ventral surface of the penis to enclose a penile urethra; and enlargement of the phallus with ultimate development of male external genitalia. Testicular production and secretion of müllerian-inhibitory substance by Sertoli cells cause the regression and disappearance of the müllerian ducts and their derivatives, such as the fallopian tubes and uterus. In the presence of testosterone, the wolffian ducts develop into the vas deferens, seminiferous tubules, and prostate.

FIGURE 177.1 Differentiation of male and female external genitalia as proceeding from a common embryonic anlage. Testosterone acts at 9-13 weeks of gestation to virilize the bipotential anlage. In the absence of testosterone action, the female phenotype develops. (From Grumbach MM, Conte FA. Disorders of sexual differentiation. In: Wilson JD, Foster DW, eds. *Textbook of Endocrinology*. 8th ed. Philadelphia: WB Saunders; 1990:873; modified from Spaulding MH, *Contrib Embryol Instit.* 1921;13:69-88.)

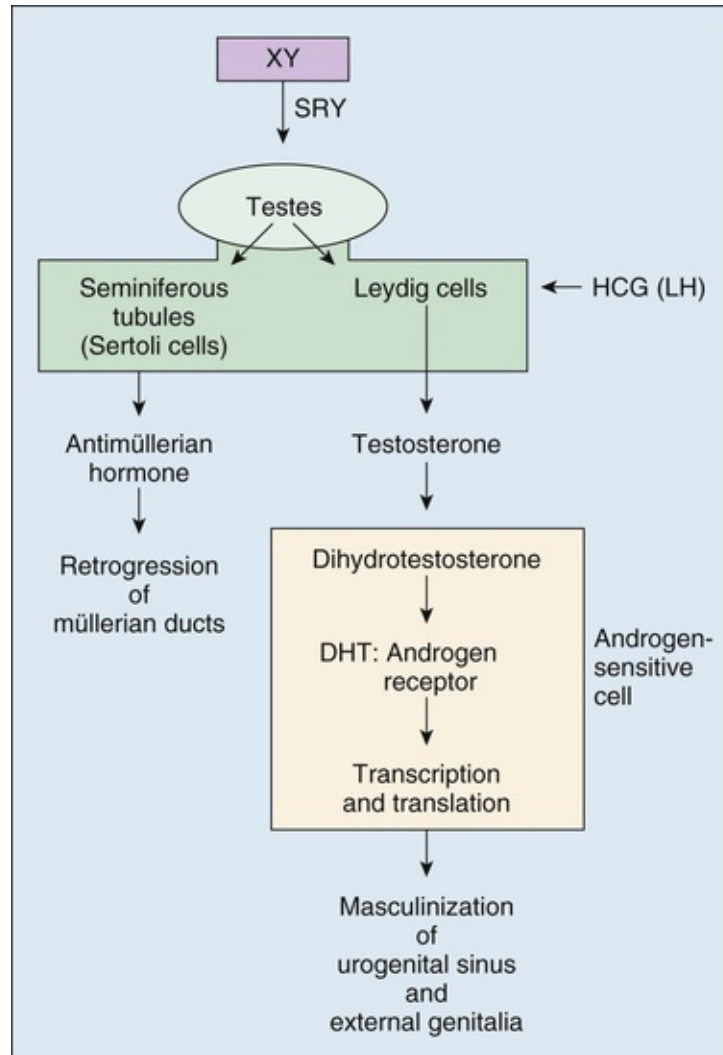

FIGURE 177.2 A diagrammatic scheme of male sex determination and differentiation. *SRY* is the master gene controlling male sex differentiation, but there are many other genes and their products that control male and female sexual differentiation. *DHT*, Dihydrotestosterone; *HCG*, human chorionic gonadotropin; *LH*, luteinizing hormone; *SRY*, the gene for the testis-determining factor. (From Wilson JD, Foster DW, eds. *Williams Textbook of Endocrinology*. 8th ed. Philadelphia: WB Saunders; 1992:918.)

The female phenotype develops unless specific *male* influences alter development, although recent studies find there are female determining genes necessary for development as well. In the absence of *SRY*, an ovary spontaneously develops from the bipotential, primitive gonad. In the absence of fetal testicular secretion of müllerian-inhibitory substance, a normal uterus, fallopian tubes, and posterior third of the vagina develop out of the müllerian ducts, and the wolffian ducts degenerate. In the total absence of androgens, the external genitalia appear female.

Classification

The terminology for conditions associated with variations in sexual development is evolving. Sometimes referred to as intersex, disorders of sex differentiation, or differences of sex development, DSDs are categorized under three main subgroups according to karyotype (XX, XY, and sex chromosome for mosaic karyotypes).

Abnormal Sexual Development

46,XX Disorders of Sexual Development

Decision-Making Algorithms

- Hypertension
- Amenorrhea
- Precocious Puberty in the Male
- Precocious Puberty in the Female
- Ambiguous Genitalia
- Alkalemia

Masculinization of the external genitalia of genotypic females (except for isolated enlargement of the clitoris, which can occur from later androgen exposure) is always caused by the presence of excessive androgens during the critical period of development (8-13 weeks of gestation) (Table 177.1). The degree of virilization can range from mild clitoral enlargement to the appearance of a *male* phallus with a penile urethra and fused scrotum with raphe. Congenital virilizing adrenal hyperplasia is the most common cause of female ambiguous genitalia; it is most commonly the result of an enzyme deficiency that impairs synthesis of glucocorticoids, but does not affect androgen production. The impaired cortisol secretion leads to adrenocorticotrophic hormone (ACTH) hypersecretion, which stimulates hyperplasia of the adrenal cortex and excessive adrenal production of androgens (see Chapter 178).

TABLE 177.1

Causes of Virilization in the Female

Causes of virilization in the Female

CONDITION	ADDITIONAL FEATURE(S)
P-450 _{c21} deficiency (21 hydroxylase)	Salt loss in some
3 β -Hydroxysteroid dehydrogenase deficiency	Salt loss
P-450 _{c11} deficiency (11 hydroxylase)	Salt retention/hypertension
Androgenic drug exposure (e.g., progestins)	Exposure between 9 and 12 weeks of gestation
Mixed gonadal dysgenesis or mosaic Turner syndrome	Karyotype = 46,XY/45,X
Ovotesticular DSD	Testicular and ovarian tissue present
Maternal virilizing adrenal or ovarian tumor	Rare, positive history

DSD, Disorder of sexual development.

46,XY Disorders of Sexual Development

Decision-Making Algorithms

Amenorrhea
Pubertal Delay
Ambiguous Genitalia
Gynecomastia

Underdevelopment of the male external genitalia occurs because of a relative deficiency of testosterone production or action (Table 177.2). The penis is small, with various degrees of hypospadias (penile or perineal) and associated chordee or ventral binding of the phallus; unilateral, but more often bilateral, cryptorchidism may be present. The testes should be sought carefully in the inguinal canal or labioscrotal folds by palpation or ultrasound. Rarely a palpable gonad in the inguinal canal or labioscrotal fold represents a herniated ovary or an ovotestis. The latter patients have ovarian and testicular tissue and usually ambiguous external genitalia. Production of testosterone by a gonad implies that testicular tissue is present and that at least some cells carry the *SRY* gene.

TABLE 177.2

Causes of Inadequate Masculinization in the Male

--

CONDITION	ADDITIONAL FEATURE(S)
P-450 _{scc} (StAR) deficiency	Salt loss
3 β -Hydroxysteroid dehydrogenase deficiency	Salt loss
P-450 _{c17} deficiency	Salt retention/hypokalemia/hypertension
Isolated P-450 _{c17} deficiency with 17,20-desmolase deficiency	Adrenal function normal
17 β -Hydroxysteroid oxidoreductase deficiency	Adrenal function normal
Dysgenetic testes	Possible abnormal karyotype; possible mutations in DAX1, SOX9, GATA4, WT1
Leydig cell hypoplasia	Rare
Complete androgen insensitivity	Female external genitalia, absence of müllerian structures
Partial androgen insensitivity	As previous with ambiguous external genitalia
5 α -Reductase deficiency	Autosomal recessive, virilization at puberty

StAR, Steroid acute regulatory protein.

Testosterone production can be reduced by specific deficiencies of the enzymes needed for androgen biosynthesis or by dysplasia of the gonads. In the latter, if müllerian-inhibiting substance production also is reduced, a rudimentary uterus and fallopian tubes are present.

The complete form of **androgen resistance** or **androgen insensitivity syndrome** is the most dramatic example of resistance to hormone action by defects in the androgen receptor. Affected patients have a **46,XY** karyotype, normally formed testes (usually located in the inguinal canal or labia majora), and female external genitalia with a short vagina and no internal müllerian structures. At the time of puberty, testosterone concentrations increase to normal or above normal male range. Because a portion of the testosterone is normally converted to estradiol in peripheral tissues and the estrogen cannot be opposed by the androgen, breast development ensues at the normal age of puberty without growth of pubic, facial, or axillary hair or the occurrence of menstruation.

5 α -Reductase deficiency presents at birth with predominantly female phenotype or with ambiguous genitalia, including perineoscrotal hypospadias. The defect is in 5 α reduction of testosterone to its metabolite DHT. At puberty, spontaneous secondary male sexual development occurs.

Sex Chromosome and Ootesticular Disorders of Sexual Development

Decision-Making Algorithms

Short Stature
Pubertal Delay
Gynecomastia

Turner syndrome and **Klinefelter syndrome** and their mosaic variants are classified as sex chromosome DSD. Mixed gonadal dysgenesis (45,X; 46,XY) often may present with genital ambiguity, asymmetric external genitalia, and inguinal hernias. There may be virilization on one side and none on the other. Similar findings may be seen with **ovotesticular DSD**, another classification of DSD.

Approach to the Infant With Genital Ambiguity

Decision-Making Algorithms

Pubertal Delay
Ambiguous Genitalia

Ambiguous genitalia in a newborn must be attended to with as little delay as possible and with informed sensitivity to the psychosocial context as required. The laboratory evaluations required might take days or weeks to complete, delaying a sex assignment and naming of the infant, such that choice often precedes diagnosis. Beyond infancy and childhood, and to offset any gender uncertainty in the patient and confusion in the parents, health care providers must help families come to an appropriate closure and gender choice. With that, most centers caring for patients with ambiguous genitalia include a behavioral health specialist with a focus on patients and families encountering these issues.

On physical examination, it is essential to note where the urethral opening lies and whether there is fusion of the anterior portion of the labioscrotal folds. Endogenous excessive production of androgen (as in congenital adrenal hyperplasia [CAH]) in a female fetus between 9 and 13 weeks of gestation leads to ambiguous genitalia. If the vaginal opening is normal, and there is no fusion,

but the clitoris is enlarged without ventral fusion of the ventral urethra, the patient likely had later exposure to androgens. In a patient with a fully formed scrotum, even if small, and a normally formed but small penis, termed a *microphallus*, the patient likely had normal exposure to and action of androgen during 9-13 weeks of gestation.

The major goal is a rapid identification of any life-threatening disorders (salt loss and shock caused by the salt-losing form of CAH). Although the classic approach to sex assignment has been based on the feasibility of genital reconstruction and potential fertility rather than on karyotype or gonadal histology, the effects of prenatal androgen must be considered. Experts recommend waiting until the child is able to be part of the dialogue regarding gender identity and reconstruction when appropriate. Present management of ambiguous genitalia involves extensive open discussion with parents involving the biology of the infant and the likely prognosis. Treatment should be individualized and managed by a team, including an experienced pediatric endocrinologist, urologist or gynecologist, psychologist, geneticist, and the primary care physician.

Diagnosis

The first step toward diagnosis is to determine whether the findings represent virilization of a genetic female (androgen excess) or underdevelopment of a genetic male (androgen deficiency; see [Fig. 177.2](#)). Inguinal gonads that are evident on palpation usually are testes and indicate that incomplete development of a male phenotype has occurred; this pattern is not consistent, and ovaries and ovotestes may feel similar. Similarly, absence of female internal genitalia (detected by ultrasound) implies that müllerian-inhibiting substance was present and secreted by fetal testes. Karyotype determination is only one of many factors needed to assist the family in the decision of sex of rearing; the *SRY* gene may be found on chromosomes other than the Y chromosome, and, conversely, a Y chromosome may lack an *SRY* gene (it may have been translocated to an X chromosome, leading to the development of a 46,XX male-XX sex reversal, testicular DSD).

Statistically, most virilized females have CAH; 90% of these females have 21-hydroxylase deficiency. The diagnosis is established by measuring the plasma concentration of 17-hydroxyprogesterone and androstenedione (see [Chapter 178](#)), which typically is hundreds of times above the normal range. Other

enzymatic defects also may be diagnosed by quantifying circulating levels of the adrenal steroid precursor proximal to the defective enzyme block.

Establishing an accurate diagnosis is more difficult in underdeveloped males. When certain types of adrenal hyperplasia coexist with defects in androgen production of the testes, excessive ACTH secretion elevates substantially levels of specific adrenal steroid precursors, allowing a diagnosis. If the defect is restricted to testosterone biosynthesis, the measurement of testosterone and its precursors in the basal state and after stimulation by HCG may be required. Patients with normal levels of testosterone either have persistent androgen resistance or have had an interruption of normal morphogenesis of the genitalia. Abnormalities of the sex chromosomes may be associated with dysgenetic gonads, which may be associated with persistence of müllerian structures.

Treatment

Treatment consists of replacing deficient hormones (cortisol in adrenal hyperplasia or testosterone in a child with androgen biosynthetic defects who will be raised as male), surgical restoration to make the individual look more appropriate for the gender of rearing, and psychological support of the whole family. Gonads and internal organs discordant for the gender of rearing may be removed. Dysgenetic gonads with Y-genetic material always should be removed because **gonadoblastomas** or **dysgerminomas** may develop in the organ. Age at which reconstructive surgery is recommended is controversial; some advocate that surgery not be performed in infancy or early childhood so that the child or young adolescent can be involved in the decision. A decision for gender of rearing is recommended from birth; however, the knowledge that the person with a DSD may change gender later on is shared with parents from the outset.

CHAPTER 178

Adrenal Gland Dysfunction

Physiology

The adrenal gland consists of an outer cortex, which is responsible for the

synthesis of steroids, and an inner medulla derived from neuroectodermal tissue, which synthesizes catecholamines. The *adrenal cortex* consists of three zones: an outer glomerulosa (end product is the mineralocorticoid aldosterone, which regulates sodium and potassium balance), a middle fasciculata (end product is cortisol), and an inner reticularis (synthesizes sex steroids). The general scheme of these synthetic steps is shown in Fig. 178.1.

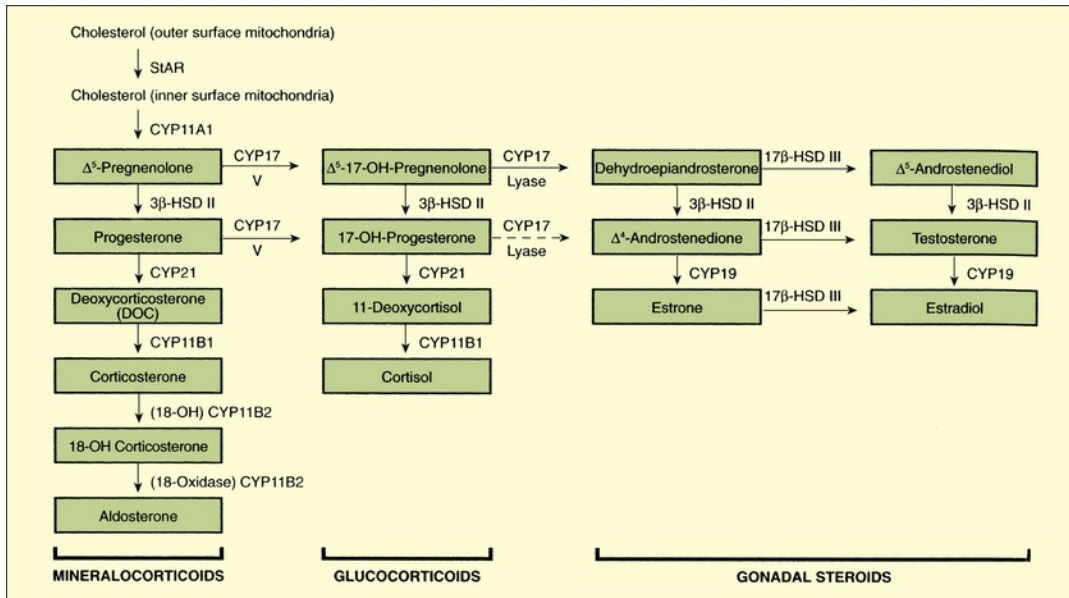

FIGURE 178.1 Diagram of the steroid biosynthetic pathways and the biosynthetic defects that result in congenital hyperplasia. The defect in patients with lipoid adrenal hyperplasia is not (except for one reported case) in the CYP11A1 (cholesterol side-chain cleavage) enzyme, but in StAR, the steroidogenic acute regulatory protein. This protein is involved in the transport of cholesterol from the outer mitochondrial membrane to the inner membrane, where the CYP11A1 enzyme is located. CYP11B1 (11 β -hydroxylase) catalyzes 11 β -hydroxylation of deoxycorticosterone and 11 β -deoxycortisol primarily. CYP17 (17 α -hydroxylase/17,20-lyase) catalyzes 17 α -hydroxylation and splitting of the 17,20 bond, but for the latter it has preferential Δ^5 -17,20-lyase activity. CYP19 (aromatase) catalyzes the conversion of corticosterone to aldosterone. 3 β -HSD I and 3 β -HSD II, 3 β -hydroxysteroid dehydrogenase/ $\Delta^{4,5}$ -isomerase types I and II; CYP21 (P450c21), 21-hydroxylase; 17 β -HSD 3, 17 β -hydroxysteroid dehydrogenase type 3. In the human, deletion of a homozygous null mutation of CYP11A (P450_{ccc}) is probably lethal in utero, but a heterogeneous mutation caused congenital lipoid adrenal hyperplasia. (From Melmed S, Polonsky K, Kronenberg H, et al, eds. *Williams Textbook of Endocrinology*. 10th ed. Philadelphia: Saunders; 2003:917.)

Hypothalamic corticotropin-releasing hormone (CRH) stimulates the release

of pituitary adrenocorticotrophic hormone (ACTH or corticotropin), derived by selective processing from pro-opiomelanocortin. ACTH governs the synthesis and release of cortisol and adrenal androgens. Primary adrenal insufficiency or cortisol deficiency from any defect in the adrenal gland results in an oversecretion of ACTH; adrenal insufficiency may also occur from ACTH (secondary) or CRH (tertiary) deficiency, resulting in low serum ACTH concentrations and low cortisol. Endogenous (or exogenous) glucocorticoids feedback to inhibit ACTH and CRH secretion. The renin-angiotensin system and potassium regulate aldosterone secretion; ACTH has little effect on aldosterone production except in excess, when it may increase aldosterone secretion.

Steroids that circulate in the free form (not bound to cortisol-binding protein [transcortin]) may cross the placenta from mother to fetus, but ACTH does not. The placenta plays an important role in steroid biosynthesis in utero by acting as a metabolic mediator between mother and child. As the fetal CRH-ACTH-adrenal axis is operational in utero, any deficiencies in cortisol synthesis lead to excessive ACTH secretion. If a virilizing adrenal enzyme defect is present, such as 21-hydroxylase deficiency, the fetal adrenal gland secretes excess androgens, resulting in a virilized fetus. Normal variation of serum cortisol and ACTH levels leads to values that are high early in the morning and lower at night. This normal diurnal variation may take months to years to fully develop in neonates.

Adrenal Insufficiency

Decision-Making Algorithms

Ambiguous Genitalia
Hyponatremia
Hyperkalemia

The **clinical manifestations** of inadequate adrenal function result from inadequate secretion or action of glucocorticoids, mineralocorticoids, or both (Table 178.1). In the case of enzyme defects that affect the gonad and the adrenal gland, overproduction or underproduction of potent androgens can occur depending on the site of enzyme blockade (see Fig. 178.1). Progressive prenatal virilization of the external genitalia may occur in females while incomplete

virilization may occur in males. Ambiguity of the external genitalia is a common manifestation of disordered fetal adrenal enzyme function. Precise *diagnosis* is essential for the prescription of appropriate therapy, long-term outlook, and genetic counseling. In patients with enzyme defects, an elevation in the precursor steroid is present proximal to the enzyme block and is metabolized through remaining normal alternate enzyme pathways, whereas a deficiency of steroids is present subsequent to the block.

TABLE 178.1

Clinical Manifestations of Adrenal Insufficiency

Cortisol deficiency
Hypoglycemia
Inability to withstand stress
Vasomotor collapse
Hyperpigmentation (in primary adrenal insufficiency with excess of adrenocorticotrophic hormone)
Apneic spells
Muscle weakness, fatigue
Aldosterone deficiency
Hyponatremia
Hyperkalemia
Vomiting
Urinary sodium wasting
Salt craving
Acidosis
Failure to thrive
Volume depletion
Hypotension
Dehydration
Shock
Diarrhea
Muscle weakness
Androgen excess or deficiency (caused by adrenal enzyme defect)
Ambiguous genitalia in certain conditions

The dominant clinical features of **congenital adrenal mineralocorticoid deficiency** are hyponatremia and hyperkalemia, usually developing by 5-7 days after birth but not immediately after birth. Vomiting, dehydration, and acidosis

soon follow as does hypotensive shock from glucocorticoid deficiency. Death may occur if the disorder remains undiagnosed and untreated. In females, the ambiguity of the external genitalia is an obvious clue that salt-losing congenital adrenal hyperplasia (CAH) or simple virilizing CAH must be ruled out. Because these forms cannot be distinguished clinically, all presentations of ambiguous genitalia should involve evaluation for mineralocorticoid deficiency. In males, 21-hydroxylase deficiency (the most common form of CAH) does not cause abnormal genitalia; although there may be hyperpigmentation of the scrotal skin, this is a subtle sign and can result in delayed diagnosis. In all infants, the diagnosis of adrenal insufficiency may be overlooked or confused with pyloric stenosis. In pyloric stenosis, vomiting of stomach contents results in hypochloremia, low or normal serum potassium, and alkalosis in contrast to CAH, which has hyponatremia, hyperkalemia, and acidosis. This distinction may be lifesaving in preventing unnecessary investigations or inappropriate therapy.

Not all forms of adrenal hyperplasia present at birth; the spectrum of disorder ranges from severe (classic) to mild (late-onset) or nonclassic. Milder forms may manifest in childhood, adolescence, or even young adulthood (not as glucocorticoid or mineralocorticoid deficiencies, but as androgen excess).

In patients with **congenital adrenal hypoplasia** or **adrenal hemorrhage**, the secretion of all adrenal steroids is low. In contrast, CAH leads to a diagnostic steroid pattern in blood and urine (see [Fig. 178.1](#)). Deficiency of 21-hydroxylase is the most common form (95%) and serves as a paradigm for these disorders.

21-Hydroxylase Deficiency

Decision-Making Algorithms

- Hypertension
- Precocious Puberty in the Male
- Precocious Puberty in the Female
- Ambiguous Genitalia
- Hirsutism

The incidence of classic 21-hydroxylase deficiency is about 1 in 15,000 among various white populations. Nonclassic CAH may occur with an incidence

of 1 in 50 in certain populations. The gene for 21-hydroxylase lies on the short arm of chromosome 6; the genotype may be determined in a proband, permitting prenatal diagnosis in a subsequent pregnancy.

Deficient 21-hydroxylase activity (P-450_{c21} deficiency) impairs the conversion of 17-hydroxyprogesterone (17-OHP) to 11-deoxycortisol and in the salt-losing form, of progesterone to deoxycorticosterone, a mineralocorticoid proximal in the pathway to the production of aldosterone. The decreased production of cortisol causes hypersecretion of ACTH, which stimulates the synthesis of steroids immediately proximal to the block and shunting of these to overproduction of androgens. The primary clinical manifestation is the virilization of the external genitalia of the affected female fetus. The development of the uterus, ovaries, and fallopian tubes are unaffected by the androgens. The degree of virilization varies, ranging from mild clitoromegaly to complete fusion of labioscrotal folds, with severe clitoromegaly simulating a phallus (see [Chapter 177](#)). A male infant with this defect appears normal at birth, although penile enlargement may be apparent thereafter. The deficiency in aldosterone, found in about 75% of patients, causes salt wasting with shock and dehydration until the diagnosis is established and appropriate treatment is given.

The treatment of 21-hydroxylase deficiency requires hydrocortisone and fludrocortisone in the case of the salt-losing form. Therapy must be adjusted throughout childhood at regular intervals. Overtreatment will cause growth stunting and weight gain (cushingoid features), whereas undertreatment will cause excessive height gain, skeletal advance, and early appearance puberty, ultimately jeopardizing adult height potential.

Late-onset CAH is typically noted years after birth. Affected subjects have milder manifestations without ambiguous genitalia, but they may have acne, hirsutism, and, in girls, irregular menstrual cycles or amenorrhea. Late-onset CAH in girls may be confused with **polycystic ovarian syndrome**.

Biochemical diagnostic studies show elevated levels of serum 17-OHP, the substrate for the defective 21-hydroxylase enzyme activity. In newborns with CAH, the values are elevated a 100-fold to a 1,000-fold. In late-onset CAH, an ACTH stimulation test may be necessary to show an abnormally high response of 17-OHP. Serum cortisol and aldosterone levels (in salt losers) are low and renin levels are high, whereas the testosterone level is elevated because it is derived from 17-OHP.

The goals of **treatment** are to achieve normal linear growth and bone age advancement. Long-term therapy consists of providing glucocorticoids at a dose

of approximately 10-15 mg/m²/24 hr in three divided doses of oral hydrocortisone or its equivalent. Mineralocorticoid therapy for salt losers consists of fludrocortisone at a dose of 0.1-0.2 mg/24 hr, often with sodium chloride supplementation in infancy and early childhood. Surgical correction of ambiguous external genitalia may be considered. The adequacy of glucocorticoid replacement therapy is monitored by determining serum concentrations of adrenal precursors, including androstenedione and 17-OHP for 21-hydroxylase deficiency. In addition, the assessment of linear growth and skeletal age, by bone age determination, is required as a reflection of appropriate therapy. To avoid adrenal insufficiency, threefold higher doses of glucocorticoids are given during **stressful states**, such as febrile illnesses and surgery. Intramuscular hydrocortisone is used in severe emergencies or with illnesses involving emesis. Mineralocorticoid therapy is monitored with serum sodium, potassium, and plasma renin activity levels. Prenatal treatment with dexamethasone to suppress fetal ACTH-induced androgen production can reduce or eliminate the ambiguity of the external genitalia in affected female fetuses, if begun at approximately 7 weeks of gestation; however, this remains controversial.

Other Enzyme Defects

Other enzyme defects are rare in contrast to 21-hydroxylase deficiency. In **11-hydroxylase deficiency**, the next most common cause of CAH, virilization occurs with salt retention and hypokalemia as a result of the buildup of deoxycorticosterone (see Fig. 178.1), a potent mineralocorticoid. Hypertension develops as a result of excessive mineralocorticoid production. Table 178.2 summarizes the clinical and biochemical features of adrenal insufficiency in infancy.

TABLE 178.2

Clinical and Biochemical Features in Newborn Adrenal Insufficiency

FEATURE	ELECTROLYTE DISTURBANCE*	AMBIGUOUS GENITALIA		SERUM CORTISOL
		VIRILIZED FEMALE	UNDERVIRILIZED MALE

17-KS, 17-Ketosteroid; 17-OHCS, 17-hydroxycorticosteroid; ACTH, adrenocorticotrophic hormone; D, decrease; HSD, hydroxysteroid dehydrogenase; I, increase; NI, normal; StAR, steroid acute regulatory protein.

Addison Disease

Decision-Making Algorithms

Hyponatremia
Hyperkalemia

Addison disease is a rare acquired disorder of childhood, usually associated with autoimmune destruction of the adrenal cortex. It is a form of primary adrenal insufficiency with absence of glucocorticoid and mineralocorticoid.

Clinical manifestations are hyperpigmentation, salt craving, postural hypotension, fasting hypoglycemia, anorexia, weakness, and episodes of shock during severe illness. Subnormal baseline and ACTH-stimulated cortisol values confirm the diagnosis. The presence of hyponatremia, hyperkalemia, and elevated plasma renin activity indicate mineralocorticoid deficiency. Addison disease may occur within the context of autoimmune polyglandular syndromes (APS I and APS II). Other rare causes of adrenal insufficiency include adrenal leukodystrophy and conditions that affect the hypothalamus-pituitary, whether acquired, such as in craniopharyngioma, or iatrogenic, such as in irradiation for treatment of malignancy.

Replacement **treatment** with 10-15 mg/m²/24 hr of hydrocortisone is indicated, with supplementation during stress at three times the maintenance dosage or the use of intramuscular hydrocortisone. The dose is titrated to allow a normal growth rate. Mineralocorticoid replacement with fludrocortisone is monitored by plasma renin activity along with serum sodium and potassium determinations.

Cushing Syndrome

Decision-Making Algorithms

Short Stature
Hirsutism
Obesity
Alkalemia
Hyponatremia
Hypokalemia

Classic **clinical manifestations** of Cushing syndrome in children include progressive central or generalized obesity, marked failure of longitudinal growth, hirsutism, weakness, a nuchal fat pad, acne, striae, hypertension, and often hyperpigmentation when ACTH is elevated. The most frequent cause is long-term administration of exogenous glucocorticoids due to chronic medical conditions. Endogenous causes include adrenal adenoma, carcinoma, nodular adrenal hyperplasia, an ACTH-secreting pituitary microadenoma resulting in bilateral adrenal hyperplasia (**Cushing disease**), or an extremely rare ACTH-secreting tumor. **Diagnostic tests** include 24-hour urinary cortisol excretion, low-dose dexamethasone suppression test, high-dose dexamethasone suppression test (helps distinguish Cushing syndrome from Cushing disease), and late evening salivary cortisol sampling.

Treatment of Cushing syndrome is directed to the etiology and may include excision of adrenal, pituitary, or ectopic ACTH-secreting tumors. Rarely, adrenalectomy is needed to control the symptoms. Parenteral glucocorticoid therapy is necessary during and immediately after surgical treatment to avoid acute adrenal insufficiency.

Pearls for Practitioners

Chapter 170

Endocrinology Assessment

- Hormones are defined as circulating messengers, with action at a distance from the organ (gland) of origin of the hormone.
- Endocrine disorders generally manifest from one of four ways: excess hormone, deficient hormone, abnormal response of end-organ, gland enlargement.
- The assessment of pituitary function may be determined by measuring some of the specific pituitary hormone in the basal state; other assessments require the measurement after stimulation.

Chapter 171

Diabetes Mellitus

- Type 1 diabetes mellitus is typically treated with multiple daily injections of a short-acting (bolus) insulin and a single dose of long acting (basal) insulin.
- Type 1 diabetes is an autoimmune disease and most often presents with hyperglycemia, ketoacidosis, polyuria, and polydipsia.
- Type 1 diabetes mellitus is a complex chronic illness that requires a team of providers, including endocrinologist, diabetes educator, nutritionist, social worker/psychologist, and close interactions for the family for success.
- Type 2 diabetes is associated with obesity and insulin resistance.

Chapter 172

Hypoglycemia

- After the initial 2-3 days of life, hypoglycemia is far less common and is more frequently the result of endocrine or metabolic disorders (although sepsis must always be ruled out).
- Clinical hypoglycemia is defined as a plasma glucose (PG) concentration low enough to cause symptoms and/or signs of impaired brain function.
- The most common causes for congenital hyperinsulinism involve inactivating K_{ATP} channel mutations and account for approximately 60% of all identifiable mutations.
- The *diagnosis* of hyperinsulinism in children is determined by evaluating markers of inappropriate insulin effects (e.g., suppressed ketogenesis) because plasma insulin concentrations are frequently not clearly elevated.
- Idiopathic ketotic hypoglycemia, usually begins at about 18

months of age in thin children and remits by 8 years of age, presents with symptoms of hypoglycemia after a period of prolonged fasting, often in the setting of an intercurrent illness with decreased feeding.

- The *diagnosis* of glycogen storage disease (GSD) is suggested by a hypoglycemia in the setting of hepatomegaly without splenomegaly (although GSD type 0 is not associated with hepatomegaly).
- A *critical sample* of blood and urine at the time of the hypoglycemic episode should be obtained before treatment for the measurement of glucose and insulin, growth hormone (GH), cortisol, free fatty acids (FFAs), and β -hydroxybutyrate and acetoacetate.

Chapter 173

Short Stature

- A normal linear growth pattern is good evidence of overall health and can be considered a *bioassay* for the well-being of the whole child.
- Insulin-like growth factor-1 (IGF-1) acts primarily as a paracrine and autocrine agent and is most closely associated with postnatal growth.
- Accurate measurements of height (standing), or length (lying down), and weight should be plotted on the Centers for Disease Control and Prevention growth charts for the timely diagnosis of growth disorders.
- Short stature is defined as subnormal height relative to other children of the same gender and age, taking family heights into consideration.
- Nutrition is the most important factor affecting growth on a worldwide basis.

- Adequacy of GH secretion may be determined by a stimulation test to measure peak GH secretion.
- A patient with classic GH deficiency has the appearance of a **cherub (a chubby, immature appearance)**, with a high-pitched voice resulting from an immature larynx.
- GH deficiency is treated with biosynthetic recombinant DNA-derived GH. Dosage is titrated to the growth rate, weight of the patient, and IGF-1 levels.
- The common condition known as **constitutional delay** in growth or puberty or both is considered a variation of normal growth, caused by a reduced tempo, or cadence, of physiological development.

Chapter 174

Disorders of Puberty

- Pubarche results from adrenal maturation or adrenarche and is marked with the appearance of pubic hair, oiliness of hair and skin, acne, axillary hair, and body odor; gonadarche is characterized by increasing secretion of gonadal sex steroids as a result of the maturation of the hypothalamic-pituitary-gonadal axis.
- Puberty is delayed when there is no sign of pubertal development by age 13 years in girls and 14 years in boys living in the United States.
- Disorders that can cause hypogonadotropic hypogonadism include congenital hypopituitarism, such as midline defects, tumors, infiltrative disease, and many syndromes, including Laurence-Moon-Bardet-Biedl, Prader-Willi, and Kallmann syndromes.
- Decreased gonadotropin function occurs when voluntary dieting, malnutrition, or chronic disease results in weight loss to

less than 80% of ideal weight.

- Hypergonadotropic hypogonadism is characterized by elevated gonadotropins and low sex steroid levels resulting from primary gonadal failure.
- Turner syndrome is a common cause of ovarian failure and short stature; Klinefelter syndrome (seminiferous tubular dysgenesis) is the most common cause of testicular failure.
- When no secondary sexual development is present after the upper age limits of normal pubertal development, serum gonadotropin levels should be obtained to determine whether the patient has a hypogonadotropic or hypergonadotropic hypogonadism.
- Central precocious puberty, resulting in gonadarche, emanates from premature activation of the hypothalamic-pituitary-gonadal axis (gonadotropin-releasing hormone [GnRH]-dependent); peripheral precocious puberty, gonadarche or adrenarche, does not involve the hypothalamic-pituitary-gonadal axis (GnRH-independent).
- Compared with girls, boys with precocious puberty have a higher incidence of CNS disorders, such as tumors and hamartomas, precipitating the precocious puberty.
- The most common cause of GnRH-independent precocious puberty, McCune-Albright syndrome, is more frequent in girls than boys and includes precocious gonadarche, a bone disorder with polyostotic fibrous dysplasia, and hyperpigmented cutaneous macules (café-au-lait spots).
- The first step in evaluating sexual precocity is to determine which characteristics of normal puberty are apparent and whether estrogen effects, androgen effects, or both are present; laboratory evaluation includes determination of adrenal androgen and sex steroid levels (testosterone, estradiol, DHEAS [dehydroepiandrosterone sulfate]) and baseline gonadotropin concentrations.

- A prepubertal GnRH response is follicle-stimulating hormone (FSH) predominant, whereas a pubertal response is more luteinizing hormone (LH) predominant.
- Long-acting, superactive analogs of GnRH (leuprolide depot, histrelin depot) are the treatment of choice for central precocious puberty; antiandrogens, antiestrogens, and aromatase inhibitors are used for peripheral precocious puberty.
- Most patients with isolated pubic hair do not have progressive virilization and simply have premature adrenarche (*pubarche*) resulting from premature activation of DHEA secretion from the adrenal gland; no treatment is needed.

Chapter 175

Thyroid Disease

- Early treatment in congenital hypothyroidism is essential to prevent delayed development.
- Hypothyroidism is common in children, and treatment with levothyroxine is typically initiated when a thyroid-stimulating hormone (TSH) is >10 mIU/L.
- Hypothyroidism must be considered in evaluation of short stature, especially if not associated with weight gain.
- Acquired hypothyroidism is an autoimmune disease and may be associated with type 1 diabetes, Addison disease, hypoparathyroidism, and celiac disease.
- Hyperthyroidism is initially treated with pharmacological therapy, and if remission does not occur, ablation or surgical removal is initiated.
- Most thyroid nodules in children and adolescents are benign.

Chapter 176

Disorders of Parathyroid Bone and Mineral Endocrinology

- Calcium and phosphate are regulated mainly by diet and three hormones: parathyroid hormone (PTH), vitamin D, and calcitonin.
- Neonatal hypocalcemia has multiple causes depending on timing of onset and may require treatment with intravenous (IV) and/or oral calcium.
- It is essential to make sure vitamin D is adequate as well as magnesium when replacing calcium.
- Hypocalcemia may be associated with multiple nonendocrine disorders and diseases, thus requiring a complete evaluation.

Chapter 177

Disorders of Sexual Development

- Genes usually determine the morphology of internal organs and of gonads (gonadal sex); this directs the appearance of the external genitalia that form the secondary sex characteristics (phenotypic sex). Self-perception of the individual (gender identity) and the perception of the individual by others (gender role) follow.
- Sometimes referred to as intersex, disorders of sex differentiation, or differences of sex development, disorders of sexual development (DSDs) are categorized under three main subgroups according to karyotype (XX, XY, and sex chromosome for mosaic karyotypes).
- Congenital virilizing adrenal hyperplasia is the most common cause of female ambiguous genitalia.
- Testosterone production can be reduced by specific deficiencies of the enzymes needed for androgen biosynthesis or by dysplasia of the gonads.
- Although the classic approach to sex assignment has been based on the feasibility of genital reconstruction and potential fertility

rather than on karyotype or gonadal histology, the effects of prenatal androgen must be considered; experts recommend waiting until the child is able to be part of the dialogue regarding gender identity and reconstruction when appropriate.

- The first step toward diagnosis of ambiguous genitalia is to determine whether the findings represent virilization of a genetic female (androgen excess) or under development of a genetic male (androgen deficiency)
- Treatment of DSDs consists of replacing deficient hormones (cortisol in adrenal hyperplasia or testosterone in a child with androgen biosynthetic defects who will be raised as male), surgical restoration to make the individual look more appropriate for the gender of rearing, and psychological support of the whole family.

Chapter 178

Adrenal Gland Dysfunction

- Early diagnosis and treatment of salt wasting congenital adrenal hyperplasia involves replacement therapy with hydrocortisone, fludrocortisone, and saline solution.
- Adrenal insufficiency is associated with hyperpigmentation, salt craving, postural hypotension, fasting hypoglycemia, anorexia, weakness, and episodes of shock during severe illness.
- Cushing syndrome is commonly a result of chronic use of high-dose oral steroids.

microcephaly; macrocephaly; spina bifida; schizencephaly; lissencephaly

CHAPTER 179

Neurology Assessment

A neurological evaluation, including history, physical examination, and judicious use of ancillary studies, allows the localization and diagnosis of nervous system pathology. The process and interpretation of the neurological examination varies with age; the newborn is unique, with many transient and primitive reflexes, whereas the examinations of adolescents and adults are similar. Careful evaluations of social, cognitive, language, fine motor, and gross motor skills, and their age appropriateness are key.

History

Gathering neurological history follows the traditional medical model with three additions: the **pace** and **localization** of the problem and the developmental assessment. The symptom evolution provides clues to the underlying process. Symptoms may evolve in a **progressive, static, or episodic** fashion. Progressive symptoms may present suddenly (seizures, stroke); acutely over minutes or hours (epidural hemorrhage); subacutely over days or weeks (brain tumor); or slowly over years (hereditary neuropathies). Static neurological abnormalities are observed early in life and do not change in character over time (cerebral palsy). Static lesions are often caused by congenital brain abnormalities or prenatal/perinatal brain injury. Intermittent attacks of recurrent, stereotyped episodes suggest epilepsy or migraine syndromes, among others. Episodic disorders are characterized by periods of symptoms, followed by partial or complete recovery (demyelinating, autoimmune, vascular diseases).

Careful evaluations of social, cognitive, language, fine motor, and gross motor skills are key ([Chapter 7](#)) to distinguish normal development from isolated or global delays. Loss of skills over time (regression) is particularly worrisome and

may suggest an underlying degenerative disease, emerging autism spectrum disorder, epileptic encephalopathy, or other neurological diagnoses.

Physical Examination

Observation of the child's appearance, movement, and behavior begins at the start of the encounter. For example, the child may display an unusual posture, abnormal gait, or lack of awareness of the environment.

The brain and skin have the same embryonic origin (ectoderm), so abnormalities of hair, skin, teeth, and nails are associated with congenital brain disorders (neurocutaneous disorders) such as neurofibromatosis (NF type 1), in which **café-au-lait macules** (flat, light brown macules) are characteristic. **Adenoma sebaceum** (fibrovascular lesions that look like acne on the nose and malar regions), nail fibromas, ash-leaf spots (hypopigmented macules), and Shagreen patches (flesh-colored soft plaques with prominent follicular openings) are commonly seen in older children and adults with tuberous sclerosis.

The **head circumference** is measured in its largest occipitofrontal circumference and plotted against standard growth curves ([Chapter 5](#)). **Microcephaly** and **macrocephaly** represent an occipitofrontal circumference 2 standard deviations below or above the mean, respectively. Measurements plotted over time may show an accelerating pattern (hydrocephalus) or decelerating pattern (brain injury, degenerative neurological disorder). The anterior fontanelle is slightly depressed and pulsatile when a calm infant is upright. A tense or bulging fontanelle may indicate increased intracranial pressure (ICP) but may also be seen in a crying or febrile infant. Premature closure of one or more sutures (**craniosynostosis**) results in an unusual shape of the head. Abnormal shape, location, or condition of the face, eyes, nares, philtrum, lips, or ears (dysmorphic features) are found in many genetic syndromes.

A careful **ocular examination** is essential and should include a search for epicanthal folds, coloboma, conjunctival telangiectasias, and cataracts. Direct ophthalmoscopy assesses the optic discs and macula for abnormalities, such as papilledema or a cherry red spot. A complete examination of the retina involves dilating the pupil and use of indirect ophthalmoscopy.

Examination of the hands and feet may reveal abnormal creases or digits ([Chapters 50](#) and [201](#)). The neck and spine should be examined for obvious (myelomeningocele) or subtle (cutaneous dimples, sinus tracts, hair tufts,

subcutaneous lipomas) midline defects. Nervous system abnormalities may result in kyphosis or scoliosis ([Chapter 202](#)).

Neurological Examination of a Neonate

The neonatal neurological examination primarily assesses the function of the basal ganglia, brainstem, and more caudal structures.

Mental Status

A healthy newborn infant should have periods of quiet, sustained wakefulness interspersed with sleep. Irritability, lethargy, or more severely depressed consciousness are nonspecific signs of abnormal brain function.

Reflexes

Examination of the **primitive reflexes** provides assessment of the functional integrity of the brainstem and basal ganglia ([Table 179.1](#)). Many of these stereotyped motor responses are present at birth. They are symmetrical and disappear at 4-6 months of age, indicating the normal maturation of descending inhibitory cerebral influences. Asymmetry or persistence of the primitive reflexes may indicate focal brain or peripheral nerve lesions.

TABLE 179.1

Central Nervous System Reflexes of Infancy

REFLEX	DESCRIPTION	AGE AT APPEARANCE	AGE AT DISAPPEARANCE
Moro	Light drop of head produces sudden extension followed by flexion of the arms and legs	Birth	6 mo
Grasp	Placing finger in palm results in flexing of infant's fingers	Birth	6 mo
Rooting	Tactile stimulus at the side of the mouth results in the mouth pursuing the stimulus	Birth	4-6 mo
Trunk incurvation (Gallant)	Stroking the skin along the edge of vertebrae produces curvature of the spine with concavity on the side of the stimulus	Birth	4 mo
Placing	When dorsum of foot is brought into contact	Birth	4-6 mo

	with the edge of a surface, infant places foot on the surface		
Asymmetrical tonic neck	With infant supine, turning of the head results in ipsilateral extension of the arm and leg with flexion of opposite extremities in a “fencing” posture	Birth	3 mo
Parachute	Infant is suspended face down by the chest. When infant is moved toward a table, the arms extend as if to protect self	8-10 mo	Never
Babinski	Stroking lateral aspect of sole from heel up results in dorsiflexion of the great toe and fanning of the remaining toes	Birth	12-18 mo

Motor Examination and Tone

Posture is the position that a calm infant naturally assumes when placed supine. An infant at 28 weeks of gestation shows an extended posture. By 32 weeks, there is a trend toward increase in tone and flexion of the lower extremities. At 34 weeks, the lower extremities are flexed; the upper extremities are extended. The term infant flexes lower and upper extremities. **Recoil**, the readiness with which an arm or leg springs back to its original position after passive stretching and release, is essentially absent in very premature infants but is brisk at term. Because of the asymmetrical tonic neck reflex, it is essential to maintain the infant's head in a neutral position (not turned to the side) during assessment of posture and tone. Spontaneous movements of premature infants are slow and writhing; those of term infants are more rapid.

Neurological Examination of a Child

The purpose of the neurological examination is to *localize* or identify the region from which the symptoms arise. The **mental status and developmental examinations** assess cerebral cortex function. The **cranial nerve examination** evaluates the integrity of the brainstem. The **motor examination** evaluates upper and lower motor neuron function. The **sensory examination** assesses the peripheral sensory receptors and their central reflections. **Deep tendon reflexes** assess upper and lower motor connections.

Mental Status and Developmental Evaluation

Alertness is assessed in infants by observing spontaneous activities, feeding

behavior, and visual ability to fix and follow objects. Responses to tactile, visual, and auditory stimuli are noted. If consciousness is altered, the response to painful stimuli is noted. Observation of toddlers at play allows a nonthreatening assessment of developmentally appropriate skills. In addition to language function, older children can be tested for reading, writing, numerical skills, fund of knowledge, abstract reasoning, judgment, humor, and memory.

The simplest way to assess intellectual abilities is through language skills. **Language function** is receptive (understanding speech or gestures) and expressive (speech and use of gestures). Abnormalities of language resulting from cerebral hemisphere disorders are referred to as **aphasias**. Anterior, expressive, or *Broca aphasia* is characterized by sparse, nonfluent language. Posterior, receptive, or *Wernicke aphasia* is characterized by an inability to understand language, with speech that is fluent but nonsensical. Global aphasia refers to impaired expressive and receptive language.

Cranial Nerve Evaluation

The cranial nerve evaluation assesses brainstem integrity, but depends on the stage of brain maturation and the ability to cooperate. A colorful toy may capture a young child's attention and permit observation of coordination, movement, and cranial nerve function.

Cranial Nerve I

Smell can be assessed in verbal, cooperative children older than 2 years of age. Aromatic substances (perfumes, vanilla) should be used instead of volatile substances (ammonia), which irritate the nasal mucosa and stimulate the trigeminal nerve.

Cranial Nerve II

Full-term newborns in a quiet awake state follow human faces, lights in a dark room, or large, optokinetic strips. Visual acuity has been estimated to be 20/200 in newborns and gradually matures throughout childhood. Standard visual charts displaying pictures instead of letters can be used to assess visual acuity in toddlers. Peripheral vision is tested by surreptitiously bringing objects into the visual field from behind. A reduced pupillary reaction to light suggests

anterior visual pathway (retina, optic nerves, chiasm) lesions. Unilateral lesions are identified by the *swinging flashlight test*. With an optic nerve abnormality, both pupils constrict when light is directed into the normal eye. When light is swung over to the abnormal eye, both pupils dilate inappropriately; this is called an *afferent pupillary defect* or **Marcus Gunn pupil**. Interruption of the sympathetic innervation to the pupil produces **Horner syndrome** (ptosis, miosis, and unilateral facial anhidrosis). In this instance, anisocoria (unequal pupils) is more pronounced in a dark room because the affected pupil is unable to dilate appropriately. Lesions of the posterior visual pathway, including the lateral geniculate, optic radiations, and occipital cortex, have normal pupillary light reactions but are expressed by loss of visual fields.

Cranial Nerves III, IV, and VI

These three cranial nerves control eye movements and are most easily examined with the use of a colorful toy to capture the child's attention. For infants too young to fix and follow, rotating the infant's head assesses **oculocephalic vestibular reflexes** (doll's eye maneuver). If the brainstem is intact, rotating a newborn or comatose patient's head to the right causes the eyes to move to the left, and vice versa. In awake, older patients, voluntary eye movements mask the reflex.

Abnormalities of these cranial nerves may cause diplopia (double vision). With unilateral third cranial nerve (oculomotor nerve) palsy, the involved eye deviates down and out (infraducted, abducted), with associated ptosis and a dilated (mydriatic) pupil. Injury to cranial nerve IV (trochlear nerve) causes weakness of downward eye movement with consequent vertical diplopia. Cranial nerve VI (abducens nerve) palsy results in the inability to move the eye outward. Cranial nerve VI has a long intracranial route within the subarachnoid space; failure of abduction of one or both eyes is a frequent, but nonspecific, sign of increased intracranial pressure (ICP).

Cranial Nerve V

The muscles of mastication can be observed as an infant sucks and swallows. The **corneal reflex** can test cranial nerves V ophthalmic division and VII at any age. Facial sensation of light touch and pain can be determined with cotton gauze and pinprick. Facial sensation can be functionally assessed in an infant by

gently brushing the cheek, which will produce the **rooting reflex** (turns head and neck with mouthing movement, as if seeking to nurse).

Cranial Nerve VII

Facial muscles are assessed by observing the face during rest, crying, and blinking. At older, cooperative ages, children can be asked to smile, blow out their cheeks, blink forcibly, and furrow their foreheads. Weakness of all unilateral muscles of the face, including the forehead, eye, and mouth, indicates a lesion of the ipsilateral peripheral facial nerve (**Bell palsy**). Since the upper third of the face receives bilateral cortical innervation, if the weakness affects only the lower face and mouth, a contralateral lesion of upper motor neurons in the brain (tumor, stroke, abscess) must be considered.

Cranial Nerve VIII

Lesions of cranial nerve VIII cause deafness, tinnitus, and vertigo. Normally, alert neonates blink in response to a bell or other abrupt, loud sound. Four-month-old infants turn their head and eyes to localize a sound. Hearing can be tested in a verbal child by whispering a word in one ear while covering the opposite ear. If there are any concerns about hearing, formal audiologic assessment is indicated. Delayed language development should trigger a referral for a formal hearing assessment.

Lesions of the vestibular component of cranial nerve VIII produce symptoms of vertigo, nausea, vomiting, diaphoresis, and nystagmus. Nystagmus is an involuntary beating eye movement with a rapid phase in one direction and a slow phase in the opposite direction. By convention, the direction of the nystagmus is defined by the fast phase and may be horizontal, vertical, or rotatory.

Cranial Nerves IX and X

The gag reflex is brisk at all ages except the very immature neonate. An absent gag reflex suggests a lesion of the brainstem, cranial nerves IX or X, neuromuscular junction, or pharyngeal muscles. Weak, breathy, or nasal speech, weak sucking, drooling, inability to handle secretions, gagging, and nasal regurgitation of food are additional symptoms of cranial nerve X dysfunction.

Cranial Nerve XI

Observing the infant's posture and spontaneous activity assesses the functions of the trapezius and sternocleidomastoid muscles. Head tilt and drooping of the shoulder suggest lesions involving cranial nerve XI. In later childhood, strength in these muscles can be tested directly.

Cranial Nerve XII

Atrophy and fasciculation of the tongue usually indicate a lesion of the anterior horn cells (spinal muscular atrophy). Assessment is most reliable when an infant is asleep. The tongue deviates toward the weak side in unilateral lesions.

Motor Examination

Strength

In infants, strength is assessed by observation of spontaneous movements and movements against gravity. Extremity movements should be symmetrical and are best seen when the infant is held supine with one hand supporting the buttocks and one supporting the shoulders. Strength is graded as follows:

- 5 Normal
- 4 Weak but able to provide resistance
- 3 Able to move against gravity but not against resistance
- 2 Unable to move against gravity
- 1 Minimal movement
- 0 Complete paralysis

Strength in toddlers is assessed by observing functional abilities, such as walking, stooping to pick up an object, and standing up from the floor. An older child should be able to easily reach high above his or her head, wheelbarrow walk, run, hop, go up and down stairs, and arise from the ground. Cooperative children can undergo individual muscle strength testing. **Gower sign** (child arises from lying on the floor by using his arms to *climb up* his legs and body) is a sign of significant proximal weakness. Subtle upper extremity asymmetry can be detected when the child extends arms out in front with the palms upward and eyes closed. The hand on the weaker side cups and begins to pronate slowly

(pronator drift). Muscle fasciculations indicate denervation from disease of the anterior horn cell or peripheral nerve.

Tone

Tone represents the dynamic resistance of muscles to passive stretch. Lower motor and cerebellar lesions produce decreased tone (**hypotonia**). Upper motor lesions produce increased tone (**spasticity**). In extrapyramidal disease, an increase in resistance is present throughout passive movement of a joint (**rigidity**).

Bulk

Muscle bulk may be decreased due to disuse or to lower motor neuron or neuromuscular disease. Excessive muscle bulk is seen in rare conditions, such as myotonia congenita; boys with Duchenne muscular dystrophy have *pseudohypertrophy* of their calves.

Coordination

Ataxia is the lack of coordination of movement, which is typically due to a dysfunction of the cerebellar pathways. Observation and functional analysis help assess coordination in infants and toddlers. Watching the child sit or walk assesses truncal stability. Exchanging toys or objects with the child permits assessment of intention tremor and **dysmetria** (errors in judging distance), signs of cerebellar dysfunction. Cooperative children can do repetitive finger or foot tapping to test rapid alternating movements. Cerebellar and corticospinal tract dysfunction produce slow and irregular alternating movements.

Gait

Watching a child creep, crawl, cruise, or walk is the best global assessment for the motor and coordination systems ([Chapter 197](#)). Subtle deficits and asymmetries in strength, tone, or balance may be observed. The toddler gait is normally wide-based and unsteady. The base of the gait narrows with age. By 6 years, a typical child is able to walk on their toes or heels and can tandem walk (heel to toe). Cerebellar dysfunction results in a broad-based, unsteady gait accompanied by difficulty in executing turns. Corticospinal tract dysfunction

produces a stiff, scissoring gait and toe walking; arm swing is decreased, and the affected arm is flexed across the body. Extrapyramidal dysfunction produces a slow, stiff, shuffling gait with dystonic postures. A waddling gait occurs with hip weakness due to lower motor neuron or neuromuscular disorders. A steppage gait results from weakness of ankle dorsiflexors (common peroneal palsy).

Reflexes

Deep tendon reflexes can be elicited at any age and are reported on a five-point scale:

- 0 Absent
- 1 Trace
- 2 Normal
- 3 Exaggerated reflex, with spread to contiguous areas (tapping a patellar reflex and observing a bilaterally brisk quadriceps response)
- 4 Clonus (self-limited or sustained)

These reflexes are decreased in lower motor neuron diseases and increased in upper motor neuron disease. **Babinski response**, or extensor plantar reflex, is an upward movement of the great toe and flaring of the toes on stimulation of the lateral foot and is a sign of corticospinal tract dysfunction. This reflex is unreliable in neonates, except when asymmetrical, because the “normal” response at this age varies. By 12-18 months of age, the plantar response should consistently be flexor (toes flexing down).

Sensory Examination

The sensory examination of newborns and infants is limited to observing the behavioral response to light touch or gentle sterile pinprick. Stimulation of a limb should produce a facial grimace. A spinal reflex alone may produce withdrawal movement of a limb. In a cooperative child, the senses of pain, touch, temperature, vibration, and joint position can be tested individually. The cortical areas of sensation must be intact to identify an object placed in the hand (**stereognosis**) or a number written in the hand (**graphesthesia**) or to distinguish between two sharp objects applied simultaneously and closely on the skin (**two-point discrimination**).

Special Diagnostic Procedures

Cerebrospinal Fluid Analysis

Analysis of cerebrospinal fluid (CSF) is essential when central nervous system infection is suspected and provides important clues to other diagnoses (Table 179.2). Differentiating hemorrhagic CSF caused by a traumatic lumbar puncture (LP) from a true subarachnoid hemorrhage may be difficult. In most cases of traumatic LP, the fluid clears significantly as the sequence of tubes is collected. If there is clinical evidence of increased ICP (papilledema, depression of consciousness, focal neurological deficits), caution must be exercised before performing an LP to limit risk of cerebral herniation. A computed tomography (CT) scan should be performed and confirmed to be normal before the LP if increased ICP is suspected. If increased ICP is present, it must be treated before an LP is performed.

TABLE 179.2

Analysis of Cerebrospinal Fluid

CSF FINDING	NORMAL CSF VALUES	
	NEWBORN	>1 MO OLD
Cell count*	10-25/mm ³	5/mm ³
Protein	65-150 mg/dL	<40 mg/dL
Glucose	>2/3 blood glucose or >40 mg/dL	>2/3 blood glucose or >60 mg/dL

CSF Change	Significance
Increased polymorphonuclear cells and decreased CSF glucose	Bacterial infection Partially treated bacterial meningitis Brain or parameningeal abscess Parasitic infection Leak of dermoid contents
Increased lymphocytes and decreased CSF glucose	Mycobacterial infection (tuberculosis) Fungal infection Carcinomatous meningitis Sarcoidosis
Increased lymphocytes and normal CSF glucose	Viral meningitis Postinfectious disease (ADEM) Vasculitis
Increased CSF protein	Infection Guillain-Barré syndrome Inflammatory disease (ADEM, multiple sclerosis)

	Leukodystrophy Venous thrombosis Hypertension Spinal block (Froin syndrome) Carcinomatous meningitis
Decreased glucose without pleocytosis	GLUT-1 transporter deficiency
Mild CSF pleocytosis	Tumor Infarction Multiple sclerosis Subacute bacterial endocarditis
Bloody CSF	Subarachnoid hemorrhage Subdural hemorrhage Intraparenchymal hemorrhage Hemorrhagic meningoencephalitis (group B streptococci, HSV) CNS trauma Vascular malformation Coagulopathy Traumatic lumbar puncture

*In normal children, cells present should be lymphocytes.

ADEM, Acute disseminated encephalomyelitis; *CNS*, central nervous system; *CSF*, cerebrospinal fluid; *HSV*, herpes simplex virus.

Electroencephalography

The electroencephalogram (EEG) records electrical activity generated by the cerebral cortex. EEG rhythms mature throughout childhood. There are three key features present: background patterns, behavioral state modulation, and presence or absence of epileptiform patterns. The background varies with age but in general should be symmetrical and synchronous between the two hemispheres without any localized area of higher amplitude or slower frequencies (focal slowing). Persistent focal slowing suggests an underlying structural abnormality (brain tumor, abscess, stroke). Bilateral disturbances of brain activity (increased ICP, metabolic encephalopathy) must be suspected when there is diffuse slow wave activity. Spikes, polyspikes, and spike-and-wave abnormalities, either in a localized region (focal) or distributed bihemispherically (generalized), suggest an increased risk for seizures.

Electromyography and Nerve Conduction Studies

Electromyography and nerve conduction velocities (NCVs) assess for

abnormalities of the neuromuscular apparatus, including anterior horn cells, peripheral nerves, neuromuscular junctions, and muscles. Normal muscle is electrically silent at rest. Spontaneous discharges of motor fibers (**fibrillations**) or groups of muscle fibers (**fasciculation**) indicate denervation, revealing dysfunction of anterior horn cells or peripheral nerves. Abnormal muscle responses to repetitive nerve stimulation are seen with neuromuscular junction disorders, such as myasthenia gravis and botulism. The amplitude and duration of the muscle compound action potentials are decreased in primary diseases of muscle. NCVs assess the action potential transmission along peripheral nerves. NCVs are slowed in demyelinating neuropathies (Guillain-Barré syndrome). The amplitude of the signal is diminished in axonal neuropathies.

Neuroimaging

Imaging the brain and spinal cord is accomplished using CT or magnetic resonance imaging (MRI). CT is quick and accessible for emergency purposes. MRI provides finer detail and, with different sequences, permits detection of posterior fossa lesions, subtle cerebral abnormalities, vascular anomalies, low-grade tumors, and ischemic changes. For a child with an acute head injury or sudden headache, cranial CT is the study of choice because it can rapidly reveal intracranial hemorrhage or other large lesions. For a child with new-onset focal seizures, MRI is the study of choice because an area of focal cortical dysplasia or other subtle lesions might not be apparent on CT. MRI also provides excellent views of the spinal cord. Cranial ultrasonography is a noninvasive bedside procedure used to visualize the brain and ventricles of infants with open fontanelles.

CHAPTER 180

Headache and Migraine

Etiology and Epidemiology

Headache is a common symptom among children and adolescents. Headaches can be a primary problem (migraines, tension-type headaches) or secondary to

another condition. Secondary headaches are most often associated with minor illnesses such as viral upper respiratory infections or sinusitis but may be the first symptom of serious conditions (meningitis, brain tumors), so a systematic approach is necessary.

Clinical Manifestations

Decision-Making Algorithm

Headaches

The temporal pattern of the headache must be clarified. Each pattern (acute, recurrent-episodic, chronic-progressive, chronic-nonprogressive) has its own differential diagnosis ([Table 180.1](#)).

TABLE 180.1

Four Temporal Patterns of Childhood Headache

Acute: Single episode of pain without a history of such episodes. The “first and worst” headache raises concerns for aneurysmal subarachnoid hemorrhage in adults, but is commonly due to *febrile illness* related to upper respiratory tract infection in children. Regardless, more ominous causes of acute headache (hemorrhage, meningitis, tumor) must be considered.

Acute recurrent: Pattern of attacks of pain separated by symptom-free intervals. Primary headache syndromes, such as *migraine* or *tension-type* headache, usually cause this pattern. Recurrent headaches are occasionally due to specific epilepsy syndromes (benign occipital epilepsy), substance abuse, or recurrent trauma.

Chronic progressive: Implies a gradually increasing frequency and severity of headache. The pathological correlate is *increasing ICP*. Causes of this pattern include pseudotumor cerebri, brain tumor, hydrocephalus, chronic meningitis, brain abscess, and subdural collections.

Chronic nonprogressive or chronic daily: Pattern of frequent or constant headache. Chronic daily headache generally is defined as >3-mo history of >15 headaches/mo, with headaches lasting >4 hr. Affected patients have normal neurological examinations; psychological factors and anxiety about possible underlying organic causes are common.

ICP, Intracranial pressure.

Tension-type headaches are the most common type of recurrent primary headaches in children and adolescents. They are generally mild and lack associated symptoms so are not typically disruptive to patients' lifestyle or activities. The pain is global and squeezing or pressing in character and can last for hours or days. There is no associated nausea, vomiting, phonophobia, or photophobia. Headaches can be related to environmental stresses or symptomatic

of underlying psychiatric illnesses, such as anxiety or depression.

Migraine headaches are another common type of recurrent headaches and frequently begin in childhood. Headaches are stereotyped attacks of frontal, bitemporal or unilateral, moderate to severe, pounding or throbbing pain that are aggravated by activity and last 1-72 hours. Associated symptoms include nausea, vomiting, pallor, photophobia, phonophobia, and an intense desire to seek a quiet, dark room for rest. Toddlers may be unable to verbalize the source of their discomfort and exhibit episodes of irritability, sleepiness, pallor, and vomiting. An aura can precede or coincide with the headache and typically persists for 15-30 minutes. Visual auras are very common and consist of spots, flashes, or lines of light that flicker in one or both visual fields. Complex, atypical auras (hemiparesis, monocular blindness, ophthalmoplegia, vertigo, confusion), accompanied by a headache, warrant careful diagnostic investigation, including a combination of neuroimaging, electroencephalogram, and appropriate metabolic studies.

Common causes of **secondary headaches** include head trauma, viral illness, and sinusitis. Medication-overuse headaches may complicate primary and secondary headaches. Serious causes of secondary headache include increased intracranial pressure (ICP) caused by a mass (tumor, vascular malformation) or intrinsic increase in pressure (pseudotumor cerebri). Increased ICP should be suspected if the headache and associated vomiting are worse when lying down or on first awakening; awaken the child from sleep; remit on arising; or are exacerbated by coughing, Valsalva maneuver, or bending over. Papilledema ([Fig. 180.1](#)) or focal neurological deficits should trigger an intensive etiological investigation.

FIGURE 180.1 Papilledema with dilation of the vessels, obliteration of the optic cup, loss of disc margin, and hemorrhages around disc. (From Kliegman RE, Behrman RM, Jenson HB, eds. *Nelson Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders; 2007:2107.)

Diagnostic Studies

For most children, a thorough history and physical examination provide an accurate diagnosis and obviate the need for further testing. Neuroimaging is usually not necessary. Imaging is warranted, however, if the patient has an abnormal neurological examination, symptoms of increased ICP, there are unusual neurological features during the headache (atypical aura), or the headaches are progressively worsening. In these cases, brain magnetic resonance imaging (MRI), with and without gadolinium contrast, is the study of choice, providing the highest sensitivity for detecting posterior fossa lesions and other, more subtle abnormalities. When the headache has a sudden, severe onset, emergent computed tomography (CT) can quickly evaluate for intracranial bleeding. If the CT is negative, a lumbar puncture should be performed to measure opening pressure and evaluate for pleocytosis, elevated red blood cells, and xanthochromia.

Treatment

Treating migraines requires an individually tailored regimen to address the frequency, severity, and disability produced by the headaches. Intermittent *symptomatic*, or abortive, analgesics are the mainstay for treatment of infrequent episodes of migraine. Symptomatic therapy requires early analgesic administration, often accompanied by rest in a quiet, dark room. Acetaminophen or a nonsteroidal antiinflammatory drug such as ibuprofen or naproxen sodium is often effective. Hydration and antiemetics are useful adjunctive therapies. If these first-line medications are insufficient, *triptan* agents may be considered. Triptans, available in injectable, nasal spray, oral disintegrating, and tablet form, are serotonin receptor agonists that can alleviate migraine symptoms promptly. Triptans are contraindicated for patients with focal neurological deficits associated with their migraines or signs consistent with basilar migraine (syncope) because of the risk of stroke.

Many children suffer with severe and frequent migraines that disrupt their daily lives. Children with more than one disabling headache per week may require **daily preventive agents** to reduce both attack frequency and severity. Preventive medications include tricyclic antidepressants (amitriptyline, nortriptyline), anticonvulsants (topiramate, valproic acid), antihistamines (cyproheptadine), beta-blockers (propranolol), and calcium channel blockers (verapamil).

Before initiating daily medications, lifestyle modifications must be put into place to regulate sleep, daily routines, and exercise and to identify and eliminate any precipitating or aggravating influences (caffeine, certain foods, stress, missed meals, dehydration). Other adjunctive treatment options include psychological support, stress management, and biofeedback.

CHAPTER 181

Seizures

A seizure is a transient occurrence of signs or symptoms resulting from abnormal excessive or synchronous neuronal activity in the brain.

Etiology and Epidemiology

Decision-Making Algorithm

Seizures and Other Paroxysmal Disorders

The differential diagnosis of paroxysmal disorders includes **seizures** and **nonepileptic events** (Table 181.1). Nonepileptic paroxysmal events are often normal or benign phenomena, although some are clinically significant and consequential. A thorough medical history from the patient and primary witnesses is the most reliable tool for establishing the correct diagnosis.

TABLE 181.1

Paroxysmal Disorders of Childhood

Seizures/epilepsy
Migraine and variants
• Paroxysmal torticollis of infancy
• Benign paroxysmal vertigo
Syncope
• Vasovagal syncope
• Breath-holding spells
• Cardiac syncope (arrhythmias, long QT syndrome)
• Apnea
Transient ischemic attack
Metabolic disorders
• Hypoglycemia
• Inborn errors of metabolism
Sleep disorders
• Narcolepsy, cataplexy
• Night terrors
Paroxysmal dyskinesias and other movement disorders
• Tics
Shudder attacks
Sandifer syndrome (gastroesophageal reflux causing paroxysmal stiffening and posturing)
Conversion disorder
Malingering
Normal behavior
• Neonatal jitteriness
• Benign sleep myoclonus
Self-stimulatory behavior

Acute symptomatic seizures are secondary to an acute problem affecting brain excitability, such as electrolyte imbalance or infection (Table 181.2). **Epilepsy** is defined as recurrent, *unprovoked* seizures. Epileptic seizures are generally

classified as *focal*, arising from one region of the cortex, or *generalized*, which arise from both hemispheres simultaneously (Table 181.3). Approximately 4-10% of children experience at least one seizure. The incidence of childhood epilepsy is 1-2%.

TABLE 181.3**Classification of Seizures and Epilepsy Syndromes**

FOCAL SEIZURES
With retained awareness
With observable motor signs (can be tonic, clonic, myoclonic)
With sensory phenomena (visual, auditory, olfactory, gustatory, vertiginous, somatosensory)
Autonomic
With impaired consciousness (dyscognitive features)
Psychic (déjà vu, jamais vu, fear)
Impaired consciousness at onset
Development of impaired consciousness
Focal seizures with evolution to bilateral convulsions
Jacksonian seizures
GENERALIZED SEIZURES
Absence (staring, unresponsiveness)
Convulsive seizures
• Tonic (sustained contraction)
• Clonic (rhythmic contractions)
• Tonic-clonic (tonic phase followed by clonic phase)
Atonic (abrupt loss of tone)
Myoclonic (rapid, shock-like contraction)

Focal Seizures

Focal seizures with retained awareness (previously termed simple partial seizures) arise from a specific anatomical focus and may or may not spread to surrounding brain regions. Clinical symptoms include motor (tonic, clonic, myoclonic), sensory, psychic, or autonomic abnormalities, but consciousness is preserved. The location and extent of spread of the seizure focus determine the clinical symptoms.

Focal seizures with altered awareness (previously termed complex partial seizures) can have similar sensorimotor signs, but also have associated alteration of consciousness. Although the child may not be completely unresponsive, subtle slowing or alteration of mental status (*dyscognitive* features) may occur. Along with altered responsiveness, patients may have automatisms or stare during these seizures. Automatisms are automatic semipurposeful movements of the mouth (lip smacking, chewing) or extremities (rubbing of fingers, shuffling of feet). Focal seizures that manifest only with psychic or autonomic symptoms, such as a feeling of *déjà vu* during a temporal lobe seizure, can be difficult to recognize.

When focal seizures spread to involve both cerebral hemispheres, they are said to have *evolved to a bilateral convulsive seizure* (previously called a secondarily generalized seizure). It is often difficult to distinguish primary generalized tonic and clonic seizures from those that evolved from focal seizures on purely clinical grounds. This distinction is important, however, because evaluation and treatment for focal or generalized epilepsy syndromes are quite different.

Generalized Seizures

Tonic, clonic, and biphasic **tonic-clonic** seizures may occur alone or in association with other seizure types. Typically the seizure begins abruptly but occasionally is preceded by a series of myoclonic jerks. During a tonic-clonic seizure, consciousness and control of posture are lost, followed by tonic stiffening and upward deviation of the eyes. Pooling of secretions, pupillary dilation, diaphoresis, and hypertension are common. Clonic jerks follow the tonic phase. In the post-ictal phase, the child might be hypotonic. Irritability and

headache are common as the child awakens.

Absence Seizures

Seizures in which the primary clinical feature is staring can be either absence (generalized) or focal seizures. The clinical hallmark of absence seizures is a brief (<15 seconds) loss of awareness accompanied by eyelid fluttering or simple automatisms, such as fumbling with the fingers and lip smacking. Absence seizures usually begin between 4 and 6 years of age. Neurological examination and brain imaging are normal. The characteristic electroencephalographic (EEG) patterns consist of **generalized 3-Hz spike-and-wave activity**. An absence seizure can often be provoked by **hyperventilation**. Differentiating absence from focal seizures with altered awareness can be difficult but is essential for appropriate evaluation and treatment (Table 181.4).

TABLE 181.4

Differentiating Absence Seizures From Focal Seizures With Altered Awareness

FEATURE	ABSENCE SEIZURE	FOCAL SEIZURE WITH ALTERED AWARENESS
Duration	Seconds	Minutes
Provoking maneuver	Hyperventilation Photic stimulation	Variable, but often none
Postictal phase	None (return immediately to baseline)	Confusion, sleepiness
Number of seizures	Many per day	Infrequent (rarely more than one per day)
EEG features	Interictal: normal except bursts of generalized spike wave and sometimes occipital intermittent rhythmic delta activity Ictal: 3-Hz generalized spike-wave	Interictal: focal slowing, sharp waves, or spikes Ictal: focal discharges (with or without spread to contiguous regions or the contralateral hemisphere)
Neurological examination	Normal	Normal, or focal deficits
Neuroimaging	Normal*	Normal, or focal abnormalities (mesial temporal sclerosis, focal cortical dysplasia, neoplasm, encephalomalacia)
First-line treatment	Ethosuximide or valproic acid [†]	Oxcarbazepine

*In the proper clinical context, and with an appropriate EEG, a diagnosis of absence epilepsy should be made without neuroimaging.

†Oxcarbazepine and carbamazepine are relatively contraindicated for children with typical absence epilepsy, as their seizures can be exacerbated by these medications.

EEG, Electroencephalographic.

Atypical Absence, Myoclonic, and Atonic Seizures

Atypical absence seizures manifest as episodes of impaired consciousness with automatisms, autonomic phenomena, and motor manifestations, such as eye opening, eye deviation, and body stiffening. They are associated with slower EEG discharges (2 Hz) and accompany other seizure types. **Myoclonus** is a sudden jerk of all or part of the body; not all myoclonus is due to epilepsy. Nonepileptic myoclonus may be benign, as in sleep myoclonus, or indicate serious disease. Myoclonic epilepsy usually is associated with multiple seizure types. The underlying disorder producing myoclonic epilepsy may be static (**juvenile myoclonic epilepsy** [JME]) or progressive and associated with neurological deterioration (neuronal ceroid lipofuscinosis). **Myoclonic absence** refers to body jerks that commonly accompany typical or atypical absence seizures. Although **atonic seizures** are typically brief (lasting 1-2 seconds), they are very disabling because of a sudden loss of postural tone that often results in falls and injuries.

Febrile Seizures

Seizures in the setting of fever may be caused by central nervous system infections (meningitis, encephalitis, brain abscess), unrecognized epilepsy triggered by fever, or **febrile seizures**. The latter represents the most common cause of seizures among children between 6 months and 6 years of age, occurring in about 4% of all children. By definition, a febrile seizure occurs in the presence of fever. **Simple febrile seizures** are generalized at onset, last less than 15 minutes, and occur only once in a 24-hour period in a neurologically and developmentally normal child. If the seizure has focal features, lasts longer than 15 minutes, recurs within 24 hours, or the child has preexisting neurological challenges, the seizure is referred to as a **complex febrile seizure**.

The prognosis of children with simple febrile seizures is excellent. Although febrile seizures recur in 30-50% of children, intellectual achievements are normal. The risk of subsequent epilepsy is not substantially greater than that of

the general population (approximately 2%). Factors that increase the risk for the development of epilepsy include abnormal neurological examination or development, family history of epilepsy, and complex febrile seizures.

Since simple febrile seizures are brief and the outcome is benign, most children require no treatment. Rectal diazepam can be administered during a seizure to abort a prolonged convulsion; it is appropriate to provide a rescue medication for children with a history of prolonged febrile seizures. Since antiseizure medications have side effects and children with febrile seizures have an excellent prognosis, daily antiseizure medication to prevent febrile seizures is not recommended. Administration of antipyretics during febrile illnesses does not prevent febrile seizures; the seizure can often be the first sign of a child's illness.

Psychogenic Nonepileptic Seizures

Psychogenic nonepileptic seizures (PNES) (previously termed pseudoseizures) may be the manifestation of conversion disorders or malingering. Additionally, children with epilepsy may, consciously or subconsciously, exhibit concurrent PNES. PNES semiology typically differs from epileptic seizures. In PNES, the patient's eyes are often closed (typically eyes are open during epileptic seizures) and the movements are tremulousness or thrashing rather than tonic or clonic. Verbalization and pelvic thrusting are seen more commonly in PNES, urinary and fecal continence is usually preserved, and injury does not usually occur. If the tongue is bitten, more often the tip of the tongue is injured (as opposed to the sides of the tongue in epileptic seizures). PNES can often be initiated or terminated by suggestion. An EEG performed during PNES does not show epileptiform patterns. The diagnosis is critical because appropriate mental health care, and not anticonvulsant medications, is the crux of treatment. Careful assessment and intervention for physical or sexual abuse, as well as other social stressors, is a key component of the care of children with PNES.

Epilepsy Syndromes

Epilepsy syndromes have distinctive EEG and clinical features (age of seizure onset, specific seizure types). Recognition of epilepsy syndromes provides useful information regarding the underlying etiologies that must be considered, treatments that may be helpful (or harmful), and long-term prognostic

information.

Benign childhood epilepsy with centrotemporal spikes, also known as **benign Rolandic epilepsy**, is among the most common epilepsy syndromes and usually begins between ages 5 and 10 years. The seizures typically occur only during sleep or on awakening. Affected children usually have focal motor seizures involving the face and arm (abnormal movement or sensation around the face and mouth, drooling, rhythmic guttural sound, impaired speech and swallowing). Seizures sometimes evolve to bilateral convulsions. The interictal EEG demonstrates independent bilateral centrotemporal sharp waves but is otherwise normal. With a classic history and EEG and a normal neurological examination, the diagnosis can be made with confidence and neuroimaging is not required. Seizures usually respond promptly to antiseizure medication. Intellectual outcome is normal, and the epilepsy resolves after puberty. Comorbid learning difficulties (especially language-based learning disabilities) and attention-deficit/hyperactivity disorder (ADHD) are common.

Childhood absence epilepsy is another common syndrome. Absence seizures typically begin in the early school years and usually resolve by late childhood or adolescence. If absence does not remit, 44% will go on to develop JME (see later discussion). Ethosuximide is the first-choice medication. A subset of patients also has generalized tonic-clonic seizures. For these children, valproic acid is the first choice as it can prevent both absence and convulsive seizures. Comorbid learning disabilities and ADHD are common. There is no contraindication to treating these children's ADHD with stimulant medication.

JME is the most common generalized epilepsy among adolescents and young adults. Onset is typically in early adolescence with myoclonic jerks (exacerbated in the morning, often causing the patient to drop objects), generalized tonic-clonic seizures, and absence seizures. Seizures usually resolve promptly with antiseizure medication. JME is classically treated with valproic acid; however, there are concerns about side effects and teratogenicity. Levetiracetam has a much lower risk of teratogenicity and is generally well tolerated. As such, levetiracetam is now favored, particularly for girls and women since treatment of JME is usually lifelong.

Infantile spasms are brief contractions of the neck, trunk, and arm muscles, followed by a phase of sustained muscle contraction lasting less than 2 seconds. Spasms occur most frequently when the child is awakening from or going to sleep. Each jerk is followed by a brief period of relaxation with repeated spasms in clusters of variable duration. When flexion of the thighs and crying are

prominent, the syndrome may be mistaken for colic or gastroesophageal reflux. **West syndrome** is the triad of infantile spasms, developmental regression, and a dramatically abnormal EEG pattern (**hypsarrhythmia**—a pattern of chaotic high-voltage slow waves, spikes, and polyspikes). The peak age at onset of infantile spasms is 3-8 months. The underlying etiology of the spasms dictates the prognosis. More than 200 different etiologies have been identified, including tuberous sclerosis, malformations of cortical development (lissencephaly), genetic syndromes (trisomy 21), acquired brain injury (stroke, perinatal hypoxic-ischemic encephalopathy), and metabolic disorders (phenylketonuria). Infants for whom an etiology is determined are classified as having *symptomatic* infantile spasms and are at very high risk for long-term neurodevelopmental difficulties. The etiology is not determined for a small subset of children; these patients have a somewhat better long-term prognosis but remain at high risk for adverse outcomes. With advances in genetic testing, fewer children have infantile spasms of uncertain etiology.

Infantile spasms are a neurological emergency since rapid initiation of effective therapy offers the best chance for favorable neurodevelopmental outcomes. First-line treatment options for infantile spasms include adrenocorticotrophic hormone, high-dose oral corticosteroids, and vigabatrin. Other antiseizure medications are much less effective. For infants with underlying tuberous sclerosis, vigabatrin is the treatment of choice. For other patients, treatment determinations are made on a case-by-case basis.

Lennox-Gastaut syndrome is a severe epilepsy syndrome with variable age of onset. Most children present before age 5 years. Frequent, multiple seizure types including atonic, focal, atypical absence, and generalized tonic, clonic, or tonic-clonic semiologies characterize the disorder. Many children have underlying brain injury, malformations, or genetic etiologies. The seizures are typically difficult to control, and most patients have significant intellectual disability.

Benign neonatal convulsions are an autosomal dominant genetic disorder linked to abnormal neuronal potassium channels. Otherwise well newborns present with focal seizures toward the end of the first week of life, leading to the colloquial term *fifth-day fits*. Response to treatment is generally excellent, and the long-term outcome is typically favorable.

Acquired epileptic aphasia (Landau-Kleffner syndrome) is characterized by the abrupt loss of previously acquired language in young children. The language disability is an acquired cortical auditory deficit (auditory agnosia).

The EEG is highly epileptiform in sleep, the peak area of abnormality often being in the dominant perisylvian region (language areas). This diagnosis should be considered for young patients with clear autistic regression, as it is a potentially treatable entity.

Status Epilepticus

Status epilepticus is a neurological emergency and is defined as (1) ongoing seizure activity or (2) repetitive seizures without recovery of consciousness for greater than 30 minutes. Status epilepticus carries an approximately 14% risk of new neurological deficits and 4-5% mortality, both related to the underlying etiology. Etiologies include new-onset epilepsy, drug intoxication, drug withdrawal (especially missed anticonvulsant doses among children with epilepsy), hypoglycemia, electrolyte imbalance, acute head trauma, infection, ischemic stroke, intracranial hemorrhage, metabolic disorders, and hypoxia.

The first priority of treatment is to ensure an adequate airway, breathing, and circulation ([Chapter 38](#)). Vital signs should be obtained and oxygen administered if needed. If respirations are inadequate, positive-pressure ventilation may be required. Intravenous (IV) access should be obtained, and laboratory evaluation should be undertaken (see below).

Several pharmacological options exist for management of status epilepticus ([Table 181.5](#)). Initial management is with a benzodiazepine and should begin if the seizure persists longer than 5 minutes. Lorazepam, diazepam, and midazolam are all effective agents and should be given as an adequate single dose (rather than successive smaller doses), which can be repeated one time. IV administration is preferred. However, when IV access is not available, benzodiazepines may be administered via rectal, intranasal, buccal, or intramuscular routes.

TABLE 181.5

Management of Status Epilepticus

STABILIZATION
ABCs (airway, breathing, circulation)
Cardiac monitoring
Oxygen and pulse oximetry
Intravenous access

Immediate laboratory tests

Glucose

Basic metabolic panel—sodium, calcium, magnesium

Anticonvulsant drug levels

Toxicology studies as appropriate

Complete blood counts, platelets, and differential

PHARMACOLOGICAL MANAGEMENT

Benzodiazepine (max rate of administration = 1 mg/min)

Lorazepam IV, IN 0.1 mg/kg (maximum 4 mg per dose)

Diazepam IV, PR 0.15-0.2 mg/kg (maximum 10 mg per dose)

Rectal diazepam 0.2-0.5 mg/kg (maximum 20 mg per dose)

Midazolam IV, IM, IN, buccal 0.1-0.2 mg/kg (maximum 10 mg per dose)

Standard anticonvulsant medications

Fosphenytoin IV, IM 20 mg/kg (phenytoin equivalents; maximum 1,500 PE per dose)

Phenobarbital IV 20 mg/kg (maximum 1,000 mg per dose)

Levetiracetam IV 60 mg/kg (maximum 4,500 mg per dose)

Valproic acid IV, PR 20 mg/kg (maximum 3,000 mg per dose)

Continuous infusions

Pentobarbital

Midazolam

General anesthesia

IM, Intramuscularly; *IN*, intranasally; *IV*, intravenous; *PE*, phenytoin; *PR*, per rectum.

If the seizure does not resolve after two doses of benzodiazepine, a second-line agent must be administered. There are few data from clinical trials to guide subsequent management. For newborns and infants, phenobarbital is reasonable. For older children, IV fosphenytoin (preferred over phenytoin due to tolerability), valproic acid, or levetiracetam may be considered. If the seizures persist, options include repeating one of the second-line medications or beginning a continuous infusion of midazolam or pentobarbital (with appropriate airway protection, blood pressure support, and strong consideration of video-EEG monitoring to evaluate for ongoing subclinical seizures; see [Table 181.5](#)). If this approach is ineffective, preparations for general anesthesia are undertaken. When status epilepticus stops, maintenance therapy is initiated with the appropriate anticonvulsant.

Laboratory and Diagnostic Evaluation

For an otherwise healthy child with a self-resolved, unprovoked seizure and a

normal physical and neurological examination, no laboratory evaluation is required. Children with *simple febrile seizures* who have recovered completely require little or no laboratory evaluation other than studies necessary to evaluate the source of the fever. If the clinical presentation does not meet these criteria and acute symptomatic seizures are suspected, evaluation for potentially life-threatening causes such as meningitis, sepsis, head trauma, and toxins must be pursued. A complete laboratory evaluation for new onset of seizures includes a complete blood count and measurement of glucose, calcium, sodium, potassium, chloride, bicarbonate, urea nitrogen, creatinine, magnesium, and phosphorus, as well as blood or urine toxicology screening. Children with clinical signs and symptoms of meningitis (neck stiffness, Kernig sign, Brudzinski sign), or history or physical examination suggestive of intracranial infection, should undergo a lumbar puncture. Cerebrospinal fluid (CSF) should be analyzed for cell counts, culture, protein, and glucose levels. In children less than 18 months old, particularly young infants, the clinical symptoms of meningitis may be subtle. Neonates also may require testing for inborn errors of metabolism; blood ammonia; CSF glycine and lactate; and a clinical trial of pyridoxine. Evaluation for infections, such as urine and stool cultures, and polymerase chain reactions for herpes simplex virus, cytomegalovirus, and enterovirus should be considered.

The **EEG** is the most useful neurodiagnostic test for distinguishing seizures from nonepileptic paroxysmal disorders and for classifying seizures as having focal or generalized onset. The EEG must be interpreted in the context of the clinical history; some normal children have focal or epileptiform EEG patterns. Conversely, children with seizures may have normal interictal EEGs. When the diagnosis is unclear, EEG with prolonged recordings and simultaneous video monitoring in an attempt to capture a typical event may be necessary.

Magnetic resonance imaging (MRI) is superior to computed tomography (CT) in showing most brain pathology, but in the emergency department setting, CT can be performed rapidly and often shows acute intracranial hemorrhage more clearly than MRI. MRI is unnecessary in patients with the primary generalized epilepsies, such as typical childhood absence and JME. Lesions (tumors, arteriovenous malformations, cysts, strokes, gliosis, focal atrophy) may be identified in 25% of patients with other epilepsy types, even when the clinical examination and EEG do not suggest focal features. Identification of some lesions, such as focal cortical dysplasia, hamartoma, and mesial temporal sclerosis, can assist in consideration of surgical treatment of pharmacoresistant epilepsy.

Long-Term Therapy

The decision to institute daily seizure medications for a first unprovoked seizure is based on the likelihood of recurrence balanced against the risk of long-term drug therapy. Determination of the recurrence risk is based on the clinical history and neurodiagnostic testing (Table 181.6). If the recurrence risk is 75% or greater, it is usually suggested that daily medication be prescribed. Absence seizures, infantile spasms, atypical absence seizures, and atonic seizures are universally recurrent at the time of diagnosis, so treatment should be initiated immediately.

TABLE 181.6

Recurrence Risk After a First Unprovoked Seizure*

SEIZURE TYPE	EEG NORMAL, EXAM NORMAL	EEG EPILEPTIFORM OR EXAM ABNORMAL	BOTH EEG AND EXAM ABNORMAL
Generalized	25%	50%	75%
Focal	50%	75%	>90%

*Most recurrences occur within 2 years

EEG, Electroencephalographic.

The goal of treatment is to maintain an optimal functional state. Medication toxicity should be weighed against the risk of the seizures. Initial drug selection is based on the seizure type (Fig. 181.1). Using a single agent limits toxicity, contains cost, and improves compliance. Approximately 60% of children obtain satisfactory seizure control and minimal side effects with the initial drug. If seizure control is not achieved, despite good compliance, addition of a second drug is considered. Measuring anticonvulsant blood levels can sometimes be helpful in adjusting dosing and monitoring compliance. Levels should be interpreted in light of the patient's clinical state; a patient with a “low” drug level who is seizure free does not necessarily need a higher dose. Anticonvulsant drug levels should be drawn at trough, usually before the morning doses. When hepatic or renal disease is present, especially in critically ill children, protein binding of medications is often altered and measurements of free and total anticonvulsant levels can be helpful.

Special circumstances:

1. For absence epilepsy, ethosuximide is the first-line treatment.
2. Adrenocorticotrophic hormone, oral corticosteroids, or vigabatrin are used to treat infantile spasms.

FIGURE 181.1 Treatment for epilepsy.

The duration of antiseizure treatment varies according to seizure type and epilepsy syndrome. For most children, medications can be weaned off after 2 years without seizures. There are some exceptions. For example, children with JME, progressive myoclonic epilepsy, atypical absence seizures, and Lennox-Gastaut syndrome usually require lifelong treatment. Children who have other neurological comorbidities, seizures that were initially difficult to control, or persistently epileptiform EEGs are at highest risk for recurrence when therapy is discontinued.

Although cognitively normal children with epilepsy have the same rates of injury as normal healthy children, there are important safety considerations for people with epilepsy. The risk of drowning is high, so swimming and bathing must only occur under direct adult supervision. Children should use appropriate helmets for sports such as bicycling or ice skating. There is no contraindication to participation in contact sports, but scuba diving, hang gliding, and free climbing are not safe for people with epilepsy. Each country and individual states have specific laws regarding driving for people with epilepsy. Most require a period of seizure freedom before driving.

Weakness and Hypotonia

Weakness is a decreased ability to voluntarily and actively move muscles. This may be generalized or localized to one aspect of the body. Hypotonia is a state of low muscle resistance to movement. Hypotonia can be associated with weakness, but in some cases is present with normal motor strength. The differential diagnosis for weakness is extensive ([Table 182.1](#)).

TABLE 182.1

Disorders Causing Weakness in Infants and Children

ANATOMICAL REGION	CORRESPONDING DISORDERS
Central nervous system —brain	Brain tumor Trauma (accidental, nonaccidental) Infection (meningitis, encephalitis, abscess, TORCH) Ischemia (arterial or venous) Hemorrhage Demyelinating disease Metabolic disease (leukodystrophy; inborn error of metabolism; mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes) Degenerative disease
Central nervous system —spinal cord	Transverse myelitis Tumor Abscess Trauma Infarction
Anterior horn cell	Spinal muscular atrophy Poliomyelitis
Peripheral nerve	Guillain-Barré syndrome Hereditary motor sensory neuropathy Tick paralysis Bell palsy
Neuromuscular junction	Myasthenia gravis (juvenile, transient neonatal, congenital) Botulism
Muscle	Muscular dystrophies (Duchenne, Becker, limb-girdle) Myotonic dystrophies Congenital myopathies Metabolic myopathies Dermatomyositis Polymyositis

TORCH, Toxoplasmosis, other [syphilis, varicella-zoster, parvovirus B19], rubella, cytomegalovirus, and herpes.

Etiology

Weakness and hypotonia may be due to disorders of **upper motor neurons** or **lower motor neurons**. Upper motor neurons originate in the cerebral motor cortex; their axons form the corticospinal tract ending in the spinal cord and control voluntary motor activity. The anterior horn cells, their motor roots, peripheral motor nerves, neuromuscular junctions, and muscles represent the lower motor neurons and muscle units. Maintenance of normal strength, tone, and coordination requires integrated communication throughout this complex system, including the cerebral cortex, cerebellum, brainstem, thalamus, basal ganglia, and spinal cord.

Clinical Manifestations

Decision-Making Algorithm

Hypotonia and Weakness

Weakness caused by upper motor neuron disease differs from weakness produced by lower motor units ([Table 182.2](#)). Dysfunction of the upper motor neuron causes loss of voluntary control, but not total loss of movement because motor nuclei of the basal ganglia, thalamus, and brainstem have tracts that produce simple or complex stereotyped patterns of movement. The corticospinal tract permits fine motor activity and is best tested by rapid alternating movements of the distal extremities. In the acute phase, upper motor neuron disorders cause hypotonia and decreased deep tendon reflexes. Over time, spasticity and hyperreflexia develop. Mild dysfunction produces slowed, stiff motions. More severe dysfunction produces stiff, abnormal involuntary postures and spasticity. A central lesion usually results in weakness that is more pronounced in the flexors of the lower extremities than in the extensors, so affected patients tend to be spastic with legs extended and adducted. In the upper extremities, the extensors are weaker than flexors, so elbows and wrists are flexed.

TABLE 182.2

Clinical Distinction Between Upper Motor Neuron and Lower Motor Neuron Lesions

CLINICAL SIGN	UPPER MOTOR NEURON (CORTICOSPINAL TRACT)	LOWER MOTOR NEURON (NEUROMUSCULAR)
Tone	Increased (spastic)	Decreased
Reflexes	Increased	Decreased
Babinski reflex	Present	Absent
Atrophy	Possible	Possible
Fasciculations	Absent	Possible

Damage to the spinal cord leaves residual simple, stereotyped reflex movements coordinated by local spinal reflexes below the level of the lesion.

Destruction of the lower motor neuron, the final common pathway producing muscle activity, leads to hypotonia and total absence of movement. Function is best tested by measuring the strength of individual muscle groups or, in a young child, by observing the ability to perform tasks requiring particular muscle groups (walk up or down stairs, arise from the ground, walk on toes or heels, raise the hands above the head, squeeze a ball). With lower motor neuron disorders, atrophy and fasciculations are common and deep tendon reflexes are typically decreased or absent.

Disease of the Upper Motor Neuron

Etiology and Epidemiology

Tumors, traumatic brain injury, infections, stroke, demyelinating syndromes, spinal cord trauma or mass, metabolic diseases, and neurodegenerative diseases (see [Chapters 100, 101, 157, 184, 185](#); [Section 10](#)) may injure the brain or spinal cord, producing an upper motor neuron pattern of weakness coupled with increased deep tendon reflexes, spasticity, and extensor plantar responses (Babinski sign). In neonates, weakness with upper motor neuron patterns may be caused by TORCH (toxoplasmosis, other [syphilis, varicella-zoster, parvovirus B19], rubella, cytomegalovirus, and herpes) infections (see [Chapter 66](#)), developmental brain anomalies, hemorrhage, stroke, hypoxia, genetic syndromes, metabolic/electrolyte disturbances, or toxic exposure.

The distribution of weakness depends on the location of the lesion. A tumor in the left parietal region may produce a right hemiparesis. A brainstem glioma may produce a slowly progressive quadriparesis. A diffuse disorder of myelin

synthesis, such as a leukodystrophy, would produce progressive symmetrical quadriparesis.

Decision-Making Algorithm

Hypotonia and Weakness

Acute disseminated encephalomyelitis (ADEM) is an acute, inflammatory demyelinating disorder that may affect infants and children after a febrile illness. Children may present with a variety of symptoms and signs including acute optic neuritis, hemiparesis, ataxia, seizures, headache, weakness, or dysphagia. The pathophysiology resembles that of multiple sclerosis. An important difference is that children with ADEM have encephalopathy. Although multiple sclerosis is most commonly diagnosed in adulthood, childhood cases have been increasingly recognized. ADEM and multiple sclerosis exacerbations are treated with high-dose steroids and intravenous immunoglobulin (IVIG). Physical and occupational therapies are often helpful.

Acute spinal cord lesions, such as infarction or compression, may produce a **flaccid, areflexic paralysis** that mimics lower motor neuron disease. A child who exhibits an acute or subacute flaccid paraparesis is most likely to have an acute cord syndrome or Guillain-Barré syndrome. The hallmarks of spinal cord disease are a sensory level and a motor level of impairment, disturbance of bowel and bladder function, and local spinal pain or tenderness. Patients may be bradycardic and hypotensive due to neurogenic shock. The acute cord syndrome may be the result of infection, cord tumor, infarction, demyelination, or trauma. **Transverse myelitis**, an acute postinfectious demyelinating disorder of the spinal cord, is treated with high-dose steroids. Symptoms of an epidural abscess include fever, spinal pain, and neurological deficits. Trauma and tumors (neuroblastoma, lymphoma, sarcoma) compressing the spinal cord necessitate immediate neurosurgical management to preserve vital function. Lesions of the spinal cord are best delineated with magnetic resonance imaging (MRI).

Diseases of the Lower Motor Neuron

Neuromuscular disease affects any component of the lower motor neuron unit. The distribution of muscle weakness can point toward specific diseases ([Table](#)

182.3).

TABLE 182.3

Topography of Neuromuscular Diseases

LOCATION	CLINICAL SYNDROMES/DISORDERS
Proximal muscle weakness	Muscular dystrophy
	Duchenne/Becker
	Limb-girdle dystrophy
	Dermatomyositis; polymyositis
	Kugelberg-Welander disease (spinal muscular atrophy type 2)

	Myotonic dystrophy
	Congenital myopathy
	Facioscapulohumeral dystrophy

Spinal Muscular Atrophy

Etiology

Progressive degeneration of anterior horn cells is the key manifestation of spinal muscular atrophy (SMA), a genetic disease with signs and symptoms that may begin in intrauterine life or any time thereafter. About 25% of patients have a severe infantile form (SMA type 1/**Werdnig-Hoffmann disease**), 50% have a

late infantile and more slowly progressive form (SMA type 2/**Kugelberg-Welander syndrome**), and 25% have a more chronic, juvenile form (SMA type 3). SMA is one of the most frequent autosomal recessive diseases, with a carrier frequency of 1 in 50.

Clinical Manifestations

Decision-Making Algorithm

Hypotonia and Weakness

The earlier in life the signs develop, the more severe the progression. Infants with SMA type 1 present in early infancy with severe hypotonia, generalized weakness, and facial involvement. Infants have normal cognitive, social, and language skills and sensation. **Fasciculations** (quivering muscle movements that are typically best seen on the lateral aspect of the tongue) are best identified by inspecting the mouth when the child is asleep. Deep tendon reflexes are absent. With disease progression, breathing becomes rapid, shallow, and predominantly abdominal. In an extremely weak child, respiratory compromise leads to atelectasis, pulmonary infection, and death. Most infants with SMA type 1 die within the first 2 years. Children with SMA type 2 may survive to adulthood. Children with SMA type 3 can initially appear normal with slower progression of weakness and a normal life expectancy.

Laboratory and Diagnostic Studies

The diagnosis of SMA is made by genetic testing. Creatine phosphokinase (CK) may be normal or mildly elevated. Electromyogram (EMG) shows fasciculations, fibrillations, and other signs of denervation. Muscle biopsy specimens show grouped atrophy.

Treatment

No specific treatment delays progression of SMA, although a number of promising agents including nusinersen, an antisense oligonucleotide, are being studied. Symptomatic therapy is directed toward minimizing contractures, preventing scoliosis, optimizing nutrition, and avoiding infections. Respiratory

infections are managed early and aggressively with pulmonary hygiene, oxygen, and antibiotics. The use or nonuse of artificial ventilation and tube feedings must be individualized for each patient in each stage of the illness.

Peripheral Neuropathy

There are many peripheral nerve diseases in childhood, but the most classic presentations are Guillain-Barré syndrome, chronic inflammatory demyelinating polyneuropathy (CIDP), hereditary motor sensory neuropathy (HMSN), and tick paralysis. Peripheral neuropathies produced by diabetes mellitus, alcoholism, chronic renal failure, exposure to toxins, vasculitis, and the effects of neoplasm are common in adults but are rare in children.

Guillain-Barré Syndrome

Guillain-Barré syndrome (acute inflammatory demyelinating polyradiculoneuropathy) is a postinfectious autoimmune peripheral neuropathy that can occur about 10 days after a respiratory or gastrointestinal infection (classically *Mycoplasma pneumonia* or *Campylobacter jejuni*). It occurs in people of all ages and is the most common cause of acute flaccid paralysis in children.

The characteristic symptoms are *areflexia*, *flaccidity*, and *symmetrical ascending weakness*. Progression can occur rapidly, in hours, or more indolently over weeks. Typically, symptoms start with numbness or paresthesia in the hands and feet, then a heavy, weak feeling in the legs. Weakness ascends to involve the arms, trunk, and bulbar muscles (tongue, pharynx, larynx). Deep tendon reflexes are absent even when strength is relatively preserved. Objective signs of sensory loss are usually minor compared with the dramatic weakness. Bulbar and respiratory insufficiency may progress rapidly. Dysfunction of autonomic nerves can lead to blood pressure changes, tachycardia and other arrhythmias, urinary retention or incontinence, or stool retention. This polyneuropathy can be difficult to distinguish from an acute spinal cord syndrome. Preservation of bowel and bladder function, loss of arm reflexes, absence of a sensory level, and lack of spinal tenderness point toward Guillain-Barré syndrome. A cranial nerve variant of Guillain-Barré syndrome called the **Miller Fisher variant** manifests with ataxia, partial ophthalmoplegia, and areflexia.

The cerebrospinal fluid in Guillain-Barré syndrome is sometimes normal early in the illness but classically shows elevated protein levels without significant

pleocytosis. MRI with gadolinium may reveal enhancement of the spinal nerve roots. EMG and nerve conduction velocity are not always required but can provide corroborative diagnostic evidence and prognostic indicators.

Children in early stages of the disease should be admitted to the hospital. Those with moderate, severe, or rapidly progressive weakness should be treated in an intensive care unit. Pulmonary and cardiac functions are monitored continuously. Endotracheal intubation is required by patients with impending respiratory failure or an inability to clear secretions. Most patients are treated initially with IVIG. Plasma exchange and immunosuppressive drugs are alternatives when IVIG is unsuccessful or in rapidly progressive disease. Physical, occupational, and speech therapies are mainstays of treatment.

The illness usually resolves spontaneously, albeit slowly; 80% of patients recover normal function within 1-12 months. Twenty percent of patients are left with mild to moderate residual weakness. Some children will suffer acute relapse or chronic symptoms.

Chronic Inflammatory Demyelinating Polyneuropathy

CIDP is an immune-mediated peripheral neuropathy and can affect patients of all ages. Patients present with both proximal and distal weakness (usually in an episodic, relapsing-remitting pattern) affecting the extremities. Patients may also experience sensation changes such as numbness, tingling, or pain. The diagnosis is clinical, although EMG or nerve biopsy may confirm the diagnosis. The mainstays of treatment for CIDP are IVIG, glucocorticoids, and plasmapheresis. Prognosis varies; some patients have complete remission, whereas others experience partial remission or severe persistent disability.

Hereditary Motor Sensory Neuropathy

HMSN (also called Charcot-Marie-Tooth disease [CMT]) is a group of progressive peripheral nerve diseases. Motor components generally dominate the clinical picture, with sensation and autonomic functions affected later. Some subtypes present with severe symptoms starting in infancy while other forms may have milder symptoms.

The peroneal and tibial nerves are the earliest and most severely affected. Most often, complaints begin in the preschool to early adolescent years, with weakness of the ankles and frequent tripping. Examination shows **pes cavus deformity of the feet** (high-arched feet), bilateral weakness of foot dorsiflexors,

and normal sensation despite occasional complaints of paresthesia. Peripheral nerves can become markedly enlarged and may be palpable on exam. Progression of HMSN is slow, extending over years and decades. Eventually, patients develop weakness and atrophy of the entire lower legs and hands and mild to moderate sensory loss in the hands and feet. Some patients never have more than a mild foot deformity, loss of ankle reflexes, and electrophysiological abnormalities. Others in the same family may be confined to a wheelchair and have difficulties performing everyday tasks with their hands.

HMSN can be characterized by demyelination (CMT1) or axonal (CMT2) damage. Specific genetic testing is available for many subtypes of HMSN. Specific treatment for HMSN is not available, but braces that maintain the feet in dorsiflexion can improve function.

Tick Paralysis

Decision-Making Algorithm

Hypotonia and Weakness

Tick paralysis produces an acute lower motor neuron pattern of weakness, clinically similar to Guillain-Barré syndrome. An attached female tick releases a toxin, similar to botulism, blocking neuromuscular transmission. Affected patients present with a severe generalized flaccid weakness, including ocular, papillary, and bulbar paralysis. A methodical search for an affixed tick, particularly in hairy areas, must be made in any child with acute weakness. Removal of the tick results in a prompt return of motor function.

Myasthenia Gravis

Decision-Making Algorithm

Hypotonia and Weakness

Myasthenia gravis is an autoimmune condition. Most commonly, antibodies

block the acetylcholine receptors (AChR) at the neuromuscular junction, decreasing the number of effective receptors, which results in rapid fatigability of striated muscle; other types of autoantibodies exist. The three childhood varieties are **juvenile myasthenia gravis** in late infancy and childhood, **transient neonatal myasthenia**, and **congenital myasthenia**.

Juvenile Myasthenia

Variable ptosis, diplopia, ophthalmoplegia, and facial weakness are the presenting symptoms. Dysphagia, poor head control, and extremity weakness may occur. Rapid fatigue of muscles distinguishes myasthenia from other neuromuscular disorders, with progressive worsening over the day or with repetitive activity. In some children, the disease never advances beyond ophthalmoplegia and ptosis (ocular myasthenia). Others have a progressive and potentially life-threatening illness that involves all musculature, including that of respiration and swallowing. Treatment includes pyridostigmine (an acetylcholinesterase inhibitor) and, depending on severity, various forms of immunosuppression.

Transient Neonatal Myasthenia Gravis

A transient myasthenic syndrome develops in the first hours to days after birth in neonates born to mothers with myasthenia gravis. Almost all infants born to mothers with myasthenia have maternal anti-AChR antibodies, but only 10-20% will develop signs. Signs include ptosis, ophthalmoplegia, weak facial movements, poor feeding, hypotonia, respiratory difficulty, and variable extremity weakness. Neonates with transient myasthenia gravis require cholinesterase inhibitors and supportive care for a few days to weeks until the weakness remits.

Congenital Myasthenia Gravis

A variety of rare disorders of the neuromuscular junction have been reported that are not autoimmune mediated. The congenital myasthenic syndromes (CMS) are due to gene mutations in the components of the neuromuscular junction. They typically present in infancy with hypotonia, ophthalmoparesis, facial diplegia, and extremity weakness, although they can present throughout childhood. Respiratory function and feeding may be compromised. Children with CMS usually have lifelong disability. Some children will respond to pyridostigmine or

other drugs that improve neuromuscular junction function.

Diagnostic Studies

Autoimmune myasthenia is most commonly diagnosed through the combination of clinical symptoms and antibody testing. The majority of individuals have antibodies to the AChR, although some have antibodies to other components of the neuromuscular junction. Nerve conduction studies classically reveal an electrodecrement with 3-Hz repetitive stimulation. Administration of a cholinesterase inhibitor (edrophonium chloride) can result in transient improvement in strength, particularly of ptosis, and thus can additionally be used for diagnostic verification.

Infant Botulism

Decision-Making Algorithm

Hypotonia and Weakness

Infant botulism results from intestinal infection by *Clostridium botulinum*, which produces a neurotoxin that blocks presynaptic cholinergic transmission. Young age and the absence of competitive bowel flora predispose infants to this disease. Infants may ingest dust, soil, or food (honey or poorly canned foods) contaminated with spores. The progressive neuromuscular blockade ranges from mild to severe. Infants typically present with constipation and poor feeding. Hypotonia and weakness develop progressively, along with cranial nerve dysfunction manifested by decreased gag reflex, diminished eye movements, decreased pupillary contraction, and ptosis. Heart rate and blood pressure may fluctuate. Affected infants may develop respiratory failure. The diagnosis is made by detecting *C. botulinum* spores and toxin in stool samples. Therapy with botulism IVIG should be administered as soon as the diagnosis is suspected. With prompt treatment and respiratory and supportive care, the prognosis is good.

Duchenne Muscular Dystrophy

Muscular dystrophies are a group of genetic muscle diseases characterized by progressive myofiber degeneration and the gradual replacement of muscle by fibrotic tissue. Duchenne muscular dystrophy is the most common muscular dystrophy and one of the most common genetic disorders of childhood.

Etiology

Duchenne muscular dystrophy is an X-linked disorder (Xp21) that arises from a mutation in the dystrophin gene. Approximately 1 in 3,500 boys is affected. **Becker muscular dystrophy** is an allelic disorder associated with more mild symptoms; its mutations at least partially preserve the function of the resulting gene product.

Clinical Manifestations

Decision-Making Algorithm

Hypotonia and Weakness

Boys are only rarely symptomatic in early infancy. At about 2-3 years of age, boys develop an awkward gait and an inability to run properly. Some have an antecedent history of mild delay in attaining motor milestones or of poor head control during infancy. Examination shows firm calf hypertrophy and mild to moderate proximal leg weakness with a hyperlordotic, waddling gait. The child typically arises from a lying position on the floor by using his arms to *climb up* his legs and body (**Gower sign**). Arm weakness is evident by age 6 years. Most boys are wheelchair dependent by age 12 years. Other manifestations include cardiomyopathy, scoliosis, respiratory decline, and cognitive and behavioral dysfunction. Many boys with Duchenne live into adulthood. Most die in their 20s or early 30s, usually as a result of progressive respiratory decline or cardiac dysfunction.

Laboratory and Diagnostic Studies

Serum CK levels are always markedly elevated. Diagnosis is established by genetic testing for the dystrophin gene mutation. Approximately one-third of cases represent new mutations. Prenatal genetic testing is possible, and newborn

screening for elevated CK is available in some states. Occasionally the diagnosis is not made until a muscle biopsy shows muscle fiber degeneration and regeneration accompanied by increased intrafascicular connective tissue.

Treatment

Chronic oral steroid therapy is now instituted to slow the pace of the disease, delay motor disability, and improve longevity. Supportive care includes physical therapy, bracing, proper wheelchairs, and treatment of cardiac dysfunction or pulmonary infections. A multidisciplinary approach is recommended.

Myotonic Dystrophy

Etiology and Epidemiology

Myotonic dystrophy (DM) is the second most common muscular dystrophy and the most common form to present in adulthood. An autosomal dominant genetic disease, DM is caused by progressive expansion of a triplet repeat, CTG, in the DM protein kinase gene. Presentation is roughly correlated with the number of CTG repeats, and the disease is characterized by genetic anticipation, where each generation presents with earlier and more severe symptoms.

Clinical Manifestations

Although DM most typically presents in adulthood, it can present at any age. Clinical features of childhood-onset “classic” DM include slowly progressive facial and *distal* extremity weakness as well as **myotonia**. Myotonia is a disorder of muscle relaxation after contraction. When patients grasp onto an object, they have difficulty releasing their grasp and may appear to peel their fingers away slowly. The facial appearance is characteristic, with hollowing of muscles around temples, jaw, and neck; ptosis; facial weakness; and drooping of the lower lip. The voice is nasal and mildly dysarthric. Not only is the striated muscle affected, but smooth muscle of the alimentary tract and cardiac muscle are involved. Patients have variable arrhythmias, endocrinopathies, immunological deficiencies, cataracts, and intellectual impairment.

A severe congenital form of DM can appear in infants of mothers with DM because of rapid expansion of the CTG repeat length. Infants are immobile and hypotonic, with ptosis, absence of sucking and Moro reflexes, poor feeding, and respiratory difficulties. Often, weakness and atony of uterine smooth muscle

during labor lead to associated hypoxic ischemic encephalopathy and its sequelae, which make the clinical diagnosis more difficult. The presence of congenital contractures, clubfoot, or a history of poor fetal movements indicates intrauterine neuromuscular disease. Those requiring prolonged ventilation have an infant mortality of 25%. Individuals with congenital DM often make significant gains in terms of motor skills, and nearly all children eventually ambulate independently. However, approximately 50% of DM patients have mental retardation. In addition, children with congenital DM experience a second progressive phase of the disease in the teen years, including potentially fatal cardiac arrhythmias. Diagnosis is established by genetic testing.

Other Forms of Childhood Muscle Disease

Congenital muscular dystrophies (CMDs) refer to a group of genetically determined conditions that present in infancy or early childhood. The most common subtypes include merosin-deficient CMD, Ullrich CMD, and the dystroglycanopathies. The characteristic clinical features include hypotonia, extremity weakness, delayed motor development, and congenital contractures. Contractures and scoliosis are often progressive and severely worsen; respiratory status diminishes with age. Diagnosis is established through the combination of elevated serum CK and dystrophic changes detected on muscle biopsy. **Emery-Dreifuss muscular dystrophy** (EDMD), also known as humeroperoneal muscular dystrophy, can be inherited as an X-linked recessive, autosomal dominant, or autosomal recessive disorder. Symptoms typically begin in childhood, although adult onset has been noted. Patients may experience early contractures, slowly progressive humeroperoneal muscle weakness or wasting, and cardiac disease with conduction defects and arrhythmias. EDMD is associated with mild elevations of serum CK levels, abnormal electrocardiograms (ECG), characteristic changes on muscle imaging, and abnormal but nonspecific muscle biopsies. There are no disease-specific modifying therapies for EDMD, although early placement of defibrillators in patients with abnormal ECGs reduces the incidence of sudden death.

Several forms of **limb-girdle muscular dystrophy** (LGMD), usually inherited in an autosomal recessive pattern, have been described. Depending on the subtype of LGMD, presentation can be throughout childhood. A subset of children will have a Duchenne-like presentation. LGMD primarily affects muscles of the hip and shoulder girdles. Distal muscles may later become weak

and atrophic; some children have progressive cardiac and respiratory failure.

Facioscapulohumeral dystrophy is an autosomal dominant myopathy. Weakness first appears in the facial and shoulder girdle muscles. Shoulder weakness results in the characteristic observation of scapular winging, which can often be asymmetrical. Patients have mild ptosis, a decrease in facial expression, inability to pucker the lips or close eyes during sleep, neck weakness, difficulty in fully elevating the arms, and thinness of upper arm musculature.

Congenital myopathies (CM) are a group of nondystrophic muscle disorders that, like CMDs, most typically present in infancy with hypotonia and weakness. Additional signs and symptoms include congenital contractures, hip subluxation/dislocation, small/atrophic muscles, thin body habitus, and characteristic facial appearance (the “myopathic facies”). Symptoms are often nonprogressive or only slowly progressive, although children often have severe lifelong disabilities including wheelchair dependence, severe scoliosis, and respiratory failure. Clinical findings may distinguish CMDs and other dystrophies (involvement of the facial musculature in CM). Diagnosis is ultimately established based on laboratory studies, biopsy findings, and genetic test results. Histopathological subtypes are distinguished by characteristic features on muscle biopsy, the most common being nemaline myopathy, centronuclear myopathy, and core myopathy. Although no specific therapies currently exist for any CM subtype, several promising therapies have shown efficacy in preclinical models of disease.

Metabolic Myopathies

Glycogen storage disease type II (Pompe disease) and muscle carnitine deficiency are discussed in [Chapters 52](#) and [55](#). **Several mitochondrial myopathies** may present with hypotonia, ophthalmoplegia, and progressive weakness, but the phenotype of these disorders is broad (see [Chapter 57](#)). **Endocrine myopathies**, including hyperthyroidism, hypothyroidism, hyperparathyroidism, and Cushing syndrome, are associated with proximal muscle weakness (see [Chapters 175](#), [176](#), and [178](#)). **Periodic paralysis** due to familial forms of hypokalemia or hyperkalemia produces episodic weakness.

Laboratory and Diagnostic Studies

The diagnostic evaluation should be guided by the clinical history and physical

examination (see [Chapter 179](#)).

Malignant Hyperthermia

Malignant hyperthermia is a life-threatening syndrome manifested by a rapid increase of body temperature, muscle rigidity, metabolic and respiratory acidosis, hypotension, arrhythmias, and convulsions. Acute episodes are precipitated by exposure to anesthetic agents in patients with a genetic predisposition. Patients with Duchenne muscular dystrophy, central core myopathy, and other myopathies are susceptible, although malignant hyperpyrexia can also occur in children without muscle disease as an autosomal dominant genetic disorder. A family history of unexplained death during anesthesia is often noted. Serum CK levels rise and myoglobinuria can result in tubular necrosis and acute renal failure. Diagnosis of idiopathic malignant hyperthermia is possible with genetic testing or an in vitro muscle contraction test that reveals excessive tonic contracture on exposure to halothane and caffeine. Treatment consists of dantrolene, sodium bicarbonate, and cooling.

Neonatal and Infantile Hypotonia

The clinical distinction between upper and lower motor neuron disorders in infants is blurred because incomplete myelination of the developing nervous system limits expression of many of the cardinal signs, such as spasticity. The two critical clinical points are whether the child is weak and the presence or absence of deep tendon reflexes. Hypotonia and weakness coupled with depressed or absent deep tendon reflexes suggest a neuromuscular disorder. A stronger child with brisk reflexes suggests an upper motor neuron source for the hypotonia. Causes of neonatal weakness are outlined earlier. A diagnostic algorithm for infants with hypotonia or weakness is presented in [Fig. 182.1](#).

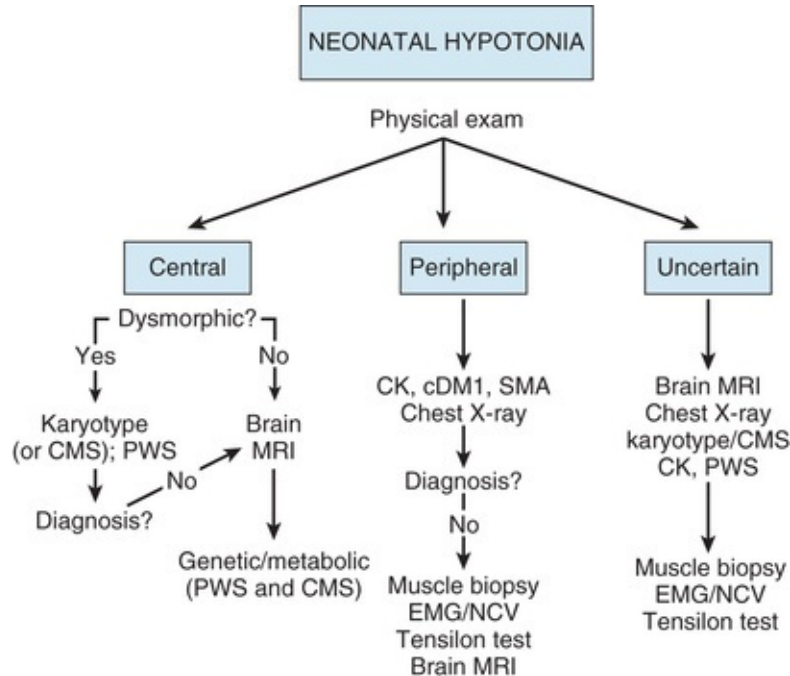

FIGURE 182.1 Evaluation of an infant with hypotonia. *cDM1*, Congenital myotonic dystrophy; *CK*, creatine kinase; *CMS*, chromosomal microarray analysis; *EMG*, electromyogram; *MRI*, magnetic resonance imaging; *NCV*, nerve conduction velocity; *PWS*, Prader-Willi syndrome; *SMA*, spinal muscular atrophy. (Courtesy James Dowling, MD, PhD.)

Hypotonia Without Significant Weakness (Central Hypotonia)

Decision-Making Algorithm

Hypotonia and Weakness

Some infants who appear to move well when supine in their cribs are *floppy* when handled or moved. When lifted, their heads flop, they *slip through* at the shoulders, do not support weight on their legs, and form an *inverted U* in prone suspension (**Landau posture**). When placed prone as neonates, they may lie flat instead of keeping their arms and legs flexed. Passive tone is decreased, but reflexes are normal. Hypotonia may be associated with significant cerebral disease or may be a benign phenomenon that is outgrown. The most common

cause of hypotonia is hypoxic-ischemic encephalopathy.

Prader-Willi syndrome (PWS) presents with severe neonatal hypotonia; severe feeding problems leading to failure to thrive; small hands and feet; and, in boys, a small penis, small testicles, and cryptorchidism. Severe hyperphagia and obesity develop in early childhood. Approximately 60-70% of affected individuals have an interstitial deletion of *paternal* chromosome 15q11q13. PWS and trisomy 21 are the most common genetic causes of neonatal hypotonia.

Infants who have a connective tissue disorder, such as **Ehlers-Danlos syndrome**, **Marfan syndrome**, or familial laxity of the ligaments, may exhibit marked passive hypotonia, ligamentous laxity, and increased skin elasticity. They have normal strength and cognition and achieve motor and mental milestones normally. They may have peculiar postures of their feet or unusual gaits.

Infants with **benign congenital hypotonia** typically present at 6-12 months old with delayed gross motor skills. They are unable to sit, creep, or crawl but have good verbal, social, and manipulative skills. Strength appears normal, and the infants can kick arms and legs briskly and bring their toes to their mouths. The children often display head lag, slip-through in vertical suspension, and floppiness of passive tone. The infant seems floppy from birth. The differential diagnosis includes upper and motor neuron disorders and connective tissue diseases. Extensive laboratory investigation is often unrevealing. Most of these children catch up to peers and appear normal by 3 years of age. Often, other family members have exhibited a similar developmental pattern.

Stroke in Childhood

Etiology

The incidence of pediatric stroke is 2.5-10 per 100,000 children and is higher among neonates, approaching that of elderly patients. A wide spectrum of conditions can produce stroke in childhood ([Table 182.4](#)). Pediatric strokes may be due to ischemia (**arterial ischemic stroke** [AIS], **cerebral sinovenous thrombosis** [CSVT]) or hemorrhage. AIS is focal brain infarction that results from occlusion of the arteries in the brain. The most common causes are vasculitis resulting in abnormal cerebral arteries (either autoimmune or infectious, such as vasculitis associated with meningitis) and cardioembolic infarcts due to congenital heart disease, sickle cell anemia, or coagulation

disorders. Coagulation disorders also increase the risk of CSVT, the occlusion of venous structures in the brain, which can result in ischemia as the cerebral venous pressure rises. CSVT can also be caused by infections or dehydration. **Hemorrhagic strokes (HS)** may be intraparenchymal (primary or secondary bleeding after AIS) or associated with intraventricular, subarachnoid, subdural, or epidural bleeds. The most common causes of HS are vascular malformations, head trauma, and vasculitis.

Clinical Manifestations

The acute onset of focal neurological deficits in a child is stroke until proven otherwise. Symptoms may be subtle and nonspecific, which can lead to a delay in diagnosis. AIS typically presents with acute, focal neurological deficits. Hemiparesis is most common, but visual, speech, sensory, or balance deficits may be present. Unlike AIS in adults, focal seizures are quite common in childhood presentation of AIS. Similarly, neonatal AIS most often presents with acute symptomatic focal seizures (typically in the first day of life) or encephalopathy.

Symptoms of CSVT may progress more gradually and be more variable and nonspecific than AIS. In CSVT, acute focal deficits may be present or the child may have progressive signs of elevated intracranial pressure, including headache, papilledema, diplopia (most often from cranial nerve VI palsy), seizures, lethargy, or confusion.

HS tends to present acutely, with a sudden “thunderclap” headache. HS may also present with loss of consciousness, nuchal rigidity, focal deficits, or seizures and can be rapidly fatal.

Some early-life strokes are not recognized until later in life, when an infant or child presents with hemiplegia. Such congenital hemiplegia becomes increasingly apparent as infants develop; they have decreased use of one side of the body, early handedness, or may seem to ignore one side of their body or of their environment. Neuroimaging reveals an area of encephalomalacia in the contralateral cerebral hemisphere that is the residual effect of a prior stroke. The area of encephalomalacia may predispose the child to epilepsy. The details of the child's intrauterine, labor, delivery, and postnatal history are often unremarkable, so the timing of the stroke typically remains uncertain.

Differential Diagnosis

There are many conditions that mimic pediatric stroke, most of which are more common than AIS, HS, or CSVT. Some of these mimics are benign (migraine, psychogenic weakness, musculoskeletal abnormalities), but others require

specific, prompt diagnosis and treatment (transient postictal weakness, intracranial infection, inflammatory disease of the central nervous system, tumor, posterior reversible leukoencephalopathy syndrome).

Diagnostic Tests and Imaging

On initial presentation, acute neuroimaging is necessary. A noncontrast head computed tomography (CT) scan is highly sensitive to acute HS and can reveal larger, mature AIS; acute, nonhemorrhagic stroke may not be seen on routine CT. Therefore MRI with diffusion-weighted imaging is required for most presentations. Angiography by magnetic resonance angiography (MRA) or CT angiography is used to confirm arterial occlusion in AIS and can identify underlying arteriopathy, vascular malformations, and aneurysms. Diagnosis of CSVT requires a high clinical suspicion and purposeful imaging of the cerebral venous system by MRI or CT. If clinical assessment does not reveal the cause of the stroke, a complete laboratory investigation should be undertaken promptly based on suspected etiologies (see [Table 182.4](#)). Many children with AIS have more than one predisposing factor, so identifying one risk factor does not obviate the need for a complete evaluation.

Treatment

Treatment must focus on limiting secondary neuronal injury and prevention of future strokes. Neuroprotection by maintaining control of temperature, blood pressure, glucose, and seizures is essential. Emergency thrombolysis with medications or catheterization is not yet established for children; it is an area of active clinical research. Anticoagulants (IV heparin, subcutaneous low molecular weight heparin, oral warfarin) and platelet antiaggregants (aspirin) are used for secondary stroke prevention in some instances. For those with acute, progressive CSVT, anticoagulation is the mainstay of therapy. Long-term rehabilitation programs are required for most survivors.

CHAPTER 183

Ataxia and Movement Disorders

Ataxia

Ataxia is the inability to make accurate, smooth, and coordinated movements. **Truncal ataxia** reflects disturbances of the midline cerebellar vermis (medulloblastoma, acute postinfectious cerebellar ataxia, ethanol intoxication). **Appendicular ataxia** reflects disturbances of the ipsilateral cerebellar hemisphere (cystic cerebellar astrocytoma). Ataxias may be acute or chronic. The most common causes of acute ataxia in childhood are postinfectious acute cerebellar ataxia and drug intoxications. Discrete lesions within the posterior fossa, tumors (medulloblastoma, ependymoma, cerebellar astrocytoma), cerebellar abscess, demyelinating diseases, acute labyrinthitis, strokes, and hemorrhages may cause ataxia. Other causes include benign paroxysmal vertigo, head trauma, seizures, postictal states, migraine, paraneoplastic opsoclonus-myoclonus syndrome associated with neuroblastoma, and inborn errors of metabolism. Congenital disorders also may produce chronic, nonprogressive ataxia. There are a number of inherited ataxia syndromes ([Table 183.1](#)).

Clinical Manifestations

Decision-Making Algorithm

Ataxia

Signs of ataxia include a broad-based, unsteady gait, difficulty sitting (truncal ataxia), and **dysmetria** (over- or undershooting of the target due to abnormal distance perception). An intention tremor worsens as the arm/hand approaches the target. Some children may be perceived as clumsy. Classically, these signs stem from disorders of the cerebellar pathways, but peripheral nerve lesions causing loss of proprioceptive inputs to the cerebellum (Guillain-Barré syndrome) may present with similar findings. In addition, weakness may intensify or mimic ataxia, so strength must be assessed, along with coordination.

Etiologies

Decision-Making Algorithm

Ataxia

Drug intoxication is the most common cause of acute ataxia among children. Overdosage of any sedative-hypnotic agent can produce acute ataxia and lethargy, but ataxia without lethargy usually results from intoxication with ethanol or anticonvulsant drugs. Over-the-counter cough syrups (dextromethorphan), essential oils (tea tree), and other toxins (e.g., pesticides) may also cause ataxia. It is important to ask about any medications, drugs of abuse, or other toxins to which the child may have access. Treatment is supportive.

Postinfectious acute cerebellar ataxia may occur 1-3 weeks following varicella, infectious mononucleosis, mild respiratory or gastrointestinal viral illnesses, or other infections. The pathogenesis is uncertain and may represent a direct viral infection of the cerebellum or, more likely, an autoimmune response precipitated by the viral infection and directed at the cerebellar white matter. Symptoms begin abruptly, causing truncal ataxia, staggering, and frequent falling. Dysmetria of the arms, dysarthria, nystagmus, vomiting, irritability, and

lethargy may be prominent. Symptoms, which may be severe enough to prevent standing or sitting, usually peak within 2 days, then stabilize and resolve over several weeks. Cerebrospinal fluid (CSF) examination sometimes shows a mild lymphocytic pleocytosis or mild elevation of protein content. Brain magnetic resonance imaging may reveal cerebellar enhancement. No specific therapy is available except to prevent injury during the ataxic phase.

Brain tumors are the second most common neoplasm in children. About 50% arise from within the posterior fossa. Tumors that arise in the posterior fossa or brainstem produce progressive ataxia with headache that may be acute or gradual in onset. There is a progressive worsening over days, weeks, or months, typically with associated signs and symptoms of elevated intracranial pressure. The ataxia and dysmetria may result from primary cerebellar invasion or from obstruction of the CSF pathways (aqueduct of Sylvius fourth ventricle) with resultant hydrocephalus. The most common tumors in this region include medulloblastoma, ependymoma, cerebellar astrocytoma, and brainstem glioma.

Rarely, a **neuroblastoma**, located in the adrenal medulla or anywhere along the paraspinal sympathetic chain in the thorax or abdomen, is associated with degeneration of Purkinje cells and the development of severe ataxia, dysmetria, irritability, myoclonus, and opsoclonus. An immunological reaction directed toward the tumor may be misdirected to attack Purkinje cells and other neuronal elements. The myoclonic movements are irregular, lightning-like movements of a limb or the head. Opsoclonus is a rapid, multidirectional, conjugate movement of the eyes, which suddenly dart in random directions. The presence of **opsoclonus-myoclonus** in a child should prompt a vigorous search for an occult neuroblastoma.

Difficulty walking with a severe staggering gait is one manifestation of **acute labyrinthitis**, but the diagnosis is usually clarified by the associated symptoms of a severe sense of spinning dizziness (vertigo), nausea and vomiting, and associated signs of pallor, sweating, and nystagmus.

Ataxia-telangiectasia, an autosomal recessive genetic disorder of the ATM gene, is the most common of the degenerative ataxias ([Chapter 73](#)). Affected patients present with ataxia around age 2 years, progressing to loss of ambulation by adolescence. In mid-childhood, telangiectasias are evident over the sclerae, nose, ears, and extremities. Abnormalities in immune function and greatly increased risk of lymphoreticular tumors result in early death.

Friedreich ataxia is a relentlessly progressive, autosomal recessive disorder. Children present in the late elementary school years with ataxia, dysmetria,

dysarthria, diminished proprioception and vibration sense, absent deep tendon reflexes, and nystagmus. Many develop hypertrophic cardiomyopathy and skeletal abnormalities (high-arched feet, hammer toes, kyphoscoliosis).

Several rare **inborn errors of metabolism** can present with intermittent episodes of ataxia and somnolence. These include Hartnup disorder, maple syrup urine disease, mitochondrial disorders, abetalipoproteinemia, and vitamin E deficiency ([Chapters 31](#) and [53](#)).

Movement Disorders

Decision-Making Algorithm

Involuntary Movements

Movement disorders or **dyskinesias** are a diverse group of entities associated with abnormal excessive, exaggerated, chaotic, or explosive movements of voluntary muscles. They are generally the result of abnormalities of the extrapyramidal system or the basal ganglia. Movement disorders in children are typically **hyperkinetic** (increased movement). The abnormal movements are activated by stress and fatigue and often, but not always, disappear in sleep. They are typically diffuse and migratory (chorea) but may be isolated to specific muscle groups (segmental myoclonus, palatal myoclonus).

Chorea is a hyperkinetic, rapid, unsustained, irregular, purposeless movement that seems to flow from one body part to another. Affected patients demonstrate difficulty keeping the tongue protruded or maintaining grip (milkmaid grip). Patients often attempt to incorporate the involuntary movements into more purposeful movements, which make them appear fidgety. Choreiform movement disorders may be autoimmune/parainfectious, infectious, genetic, structural, metabolic, or toxic in origin ([Table 183.2](#)). The movements may occur alone or as part of a more extensive neurological disorder (Sydenham chorea, Huntington chorea, systemic lupus erythematosus, encephalitis).

TABLE 183.2

Causes of Movement Disorders

CHOREA
Autoimmune/parainfectious (acute rheumatic fever,* systemic lupus erythematosus) Infectious (human immunodeficiency virus, neurosyphilis, scarlet fever, encephalitis) Genetic (Huntington disease, ataxia-telangiectasia) Structural (stroke, neoplasm) Metabolic/toxic (hepatic/renal failure, hyperthyroidism) Drug induced

Common

Athetosis is a hyperkinetic, slow, coarse, writhing movement that is most pronounced in the distal muscle groups. Athetosis is seen frequently in combination with chorea (choreoathetosis) and is usually present in conjunction with other neurological signs. It may be seen in virtually all the disorders mentioned as causes of chorea. Many children with mixed forms of cerebral palsy have spasticity and choreoathetosis.

Dystonia is characterized by abnormally sustained muscle contraction,

causing twisting motions (torsion spasm) and repetitive movements or abnormal postures, usually associated with basal ganglia or thalamic lesions. Cerebral palsy is the most common cause of dystonia among children, but many genetic mutations have been implicated in primary dystonias. Antipsychotics and antiemetics can produce **acute dystonic reactions**, typically involving the face and neck with torticollis, retrocollis, tongue protrusions, and oculogyric crises (eye rotation). **Tardive dyskinesia** is usually associated with chronic antipsychotic drug use and presents with characteristic facial involvement (tongue thrusting, chewing).

Tremor is a hyperkinetic, rhythmic, oscillatory movement caused by simultaneous contractions of antagonistic muscles. The amplitude and frequency are regular. In children, tremor is usually due to a physiological tremor, or essential tremor. Essential tremor is the most common movement disorder in adults, and half report onset in childhood. Other causes of tremor include thyrotoxicosis, hypoglycemia, or drugs (caffeine, bronchodilators, amphetamines, tricyclic antidepressants).

Myoclonus is a hyperkinetic, brief contraction of a muscle group, resulting in a sudden jerk. Myoclonus may be caused by seizures or by other etiologies (see [Chapter 181](#)). Nonepileptic myoclonus is distinguished from tremor in that it is a simple contraction of an agonist muscle, whereas tremor is a simultaneous contraction of agonist and antagonist muscles. Myoclonus is seen as a manifestation of various epilepsies and infectious, toxic, and metabolic encephalopathies. Benign myoclonus is commonly observed during sleep and may be particularly pronounced in neonates.

Tics are rapid, purposeless, involuntary, stereotyped movements and typically involve the face, eyes, shoulder, and arm. Examples of simple motor tics include blinking, nose twitching, and extremity jerking. Complex motor tics are more orchestrated movements, including head shaking, gesturing, or jumping. Phonic tics may be simple (grunting, throat clearing) or complex (uttering words, phrases). Approximately 25% of children have transient tics. Most tic disorders in children are transient and not intrusive into the child's life, but may be a source of parental anxiety. Occasionally, tics may be unmasked by stimulant agents. Persistent motor tics (lasting >12 months) in association with vocal tics are characteristic of **Tourette syndrome**, a chronic tic disorder that usually begins before age 7 years. The pathophysiology underlying tics is unknown, but a family history of tics is elicited in more than 50% of cases. Comorbid features, such as obsessive-compulsive disorder and attention-deficit/hyperactivity

disorder, are present in half of children with Tourette disorder (see [Chapters 13 and 19](#)). Tic disorders are clinical diagnoses, and neurodiagnostic studies have limited value. Many children with tic disorders or Tourette syndrome are unperturbed by their tics and require no therapy. Others may benefit from psychological support, including habit reversal training, and pharmacological therapy with α -adrenergic receptor agonists (clonidine) or neuroleptics (pimozide, haloperidol, risperidone). Chronic tic disorders wax and wane regardless of intervention and most often improve substantially or resolve entirely by late adolescence.

CHAPTER 184

Altered Mental Status

Disorders of Consciousness

Consciousness is a cortical function that allows for awareness of self and environment (place, time). **Arousal** represents the system that initiates and maintains consciousness and is mediated by the ascending reticular activating system (ARAS), which extends from the pons through the midbrain to the hypothalamus and thalamus. **Lethargic** patients have difficulty maintaining an aroused state. Patients who are **obtunded** have decreased arousal but are responsive to stimuli. **Stupor** is a state of responsiveness to pain but not to other stimuli. **Coma** is a state of unresponsive unconsciousness and is caused by dysfunction of the cerebral hemispheres bilaterally, the brainstem, or both.

Acute Disorders of Consciousness

Decision-Making Algorithm

Altered Mental Status

Acute changes in consciousness vary in degree from mild lethargy and

confusion to deep coma. In childhood, the most common causes of coma are toxins, infections, head trauma, hypoxia-ischemia (cardiac arrest, near-drowning), and seizures (postictal state, subclinical status epilepticus; [Table 184.1](#)).

TABLE 184.1

Causes of Coma and Diagnostic Approach

CAUSES

DIAGNOSTIC APPROACH
Routine laboratory testing Glucose Sodium, potassium, calcium, magnesium, chloride, bicarbonate, BUN, creatinine, AST, ALT, blood gases, ammonia Blood, urine analyses for toxic substances Blood, urine cultures if infection suspected Skeletal survey, ophthalmological examination if child abuse suspected
CSF analysis including opening pressure, white and red blood cell counts, protein, glucose, and culture (\pm viral PCR testing) Neuroimaging Head CT Brain MRI, MRA, MRV Electrodiagnostic studies EEG Secondary laboratory testing (if cause remains unknown) Lead level, pyruvate, lactate, serum amino acids, urine organic acids, acylcarnitine profile

ADEM, Acute disseminated encephalomyelitis; *ALT*, alanine aminotransferase; *AST*, aspartate aminotransferase; *BUN*, blood urea nitrogen; *CSF*, cerebrospinal fluid; *CT*, computed tomography; *EEG*, electroencephalogram; *MRI/MRA/MRV*, magnetic resonance imaging/angiography/venography; *PCR*, polymerase chain reaction.

Assessment

The most common cause of long-term morbidity in a patient with depressed consciousness is hypoxia; therefore, airway, breathing, and circulation are

addressed first. Vital signs, including pulse oximetry, must be assessed. Breathing patterns may provide important clues to the depth, neurological localization, and etiology of the depressed consciousness. A low respiratory rate may be associated with central nervous system (CNS) depressants or increased intracranial pressure (ICP). Tachypnea may be due to hypoxia, metabolic acidosis, or fever, but in more ominous situations may be due to brainstem herniation. Systemic diseases such as sepsis, ingestions, or cardiac failure may lead to shock. Hypotension may also result from severe traumatic brain injury (TBI) or spinal cord injury. Hypertension may be due to increased ICP. The glucose level should also be checked immediately because hypoglycemia is a rapidly treatable cause of altered mental status. Physical examination searches for clues as to the cause of altered consciousness, such as unusual odors, needle tracts, trauma, or signs of dehydration or organ system failure.

The **Glasgow Coma Scale** (see [Table 42.1](#)) can be used to assess unresponsive patients regarding their best verbal and motor responses and eye opening to stimulation with scores ranging from 3-15 points.

Diminished levels of consciousness require either bilateral hemispheric or ARAS dysfunction, so testing the structures immediately adjacent to the reticular system is essential. Changes in pupillary response suggest midbrain lesions. In comatose patients, eye movements are observed or elicited with the **oculocephalic vestibular reflexes** (doll's eye maneuver) (see [Chapter 179](#)). If the oculocephalic responses are not elicited or are unclear, the **oculovestibular response** (cold caloric stimulation) is elicited by flushing cold water into the external ear canal. In a comatose patient, cold water irrigation into the ear canal elicits a tonic eye deviation toward the irrigated ear if the brainstem is functioning.

Body posture at rest and after noxious stimulation can indicate the anatomical level responsible for the alteration of consciousness. Mildly altered mental status may be manifested by a comfortable *sleeping* posture with frequent spontaneous readjustments of position, yawns, and sighs. Patients who lie in a flat, extended, unvarying position with eyes half-open exhibit a deeper coma. An asymmetrical posture suggests motor dysfunction of one side. This asymmetry may be subtle, such as mild external rotation of the affected leg.

Posturing in response to noxious stimulation indicates more serious neurological conditions. **Decorticate posturing** consists of rigid extension of the lower extremities, flexion and supination of the arms, and fisting of the hands. It indicates bilateral cortical or subcortical abnormalities or herniation, with

preserved brainstem function. **Decerebrate posturing** (rigid extension and internal rotation of the upper and lower extremities) is associated with herniation with midbrain compression or toxic-metabolic abnormalities. These postures may be symmetrical or asymmetrical. A structural cause is most likely when posturing is asymmetrical, whereas symmetrical posturing may suggest an underlying toxic-metabolic etiology.

Etiology

The evolution of change in consciousness is an important clue to the etiology. A detailed history and physical examination usually provide sufficient clues to differentiate among the three major diagnostic categories producing coma: **metabolic/toxic**, **infectious**, and **structural**. In most clinical situations, the cause of coma is readily identified.

Care must be taken to investigate background medical conditions that may produce a decline in consciousness (diabetes mellitus, leukemia, kidney failure, liver disease). Metabolic derangements are common causes of altered mental status and are suggested by spontaneous fluctuations in the level of consciousness, tremors, myoclonus, asterixis, visual and tactile hallucinations, and deep coma with preservation of pupillary light reflexes. Disturbances of blood chemistries (glucose, sodium, calcium, bicarbonate, blood urea nitrogen, ammonia) may produce depressed mental status, as can hypoxemia (inadequate oxygen delivery to the brain) and cerebral ischemia (inadequate cerebral perfusion). Acute metabolic or toxic disorders usually produce a hypotonic, limp state, but hypertonia, rigidity, and decorticate and decerebrate posturing are sometimes observed in coma caused by hypoglycemia, hepatic encephalopathy, and short-acting barbiturates.

Intoxication and ingestion are common causes of acute alteration of consciousness. A thorough history must be taken to search for the offending agent (see [Chapter 45](#)). A history of social or emotional difficulties, drug abuse, or depression raises concern for self-inflicted injury or toxic ingestion. A subacute course of somnolence progressing to difficulty arousing from a deep *sleep* (stupor) over hours suggests drug intoxication or organ system failure (kidney, liver) producing a metabolic encephalopathy. CNS infection, usually causes abrupt alteration of mental status, although viral meningoencephalitis (particularly herpes simplex virus) can present with subacute alterations in mental status. The presence of fever, petechiae, chills, and sweats suggests infection. Prodromal photophobia and pain on movement of the head or eyes are

symptoms of meningeal irritation. Premonitory symptoms, such as abdominal pain, diarrhea, sore throat, conjunctivitis, cough, or rash, point toward viral encephalitis or postinfectious syndrome as the cause of the altered consciousness.

Structural processes, such as hemorrhage, acute hydrocephalus, or stroke, can cause sudden depressed consciousness in children. An evolution of headache and morning vomiting suggests increased ICP. A gradual fading of alertness or declining school performance over preceding weeks suggests an expanding intracranial mass, subdural hematoma, or chronic infection (tuberculous meningitis, human immunodeficiency virus).

Clinical Manifestations

Papilledema or paralysis of cranial nerves III or VI in a patient with depressed consciousness is strong evidence of elevated ICP, a medical and neurosurgical emergency. **Herniations** can occur under the falx, through the tentorial notch, or into the foramen magnum (Table 184.2). Recognition of the signs associated with the major herniation syndromes can be lifesaving if emergent neuroimaging and treatment are initiated. **Uncal herniation** implies displacement of the mesial temporal lobe over the tentorial edge, producing a unilateral third nerve palsy (“blown pupil”) and hemiparesis (which can be ipsilateral due to compression of the contralateral cerebral peduncle or contralateral if the uncus compresses the ipsilateral peduncle). **Transtentorial (central) herniation** occurs with gradual downward pressure from the diencephalon through the tentorium, resulting in compression of the brainstem (first midbrain, then progressing to pons and medulla). A progressive loss of consciousness accompanied by miosis, decorticate posturing, and Cheyne-Stokes respirations (rhythmic waxing and waning of respiratory amplitude) suggests incipient transtentorial herniation. Late findings include decerebrate posturing and Cushing's triad (bradycardia, irregular respirations, hypertension).

TABLE 184.2

Herniation Syndromes

LOCATION	ETIOLOGY	DESCRIPTION	CLINICAL FINDING(S)
Transtentorial Unilateral	Supratentorial mass lesions, diffuse	Downward displacement of supratentorial brain tissue into infratentorial compartment (below	Headache Altered

(uncal) or bilateral	brain swelling, focal edema, or acute hydrocephalus	tentorium), compressing the cerebral peduncles, midbrain, third cranial nerve, and posterior circulation	consciousness Dilated ipsilateral pupil Cranial nerve III palsy Hemiparesis Decerebrate posturing Cushing triad Respiratory arrest
Subfalcian	Increased pressure in one hemisphere (mass, focal edema)	Brain tissue displaced under the falx cerebri, compressing the anterior cerebral artery	Weakness, bladder incontinence, coma
Foremen magnum	Cerebellar mass or edema	Downward displacement of cerebellar tonsils, compressing the medulla oblongata and upper spinal cord	Bradycardia, bradypnea, hypertension, death

Laboratory and Diagnostic Imaging

Evaluation is guided by the history and physical examination. Clinicians should rapidly consider causes of unresponsiveness that could easily and quickly be reversed (see [Table 184.1](#)). If trauma or immersion injuries are suspected, neck manipulation should be avoided until cervical spine imaging excludes vertebral fracture or subluxation.

Computed tomography (CT) remains the preferred imaging technique in emergency situations because it can be performed rapidly and accurately identifies intracranial acute hemorrhages, large space-occupying lesions, edema, and shifts of the midline. The initial head CT scan is done without contrast to identify blood and calcifications. Contrast can be administered to identify inflammatory and neoplastic lesions but is not usually required for identification of major lesions.

Examination of the cerebrospinal fluid (CSF) may establish the cause of the alteration of consciousness. Lumbar puncture (LP) in a patient with elevated ICP can result in transtentorial herniation, so neuroimaging must be performed before LP if elevated ICP is suspected, especially if there are any focal neurological deficits on exam. The presence of red blood cells in the CSF may suggest primary subarachnoid hemorrhage, parenchymal hemorrhage, or hemorrhagic infection (herpes simplex virus), or it may be due to a traumatic procedure. White blood cells in the CSF usually denote infectious meningitis or meningoencephalitis but may also be associated with vasculitis, autoimmune disorders, or parainfectious syndromes. Elevated CSF protein is seen in patients with meningeal inflammation, tumors, or white matter diseases, whereas

abnormal CSF glucose levels are also markers of infection and inflammation.

Treatment

Beyond supportive measures, the etiology of altered mental status determines the treatment. Ingestions may necessitate gastric lavage, charcoal administration, forced diuresis, dialysis, or specific antidotes (see [Chapter 45](#)). Infections are treated with appropriate antibiotics or antiviral agents (see [Chapters 100, 101](#)). If mental status changes are due to increased ICP, acute medical interventions (osmotic agents, steroids, a trial of hyperventilation, elevating the head of the bed to 30 degrees) must be instituted, emergent neuroimaging performed, and urgent neurosurgical consultation obtained. Structural brain lesions may necessitate medical treatment of increased ICP or surgical excision.

Prognosis

The outcome of altered mental status relates to many variables, including etiology. Intoxication typically carries a good prognosis, whereas herniation carries a poor prognosis. Other prognostic factors include the duration of coma and the age of the patient; children have better outcomes than adults. Complete recovery from traumatic coma of several days' duration is possible in children; however, many survivors of prolonged coma are left in a persistent vegetative state or with severe neuropsychiatric disability.

Transient, Recurrent Depression of Consciousness

Episodic alteration or depression of consciousness with full recovery is usually due to seizure, migraine, syncope, or metabolic abnormality (hypoglycemia). Consciousness can be impaired during seizures or in the postictal state. Nonconvulsive (subclinical) status epilepticus (generalized or focal) can directly impair consciousness and is a common complicating factor for infants and children with acute neurological disorders (head trauma, meningitis, stroke, following convulsive status epilepticus). Basilar artery or **confusional migraines** can last hours and be accompanied by agitation, ataxia, cortical blindness, vertigo, or cranial nerve palsies. Headache may precede or follow the neurological signs.

Syncope is one of the most common causes of abrupt, episodic loss of

consciousness. Neurocardiogenic syncope, cardiac arrhythmia, or obstructive cardiomyopathy can cause recurrent episodes of loss of consciousness. Two thirds of children with syncope have irregular, myoclonic movements as they lose consciousness (anoxic seizures), which must be distinguished from epilepsy (unprovoked seizures). Children with unexplained syncope require a complete cardiac evaluation (see [Chapter 140](#)).

Metabolic derangements, particularly **hypoglycemia**, give rise to episodes of lethargy, confusion, seizures, or coma. Several other metabolic disorders cause recurrent bouts of **hyperammonemia** (see [Chapter 53](#)). Symptoms include nausea, vomiting, lethargy, confusion, ataxia, hyperventilation, and coma.

Increased Intracranial Pressure

Etiology

When the cranial sutures are fused, the skull becomes a rigid container enclosing a fixed volume, including the brain (80-85%), CSF (10-15%), and blood (5-10%). The exponential relationship between the volume within a closed container and pressure results in a massive increase in ICP as intracranial volume increases. The brain accommodates increased ICP initially by expelling CSF and blood from the intracranial compartment into the spinal subarachnoid space. When the limits of this accommodation are reached, the brain itself begins to shift in response to the continuing elevation of ICP. Brain shifts may cause herniations across the dural extensions or skull barriers ([Table 184.2](#)).

The most common causes of increased ICP include mass lesions, hydrocephalus, cerebral edema due to trauma or infection, and idiopathic intracranial hypertension ([Tables 184.3](#) and [184.4](#)).

CSF, Cerebrospinal fluid.

Mass lesions (brain tumor, abscess, hemorrhage) may produce increased ICP not only by virtue of large size, but by blockage of CSF pathways, blockage of venous outflow, or production of vasogenic cerebral edema. Brain abscesses usually present as mass lesions, producing focal neurological signs and increased ICP. Symptoms of infection, including fever, malaise, anorexia, and stiff neck, may be subtle or absent. Children with chronic cardiac or pulmonary disease may embolize infected material to their brains, predisposing them to brain abscesses. Brain tumors in children are most often located in the posterior fossa and can result in elevated ICP due to obstruction of CSF flow through the cerebral aqueduct and fourth ventricle. Brain tumors and abscesses can both result in vasogenic edema, which further increases ICP.

Hydrocephalus from congenital abnormalities or due to an intracranial mass is typically characterized by a slowly evolving syndrome of increased ICP extending over weeks or months. CSF is continuously produced by the choroid plexus within the lateral, third, and fourth ventricles. CSF circulates through the ventricular systems and is then absorbed, predominantly by the arachnoid villi into the large dural sinuses. Hydrocephalus is due to the obstruction of CSF flow anywhere along its course (see [Table 184.4](#)). **Obstructive hydrocephalus** is caused by a block before the CSF flows to the subarachnoid space, usually within the fourth ventricle or at the level of the aqueduct. Congenital hydrocephalus can result from CNS malformations, intrauterine infection, intraventricular hemorrhage, genetic defects, trauma, and teratogens. Acquired hydrocephalus may be caused by CNS infections, brain tumors, or hemorrhage. Impairment of CSF flow within the subarachnoid space or impairment of absorption is known by the misnomer *communicating hydrocephalus*, where there is actually extraventricular obstruction of CSF flow (*external hydrocephalus*). Hydrocephalus caused by overproduction of CSF without true obstruction is seen in choroid plexus papillomas, which account for 2-4% of childhood intracranial tumors.

Bacterial meningitis may produce increased ICP by blockage of CSF pathways, cytotoxic cerebral edema, increase in cerebral blood flow, or multifocal cerebral infarctions (see [Chapter 100](#)). Most children with bacterial meningitis can undergo LP safely because the brain swelling is diffuse and distributed evenly throughout the brain and spinal CSF compartments. A few patients with meningitis, however, develop transtentorial herniation within a few hours of LP. Focal neurological signs, poorly reactive pupils, and a tense fontanelle are contraindications to LP in a patient with suspected bacterial

meningitis.

Idiopathic intracranial hypertension (pseudotumor cerebri) is a cause of increased ICP with normal brain imaging. Patients exhibit a daily debilitating headache associated with diplopia, abducens palsy, transient visual obscurations, and papilledema. If untreated, permanent visual field loss may develop. The syndrome has been associated with ingestion of medications (tetracycline, vitamin A, oral contraceptive agents) and endocrine disturbances (thyroid disease, Addison disease). Most commonly, this condition is idiopathic and affects children who are otherwise well except for being overweight, with rapid weight gain being a predisposing factor. **Treatment** including acetazolamide or other diuretic, topiramate, or corticosteroids, is generally effective. Weight loss and cessation of triggering medications are also mainstays of treatment. Infrequently, chronic papilledema from persistent idiopathic intracranial hypertension produces visual impairment, and more aggressive management is required (optic nerve fenestration) to preserve visual function.

Clinical Manifestations

Decision-Making Algorithms

Strabismus
Vomiting
Headaches
Altered Mental Status

The symptoms and signs of increased ICP include headache, vomiting, lethargy, irritability, altered consciousness, sixth nerve palsy, strabismus, diplopia, and papilledema. Headaches suggestive of increased ICP are those associated with nocturnal wakening; worse in the morning; with cough, micturition, defecation, or Valsalva maneuver; or progressively worsening. Specific signs of increased ICP in the infratentorial compartment (posterior fossa) include stiff neck and head tilt. Focal neurological deficits reflect the site of the lesion that is producing the increased ICP and may include hemiparesis from supratentorial lesions, or ataxia and cranial nerve palsies from infratentorial lesions. Critically increased ICP may result in herniation syndromes, as

discussed earlier. In addition, the **Cushing triad** of elevated blood pressure, bradycardia, and irregular respirations is a late sign of critically elevated ICP. Infants who have an open fontanelle may present with less specific symptoms such as irritability, lethargy, and poor feeding. Specific signs of increased ICP in infants consist of a bulging fontanelle, suture diastasis, distended scalp veins, a persistent downward deviation of the eyes (*sunsetting*), and rapid growth of head circumference. Manifestations of increased ICP may evolve slowly when there is slow growth of a mass or incomplete obstruction allowing for transependymal absorption of CSF into the veins. On the other hand, symptoms may develop rapidly in the setting of acute intracranial hemorrhage or abrupt CSF obstruction.

Laboratory and Diagnostic Studies

The cause of increased ICP is determined by brain imaging with either head CT or brain magnetic resonance imaging (MRI). CT is rapid, readily available, and provides clear visualization of an acute hemorrhage, dilated ventricles, or mass lesions. Diffuse brain swelling produced by hypoxic-ischemic injury, meningitis, encephalitis, metabolic abnormalities, or toxins may be better delineated by MRI. MRI is also superior to CT for visualizing the posterior fossa and cortical contusions. In order to avoid radiation from head CT, many centers now use limited sequences to allow for a rapid MRI without sedation as an initial screen for acute causes of elevated ICP. LP is the diagnostic test for infection and for documentation of elevated ICP (essential for patients with idiopathic intracranial hypertension). However, LP is contraindicated in the setting of an intracranial mass lesion or clear hydrocephalus because withdrawal of CSF can change pressures between the intracranial compartments and promote brainstem shifts and herniation. Idiopathic intracranial hypertension is diagnosed when direct measurement of ICP with a manometer during LP reveals elevated ICP in the absence of other CSF or imaging abnormalities.

Treatment of Elevated Intracranial Pressure

The treatment of acute increased ICP should be carried out in an intensive care setting with continuous monitoring and vigilant attention to vital signs. The first goal is stabilization of the cardiopulmonary status. Once the child is stabilized, the head is placed at midline and the head of the bed is elevated to 30 degrees. Indications for endotracheal intubation include refractory hypoxia,

hypoventilation, Glasgow coma score of ≤ 8 , loss of airway protective reflexes, and acute herniation requiring controlled hyperventilation. Slight hyperventilation (to a PaCO_2 not lower than 35 mm Hg) produces rapid, but transient, reduction in ICP by cerebral vasoconstriction, leading to decreased cerebral blood volume. More aggressive hyperventilation may cause cerebral ischemia and is only indicated if there are clinical signs of acute herniation. Mannitol or 3% saline may be used acutely to produce an osmotic shift of fluid from the brain to the plasma. A ventricular catheter may be used to monitor the ICP continuously and to remove CSF. In refractory cases, a pentobarbital-induced coma reduces pressure by severely suppressing cerebral metabolism. The antiinflammatory effects of corticosteroids may be helpful in the management of vasogenic edema associated with tumors and abscesses. Acetazolamide and furosemide may transiently decrease CSF production in idiopathic intracranial hypertension. Because acute interventions such as hyperventilation, osmotic therapies, and barbiturates can have negative impacts on systemic and cerebral perfusion and have only transient effects on ICP, they must be used judiciously.

Vasopressor drugs may be necessary to maintain adequate arterial blood pressure and cerebral perfusion pressure. Serum electrolytes and osmolarity should be monitored because of risk of the syndrome of inappropriate antidiuretic hormone or cerebral salt wasting ([Chapter 35](#)). Maintaining normoglycemia may have a positive impact on outcomes. Other supportive measures include controlling agitation, fever, and seizures.

The **treatment of hydrocephalus** may be medical or surgical, depending on the etiology. After subarachnoid hemorrhage or meningitis, the flow or absorption of CSF may be transiently impaired. In this circumstance, the use of medication that decreases CSF production, such as acetazolamide, may be beneficial. Surgical management consists of removing the obstructive lesion, placing a shunt, or both. A shunt consists of polyethylene tubing extending usually from a lateral ventricle to the peritoneal cavity (**ventriculoperitoneal shunt**). Shunts carry the hazards of infection or sudden occlusion with signs and symptoms of acute hydrocephalus.

All treatments for increased ICP are temporary measures intended to prevent herniation until the underlying disease process either is treated or resolves spontaneously. Timely intervention can prevent or reverse cerebral herniation. Complete neurological recovery is possible, but rare, after signs of transtentorial or foramen magnum herniation have begun. When these signs are complete,

however, with bilaterally dilated, unreactive pupils, absent eye movements, and flaccid quadriplegia, recovery is no longer possible.

Traumatic Brain Injury

Following head injury, children may have immediate depression of consciousness and neurological deficits or may be completely alert without any immediate signs of neurological injury. Most serious trauma results from motor vehicle crashes, sports, recreation-related injuries, and violence. Head trauma may result in concussion, posttraumatic intracranial hemorrhage, skull fractures, or cranial nerve or cervical spine injuries. Head injury, or other injuries, with associated retinal hemorrhages in infants and young children should raise the suspicion of abusive head trauma (see [Chapter 22](#)).

Concussion

Concussion is the process in which traumatic forces on the brain result in the rapid onset of short-lived neurological impairment that typically resolves spontaneously. In some cases, however, symptoms and signs may evolve over minutes to hours, so patients should not be left alone following the injury. Patients may have signs or symptoms in one or more domain: somatic (headache), cognitive (slowed reaction times, poor attention), emotional (lability, irritability), sleep disturbance (drowsiness), or physical signs (loss of consciousness, amnesia). A player with any features of a concussion should be evaluated by a licensed health care provider onsite or be referred to a physician. Acute symptoms usually reflect a functional disturbance rather than structural injury, and no abnormalities are seen on standard imaging. If the child appears well after several hours and is discharged home, parents should be instructed to call their physician for any change in alertness, orientation, or neurological functioning. An increase in somnolence, headache, or vomiting is cause for concern and emergent neuroimaging. The majority of concussions resolve within 10 days, although the recovery may be slower in children, and in a small percentage of cases, the symptoms are prolonged. Physical and cognitive rest are the cornerstones of concussion management. Children must not be permitted to resume physical activities until well after the symptoms resolve ([Table 184.5](#)). Repeated concussions, especially within a short time frame (days or weeks), carry a significant risk of permanent brain injury (**second impact syndrome**).

TABLE 184.5

Protocol for Return to Sport After Concussion

Return to play protocol follows a stepwise progress with each step taking ≥ 24 hours. The athlete should continue to the next level if asymptomatic at the current level.
<ol style="list-style-type: none">1. No activity, complete physical and mental rest.2. Light aerobic exercise such as walking or stationary cycling; no resistance training.3. Sport-specific exercise (skating in hockey, running in soccer).4. Noncontact, more progressive training drills; resistance training.5. Full-contact training after medical clearance.6. Game play.

Modified from McCrory P, Meeuwisse W, Aubry M, et al. Consensus statement on concussion in sport: the 4th International Conference on Concussion in Sport, held in Zurich, November 2012. *Br J Sports Med.* 2013;47:250–258.

Traumatic Intracranial Hemorrhage

Head trauma can result in epidural, subdural, parenchymal, and subarachnoid intracranial hemorrhages, as well as brain contusions (Table 184.6). Symptoms include headache, vomiting lethargy, decreased consciousness, and seizures. The classic presentation of **epidural hemorrhages** involves a lucid interval: following the primary brain injury, a child has a decreased level of consciousness, then returns to normal for several hours before developing rapidly progressive neurological symptoms. When associated with neurological decompensation, prompt evacuation of the epidural hematoma is the primary therapy. **Subdural hemorrhages** may result from direct trauma or rotational forces from vigorous shaking (abusive head trauma). In neonates and infants with open fontanelles, signs and symptoms may be absent or nonspecific. **Subarachnoid hemorrhages** classically present as a sudden, severe headache due to rupture of an intracranial aneurysm. Brain **contusions** are areas of bruising with associated localized ischemia, edema, and mass effect.

TABLE 184.6

Syndromes of Posttraumatic Intracranial Hemorrhage

SYNDROME	CLINICAL AND RADIOLOGICAL CHARACTERISTICS	TREATMENT
Epidural	Onset over minutes to hours Lucid interval followed by progressive neurological	Surgical evacuation or observation Prognosis good with prompt

	deficits Lens-shaped extracerebral hemorrhage compressing brain	treatment, otherwise poor
Acute subdural	Onset over hours Focal neurological deficits Crescentic extracranial hemorrhage compressing brain	Surgical evacuation Prognosis guarded
Chronic subdural	Onset over weeks to months Anemia, macrocephaly Seizures, vomiting Crescentic, low-density mass on CT	Subdural taps or subdural shunt as necessary Prognosis can be good
Intraparenchymal	Depressed consciousness Focal neurological deficits ± Additional multiple contusions	Supportive care Prognosis guarded
Subarachnoid	Stiff neck Worst headache of life Late hydrocephalus	Supportive care Prognosis variable
Contusion	Focal neurological deficits Brain swelling with transtentorial herniation CT findings: multifocal low-density areas with punctate hemorrhages	Medical treatment of elevated intracranial pressure* Prognosis guarded

*Mannitol, elevation of head of bed, diuresis, hyperventilation (pCO₂ 32-38 torr unless acutely herniating), steroids.

CT, Computed tomography.

Skull Fractures

Skull fractures may present with localized swelling and pain; subcutaneous bleeding over the mastoid process (**Battle sign**) or around the orbit (**raccoon eyes**); blood behind the tympanic membrane (**hemotympanum**); or CSF leak from the nose (rhinorrhea) or ear (otorrhea). Skull fractures may be linear, diastatic (spreading the suture), depressed (an edge displaced inferiorly), or compound (bone fragments breaking the skin surface). Linear, diastatic, and minimally depressed fractures necessitate no specific treatment, but imaging is indicated to evaluate for associated intracranial hemorrhages. If the depression is more than 0.5-1 cm, surgical elevation of bone fragments and repair of associated dural tears are generally recommended. Compound fractures or penetrating injuries necessitate emergent surgical debridement and tetanus prophylaxis. The risk of associated brain contusion and early seizures is high in compound fractures.

Rarely, a few weeks to months after linear skull fractures, a soft, pulsatile scalp mass is palpable; the fracture edges are separated by a soft tissue mass that consists of fibrotic tissue and accumulated brain and meningeal tissue and,

possibly, a **leptomeningeal cyst**.

CSF leak occurs when a skull fracture tears adjacent dura, creating communications between the subarachnoid space and the nose, paranasal sinuses, mastoid air cells, or ear. Clear fluid that leaks from the nose or ear after head trauma is presumed to be CSF until proved otherwise. The presence of air within the subdural, subarachnoid, or ventricular space also indicates a dural tear and open communication between the nose or paranasal sinuses and brain. In most cases, the dura heals spontaneously when the patient's head is kept elevated. Patients with CSF leaks are at risk for the development of meningitis or extradural abscesses. If the leak persists or recurs or if meningitis develops, the dura is surgically repaired. **Cranial nerve palsies**, secondary to a laceration or contusion of the cranial nerves, may result from a skull fracture and may be transitory or permanent.

Other Complications of Head Trauma

Cervical spine injuries must be suspected in any unconscious child, especially if bruises are present on the head, neck, or back. In conscious children, findings of neck or back pain, burning or stabbing pains radiating to the arms, paraplegia, quadriplegia, or asymmetrical motor or sensory responses of arms or legs suggest spinal cord injury. Cervical spine injury (displaced or fractured vertebra) may result in complete transection of the cord with spinal shock, loss of sensation, and flaccid paralysis. A contused cord (without vertebral abnormality) may present in a similar manner. Any patient with a clinical or radiological abnormality of the spine requires immediate spine immobilization, cardiopulmonary stabilization, and neurosurgical consultation.

Posttraumatic seizures are divided into one of three patterns: impact seizures, early posttraumatic seizures, and late posttraumatic seizures. Impact seizures occur within seconds of the injury and are presumed to reflect a direct mechanical stimulation to the cortex. The prognosis is excellent and likelihood of later epilepsy is negligible. Early posttraumatic seizures occurring within the first week of the head injury are likely the result of a localized area of cerebral contusion or edema. The long-term prognosis for these seizures is quite favorable. Late posttraumatic seizures arise more than a week after the trauma and most likely indicate an area of cortical gliosis or scarring that will be a source for long-term epilepsy. These patients often require long-term antiepileptic drug therapy.

Transient neurological disturbances may develop a few minutes after head

trauma and last for minutes to hours before clearing. The most common symptoms are cortical blindness and confusional states, but hemiparesis, ataxia, or any other neurological deficit may appear. These symptoms may represent a trauma-triggered migraine in susceptible children. Care must be exercised to exclude intracranial pathology.

Drowsiness, headache, and vomiting are common after head trauma. They are not, by themselves, of concern if consciousness is preserved, the clinical trend is one of improvement, and results of the neurological examination are normal. Children are especially susceptible to somnolence after head trauma but should be easily arousable. If symptoms worsen or persist for more than 1-2 days, neuroimaging may be indicated to evaluate for intracranial hemorrhage or cerebral edema.

Evaluation and Treatment

Children who have loss of consciousness or amnesia following a head injury should be evaluated in an emergency department. High-risk patients include those with persistent depressed or decreasing level of consciousness, focal neurological signs, penetrating skull injury, depressed skull fractures, or worsening symptoms. Because patients with intracranial hemorrhage may progressively deteriorate and require immediate neurosurgical care, these patients warrant care in a skilled trauma center.

The **Glasgow Coma Scale** is a valuable tool for monitoring the course of patients' after trauma for signs of deterioration (see [Chapter 42](#)). Management includes ensuring an appropriate airway, breathing, and circulation. Neuroimaging with CT or MRI, and skull and cervical spine radiographs are obtained emergently. Neuroimaging is not necessary for uncomplicated concussions but should be employed whenever suspicion of structural intracranial lesion exists.

The observation period varies with the severity of the injury and may include hospitalization. Patients with intracranial hemorrhage may require emergent surgical intervention for decompression and drainage of the blood collection. Increased ICP may require monitoring, placement of a ventricular drain, and aggressive medical management, including intubation and ventilation, osmotic therapy, and sedation. ICP may rise abruptly after fluid resuscitation for a child with both head injury and systemic injuries; such children must be monitored intensively so that interventions to maintain cerebral perfusion pressure are immediately available.

Prognosis

Children with TBI without subsequent neurological deficits have a favorable long-term prognosis and late sequelae are rare. Children with moderate TBI usually make good recoveries even when neurological signs persist for weeks. Long-term sequelae may include poor memory, slowing of motor skills, decline in cognitive skills, behavioral alterations, or attention deficits. Language function, especially in a young child, frequently makes a good recovery. Rehabilitation programs with physical therapy, behavioral management, and appropriate education may be necessary.

Coma lasting for weeks after head trauma may be compatible with a good outcome, although the risk of late sequelae is significant. Mortality rates for children with severe TBI range from 10% to 30%. Poor prognostic signs include a Glasgow Coma Scale score <4 on admission without improvement in 24 hours, absent pupillary light reflexes, and persistent extensor plantar reflexes. Extracranial trauma also contributes to the morbidity of these patients (aspiration pneumonia, acute respiratory distress syndrome, sepsis, emboli). Children with TBI who experience acute cerebral swelling may improve gradually or may remain in a vegetative state. Maximal recovery may take weeks or months. Patients who remain in a vegetative state for months after head injury are unlikely to improve.

CHAPTER 185

Neurodegenerative Disorders

Children typically acquire developmental milestones in a variable but predictable sequence (see [Chapter 7](#)). Rarely, children present with stagnation of development or frank loss of previously acquired skills. The **neurodegenerative disorders** encompass a large heterogeneous group of diseases that result from specific genetic and biochemical defects and varied unknown causes. Neurodegenerative disorders can present at any age. Clinical phenotypes also vary, but neurological deterioration may be demonstrated as loss of speech, vision, hearing, and intellectual or motor abilities—sometimes in concert with seizures, feeding difficulties, and intellectual disability. Progression may be slow over many years or may lead to death in early childhood.

Hereditary and Metabolic Degenerative Diseases

Degenerative diseases may affect gray matter (**neuronal degenerative disorders**), white matter (**leukodystrophies**), both gray and white matter, or specific, focal regions of the brain. Early seizures and intellectual impairment mark gray matter disorders, whereas upper motor neuron signs and progressive spasticity are the hallmarks of white matter disorders. Many neurodegenerative illnesses result from enzymatic disorders within subcellular organelles, including lysosomes, mitochondria, and peroxisomes (Table 185.1). Therefore any patient with a degenerative neurological condition of unknown cause should have leukocytes or skin fibroblasts harvested for measurement of a standard battery of lysosomal, peroxisomal, and mitochondrial enzymes (see Chapters 56 and 57). Neuroimaging, usually with brain magnetic resonance imaging (MRI), is also typically warranted. The diagnosis of leukodystrophy can usually be made confidently on the basis of extensive cerebral white matter changes on MRI. Histological and biochemical studies may be normal in gray matter encephalopathy, making the diagnosis much less secure. Acquired lesions (infectious, inflammatory, vascular, toxic) are difficult to exclude completely. Brain biopsy is not likely to be helpful.

TABLE 185.1

Selected Clinical Features of Neurodegenerative Disorders and Relevant Diagnostic Tests

SPHINGOLIPIDOSES
Niemann-Pick Disease
Cognitive regression, hepatosplenomegaly, jaundice, seizures Test: acid sphingomyelinase enzyme activity
Gaucher Disease
Hepatosplenomegaly, cytopenia, spasticity, hyperextension, extraocular palsies, trismus, difficulty swallowing Test: glucosylceramidase enzyme activity
GM1 Gangliosidoses
Infantile form—early feeding difficulties, global retardation, seizures, coarse facial features, hepatosplenomegaly, cherry red spot Juvenile form—incoordination, weakness, language regression; later, seizures, spasticity, blindness Adult form Test: GM1 ganglioside enzyme activity; <i>GLB1</i> gene testing
GM2 Gangliosidoses
Tay-Sachs Disease—progressive weakness, marked startle reaction, blindness, convulsions, spasticity, and cherry red spots

<p>Test: β-hexosaminidase A enzymatic activity Sandhoff Disease—phenotype similar to Tay-Sachs Test: β-hexosaminidase A and B enzyme activity (both deficient)</p>
Krabbe Disease/Globoid Cell Leukodystrophy
<p>Irritability, hyperpyrexia, vomiting, seizures, hypertonia, blindness Test: galactocerebrosidase enzyme activity</p>
Metachromic Leukodystrophy
<p>Late infantile form—stiffening and ataxia of gait, spasticity, optic atrophy, intellectual deterioration, absent reflexes Juvenile and adult forms Tests: 1. arylsulfatase A (ARSA) enzyme activity 2. If ARSA activity is <10% of controls, exclude ARSA pseudodeficiency with genetic testing of ARSA and/or abnormal urinary sulfatide excretion</p>
NEURONAL CEROID LIPOFUSCINOSES
<p>Visual loss, progressive dementia, seizures, motor deterioration Tests: Diagnostic algorithm depends on age of symptom onset, and relies on stepwise testing for palmitoyl-protein thioesterase 1 and tripeptidyl-peptidase 1 enzyme activity</p>
X-LINKED ADRENOLEUKODYSTROPHY
Classic Adrenoleukodystrophy
Academic difficulties, behavioral disturbances, hypoadrenalism, seizures, spasticity, ataxia, and swallowing difficulties.
Adrenomyeloneuropathy
<p>Spastic paraparesis, urinary incontinence, adrenal insufficiency Test: very long chain fatty acids</p>
MUCOPOLYSACCHARIDOSES (MPS)
Short stature, kyphoscoliosis, coarse facies, hepatosplenomegaly, cardiovascular abnormalities, and corneal clouding
TYPES
<p>Hurler (MPS type I-H) Hunter (MPS type II) Sanfilippo Disease (MPS type III) Sly Syndrome (MPS type VII) Tests: 1. lysosomal enzymes 2. urinary glycosaminoglycan excretion</p>
MITOCHONDRIAL DISORDERS
MELAS
Mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes
MERRF
Myoclonus, epilepsy, and ragged red fibers, dementia, hearing loss, optic nerve atrophy, ataxia, and loss of deep sensation
NARP
<p>Neuropathy, ataxia, and retinitis pigmentosa Tests: testing for mitochondrial disorders is complex and must be tailored to the individual clinical scenario; screening for blood and serum lactate and pyruvate is reasonable</p>
SUBACUTE NECROTIZING ENCEPHALOMYELOPATHY (LEIGH DISEASE)
<p>Hypotonia, feeding difficulties, respiratory irregularity, weakness of extraocular movements, and ataxia Test: depends on clinical phenotype; blood and CSF lactate and pyruvate are elevated</p>

RETT SYNDROME
Loss of purposeful hand movements and communication skills, social withdrawal, gait apraxia, seizures, spasticity, and kyphoscoliosis Test: <i>MECP2</i> gene testing
WILSON DISEASE
Inborn error of copper metabolism resulting in signs of cerebellar and basal ganglia dysfunction Tests: serum ceruloplasmin levels, urinary copper excretion

CSF, Cerebrospinal fluid; *MECP2*, methyl CpG binding protein 2; *MPS*, mucopolysaccharidoses; *MERRF*, myoclonus, epilepsy, and ragged red fibers; *NARP*, neuropathy, ataxia, and retinitis pigmentosa.

Spingolipidoses

The sphingolipidoses are characterized by intracellular storage of lipid substrates resulting from defective catabolism of the cell membrane sphingolipids. They are inherited in an autosomal recessive pattern. In most cases, there are several forms of these diseases and the tempo of disease progression reflects the amount of residual enzyme activity. The infantile forms are generally the most severe, usually presenting in the first or second year of life with rapid disease progression; affected individuals have virtually no normal enzyme activity. Juvenile and chronic forms are manifest somewhat later in childhood or even adulthood and have a less fulminant disease course as there is some residual enzyme activity.

Classic **Niemann-Pick disease** is caused by a deficiency of sphingomyelinase and should be suspected in infants who exhibit the combination of hepatosplenomegaly, developmental delay, interstitial lung disease, and **retinal cherry red spots**. The ganglion cells of the retina and macula are distended and appear as a large area of white surrounding a small red fovea that is not covered by ganglion cells. Cognitive regression, myoclonic seizures, hypotonia, and jaundice are also noted within the first year of life. Genetic testing for *SMPD1* mutations is clinically available.

Although the most common form of **Gaucher disease** is an indolent illness of adults, there is a rapidly fatal infantile form featuring severe neurological involvement caused by deficiency of the enzyme glucocerebrosidase. Glucoceramide accumulates in the liver, spleen, and bone marrow. The characteristic neurological signs are opisthotonos (arching of the trunk), trismus (difficulty opening mouth), eye movement abnormalities, and bulbar signs including difficulty swallowing.

Decision-Making Algorithm

Splenomegaly

Tay-Sachs disease (GM₂ gangliosidosis) is caused by deficiency of hexosaminidase A and results in the accumulation of GM₂ ganglioside in cerebral gray matter and cerebellum. Infants are typically normal, except for a marked startle response, until 6 months of age, when they develop listlessness, irritability, hyperacusis, cognitive regression, and retinal cherry red spots. Within months, blindness, convulsions, spasticity, and opisthotonos develop.

Metachromatic leukodystrophy (MLD) is a lipidosis caused by deficiency of arylsulfatase that results in demyelination of the central nervous system (CNS) and peripheral nervous system. Children with the late-infantile form present between 1 and 2 years of age. After a period of normal development, progressive gait ataxia, spasticity, optic atrophy, intellectual deterioration, and absent reflexes occur. Diagnostic testing reveals increased cerebral spinal fluid protein (a sign of CNS demyelination) and slowing of motor nerve conduction velocity (a sign of peripheral demyelination). Older school-age children with the juvenile form of MLD may present with gradual onset of behavior difficulties and declining academic abilities, followed by gait difficulties, clumsiness, slurred speech, and, sometimes, seizures. Relentless progression is the rule. Bone marrow transplant is a treatment option, particularly if a sibling is diagnosed with MLD before symptom onset.

Krabbe disease (globoid cell leukodystrophy) is caused by a deficiency of galactocerebrosidase. Individuals with the infantile form (85-90% of cases) appear to be normal during the first months of life. Symptoms begin by 6 months of age and include extreme irritability, hyperpyrexia, vomiting, seizures, hypertonia, and blindness. Demyelination of the CNS and peripheral nervous system results in upper and lower motor neuron signs. Bone marrow transplant during infancy may be a treatment option.

Neuronal Ceroid Lipofuscinoses

The neuronal ceroid lipofuscinoses are a group of inherited, neurodegenerative lysosomal storage disorders characterized by progressive vision loss, seizures, declining cognitive abilities, motor deterioration, and early death. Ten different

types have been characterized, including infantile, late-infantile, and juvenile types.

Adrenoleukodystrophy

The adrenoleukodystrophies (ALDs) are a group of X-linked neurodegenerative disorders that are often associated with adrenocortical insufficiency. ALD is caused by accumulation of very long chain fatty acids in neuronal and adrenal tissue (see [Chapter 178](#)) and is diagnosed by abnormal very long chain fatty acid testing. The most common leukodystrophy is **classic X-linked adrenoleukodystrophy**, caused by a mutation in the *ABCD1* gene. Boys present between ages 5 and 15 years with academic difficulties, behavioral disturbances, and gait abnormalities, progressing to seizures, spasticity, ataxia, and swallowing difficulties. Brain MRI demonstrates a classic pattern of symmetrical abnormal white matter signal in the parietal-occipital regions, with contrast enhancement at the anterior margin. Symptomatic *adrenocortical insufficiency* with fatigue, vomiting, and hypotension develops in 20-40% of patients with X-linked ALD. ALD should be considered in any male with primary adrenocortical insufficiency, even in the absence of clear-cut neurological abnormalities. **Adrenomyeloneuropathy**, a chronic disorder of the spinal cord and peripheral nerves, presents in the third decade of life. Female carriers of the *ABCD1* mutation may also have symptoms similar to adrenomyeloneuropathy, beginning later in life (>35 years of age).

Mucopolysaccharidoses

Mucopolysaccharidoses are caused by defective lysosomal hydrolases resulting in the accumulation of mucopolysaccharides within lysosomes (see [Chapter 56](#)). The clinical manifestations include coarse facies, short stature, kyphoscoliosis, hepatosplenomegaly, cardiovascular abnormalities, and corneal clouding. Neurological involvement is seen in mucopolysaccharidosis types I (**Hurler syndrome**), II (**Hunter syndrome**), III (**Sanfilippo syndrome**), and VII (**Sly syndrome**). Children with Hurler syndrome, the most severe of these illnesses, appear normal during the first 6 months of life, then develop the characteristic skeletal and neurological features. Intellectual disability, spasticity, deafness, and optic atrophy are progressive. Hydrocephalus frequently occurs because of obstruction to cerebrospinal fluid (CSF) flow by thickened leptomeninges.

Mitochondrial Disorders

Mitochondrial diseases represent a clinically heterogeneous group of disorders that fundamentally share a disturbance in oxidative phosphorylation (adenosine triphosphate synthesis; see [Chapter 57](#)). Abrupt symptoms are often manifest concurrent with periods of physiological stress such as febrile illness or fasting. Specific genetic diagnoses are often difficult to identify because several different gene mutations can cause the same disease, single mutations can have multiple phenotypes, and analysis of mitochondrial protein function is technically demanding. Specific syndromes include **MELAS** (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes); **MERRF** (myoclonus, epilepsy, and ragged red fibers), which can also manifest as combinations of dementia, sensorineural hearing loss, optic nerve atrophy, peripheral neuropathy, and occasionally cardiomyopathy with Wolff-Parkinson-White syndrome; and **NARP** (neuropathy, ataxia, and retinitis pigmentosa).

Rett Syndrome

Rett syndrome is a neurodevelopmental disorder that classically affects girls. Typically development appears normal during the first 6-18 months of life, but this is followed by developmental *regression*, loss of purposeful hand movements, loss of verbal communication skills, gait apraxia, and stereotypic repetitive hand movements that resemble washing, wringing, or clapping of the hands. Girls also develop *acquired microcephaly*. Episodic apnea and/or hyperpnea, peripheral vasomotor disturbances, growth retardation, abnormal muscle tone, and prolonged QTc interval often occur. The developmental regression plateaus and stabilizes, but seizures, spasticity, and kyphoscoliosis develop. The etiology is a mutation on an X chromosome gene coding for methyl-CpG-binding protein 2 (*MECP2*) transcription factor. Boys with *MECP2* mutations usually do not survive to delivery but can present with severe neonatal encephalopathy, seizures, microcephaly, abnormal tone, and respiratory insufficiency.

Degenerative Diseases With Focal Manifestations

Some neurodegenerative disorders have predilections to target specific regions

or systems within the neuraxis and produce symptoms referable to the affected region.

Wilson disease is a treatable degenerative condition that manifests as cerebellar and basal ganglia dysfunction. It is an autosomal recessive inborn error of copper metabolism. Serum ceruloplasmin levels are low. Abnormal copper deposition is found in the liver, producing cirrhosis; in the peripheral cornea, producing a characteristic green-brown (Kayser-Fleischer) ring; and in the CNS, producing neuronal degeneration and protoplasmic astrocytosis. Neurological symptoms characteristically begin in the early teenage years with dysarthria, dysphasia, drooling, fixed smile, tremor, dystonia, and emotional lability. MRI shows abnormalities of the basal ganglia. Treatment is with a copper-chelating agent, such as oral penicillamine.

Decision-Making Algorithms

Jaundice
Hepatomegaly
Involuntary Movements
Hypocalcemia

Subacute necrotizing encephalomyelopathy, or Leigh disease, is a neuropathologically defined, degenerative, inherited CNS disease primarily involving the periaqueductal region of the brainstem, caudate, and putamen. Symptoms usually begin before 2 years of age and consist of hypotonia, feeding difficulties, respiratory irregularity, weakness of extraocular movements, and ataxia. Blood and CSF lactate and pyruvate levels are elevated. Several alterations of mitochondrial function produce this clinical syndrome.

Acquired Illnesses Mimicking Degenerative Diseases

Children with poorly controlled epilepsy may be continuously in either an ictal or a postictal state and may appear stuporous because of their *epileptic encephalopathy*. Antiepileptic drugs that are sedating or affect mood, memory, motivation, or attention may contribute to the lack or loss of developmental

abilities and school failure.

Chronic drug use or overuse (sedatives, tranquilizers, anticholinergics) can cause progressive confusion, lethargy, and ataxia. Intoxications with heavy metals, such as lead, may cause chronic learning difficulties or may present acutely with irritability, listlessness, anorexia, and pallor, progressing to fulminant encephalopathy. Vitamin deficiency of thiamine, niacin, vitamin B₁₂, and vitamin E can produce encephalopathy, peripheral neuropathy, and ataxia.

Congenital and acquired hypothyroidism impairs cognition and slows developmental progress. Unrecognized congenital hypothyroidism produces irreversible damage if it is not treated immediately after birth (see [Chapter 175](#)).

Structural brain diseases, such as hydrocephalus and slowly growing tumors, may cause slowly progressive cognitive decline and other focal deficits. Certain indolent brain infections, such as rubeola (measles, causing subacute sclerosing panencephalitis), rubella (German measles), syphilis, and some fungal infections, cause neurological deterioration over months and years. Congenital human immunodeficiency virus infection causes failure of normal development and regression of acquired skills.

Psychiatric disorders, such as depression and severe psychosocial deprivation in infancy, can give rise to apathy and failure to attain developmental milestones (see [Chapter 21](#)). Children with autism spectrum disorder may go through a phase of developmental stagnation or disintegration at about 12-18 months of age after a period of early normal milestones. Depression in older children can lead to blunting of affect, social withdrawal, and poor school performance, which raise the question of encephalopathy or dementia.

CHAPTER 186

Neurocutaneous Disorders

The skin, teeth, hair, nails, and brain are derived embryologically from ectoderm. Abnormalities of these surface structures may indicate abnormal brain development. Not all of the so-called neurocutaneous disorders have characteristic cutaneous lesions, however, and not all are of ectodermal origin. Neurofibromatosis (types 1 and 2), tuberous sclerosis, Sturge-Weber syndrome, von Hippel-Lindau disease, and ataxia-telangiectasia are the most common of

the more than 40 neurocutaneous disorders.

Neurofibromatosis Type 1

Etiology

Neurofibromatosis type 1 (NF1), also known as von Recklinghausen disease, is an autosomal-dominant disorder with an incidence of approximately 1 in 3,000. It is caused by mutations of the *NF1* gene, which codes for a tumor suppressor gene, neurofibromin. Neurofibromin is a major negative regulator of a key signal transduction pathway, the Ras pathway. Mutations result in increased downstream mitogenic signaling. Somatic mosaicism, in which an abnormality in one copy of the *NF1* gene is present in some cells but not others, indicates a postzygotic mutation and is called **segmental neurofibromatosis**.

Clinical Manifestations

Decision-Making Algorithms

Hearing Loss
Gynecomastia

The cardinal features of neurofibromatosis are café-au-lait spots, axillary or inguinal freckling, cutaneous neurofibromas, and iris hamartomas (Lisch nodules). **Café-au-lait spots** are present in more than 90% of patients who have NF1 (Fig. 186.1). They typically appear in the first few years of life and increase in number and size over time. The presence of six or more café-au-lait spots larger than 5 mm in a prepubescent child suggests the diagnosis. **Lisch nodules** also increase in frequency with age and are present in more than 90% of adults who have NF1.

FIGURE 186.1 Café-au-lait macules. (From Kliegman RE, Behrman RE, Jenson HB, eds. *Nelson Textbook of Pediatrics*. 19th ed. Philadelphia: Saunders; 2007:2680.)

Neurofibromas are composed of various combinations of Schwann cells, fibroblasts, mast cells, and vascular elements. Dermal neurofibromas are nearly universal and consist of discrete, small, soft lesions that lie within the dermis and epidermis and move passively with the skin. They rarely cause any symptoms but can cause significant cosmetic concerns. Neurofibromas may also be situated within viscera or along blood vessels and peripheral nerves. Plexiform neurofibromas are large, occasionally nodular, subcutaneous lesions that lie along the major peripheral nerve trunks. They often cause symptoms including pain, weakness, and invasion of adjacent viscera, bone, or spinal cord. Sarcomatous degeneration may occur. Surgical treatment may be attempted, but results are often unsatisfactory.

Common complications are learning disability, scoliosis, seizures, and cerebral vasculature abnormalities. Other tumors that occur in NF1 are optic nerve gliomas, astrocytomas of brain and spinal cord, and malignant peripheral nerve tumors. T2-weighted magnetic resonance images (MRIs) reveal

hyperintense lesions (hamartomas) in the optic tracts, internal capsule, thalamus, cerebellum, and brainstem that are common and distinctive for the disease. They are benign and disappear in adulthood.

The average life expectancy of patients with NF1 may be reduced by 10-15 years. Malignancy is the most common cause of death. Genetic and psychological counseling are important components of care for this chronic disorder. Although it is an autosomal-dominant disorder, spontaneous mutations account for 30-50% of cases.

Neurofibromatosis Type 2

Neurofibromatosis type 2 (NF2) is an autosomal-dominant disorder with an incidence of 1 in 25,000. Half the cases have no family history. The *NF2* gene is a tumor suppressor gene and disease results in neurological, eye, and skin lesions. NF2 predisposes patients to multiple intracranial and spinal tumors, including bilateral acoustic schwannomas, schwannomas of other cranial and spinal nerves, meningiomas, and gliomas. Posterior capsular or cortical cataracts are common, and skin lesions include plaque-like lesions, subcutaneous nodules, and cutaneous schwannomas. Lisch nodules, café-au-lait spots, and axillary freckling (seen in NF1) are *not* features of NF2.

Tuberous Sclerosis Complex

Etiology

Tuberous sclerosis complex (TSC), an autosomal-dominant disorder, is characterized by hamartomas in many organs, especially the brain, eyes, skin, kidneys, and heart. The incidence is 1 in 10,000 births. Two thirds of cases are sporadic and thought to represent new mutations. Germline mosaicism is uncommon but explains how parents who apparently do not have the disease can have multiple children with tuberous sclerosis. Mutations affecting either of the presumed tumor suppressor genes, *TSC1* or *TSC2*, cause tuberous sclerosis. The *TSC1* and *TSC2* genes encode distinct proteins, hamartin and tuberin, which are widely expressed in the brain and result in constitutive activation of the protein kinase mTOR (mammalian target of rapamycin), leading to the formation of numerous benign tumors (hamartomas).

Clinical Manifestations

TSC is an extremely heterogeneous disease with variable expression and a wide clinical spectrum varying from normal intelligence without seizures to severe intellectual disability with refractory seizures and autism, often within the same family. People with TSC may have retinal lesions (retinal hamartomas, white depigmented patches) and brain lesions (cortical tubers, subependymal nodules, hydrocephalus). **Tubers** in the cerebral cortex are areas of dysplasia that, in combination with other microscopic areas of abnormal development, are responsible for the symptoms of intellectual disability and epilepsy. TSC is one of the most common causes of infantile spasms; in this context, the infantile spasms often respond to treatment with vigabatrin. **Subependymal nodules** are hamartomas that may mutate into a growth phase and become **subependymal giant cell astrocytomas** (SEGAs), causing obstruction of cerebrospinal fluid outflow and resultant hydrocephalus. SEGAs can be treated with everolimus, a mammalian target of rapamycin inhibitor, and preliminary studies suggest that this medication can also reduce seizure burden for people with TSC.

Extracerebral manifestations include typical skin findings of hypomelanotic macules (**ash leaf spots**), which are easiest to visualize under a Wood ultraviolet lamp and are apparent in infancy. Facial angiofibromas (**adenoma sebaceum**) appear as small red nodules over the nose and cheeks that are sometimes confused with acne. **Shagreen patches** are elevated, rough plaques of skin with a predilection for the lumbar and gluteal regions that develop in late childhood or early adolescence. Cardiac rhabdomyomas are largest during prenatal life and infancy and are rarely symptomatic. Occasionally, they may cause arrhythmias or cardiac outflow obstruction. Renal angiomyolipomas may undergo malignant transformation and are the most common cause of death in adults with TSC. Interstitial pulmonary disease also affects adults with TSC (pulmonary lymphangiomyomatosis).

Sturge-Weber Syndrome

Sturge-Weber syndrome is sporadic (not inherited) and is caused by a somatic mosaic mutation of the *GNAQ* gene. It is characterized by abnormal blood vessels (**angiomas**) of the leptomeninges overlying the cerebral cortex in association with an ipsilateral facial **port-wine stain** involving the ophthalmic division of the trigeminal nerve (forehead and upper eyelid) and, often,

glaucoma. The port-wine stain, also known as nevus flammeus, is due to an ectasia of superficial venules and may have a much more extensive and even bilateral distribution. Not all children with a facial port-wine stain have Sturge-Weber syndrome.

MRI with contrast demonstrates leptomeningeal angioma and white matter abnormalities thought to be due to chronic hypoxia and atrophy. Angiomas produce venous engorgement and, presumably, stasis within the involved areas, which are thought to result in hypoxia. Seizures are the most common associated neurological abnormality, occurring in 75% of patients. Children may also present with hemiparesis, stroke-like episodes, headaches, developmental delay, and learning disabilities. Many children with Sturge-Weber syndrome are intellectually normal, and seizures are well controlled with standard anticonvulsants. However, progressive ischemia of the underlying brain develops in some children with Sturge-Weber syndrome, resulting in hemiparesis, hemianopia, intractable focal seizures, and cognitive impairment. Hemispherectomy has been proposed for individuals with unilateral disease whose seizures are difficult to control, both to control the epilepsy and to preserve cognitive and motor development. Low-dose aspirin may result in improved perfusion and thereby reduce stroke-like events and seizures. Pulse dye laser surgery is the most promising therapeutic option for cosmetic management of the facial nevus flammeus. Expert ophthalmological management of glaucoma is required. Endocrinology evaluations are also necessary, as these patients often have growth hormone deficiency and/or hypothyroidism.

CHAPTER 187

Congenital Malformations of the Central Nervous System

Central nervous system malformations include disorders of spinal cord and neural tube formation, structure specification (neuronal migration, gray matter), brain growth and size, and skull growth and shape.

The precursor of the nervous system is the neural plate of the embryonic

ectoderm, which develops at 18 days of gestation. The neural plate gives rise to the neural tube, which forms the brain and spinal cord, and neural crest cells, which form the peripheral nervous system, meninges, melanocytes, and adrenal medulla. The neural tube begins to form on day 22 of gestation. The rostral end forms the brain, and the caudal region forms the spinal cord. The lumen of the neural tube forms the ventricles of the brain and the central canal of the spinal cord. Most brain malformations are produced by a variety of injuries occurring during a vulnerable period of gestation. Precipitating factors include chromosomal, genetic, and metabolic abnormalities; infections (toxoplasmosis, rubella, cytomegalovirus, herpes); and exposure to irradiation, certain drugs, and maternal illness during pregnancy.

Congenital Anomalies of the Spinal Cord

Etiology and Clinical Manifestations

Defective closure of the caudal neural tube at the end of week 4 of gestation results in anomalies of the lumbar and sacral vertebrae or spinal cord called **spina bifida**. These anomalies range in severity from clinically insignificant defects of the L5 or S1 vertebral arches to major malformations, leaving the spinal cord uncovered by skin or bone on the infant's back. The latter severe defect, called a **myelomeningocele**, results in flaccid paralysis and loss of sensation in the legs and incontinence of bowel and bladder, with the extent and degree of neurological deficit dependent on the location of the myelomeningocele. In addition, affected children usually have an associated **Chiari type II malformation** (downward displacement of the cerebellar tonsils and medulla), resulting in hydrocephalus and weakness of face and swallowing. In a **meningocele**, the spinal canal and cystic meninges are exposed on the back, but the underlying spinal cord is anatomically and functionally intact. In **spina bifida occulta**, the skin of the back is apparently intact, but defects of the underlying bone or spinal canal are present. Meningoceles and spina bifida occulta may be associated with a lipoma, dermoid cyst, or tethering of the cord to a thick filum terminale. A dimple or tuft of hair may be present over the affected area. Patients may also have an associated dermoid sinus, an epithelial tract extending from the skin surface to the meninges; this increases the risk of meningitis. Patients with spina bifida occulta or meningocele may have weakness and numbness in the feet that can result in recurrent ulcerations, or

difficulties controlling bowel or bladder function that may result in recurrent urinary tract infections, reflux nephropathy, and renal insufficiency. In **diastematomyelia**, a bone spicule or fibrous band divides the spinal cord into two longitudinal sections. An associated lipoma that infiltrates the cord and tethers it to the vertebrae may be present. Symptoms include weakness and numbness of the feet and urinary incontinence.

Diagnostic Studies

Myelomeningocele in the fetus is suggested by an elevated **alpha-fetoprotein** in the mother's blood and confirmed by ultrasound and high concentrations of alpha-fetoprotein and acetylcholinesterase in the amniotic fluid. After birth, screening ultrasound may be used with magnetic resonance imaging to confirm less dramatic underlying spinal abnormalities.

Treatment and Prevention

Neonates with myelomeningocele must undergo operative closure of the open spinal defects (fetal or postnatal surgery) and often require treatment of hydrocephalus by placement of a ventriculoperitoneal shunt. Compared to postnatal surgery, fetal surgery prior to 26 weeks' gestation to close the myelomeningocele reduces the need for cerebrospinal fluid (CSF) shunting and improves neurodevelopmental outcomes. Toddlers and children with lower spinal cord dysfunction require physical therapy, bracing of the lower extremities, and intermittent bladder catheterization. In the absence of associated brain anomalies, most survivors have normal intelligence, but learning problems and epilepsy are more common than in the general population.

Spina bifida can be prevented in many cases by **folate** administration to the pregnant mother. Because the defect occurs so early in gestation, all women of childbearing age are advised to take oral folic acid daily.

Congenital Malformations of the Brain

Defective closure of the rostral neural tube produces anencephaly or encephaloceles. Neonates with **anencephaly** have a rudimentary brainstem or midbrain, but no cortex or cranium. This is rapidly fatal after delivery. Patients with **encephalocele** usually have a skull defect and exposure of meninges alone

or meninges and brain. The recurrence risk in subsequent pregnancies for either cranial or spinal neural tube defects is 3-4%. Within a family, an anencephalic birth may be followed by the birth of a child affected with a lumbosacral myelomeningocele. The inheritance of neural tube defects is polygenic.

Agenesis of the corpus callosum may be partial or complete and may occur in an isolated fashion or in association with other anomalies of cellular migration. **Dandy-Walker malformation** is diagnosed on the basis of the classic triad: complete or partial agenesis of the cerebellar vermis, cystic dilation of the fourth ventricle, and enlarged posterior fossa. There may be associated hydrocephalus, absence of the corpus callosum, and neuronal migration abnormalities. Intelligence may be normal or impaired, depending on the degree of associated cerebral dysgenesis.

Holoprosencephaly represents varying degrees of failure of the forebrain (prosencephalon) to divide into two distinct cerebral hemispheres. Holoprosencephaly is often associated with midline facial defects (hypotelorism, cleft lip, cleft palate). This anomaly may be isolated or associated with a chromosomal or genetic disorder. The prognosis for infants with severe (*alobar*) holoprosencephaly is uniformly poor, but those with milder forms (*semilobar*, *lobar*) may have less severe neurological outcomes. Children with trisomy 13 and trisomy 18 characteristically have varying degrees of holoprosencephaly.

Hydranencephaly is a condition in which the brain presumably develops normally, but then is destroyed by an intrauterine, probably vascular, insult. The result is virtual absence of the cerebrum with an intact skull. The thalamus, brainstem, and some occipital cortex are typically present. Children may have a normal external appearance at the time of birth, but do not achieve developmental milestones.

Macrocephaly and Microcephaly

Macrocephaly represents a head circumference above the 97th percentile and may be the result of **macrocrania** (increased skull thickness), **hydrocephalus** (enlargement of the ventricles; see [Chapter 184](#)), or **megalencephaly** (enlargement of the brain). Diseases of bone metabolism or hypertrophy of the bone marrow causes macrocrania. Megalencephaly may be the result of a significant disorder of brain development or an accumulation of abnormal metabolic substances ([Table 187.1](#)). Most often, however, macrocephaly is a familial trait of no clinical significance. If the child is developmentally normal

but has macrocephaly, plotting the parents' head circumference on a growth chart can provide reassurance and help to avoid unnecessary neurodiagnostic testing.

TABLE 187.1

Causes of Macrocephaly

Macrocrania (increased skull thickness)
Achondroplasia
Hypochondroplasia
Fragile X syndrome
Osteopetrosis
Chronic, severe anemia
Hydrocephalus (enlargement of the ventricles; see Chapter 184)
Masses
Cysts
Arteriovenous malformations
Subdural fluid collections/hematoma
Neoplasm
Megalencephaly (enlargement of the brain)
Embryological disorder causing abnormal proliferation of brain tissue
• Neurofibromatosis
• Tuberous sclerosis
• Sturge-Weber syndrome
• Sotos syndrome
• Riley-Smith syndrome
• Hemi-megalencephaly
Accumulation of abnormal metabolic substances
• Alexander disease
• Canavan disease
• Gangliosidoses
• Mucopolysaccharidoses
Benign causes
Benign extracerebral collections of infancy
Familial macrocephaly

Microcephaly represents a head circumference below the 3rd percentile. A myriad of syndromes and metabolic disorders are associated with microcephaly, some of which are hereditary (Table 187.2). In most instances, a small head circumference is a reflection of a small brain. Brain growth is rapid during the perinatal period, and any insult (infectious, metabolic, toxic, vascular) sustained during this period or during early infancy is likely to impair brain growth and result in microcephaly. Rarely, a small head is the result of premature closure of one or more skull sutures, called **craniosynostosis**. This diagnosis is readily made by the abnormal shape of the skull. As a rule, macrocephaly and microcephaly raise a concern about cognitive ability, but head circumference alone should never be used to establish a prognosis for intellectual development.

TABLE 187.2**Causes of Microcephaly**

PRIMARY MICROCEPHALY
Microcephaly vera
Chromosomal disorders
Trisomy 21
Trisomy 13
Trisomy 18
5p microdeletion
Angelman syndrome
Prader-Willi syndrome
Central nervous system (CNS) malformation
Holoprosencephaly
Encephalocele
Hydranencephaly
CNS migrational disorder
Lissencephaly
Schizencephaly
Pachygyria
Micropolygyria
Agenesis of the corpus callosum
Sex-linked microcephaly syndromes
Smith-Lemli-Opitz syndrome
Cornelia de Lange syndrome
Seckel dwarfism syndrome
Cockayne syndrome
Rubinstein-Taybi syndrome
Hallermann-Streiff syndrome
SECONDARY (ACQUIRED) MICROCEPHALY
Infections (congenital)
Rubella
Cytomegalovirus
Toxoplasmosis
Syphilis
Human immunodeficiency virus (HIV)
Zika virus
Infections (noncongenital)
Meningitis
Encephalitis
Stroke
Toxic
Radiation exposure—fetal
Fetal alcohol syndrome
Maternal phenylketonuria
Hypoxic-ischemic or other severe brain injury
Periventricular leukomalacia
Systemic disease
Chronic cardiac or pulmonary disease
Chronic renal disease
Malnutrition
Craniosynostosis totalis

Disorders of Neuronal Migration

Many malformations result from the failure of normal migration of neurons from the periventricular germinal matrix zone to the cortical surface at 1-5 months of gestation. Multiple malformations may exist in the same patient. Neurological development with these anomalies varies and depends on the type and extent of the malformation. Many children with disorders of neuronal migration have treatment-resistant epilepsy.

Schizencephaly is characterized by clefts within the cerebral hemispheres that extend from the cortical surface to the ventricular cavity. Unilateral clefts can cause isolated congenital hemiparesis, whereas bilateral schizencephaly causes spastic quadriplegia and associated intellectual disability. Affected individuals are at high risk for focal epilepsy.

A severe defect in cortical migration, **lissencephaly** results in a smooth brain without sulcation (agyria). The normal six-layered cortex does not develop. Affected children have difficult-to-control seizures and profound developmental retardation. This anomaly most commonly is part of a genetic disorder, which may be x-linked (*DCX* mutations) or caused by de novo autosomal-dominant gene mutations (*Lis-1* mutations). In **pachygyria**, the gyri are few in number and too broad. In **polymicrogyria**, the gyri are too many and too small. Sometimes pachygyria and polymicrogyria affect an entire hemisphere, producing enlargement of that hemisphere and a clinical syndrome of severe, medically intractable seizures that begin in early infancy. **Gray matter heterotopias** are abnormal islands within the central white matter of neurons that have never completed the migratory process.

Pearls for Practitioners

Chapter 179

Neurology Assessment

- The pediatric neurological examination varies with age; the newborn is unique, with many transient and primitive reflexes, which provide assessment of the functional integrity of the brainstem and basal ganglia.
- Careful evaluations of social, cognitive, language, fine motor and gross motor skills, and their age appropriateness are key in the neurological assessment of children.
- Watching a child creep, crawl, cruise, or walk is the best global assessment for the motor and coordination systems.

Chapter 180

Headache and Migraine

- There are four temporal patterns of childhood headache: acute;

acute recurrent; chronic progressive; and chronic nonprogressive or chronic daily.

- Additional investigation is warranted for headaches in the presence of an abnormal neurological exam (especially papilledema), symptoms of increased intracranial pressure, atypical headache, progressive chronic headache, signs of increased intracranial pressure, or “worst headache of my life.”
- Symptoms of increased intracranial pressure include early morning vomiting or headache that awakens the child from sleep.

Chapter 181

Seizures

- Focal seizures with retained awareness (previously termed simple partial seizures) arise from a specific anatomical focus.
 - Clinical symptoms include motor (tonic, clonic, myoclonic), sensory, psychic, or autonomic abnormalities, but consciousness is preserved.
- Focal seizures with altered awareness (previously termed complex partial seizures) can have similar sensorimotor signs but also have associated alteration of consciousness.
- The clinical hallmark of absence seizures is a brief (less than 15 seconds) loss of awareness accompanied by eyelid fluttering or simple automatisms, such as fumbling with the fingers and lip smacking. Absence seizures usually begin between 4 and 6 years of age.
- Children with febrile seizures have an excellent prognosis, and daily antiseizure medication to prevent febrile seizures is not recommended.
- Infantile spasms are clusters of brief contractions of the neck, trunk, and arm muscles, followed by a phase of sustained muscle contraction lasting less than 2 seconds. Rapid initiation of

effective therapy offers the best chance for favorable neurodevelopmental outcomes.

- Initial management of status epilepticus is with a benzodiazepine and should begin if the seizure persists longer than 5 minutes.
 - If the seizure does not resolve after two doses of benzodiazepine, a second-line agent must be administered, typically phenobarbital for newborns and infants and intravenous fosphenytoin, valproic acid, or levetiracetam for older children.
- Psychogenic nonepileptic seizures (PNES) may be the manifestation of conversion disorders or malingering.
 - Children with epilepsy may, consciously or subconsciously, exhibit concurrent PNES.
 - Careful assessment and intervention for abuse, as well as other social stressors, is a key component of the care of children with PNES.

Chapter 182

Weakness and Hypotonia

- Weakness is a decreased ability to voluntarily and actively move muscles; hypotonia is a state of low muscle resistance to movement.
- An upper motor neuron pattern of weakness with increased deep tendon reflexes, spasticity, and extensor plantar responses may be caused by tumors, traumatic brain injury, infections, stroke, demyelinating syndromes, spinal cord trauma or mass, metabolic diseases, or neurodegenerative diseases.
- Acute spinal cord lesions, such as infarction or compression, may produce a flaccid, areflexic paralysis that mimics lower motor neuron disease. Lesions of the spinal cord are best

delineated with magnetic resonance imaging.

- Spinal muscular atrophy is a genetic disease characterized by progressive degeneration of anterior horn cells, which results in weakness.
- Guillain-Barré syndrome (acute inflammatory demyelinating polyradiculoneuropathy) is a postinfectious autoimmune peripheral neuropathy that can occur after an infection and is the most common cause of acute flaccid paralysis in children. It presents with areflexia, flaccidity, and symmetrical ascending weakness.
- Muscular dystrophies are characterized by progressive myofiber degeneration and the gradual replacement of muscle by fibrotic tissue. Duchenne muscular dystrophy is the most common muscular dystrophy.
- The acute onset of focal neurological deficits in a child is stroke until proven otherwise.
 - The most common causes of pediatric stroke are autoimmune vasculitis, infection, cardioembolic infarcts due to congenital heart disease, sickle cell anemia, or coagulation disorders, dehydration, vascular malformations, and head trauma.

Chapter 183

Ataxia and Movement Disorders

- The most common causes of acute ataxia in childhood are postinfectious acute cerebellar ataxia and drug intoxications.
- Movement disorders in children are typically hyperkinetic.
- Tics are rapid, purposeless, involuntary, stereotyped movements and typically involve the face, eyes, shoulder, and arm. Approximately 25% of children have transient tics.
- A child who is unsteady and has erratic eye movements may

have opsoclonus myoclonus and should be evaluated for occult neuroblastoma.

Chapter 184

Altered Mental Status

- In childhood, the most common causes of coma are toxins, infections, head trauma, hypoxia-ischemia (cardiac arrest, near-drowning), and seizures.
- Computed tomography is the preferred head imaging technique in emergency situations because it can be performed rapidly without sedation and accurately identifies acute hemorrhages and mass lesions.
- Cerebral herniation is a medical emergency. Signs include altered mental status, signs of increased intracranial pressure (ICP) with dilated pupil or miosis, hemiparesis, decorticate or decerebrate posturing, and irregular respirations.
- Lumbar puncture is contraindicated in the setting of an intracranial mass lesion or clear hydrocephalus, because withdrawal of cerebrospinal fluid (CSF) can change pressures between the intracranial compartments and promote brainstem shifts and herniation.
- Head trauma may result in concussion, posttraumatic intracranial hemorrhage, skull fractures, or cranial nerve or cervical spine injuries.
 - Concussion is the rapid onset of short-lived neurological impairment that typically resolves spontaneously.
 - Symptoms may include headache, slowed reaction times, emotional lability, drowsiness, loss of consciousness, or amnesia.
 - Epidural, subdural, parenchymal, and subarachnoid intracranial hemorrhages can occur following head

trauma.

- Intracranial bleeding accompanied by neurological deterioration requires prompt assessment for likely evacuation of the blood.
- Linear, diastatic, and minimally depressed fractures necessitate no specific treatment; fractures with more than 0.5-1.0 cm depression usually require surgical elevation.

Chapter 185

Neurodegenerative Disorders

- Neurodegenerative disorders encompass a large heterogeneous group of diseases that result from specific genetic and biochemical defects and varied unknown causes.
 - Neuronal degenerative disorders affect gray matter.
 - Early signs are seizures and intellectual impairment
 - Leukodystrophies affect white matter.
 - Early signs include upper motor neuron signs and progressive spasticity
- Mitochondrial diseases represent a clinically heterogeneous group of disorders in oxidative phosphorylation.
 - Abrupt symptoms often manifest during physiological stress (febrile illness, fasting).

Chapter 186

Neurocutaneous Disorders

- Abnormalities of skin, teeth, hair, and nails may indicate abnormal brain development, as all are derived from ectoderm.

Chapter 187

Congenital Malformations of the Central Nervous System

- CNS malformations include disorders of the spinal cord, neural tube formation, structure specification (neuronal migration), brain growth, and skull growth and shape.
 - Spina bifida is the defective closure of the caudal neural tube and ranges in severity from insignificant defects of vertebral arches to myelomeningocele.
 - An elevated alpha-fetoprotein in mother's blood suggests myelomeningocele in the fetus.
 - Children with myelomeningocele often have an associated Chiari type II malformation.
- Defective closure of the rostral neural tube produces anencephaly or encephaloceles.
 - Holoprosencephaly represents varying degrees of failure of the forebrain to divide into two distinct cerebral hemispheres.
- Hydranencephaly is a condition in which the brain presumably develops normally, but is destroyed by an intrauterine, probably vascular, accident.
- Schizencephaly and lissencephaly are disorders of neuronal migration that result in abnormal neurological development and often are associated with treatment-resistant epilepsy.

CHAPTER 188

Dermatology Assessment

Approximately one in three Americans of any age has at least one recognizable skin disorder at any time. The most common cutaneous diseases encountered in community settings are dermatophytosis, acne vulgaris, seborrheic dermatitis, atopic dermatitis (eczema), verrucae (warts), tumors, psoriasis, vitiligo, and infections such as herpes simplex and impetigo. The most common diagnoses in children attending pediatric dermatology clinics include atopic dermatitis, impetigo, tinea capitis, acne vulgaris, verrucae vulgaris, and seborrheic dermatitis.

History

The age of the patient, onset, duration, progression, associated cutaneous symptoms (pain, pruritus), previous treatments, and associated systemic signs or symptoms (fever, malaise, weight loss) are important clues. Obtaining an accurate description of the original lesion improves diagnostic accuracy. Patients often do not consider a topical antibiotic or antiitch medication as treatment. As over-the-counter remedies may alter the appearance of a rash, it is important to probe deeply with related questions in the history. Other important information includes a history of allergies, environmental exposure, travel history, previous treatment, affected contacts, and family history.

Physical Examination

A careful examination of the skin requires a visual and a tactile assessment. Examination of the skin over the entire body must be performed systematically. Mucous membranes, hair, nails, and teeth, all of ectodermal origin, also may be

involved in cutaneous disorders and should be assessed.

Common Manifestations

Decision-Making Algorithms

Alopecia
Vesicles and Bullae
Fever and Rash

A descriptive nomenclature of skin lesions helps with generating a differential diagnosis and with communication between health care providers. Determination of the primary lesion and secondary change is the cornerstone of dermatological diagnosis. A **primary lesion** is defined as the basic lesion that arises de novo and is most characteristic of the disease process (Table 188.1 and Fig. 188.1). Primary lesions are often not seen on a patient at the time of presentation, as most lesions are altered by time or external factors such as medication applied, secondary infection, or physical manipulation (e.g., scratching). A search for the primary lesion often proves worthwhile and focuses the differential diagnosis to a category of lesion that is specific for the underlying diagnosis. On occasion, two different types of primary lesions may be present. In most cases, **secondary lesions** are the result of the effects of the primary lesion (Table 188.2). They may be created by scratching or secondary infection and may be seen in the absence of a primary lesion.

TABLE 188.1

Primary Skin Lesions

LESION	DESCRIPTION
Macule	Flat, nonpalpable lesion <1 cm in diameter
Patch	Similar to macule, but >1 cm in diameter
Papule	Elevated, solid lesion <1 cm in diameter
Plaque	Similar to papule, but >1 cm in diameter; has a flat and broad surface in contrast to a nodule
Nodule	Similar to papule, but >1 cm in diameter; has a rounded surface in contrast to a plaque
Tumor	Similar to nodule, but implies a neoplastic growth rather than an inflammatory process

Vesicle	Fluid-filled (usually clear or straw-colored) epidermal lesion <1 cm in diameter
Bulla	Similar to vesicle, but >1 cm in diameter
Pustule	Pus-filled epidermal lesion, which often is surrounded by erythema
Purpura	Red-purple macule or papule resulting from extravasated blood into the skin; does not blanch with pressure
Petechia	Similar to purpura, but less than a few millimeters in diameter
Ecchymosis	Larger, hemorrhagic patch or plaque resulting from extravasated blood
Wheal (hive)	Pink, edematous papules and plaques that vary greatly in size and configuration; characterized by transient nature with individual lesions resolving within 24 hr
Telangiectasia	Collection of small superficial red blood vessels
Milia	Superficial, white, small epidermal keratin cysts
Comedo	Plug of keratin and sebum within the orifice of a hair follicle, which can be open (blackhead) or closed (whitehead); characteristic lesion of acne vulgaris
Cyst	Papule or nodule with an epidermal lining and filled with solid material

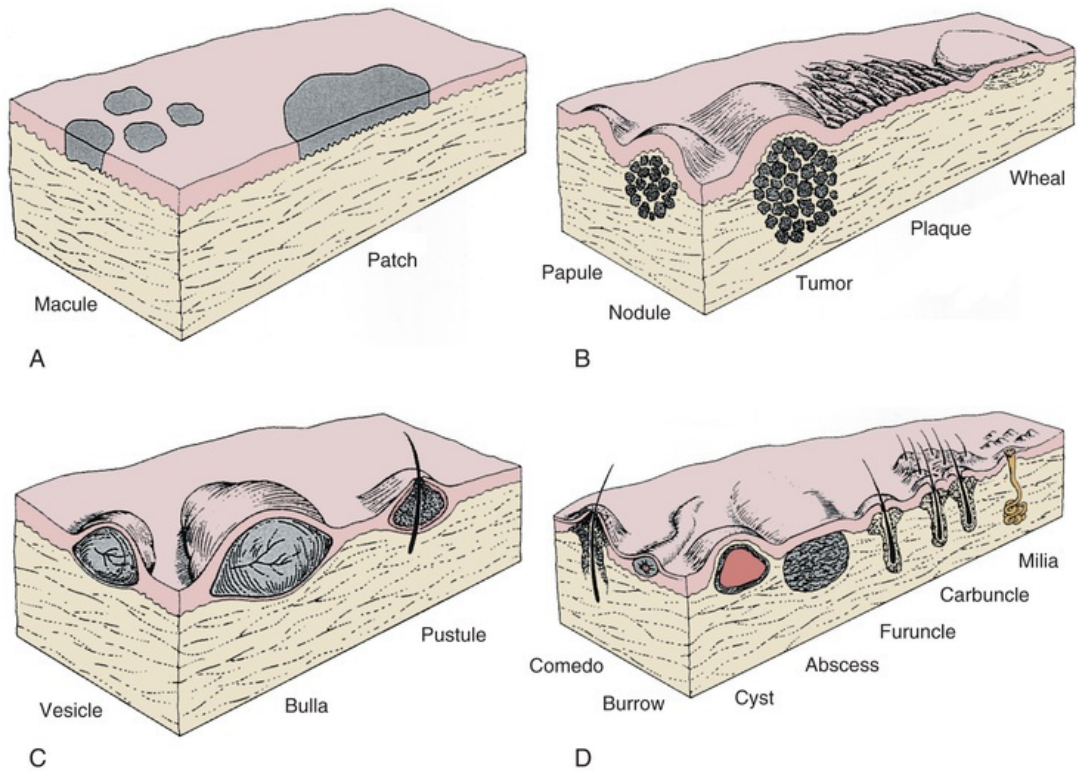

FIGURE 188.1 Morphology of Primary Skin Lesions. **(A)** Flat lesions. **(B)** Palpable lesions. **(C)** Fluid-filled lesions. **(D)** Special primary lesions. (From Swartz MH. *Textbook of Physical Diagnosis: History and Examination*. Philadelphia: WB Saunders; 1989.)

TABLE 188.2**Secondary Skin Lesions**

LESION	DESCRIPTION
Scale	Results from abnormal keratinization; may be fine or sheet-like
Crust	Dried collection of serum and cellular debris
Erosion	Shallow depression with loss of the superficial epidermis
Ulcer	Deeper depression with loss of the entire epidermis into dermis; heals with scarring
Atrophy	Thinning of epidermis (surface appears shiny and translucent) or dermis (skin is depressed with epidermis intact)
Scar	Thickened, firm, and discolored collection of connective tissue that results from dermal damage; initially pink, but lightens with time
Sclerosis	Circumscribed or diffuse hardening of skin
Lichenification	Accentuated skin lines/markings that result from thickening of the epidermis due to rubbing
Excoriation	Superficial linear erosion that is caused by scratching
Fissure	Linear break within the skin surface that usually is painful

The color, texture (e.g., rough, smooth), configuration (e.g., annular, serpiginous, linear), location, and distribution (e.g., localized, widespread, symmetrical, dermatomal) of the lesion should be recorded. Lesions on mucous membranes are usually short-lived and harder to definitively diagnose. Lesions in thick-skinned areas, such as the palms and soles, may be particularly difficult to characterize.

Initial Diagnostic Evaluation and Tests

A thorough history and physical examination are usually sufficient for diagnosis because of the visibility of the skin. Adjunctive tests at the time of examination include potassium hydroxide (KOH) examination for fungi and dermatophytes, skin scrapings for scabies, cytological examination (Tzanck test) for herpesvirus and varicella-zoster virus infection, and Wood light examination for the yellowish-gold fluorescence of tinea versicolor, depigmentation (e.g., vitiligo), or hypopigmentation (e.g., ash leaf macules of tuberous sclerosis). A skin biopsy may be performed to help with the diagnosis. The biopsy specimen can be accomplished by either shave or punch biopsy. Both are simple in-office procedures. Occasionally, laboratory or imaging studies are necessary.

Acne

Etiology

Acne vulgaris (or acne) is a chronic inflammatory disorder that affects areas with the greatest concentration of sebaceous glands, such as the face, chest, and back. The pathogenesis of acne is multifactorial. Gender, age, genetic factors, and environment are all major contributing factors. Stress may trigger acne, possibly by affecting hormone levels. A high glycemic diet and milk intake may be associated with acne, although remain controversial as potential causes.

Acne is caused by chronic inflammation of the pilosebaceous unit (hair follicle with an associated sebaceous gland). The primary event in all acne lesions is the development of the **microcomedo**, which results from the obstruction of the hair follicle with keratin, increased sebum production from sebaceous glands, and overgrowth of normal skin flora, leading to pilosebaceous occlusion and enlargement. Androgens are a potent stimulus of the sebaceous gland. The subsequent inflammatory component and pustule formation results from proliferation of *Propionibacterium acnes* (*P. acnes*), a commensal organism of the skin. The pathogenesis of acne thus involves three components: increased sebum production, hyperkeratosis, and bacterial proliferation. Effective treatment focuses on minimizing these factors.

Epidemiology

Acne is the most common skin disorder in adolescents, occurring in 85% of teenagers. The incidence is similar in both sexes, although boys often are more severely affected. Acne may begin as early as 8 years of age and may continue into adulthood.

Clinical Manifestations

Acne primarily affects areas with increased sebaceous gland density, such as the face, upper chest, and back. Superficial plugging of the pilosebaceous unit results in noninflammatory small (1- to 2-mm) **open (blackhead)** and **closed**

(whitehead) comedones. An open comedo is less likely to become inflammatory than a closed comedo. Rupture of a comedo into adjacent dermis and proliferation of *P. acnes* induce an inflammatory response and development of inflammatory **papules** and **pustules**. Larger, skin-colored or red cysts and nodules represent deeper plugging and **cystic acne**. Increased and persistent inflammation, especially with rupture of a deep cyst, increases the risk of scarring.

The diagnosis of acne is usually not difficult because of the characteristic and chronic lesions. Laboratory studies and imaging studies are usually not necessary to diagnose acne. Screening tests may be necessary if there are signs of hyperandrogenism due to polycystic ovarian syndrome (irregular menses, hirsutism, insulin resistance) or an underlying androgen-secreting tumor (irregular menses, hirsutism, deepening voice, clitoromegaly).

Treatment

The mainstays of treatment of acne are topical comedolytic agents and topical antibiotics. Creams, lotions, gels, foams, and solutions are available. Gels and solutions are commonly used because acne skin is generally greasier and these agents tend to be drying. They also have the tendency to be irritating and may not be as well tolerated. Creams and lotions are better tolerated but may not be as effective.

The comedolytic agents (salicylic acid, azelaic acid, tretinoin, adapalene, tazarotene) produce superficial desquamation and, subsequently, relieve follicular obstruction. They are a mainstay of first-line therapy. The topical retinoids (tretinoin, adapalene, tazarotene) are based on the vitamin A molecule. They decrease keratin and sebum production and have some antiinflammatory and antibacterial activity; thus they can be the most effective when used as monotherapy.

Topical antimicrobials (benzoyl peroxide, dapsone) and topical antibiotics (erythromycin, clindamycin) are anti-inflammatory and inhibit *P. acnes* proliferation. Erythromycin efficacy has decreased as *P. acnes* has become increasingly resistant to this antibiotic and should no longer be used. Topical antibiotics should be combined with an antimicrobial, such as benzoyl peroxide, to prevent the development of resistance. Combination therapy of a topical comedolytic agent and a topical antimicrobial is more effective than either agent alone for inflammatory acne.

Oral antibiotics (tetracycline, doxycycline, minocycline) are typically used for deeper cystic lesions but should always be used in combination with a topical regimen. Tetracyclines are the most effective antibiotics because of their significant antiinflammatory activity. Tetracyclines should not be used in children 8 years of age and younger. As with topical erythromycin, oral erythromycin is no longer used because of bacterial resistance. Given their increased risk of bacterial resistance and reported associations with inflammatory bowel disease, Candida, and *Clostridium difficile* infections, judicious use of systemic antibiotics in the treatment of acne vulgaris is emphasized for those who treat acne.

For recalcitrant or severe nodulocystic acne, oral isotretinoin may be instituted. Isotretinoin, an oral analog of vitamin A, normalizes follicular keratinization, reduces sebum production, and decreases 5 α -dihydrotestosterone formation and androgen receptor-binding capacity. A course of isotretinoin (0.5-1 mg/kg/day to reach a cumulative dose of 120-150 mg/kg) is the only medication that can permanently alter the course of acne and induce a durable remission. Because of the high incidence of adverse effects, it should be used only by physicians familiar with this medication. Isotretinoin therapy requires careful patient selection, pretreatment counseling, and laboratory monitoring. It is teratogenic and must not be used immediately before or during pregnancy.

For females, hormonal agents can also be considered for anti-acne therapy. These include the estrogen-containing combined oral contraceptives (although use should be limited to those without contraindications) and spironolactone.

Complications

Acne has significant and frequently devastating effects on an adolescent's body image and self-esteem. There may be little correlation between severity and psychosocial impact. Scarring may result in permanent morbidity.

Prognosis

Classically, acne lasts 3-5 years, although some individuals may have disease for 15-20 years. Only early treatment with isotretinoin may alter the natural course of acne. Acne lesions often heal with temporary postinflammatory erythema and hyperpigmentation. Depending on the severity, chronicity, and depth of involvement, pitted, atrophic, or hypertrophic scars may develop. **Cystic acne**

has the highest incidence of scarring because rupture of a deep cyst induces the greatest inflammation, although scarring may be caused by milder pustular or even comedonal acne.

Prevention

Greasy hair and cosmetic preparations should be avoided because they exacerbate preexisting acne. There are no effective means for preventing acne, although a low milk or low glycemic diet may improve acne. Repetitive cleansing with soap and water or use of astringents or abrasives removes only surface lipids; their use makes the skin appear less oily but does not prevent formation of microcomedones and may paradoxically worsen acne.

CHAPTER 190

Atopic Dermatitis

Etiology

Atopic dermatitis is a chronic inflammatory disease with no known cure. It is associated with significant psychosocial morbidity and decreased health-related quality of life. For many affected individuals, atopic dermatitis is the skin manifestation of atopy accompanied by asthma and allergic rhinitis.

Atopic dermatitis manifests with a defective skin barrier, reduced innate immune responses, and exaggerated immune responses to allergens and microbes. Both genetic predisposition and environmental factors play a role in the development of atopic dermatitis. Genes associated with skin barrier dysfunction and inflammation have been linked with atopic dermatitis. Inflammatory mediators involved include predominantly T helper (T_H) cells, with the T_{H2} pathway implicated early in acute lesions and a T_{H1} predominance found in chronic lesions. Langerhans cells, immunoglobulin (Ig)E, and eosinophils play a prominent role, as well as many other inflammatory mediators. Environmental and contact allergens, infections, irritants, extremes of temperature, sweat, and lack of humidity can exacerbate the condition, as can scratching or rubbing. Triggers are somewhat variable from individual to

individual.

Epidemiology

Atopic dermatitis is the most common skin disease in children, with an estimated prevalence of up to 20% of children. Only 1-2% of adults manifest disease. In addition to genetic factors, an environmental influence contributes. Atopic dermatitis occurs more frequently in urban areas and in higher socioeconomic classes. Prevalence is lower in areas where industrial pollution is less and where eosinophil-mediated infections such as helminthic infections are endemic.

Patients generally have a family history of atopy. Children with atopic dermatitis are predisposed to the development of allergy and allergic rhinitis, referred to as the *atopic march*. Asthma develops in up to half of children with atopic dermatitis, and allergic rhinitis develops even more frequently. Food allergies are commonly present in children with atopic dermatitis but are a rare cause of atopic dermatitis itself.

Clinical Manifestations

Atopic dermatitis is a chronic, relapsing skin disease characterized by xerosis, pruritus, and characteristic skin findings. The condition generally improves with age and remits in adulthood, although some childhood cases will continue into adulthood.

Characteristic lesions of atopic dermatitis are erythematous papules or plaques with ill-defined borders and overlying scale or hyperkeratosis. Weeping may be present in acute stages, which then develops into yellow crust. Lesions can be secondarily excoriated and result in hemorrhagic crusting and lichenification in older lesions. Formation of fissures is common in both acute and chronic lesions. Temporary hypo- and hyperpigmentation can be seen after lesions resolve, but atopic dermatitis is not usually scarring unless secondary features become severe (e.g., infection or scratching).

Characteristic locations vary with the age of the patient. Infantile atopic dermatitis typically affects the face and extensor surfaces of the extremities and is often generalized. Childhood lesions predominate in flexural surfaces (antecubital and popliteal fossae), wrists, ankles, hands, and feet (Fig. 190.1). The adult phase occurs after puberty and manifests in the flexural areas, including the neck, as well as predominant involvement on the face, hands,

fingers, toes, and the upper arms and back.

FIGURE 190.1 Atopic dermatitis (arm).

Secondary bacterial infection, most commonly with *Staphylococcus aureus* or less commonly with *Streptococcus pyogenes*, is frequently present. Patients are at increased risk for infections with cutaneous viruses and can develop disseminated skin infections with viruses such as herpes simplex virus (HSV; eczema herpeticum), varicella-zoster virus, coxsackievirus (eczema coxsackium), smallpox virus (eczema vaccinatum), and molluscum contagiosum. Atopic skin is more susceptible to fungal infections as well. Signs of concomitant infection include acute worsening of disease in an otherwise well-controlled patient, resistance to standard therapy, fever, and presence of pustules, fissures, punched out erosions, or exudative or crusted lesions (Fig. 190.2). Eczema herpeticum and eczema vaccinatum can be life threatening if not treated.

FIGURE 190.2 Atopic dermatitis with *Staphylococcus* superinfection.

Laboratory and Imaging Studies

Diagnosis of atopic dermatitis is based on clinical signs and symptoms. Skin biopsy findings are generally characteristic but not exclusively diagnostic and can overlap with other skin conditions. Peripheral blood eosinophilia and elevated IgE levels can be found but are not specific and not routinely obtained. Skin prick testing or measurement of specific IgE antibody levels can detect sensitization to food and environmental allergens, although false-positive findings occur.

Differential Diagnosis

The differential diagnosis of atopic dermatitis is extensive, but the history of a relapsing pruritic condition in the setting of atopy and skin lesions in a characteristic distribution is typical.

The lesions of **seborrheic dermatitis** have circumscribed and well-defined borders. The scale or hyperkeratosis is thicker, greasy, and yellowish. The distribution of seborrheic dermatitis is different from that of atopic dermatitis, typically involving the scalp, eyebrows, perinasal region, upper chest, and back. The two conditions occasionally coexist.

Psoriasis tends to localize on the elbows, knees, lower back, and scalp. The

lesions of psoriasis on exposed surfaces are salmon color at the base with an overlying hyperkeratosis that is much thicker with silver coloration. They are generally very well demarcated, oval or round, thick plaques.

Allergic contact dermatitis has a distribution limited to one area of the body corresponding to contact with the allergen. The lesions generally make well-demarcated, bizarre, linear, square, or angulated shapes corresponding to the source. **Nickel dermatitis** is common and results from contact sensitization to nickel in metals. It occurs in characteristic locations, such as the periumbilical area (where metal from pant buttons rub against skin); on the ear lobule or neck (where earrings contact skin); circumferentially around the neck (necklaces); and under rings or wristbands. Patients with atopic dermatitis can have concomitant contact dermatitis as well.

Treatment

Ideal therapy for atopic dermatitis includes three main components: frequent liberal use of bland moisturizers to restore the skin barrier, avoidance of triggers of inflammation, and use of topical antiinflammatory medication to affected areas of skin when needed. Control of pruritus and infection should be considered on an individual basis. If topical therapy and these measures are inadequate, systemic therapy with immunosuppressive agents or ultraviolet light therapy may be indicated.

A daily short bath with warm but not hot water is generally recommended, although this is controversial and there are some who advocate less frequent bathing. A moisturizing cream or ointment should be applied to the entire body immediately afterward to trap moisture. Application of topical medications is also most effective immediately after bathing. Additional information for patients and families can be found at the website of the National Eczema Association for Science and Education (<http://www.nationaleczema.org>).

Common triggers of inflammation in atopic dermatitis include rubbing or scratching, contact with saliva or acidic foods, soaps and detergents, wool or other harsh materials, fragranced products, sweat, highly chlorinated pools, low humidity, tobacco smoke, dust mites, animal dander, environmental pollens, and molds. Exposure to these triggers should be limited whenever possible. Infections that are unrelated to skin disease, such as an upper respiratory infection, can also exacerbate atopic dermatitis. Food allergy is commonly seen in patients with atopic dermatitis but typically presents with urticaria or

anaphylaxis rather than exacerbation of the atopic dermatitis.

Topical corticosteroids are the mainstay of antiinflammatory therapy for atopic dermatitis. Hundreds of topical corticosteroids are available and are classified according to strength from I to VII. Class I is the highest potency and class VII is the lowest potency. Potency varies according to the steroid molecule (active ingredient), and, for a given ingredient, strength can vary according to relative concentration and vehicle base. Enhanced penetration occurs in areas of natural occlusion (flexures such as axillae and groin), with external occlusion (diapers or bandages), in areas of open skin (excoriations), and with heat or hydration. Use of wet wraps with topical corticosteroid application takes advantage of this principle of heat and hydration for enhanced penetration for recalcitrant lesions. Class I and II steroids are typically avoided in young children or in areas of thinner skin or enhanced penetration.

Corticosteroids are available in different vehicles. In general, ointments are preferred because of their increased efficacy, occlusive nature, and tolerability. Creams may be slightly less effective for a given steroid ingredient, but may be more cosmetically acceptable for older patients or in warmer climates. Lotions may cause more irritation and are generally less potent. Sprays, foams, solutions, and gels can be especially useful for hair-bearing areas. Creams, lotions, sprays, solutions, and gels can be particularly irritating when applied to atopic skin and should generally be avoided on areas of open skin.

Topical corticosteroids should be used in conjunction with adequate skin care, such as avoiding triggers of inflammation and frequent application of moisturizers. Twice-daily application of corticosteroids is recommended. The goal is to limit the need for antiinflammatory medications and thereby avoid potential for adverse effects. Local side effects such as skin atrophy, striae, acne, and hypopigmentation are related to corticosteroid potency, site of application, and duration of application. Systemic side effects of adrenal suppression or Cushing syndrome can result with application of a potent topical corticosteroid to large surface areas or occluded areas at risk of enhanced penetration.

Topical **calcineurin inhibitors** (also referred to as topical immune modulators) such as topical tacrolimus and pimecrolimus may be part of the treatment regimen for atopic dermatitis. These agents selectively inhibit T-cell proliferation by inhibiting calcineurin and subsequent interleukin 2 production. There is no potential for skin atrophy; thus these agents are particularly useful for face or genital lesions. They are currently approved for intermittent therapy as second-line treatments for mild to moderate atopic dermatitis. Long-term

studies, combined with other modalities for treatment, are underway.

Sedating antihistamines (e.g., diphenhydramine, hydroxyzine) have only mild effect on pruritus but can improve the sleeplessness due to scratching during the night. A dose before bedtime is most effective. Additional daytime doses can be added on an individual basis when needed. Nonsedating antihistamines are of little benefit in controlling the pruritus of atopic dermatitis.

Short-term administration of systemic corticosteroids is rarely indicated for cases of severe disease and may be considered when adequate topical therapy failed or is being instituted. Systemic corticosteroid courses should be adequately tapered and used in conjunction with an appropriate atopic skin care regimen. Rebound flare of atopic dermatitis is common following withdrawal of corticosteroids and should be anticipated to avoid misinterpretation of the natural disease severity. Long-term and frequent repeated courses should be avoided to prevent adverse effects.

Ultraviolet light therapy (UVB, narrow band UVB, UVA, or UVA1) can be an option for moderate to severe cases in older children. Typically light therapy is administered two to three times weekly until improvement is seen and then is tapered or discontinued once the acute flare has resolved. More frequent use of light therapy in children is hindered by requirements for frequent office visits, ability to cooperate with standing in a light box while wearing protective goggles, and risk of long-term skin damage, including the potential for skin cancer development with excessive UV light exposure. Systemic immunosuppressants such as cyclosporine, methotrexate, azathioprine, or mycophenolate mofetil can be effective therapies for atopic dermatitis in severe cases.

Complications

Decision-Making Algorithm

Fever and Rash

An increased tendency toward bacterial, viral, and fungal skin infections is due to an impaired skin barrier and decrease in innate immune proteins in the skin as well as maladaptive secondary immune responses.

Secondary impetigo with *S. aureus* is the most common secondary skin infection found in atopic dermatitis. Group A streptococcus infection is also common. Infection manifests with pustules, erythema, crusting, flare of disease, or lack of response to adequate antiinflammatory therapy. Localized lesions can be treated with topical mupirocin. Widespread and generalized lesions require oral antibiotic therapy, most commonly with a first-generation cephalosporin such as cephalexin. Methicillin-resistant *S. aureus* infection is increasingly common, and antibiotic therapy should be tailored based on local resistance rates and patient factors. Diagnosis of superinfection may be made clinically, but a superficial bacterial culture can confirm the diagnosis and provide antimicrobial susceptibilities. Treatment should include a concomitant atopic skin care routine including the continued use of topical corticosteroids. Although secondary skin infection with *S. aureus* is common, progression to cellulitis or septicemia is unusual. Rarely, intravenous antibiotics may be required. Children with colonization and frequent infections may benefit from dilute bleach baths two to three times weekly; one-fourth to one-half cup of household bleach is added to a half-full or full bathtub.

Eczema herpeticum (Kaposi varicelliform eruption) is one of the potentially serious infectious complications in atopic dermatitis. After HSV infection, an eruption of multiple, pruritic, vesiculopustular lesions occurs in a disseminated pattern, both within plaques of atopic dermatitis and on normal-appearing skin. These characteristically rupture and form crusted umbilicated papules and punched-out hemorrhagic erosions (Fig. 190.3). Irritability, anorexia, and fever can also be seen. Systemic and central nervous system disease have been reported. Bacterial superinfection of eroded areas of the skin often occurs. Diagnosis can be made rapidly from a scraping of the skin lesion stained with Giemsa or Wright's stain (**Tzanck test**), although these are not highly sensitive. These stains allow microscopic visualization of the presence of multinucleated giant cells indicative of HSV or varicella-zoster virus infection. Vesicle fluid can also be sent for polymerase chain reaction (PCR) detection of HSV DNA, rapid direct fluorescent antibody testing, or viral culture. Laboratory confirmation of infection is important because similar clinical manifestations can occur with bacterial infections.

FIGURE 190.3 Eczema herpeticum (hand).

The psychosocial impact of atopic dermatitis can be significant. There is often disfigurement, lack of sleep from pruritus resulting in irritability and fatigue, and limitations on participation in sports. Significant time, as well as financial strain, is involved in caring for a child with atopic dermatitis. Thus management should address these potential issues and provide adequate anticipatory guidance.

Prognosis

Atopic dermatitis frequently remits during childhood and is much less common after puberty. The condition is generally most severe and widespread in infancy and early childhood. Relapse of disease in adults can occur and commonly manifests as face or hand dermatitis. Frequently, adults have generalized dry skin and are aware that their skin is sensitive to many over-the-counter preparations. Patients with atopic dermatitis can also develop asthma and allergic rhinitis. Asthma is more commonly associated with more severe skin disease.

Prevention

Individual flares of atopic dermatitis can be prevented by avoiding triggers of inflammation and can be lessened with frequent moisturizer application.

Evidence suggests that breast feeding for at least 4 months, with or without formula supplementation, decreases the incidence and severity of atopic dermatitis in individuals at high risk (i.e., those who have a first-degree relative with atopic dermatitis). For infants at high risk who are not exclusively breast fed, there is modest evidence that the onset of atopic dermatitis may be delayed or prevented by the use of extensively hydrolyzed casein-based formulas. There is no convincing evidence that an antigen avoidance diet in pregnant or lactating mothers prevents the development of atopic disease. Early introduction of peanuts among children at high risk for this allergy (i.e., infants with severe eczema, egg allergy, or both) significantly decreased the frequency of the development of peanut allergy in these infants in one large randomized study.

CHAPTER 191

Contact Dermatitis

Etiology and Epidemiology

Inflammation in the top layers of the skin, caused by direct contact with a substance, is divided into two subtypes: irritant contact dermatitis and allergic contact dermatitis. **Irritant contact dermatitis** is observed after the skin surface is exposed to an irritating chemical or substance. Contact dermatitis may occur in any age, and girls are more frequently affected than boys. **Allergic contact dermatitis** is a cell-mediated immune reaction, also called type IV or delayed-type hypersensitivity. The antigens, or haptens, involved in allergic contact dermatitis readily penetrate the epidermis and are bound by Langerhans cells, the antigen-presenting cells of the skin. The hapten is presented to T lymphocytes and an immune cascade follows.

Clinical Manifestations

Irritant contact dermatitis is characterized by ill-defined, scaly, pink or red patches and plaques (Fig. 191.1). The eruption is localized to skin surfaces that are exposed to the irritant. Irritant contact dermatitis is observed frequently on the dorsal surfaces of the hands in patients, often from repeated handwashing or

exposure to irritating chemicals.

FIGURE 191.1 Irritant diaper dermatitis.

Diaper dermatitis is a common problem in infants and most commonly is a form of irritant contact dermatitis. The dermatitis is caused by irritation from urine and feces, typically affecting the perianal region and the buttocks while sparing the protected groin folds and other occluded areas. Secondary infection by *Candida albicans* or bacterial pathogens may complicate diaper dermatitis as well.

Allergic contact dermatitis may be acute (such as *Rhus* dermatitis) or chronic (such as nickel dermatitis). Acute lesions are bright pink, pruritic patches, often in linear or sharply marginated bizarre configurations. Within the patches are clear vesicles and bullae (Fig. 191.2). Signs and symptoms of the disease may be delayed for 7-14 days after exposure if the patient has not been sensitized previously. On re-exposure, symptoms begin within hours and are usually more severe. The eruption may persist for weeks. Chronic lesions are pink, scaly, pruritic plaques, often mimicking atopic dermatitis. Even intermittent exposure can result in a persistent dermatitis.

FIGURE 191.2 Allergic contact dermatitis to tincture of benzoin.

Laboratory and Imaging Studies

The diagnosis is established by clinical presentation and history of exposure to a recognized irritant or allergen. Skin-prick testing and serum IgE levels are not helpful in determining the cause of allergic contact dermatitis. Patch testing may be used to determine the allergen causing the reaction in difficult cases.

Differential Diagnosis

The distribution and appearance of the dermatitis and a detailed exposure history are the most useful diagnostic tools. Involvement of the lower legs and distal arms suggests exposure to plants of the *Rhus* species (poison ivy or poison oak), especially when linear configurations of lesions are present. Dermatitis of the ears (earrings), wrist (bracelet or watch), or periumbilical region (belt buckle or pant buttons) suggests a metal allergy to nickel. Distribution on the dorsal surfaces of the feet indicates a shoe allergy, usually to dyes, rubber, or leather. Topical antibiotics (neomycin) and fragrances (soaps, perfumes, cosmetics) are frequent causes of allergic contact dermatitis.

Diaper rashes caused by *Candida* are quite common. Irritant contact

dermatitis primarily affects the prominent, exposed surfaces, whereas *Candida* primarily affects intertriginous areas. The two are frequently present simultaneously, as secondary *Candida* infection may complicate irritant dermatitis.

Psoriasis, seborrheic dermatitis, and Langerhans cell histiocytosis can present with an erythematous rash in the diaper area. Referral to a dermatologist should be considered for any child with a severe rash or with a diaper rash that does not respond to conventional therapy.

Treatment

Topical corticosteroids are effective in treatment of allergic and irritant contact dermatitis. High-potency corticosteroids, and even short courses of oral corticosteroids, may be necessary for severe reactions of allergic contact dermatitis. Oral antihistamines may be required to control itching.

Treatment of candidal diaper dermatitis consists of topical nystatin or topical azole antifungals. Low-potency topical corticosteroids are frequently used in addition to topical antifungal therapy to treat the irritant component of the diaper dermatitis when present concomitantly.

Complications

In addition to superinfection of diaper dermatitis by *C. albicans*, bacterial superinfection may complicate any form of contact dermatitis. This is especially common if the skin barrier is no longer intact because of blistering or scratching.

Prevention

Every effort should be made to identify the trigger of allergic or irritant contact dermatitis. With allergic contact dermatitis, re-exposure often leads to increasingly severe reactions.

CHAPTER 192

Seborrheic Dermatitis

Etiology

Seborrheic dermatitis is a common, chronic inflammatory disease that has different clinical presentations at different ages. Seborrheic dermatitis classically presents in infants as cradle cap or dermatitis in the intertriginous areas of the axillae, groin, antecubital and popliteal fossae, and umbilicus. It is seen in adolescents as dandruff. The pathogenesis of seborrheic dermatitis is unclear, but it is theorized that there is an abnormal inflammatory response to commensal *Malassezia* species in sebum-rich areas. Areas prone to seborrheic dermatitis include the scalp, eyebrows, eyelids, nasolabial folds, external auditory canals, and posterior auricular folds.

Clinical Manifestations

Seborrheic dermatitis in infants begins during the first month and persists during the first year of life. It is also called **cradle cap** because of the thick, greasy and waxy, yellow-white scaling and crusting of the scalp (Fig. 192.1). It is usually prominent on the vertex of the scalp, but it may be diffuse. Greasy, scaly, erythematous, nonpruritic patches and plaques may extend to the face and posterior auricular folds, sometimes involving the entire body. Diaper and intertriginous areas can have sharply demarcated, shiny, erythematous patches with minimal scale. Hypopigmentation may persist after the inflammation has faded. The eruption is usually asymptomatic, which helps differentiate it from infantile atopic dermatitis, which is pruritic.

FIGURE 192.1 Seborrheic dermatitis (cradle cap).

Classic seborrheic dermatitis during adolescence is typically localized to the scalp. The mild form is commonly known as **dandruff**, a fine, white, dry scaling of the scalp with minor itching. Additional findings of seborrheic dermatitis vary from diffuse, brawny scaling to focal areas of thick, oily, yellow crusts with underlying erythema. The external auditory canals, eyebrows, eyelids, and intertriginous areas may be involved as well. Pruritus may be minimal or severe.

Laboratory and Imaging Studies

Laboratory studies and imaging studies are not necessary to diagnose seborrheic dermatitis. Fungal cultures and potassium hydroxide studies may be necessary to help differentiate seborrheic dermatitis of the scalp from tinea capitis (see [Chapter 98](#)).

Differential Diagnosis

Seborrheic dermatitis in an infant may be difficult to differentiate from atopic dermatitis, and in fact, some cases may represent an overlap. In a teenager, seborrheic dermatitis of the scalp and psoriasis of the scalp may have very similar clinical findings; it may be very difficult to differentiate the two disorders, especially if there are no other cutaneous findings to provide additional clues. Intractable, severe, generalized seborrheic dermatitis suggests

Langerhans cell histiocytosis. Intractable seborrheic dermatitis, accompanied by chronic diarrhea and failure to thrive, suggests erythroderma desquamativum (Leiner disease) or acquired immunodeficiency syndrome (AIDS).

Treatment

Seborrheic dermatitis of the scalp is usually asymptomatic and generally does not require treatment. Minor amounts of scale can be removed easily by frequent shampooing. For infants with cradle cap, oil (such as mineral oil or olive oil) may be gently massaged into the scalp and left on for a few minutes before gently brushing out the scale and shampooing. Daily shampooing with ketoconazole, zinc pyrithione, selenium sulfide, or salicylic acid shampoos can treat scalp scale. Seborrheic dermatitis with inflamed lesions responds rapidly to treatment with low-potency steroids two times daily.

The response to treatment is usually rapid. Secondary bacterial infection can occur but is uncommon. Intractable disease and other complications warrant further evaluation for other etiologies.

Prognosis

Cradle cap is self-limited and resolves during the first year of life. Seborrheic dermatitis does not cause permanent hair loss. For teenagers, continued use of an antiseborrheic shampoo is often required for control of dandruff.

Prevention

Frequent shampooing, especially with early signs of seborrheic dermatitis, may help prevent progression.

Other Papulosquamous Dermatoses

Pityriasis Rosea

Pityriasis rosea is a benign, self-limited eruption that may occur at any age, with peak incidence during adolescence. A solitary 2- to 5-cm, pink, oval patch with central clearing, the so-called **herald patch**, is the first manifestation of the eruption. The herald patch typically is found on the trunk or proximal thigh and is often misdiagnosed as fungal or eczematous in origin. One to 2 weeks later, a

generalized eruption occurs on the torso and proximal extremities. Multiple 0.5- to 2-cm, oval to oblong, red or tan macules with a fine, bran-like scale are characteristically arranged parallel to skin tension lines (**Christmas-tree pattern**). Rarely the eruption may have an inverse distribution involving the axillae and groin or a papular or papulovesicular appearance. Mild prodromal symptoms may be present with the appearance of the herald patch, and pruritus is present in 25% of cases. The eruption lasts 4-14 weeks, with gradual resolution. Residual hyperpigmentation or hypopigmentation can take additional months to clear. Treatment is unnecessary, though pruritus can be managed with oral antihistamines, phototherapy, and low-potency topical corticosteroids.

Psoriasis

Psoriasis is a common papulosquamous condition characterized by well-demarcated, erythematous, scaling papules and plaques. Psoriasis occurs at all ages, including infancy, with onset of 30% of cases during childhood. The disease is characterized by a chronic and relapsing course, although spontaneous remissions can occur. Infections (especially *Streptococcus pyogenes*), stress, trauma, and medications may cause disease exacerbations. Various subtypes of psoriasis exist. The most common variety is **plaque-type psoriasis (psoriasis vulgaris)**, which can be localized or generalized. The lesions consist of round, well-demarcated, red plaques measuring 1- to 7-cm with micaceous scale, which is distinctive in its thick, silvery appearance with pinpoint bleeding points revealed on removal of the scales (**Auspitz sign**). The lesions of psoriasis have a distinctive distribution involving the extensor aspect of the elbows and knees, posterior occipital scalp, periumbilical region, lumbosacral region, and intergluteal cleft. Children often have facial lesions involving the superomedial aspect of the eyelids. Nail plate involvement is common and includes pitting, onycholysis, subungual hyperkeratosis, and oil staining (reddish brown subungual macular discoloration). **Guttate** (numerous small papules and plaques diffusely distributed on the torso), **erythrodermic** (covering large body surface areas), **inverse** (moist red patches affecting body folds), and **pustular** forms may occur.

The foundation of therapy is topical corticosteroids. Treatment of psoriasis with oral corticosteroids can induce pustular psoriasis and should be avoided. Because of the risk of atrophy, striae, and telangiectases, especially when potent fluorinated corticosteroid preparations are administered long term, the goal is to

use the least potent corticosteroid necessary. Topical vitamin D analogs, salicylic acid, and tar preparations are useful adjuvants to topical corticosteroids. Phototherapy with ultraviolet B (UVB) light can be useful as secondary therapy in older children. Extensive plaque or guttate, erythrodermic, and pustular psoriasis may necessitate systemic treatments with immune suppressive medication (methotrexate, cyclosporine, tumor necrosis factor- α antagonists). Disease triggers such as infection or medications should be identified and removed.

CHAPTER 193

Pigmented Lesions

Birthmark is a term that describes congenital anomalies of the skin. It should not be used as a definitive diagnosis because congenital skin lesions vary greatly in their appearance and prognosis. The differential diagnosis of various birthmarks is listed in [Table 193.1](#).

TABLE 193.1

Common Birthmarks

COLOR/LESION	BIRTHMARK	LOCATION	OTHER FEATURES
Brown/macule or patch	Café-au-lait macule	Variable	May be associated with genetic syndromes
Brown (<20 cm)/patch or plaque	Congenital melanocytic nevus	Variable	Low risk of melanoma
Brown (>20 cm)/patch or plaque	Giant congenital melanocytic nevus	Trunk most common	Risk of melanoma and neuromelanosis
Brown or skin-colored/patch or plaque	Epidermal nevus	Variable, trunk and neck	May enlarge with time
Red/patch	Port-wine stain (nevus flammeus)	Variable, face most common	May be associated with Sturge-Weber syndrome
Red/patch	Salmon patch (nevus simplex)	Glabella, eyelids, nape of neck	Improves or resolves with time
Red/papule or plaque	Hemangioma	Variable	May be associated with liver

			hemangiomas, airway hemangiomas, and PHACE syndrome
Gray-blue/patch	Dermal melanosis	Lower trunk (Mongolian spot); face (nevus of Ota); posterior shoulder (nevus of Ito)	Nevus of Ota may be associated with ocular pigmentation
Blue-purple/plaque	Venous, lymphatic, or mixed malformation	Variable	Intermittent swelling and pain
Yellow-orange/plaque	Nevus sebaceus	Head and neck	Malignant and benign tumors may arise within
Yellow-orange/papule	Juvenile xanthogranuloma	Head and neck most common	Spontaneously involutes
Yellow-brown/papule or plaque	Mastocytoma	Variable	Spontaneously involutes
Hypertrichosis/plaque	Smooth muscle hamartoma	Trunk	
Hypertrichosis/tumor	Plexiform neurofibroma	Trunk most common	Associated with neurofibromatosis type 1
White/patch	Nevus anemicus	Variable	Surrounding redness and telangiectasia
White/patch	Nevus depigmentosus	Variable	

Dermal Melanosis

The most frequently encountered pigmented lesion is **dermal melanosis**, which occurs in 70-90% of African-American, Hispanic, Asian, and Native American infants and in approximately 5% of white infants. This is a congenital lesion caused by entrapment of melanocytes in the dermis during their migration from the neural crest into the epidermis. Although most of these lesions are found in the lumbosacral area (Mongolian spot), they also occur at other sites, such as the buttocks, flank, extremities, or rarely, the face (Fig. 193.1). Single or multiple, poorly demarcated, gray-blue patches up to 10 cm in size may be present. Most lesions gradually disappear during the first few years of life; aberrant lesions in unusual sites are more likely to persist.

FIGURE 193.1 Dermal hypermelanosis (back).

Café-Au-Lait Macules

Café-au-lait macules are pigmented macules or patches, which may be present in a newborn but tend to develop during childhood (Fig. 193.2). They range in color from very light brown to a chocolate brown. Up to five café-au-lait macules are found in 1.8% of newborns and 25-40% of normal children, and have no significance. Children with six or more café-au-lait macules (0.5 cm in diameter before puberty or greater than 1.5 cm in diameter after puberty), especially when accompanied by **axillary or inguinal freckling**, should be evaluated carefully for additional stigmata of neurofibromatosis type 1. Other disorders also associated with café-au-lait macules include the other forms of neurofibromatosis, Legius syndrome, tuberous sclerosis, McCune-Albright syndrome, Noonan syndrome, and Russell-Silver syndrome.

FIGURE 193.2 Café-au-lait spots (leg).

Congenital Melanocytic Nevi

Approximately 1-2% of newborns have **congenital melanocytic nevi**. Smaller lesions (as opposed to giant pigmented nevi) are brown patches or plaques, often with an oval or lancet configuration. Lesions may resemble café-au-lait macules initially, but darker pigmentation, variegated speckles, textural changes, and elevation develop with time and help to differentiate these lesions (Fig. 193.3). Thick, dark, coarse hair frequently is associated with congenital melanocytic nevi (Fig. 193.4). These lesions vary in site and size but are most often solitary. Congenital melanocytic nevi pose a very slightly increased risk for the development of malignant melanoma, usually during adulthood. Surgical removal may be considered to improve the cosmetic appearance of the patient or to reduce the likelihood of malignant transformation, although some patients and physicians elect for observation. Excisional biopsy is indicated when malignant change is suspected.

FIGURE 193.3 Congenital melanocytic nevus (buttock).

FIGURE 193.4 Hairy congenital nevus.

Giant Congenital Melanocytic Nevi

Giant congenital melanocytic nevi are defined as nevi that would be approximately 20 cm in length in adulthood; in a neonate, this translates to 9 cm on the head and neck and 6 cm on the rest of the body. These lesions appear as color variegated, light brown to black patches or plaques, sometimes with smaller macules and papules (**satellite nevi**) in addition. The affected skin may be smooth, nodular, or leathery. Prominent, dark hypertrichosis is often present. **Neuromelanosis**, the presence of melanocytes in the central nervous system, may be associated with giant congenital melanocytic nevi. Affected patients may be asymptomatic or have hydrocephalus and seizures; in symptomatic patients, death often results during early childhood. **Malignant melanoma** develops in

approximately 2-10% of patients with giant congenital melanocytic nevi, in either the cutaneous lesion or the neural melanocytes. In contrast to small and medium congenital melanocytic nevi, melanoma is more likely to develop during childhood. Because of the incidence of malignant degeneration and extensive deformity, surgical excision should be considered for resectable lesions. The use of tissue expansion techniques has greatly improved the capability for surgical removal of large lesions.

Acquired Melanocytic Nevi

Acquired melanocytic nevi are common skin lesions. Melanocytic nevi may occur at any age; however, the lesions develop most rapidly in prepubertal children and teenagers. Melanocytic nevi are well-delineated, round to oval, brown macules and papules. Lesions are most common on the face, upper torso, and arms. Family history, fair skin, and sun exposure are considered major risk factors. Irregular pigmentation, rapid growth, bleeding, and a change in configuration or borders suggest signs of malignant degeneration and biopsy should be performed. Malignant melanoma is rare in childhood; however, there is an alarming increase in incidence in adolescence, especially in those who use indoor tanning. Education of parents and children regarding the risks of sun exposure, appropriate sun protection, and recognition of worrisome lesions is important.

CHAPTER 194

Vascular Anomalies

Vascular anomalies can be divided into two major categories: tumors and malformations. Vascular tumors are characterized by hypercellularity, proliferation, and growth. Vascular malformations, however, are developmental defects derived from the capillary, venous, arterial, or lymphatic vessels. In contrast to hemangiomas, vascular malformations remain relatively static and grow very slowly over time. Differentiating between these entities is important because they have different prognoses and clinical implications.

Vascular Tumors

Infantile Hemangiomas

Decision-Making Algorithms

Neck Masses
Stridor

Infantile hemangiomas are the most common soft tissue tumors of infancy, occurring in approximately 5-10% of 1-year-old infants. In newborns, hemangiomas may originate as a pale white macule with threadlike telangiectasia. When the tumor proliferates, it assumes its most recognizable form as a bright red, lobulated plaque or nodule (superficial type, [Fig. 194.1](#)). Hemangiomas that lie deeper in the skin are soft, warm masses with a blue discoloration (deeper type). Frequently, hemangiomas have both a superficial and a deep component (mixed type). They range from a few millimeters to several centimeters in diameter and are usually solitary; 20% of affected children have multiple lesions. Hemangiomas occur predominantly in females (3 : 1) and have an increased incidence in low birth weight infants. Approximately 55% are present at birth; the rest develop in the first weeks of life. Superficial hemangiomas reach their maximal size by 6-8 months, but deep hemangiomas may grow for 12-14 months. They then undergo slow, spontaneous resolution, which takes 3-10 years.

FIGURE 194.1 Hemangioma (chest).

Despite the benign nature of most cutaneous hemangiomas, there may be the risk of functional compromise or permanent disfigurement, depending on the location and extent. Ulceration, the most frequent complication, can be painful and increases the risk of infection, hemorrhage, and scarring. Areas frequently associated with complications include the periorcular region, lip, nasal tip, beard, face (large lesions), groin, and buttocks.

Periorbital hemangiomas pose considerable risk to vision and should be monitored carefully. Amblyopia can result from the hemangioma, causing obstruction of the visual axis or pressure on the globe, resulting in astigmatism. If there is any concern, the patient should have urgent evaluation by an ophthalmologist. Treatment may be indicated to prevent blindness. **Subglottic hemangiomas** manifest as hoarseness and stridor; progression to respiratory failure may be rapid. Symptomatic airway hemangiomas develop in more than 50% of infants with extensive facial hemangiomas on the chin and jaw (beard distribution); any infant with a beard hemangioma should be urgently referred for laryngoscopy. Multiple cutaneous (diffuse hemangiomatosis) and large facial hemangiomas may be associated with visceral hemangiomas. Extensive cervicofacial hemangiomas may be associated with multiple anomalies, including posterior fossa malformations, hemangiomas, arterial anomalies of the cerebrovasculature, coarctation of aorta and cardiac defects, and eye abnormalities (**PHACE syndrome**). **Lumbosacral hemangiomas** suggest an occult spinal dysraphism with or without anorectal and urogenital anomalies. Magnetic resonance imaging of the spine is indicated in all patients with large midline cutaneous hemangiomas in the lumbosacral area.

Most hemangiomas do not necessitate medical intervention and involute spontaneously; however, if complications arise and treatment is warranted, oral propranolol or topical timolol are the mainstays of therapy.

Pyogenic Granuloma

A pyogenic granuloma is an acquired, benign vascular tumor commonly seen in children. Initially, the lesions appear as pink-red papules that often arise after minor trauma, growing rapidly over a period of weeks into a bright red, vascular, often pedunculated papule measuring 2-10 mm. The lesions often have the appearance of granulation tissue and are very friable. They may occur anywhere on the body, but the head, neck, and upper extremities are most commonly affected. When traumatized, these lesions may bleed profusely, often requiring emergent medical attention. Surgical excision is the most definitive treatment option, although pulsed dye laser can be useful for very small lesions.

Vascular Malformations

Port-Wine Stain

Port-wine stains (nevus flammeus, capillary malformation) are malformations of the superficial capillaries of the skin. These lesions are present at birth and should be considered permanent developmental defects. They do not enlarge after birth; any apparent increase in size is caused by growth of the child. A port-wine stain may be localized to any body surface, but facial lesions are the most common. They are pink-red, sharply demarcated macules and patches in infancy (Fig. 194.2). With time, they darken to a purple or *port-wine* color and may develop a pebbly or slightly thickened surface. Vascular blebs may form within the lesions and become symptomatic or bleed. The most successful treatment modality in use is the pulsed dye laser, which can result in 80-90% improvement in these lesions after a series of treatment sessions and can avoid future complications associated with vascular dilation. Treatment is more effective if undertaken in infancy. Overgrowth of underlying bone can occur and is frequently seen with facial lesions. Affected patients often need maxillofacial intervention from malalignment that develops.

FIGURE 194.2 Port-wine stain (face).

Most port-wine stains occur as isolated defects and do not indicate systemic malformations. Rarely, they may suggest ocular defects or specific neurocutaneous syndromes. **Sturge-Weber syndrome** (encephalotrigeminal angiomatosis) may occur with a facial port-wine stain, usually in the cutaneous distribution of the first branch of the trigeminal nerve. Other features include leptomeningeal angiomatosis, mental retardation, seizures, hemiparesis contralateral to the facial lesions, ipsilateral intracortical calcification, and frequent ocular manifestations such as buphthalmos, glaucoma, angioma of the choroid, hemianoptic defects, and optic atrophy. Anticonvulsant therapy and neurosurgical procedures have been of value in some patients. Glaucoma can occur in association with port-wine stains located on the eyelid, even in the absence of Sturge-Weber syndrome, and these patients need lifelong monitoring of ocular pressures. **Klippel-Trénaunay-Weber** syndrome is characterized by the triad of capillary and venous malformations, venous varicosities, and hyperplasia of the soft tissues—and often bone—of the involved area. The lower limb is most commonly affected. A port-wine stain overlying the spine may rarely be a marker of spinal dysraphism or an intraspinal vascular malformation.

Nevus Simplex

A nevus simplex (salmon patch, stork bite, angel's kiss) is a vascular birthmark

that is present in 70% of normal newborns. They are red, irregular, macular patches resulting from dilation of dermal capillaries and are usually found on the nape of the neck, the eyelids, and the glabella. Most of the facial lesions fade by 1 year of age, but lesions on the neck may persist for life. Surveys of adult populations confirm the persistence of the nuchal lesions in approximately 25% of the population.

CHAPTER 195

Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis

Erythema multiforme (EM), Stevens-Johnson syndrome (SJS), and toxic epidermal necrolysis (TEN) are acute hypersensitivity reactions characterized by cutaneous and mucosal necrosis. These syndromes represent a hypersensitivity reaction to a precipitating cause, usually infectious organisms or drugs. These disorders were historically thought to represent a spectrum of the same disease process, and inconsistent use of these disease names led to further confusion. A consensus definition was published in 1993, and current literature favors that EM is distinct from the SJS/TEN spectrum of disease. The differential diagnosis of vesiculobullous eruptions is listed in [Table 195.1](#).

TABLE 195.1

Vesiculobullous Eruptions

ENTITY	CLINICAL CLUES
INFECTIOUS	
Bacterial	
Staphylococcal scalded skin syndrome	Generalized, tender erythema Nikolsky sign Occasionally associated with underlying infection such as osteomyelitis, septic arthritis, pneumonia Desquamation and moist erosions observed, especially in intertriginous areas

	More common in children younger than 5 yr of age
Bullous impetigo	Localized blisters from staphylococcal infection
Viral	
Herpes simplex	Grouped vesicles on erythematous base May be recurrent at same site—lips, eyes, cheeks, hands Reactivated by fever, sunlight, trauma, stress
Varicella	Crops of vesicles on erythematous base (“dewdrops on rose petal”) Highly contagious May see multiple stages of lesions simultaneously Associated with fever
Herpes zoster	Grouped vesicles on erythematous base limited to one or several adjacent dermatomes Thoracic dermatomes most commonly involved in children Usually unilateral Burning, pruritus
Hand-foot-mouth syndrome (coxsackievirus infection)	Prodrome of fever, anorexia, sore throat Oval blisters in acral distribution, usually few in number Shallow, oral erosions on erythematous base in oral mucosa Highly infectious Peak incidence in late summer and in fall
HYPERSENSITIVITY	
Erythema multiforme	Target lesions on acral sites May have involvement of mucosal surfaces Associated with herpes simplex virus infection
Stevens-Johnson syndrome and toxic epidermal necrolysis	Prodrome of fever, headache, malaise, sore throat, cough, vomiting, diarrhea Extensive epidermal necrosis with mucosal involvement Frequently related to drugs (e.g., sulfonamides, anticonvulsants) Nikolsky sign
EXTRINSIC	
Contact dermatitis	Irritant or allergic Distribution dependent on the irritant or allergen Distribution helpful in identifying cause
Insect bites	Occur occasionally following flea or mosquito bites May be hemorrhagic bullae Often in linear or irregular clusters Very pruritic
Burns	Irregular shapes and configurations May be suggestive of abuse Bullae with second- and third-degree injuries
Friction	Usually on acral surfaces May be related to footwear Often activity-related
MISCELLANEOUS	
Urticaria pigmentosa	Red-brown macules and papules; bullous lesions are rare Darier sign

	Lesions appear in infancy and spontaneously resolve in childhood
Miliaria crystallina	Clean, 1- to 2-mm superficial vesicles occurring in crops Rupture spontaneously Intertriginous areas, especially neck and axillae
Hereditary: epidermolysis bullosa, incontinentia pigmenti, epidermolytic hyperkeratosis	
Autoimmune: linear immunoglobulin A disease, bullous pemphigoid, dermatitis herpetiformis	

Modified from Nopper AJ, Rabinowitz RG. Rashes and skin lesions. In: Kliegman RM, ed. *Practical Strategies in Pediatric Diagnosis and Therapy*. Philadelphia: WB Saunders; 1996.

Decision-Making Algorithm

Vesicles and Bullae

Erythema Multiforme

EM is a common, self-limiting, acute hypersensitivity syndrome characterized by the abrupt onset of round, deep red, well-demarcated macules and papules with a dusky gray or bullous center. The size may range from a few millimeters to a few centimeters, but most lesions are approximately 1 cm in diameter. The classic **target lesion** consists of three concentric rings; the outermost is red, the intermediate is white, and the center is a dusky red or purple. These can progress to edematous plaques or bullae. If blistering occurs, it is circumscribed and involves less than 10% of the body surface area. Cutaneous lesions are symmetrically distributed and commonly involve acral areas such as the hands, feet, elbows, and knees. Involvement of the ocular, oral, and genital mucosa can be seen in some cases.

Most EM cases in children are precipitated by herpes simplex virus infection, although the infection may no longer be apparent by the time EM develops. Other infectious organisms may also trigger EM. Symptomatic treatment is usually sufficient. Oral antihistamines help suppress pruritus, stinging, and burning. The use of systemic corticosteroids is controversial but may be considered for severe mucosal disease. Antiviral medications targeting herpes simplex virus do not alter the course of the EM, although children with recurrent EM may be candidates for prophylactic antivirals. The prognosis is excellent,

with most lesions lasting no more than 2 weeks. Healing occurs without scarring.

Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis

SJS, TEN, and SJS/TEN overlap are severe, life-threatening disorders thought to represent the same disease continuum. They are usually preceded by a prodrome of fever, malaise, and upper respiratory symptoms 1-14 days before the onset of cutaneous lesions. Red macules appear suddenly and tend to coalesce into large patches, with a predominant distribution over the face and trunk. Atypical targets may be present, causing diagnostic confusion initially with EM, although the atypical targets lack the characteristic three zones. Skin lesions evolve rapidly into bullae and areas of necrosis. SJS is defined as epidermal detachment of less than 10% of the body surface area, whereas SJS/TEN overlap has 10-30% and TEN has greater than 30% body surface area involvement. Any mucosal surface may be involved. The upper and lower lips are generally swollen and bright red with erosions and hemorrhagic crusts. The remainder of the oral mucosa may also be involved. Early in the disease process, there is bilateral conjunctival injection; this usually progresses to conjunctival erosions. There may be erosions of the penile, vaginal, or perianal mucosa. Urogenital, esophageal, and tracheal surfaces may be involved in the most severe cases.

Drugs are the most common causes of SJS/TEN in children. The most common drugs implicated are nonsteroidal antiinflammatory drugs, sulfonamides, anticonvulsants, and antibiotics. Other precipitating factors are viral infections, bacterial infections, syphilis, and deep fungal infections.

SJS/TEN can occur at any age. The diagnosis of SJS/TEN is clinical; there are no diagnostic tests. Confusion with EM, Kawasaki disease, and bacterial toxin-mediated diseases (scarlet fever, toxic shock syndrome, and staphylococcal scalded skin syndrome) may occur. Patients with Kawasaki disease have conjunctival injection and hyperemia of the mucous membranes. Necrosis of the mucosal surfaces does not occur; blistering, erosions, and severe crusting are not observed. The mucosal changes of staphylococcal scalded skin syndrome are minor, and frank erosions are not present. The blistering of the skin is more superficial and favors intertriginous regions. *Mycoplasma pneumoniae* may induce a SJS/TEN-like disorder that is newly recognized as a distinct disease called mycoplasma pneumonia-associated mucocutaneous disease.

SJS/TEN is a serious illness with a mortality rate as high as 35% for severe

cases of TEN. Prompt discontinuation of the offending agent is key. No controlled clinical trials regarding medical therapy exist, although early initiation of intravenous immunoglobulin has been proposed. Supportive care is another essential component of therapy. A multidisciplinary care team is often necessary. Sepsis is the major cause of morbidity and mortality, so meticulous wound care is crucial, with stringent surveillance for cutaneous infections and use of antibiotics as warranted. Parenteral or nasogastric feeding should be instituted early to accelerate the healing process. Careful fluid management and monitoring of electrolytes are critical. Ocular complications are a major cause of long-term morbidity, making early involvement of an ophthalmologist important.

CHAPTER 196

Cutaneous Infestations

Arthropods are common in the environment. Although many can bite or sting humans, only a few infest humans. Arachnids (mites) are the most common, parasitizing humans and animals by burrowing into the skin and depositing eggs within the skin.

Scabies

Decision-Making Algorithm

Vesicles and Bullae

Scabies is caused by the mite *Sarcoptes scabiei*. The female mite burrows into the epidermis and deposits her eggs, which mature in 10-14 days. The disease is highly contagious, as infested humans do not manifest the typical signs or symptoms for 3-4 weeks, facilitating transmission. An immunocompetent person with scabies typically harbors only 10-20 mites.

The clinical presentation varies depending on the age of the patient, duration of infestation, and immune status of the patient. Severe and paroxysmal itching

is the hallmark, with complaints of itching that is frequently worse than the eruption would suggest. Most children exhibit an eczematous eruption composed of red, excoriated papules and nodules. The classic linear papule or burrow is often difficult to find. Distribution is the most diagnostic finding; the papules are found in the axillae, umbilicus, groin, penis, instep of the foot, and web spaces of the fingers and toes (Fig. 196.1). Infants infested with scabies have diffuse erythema, scaling, and pinpoint papules. Pustules, vesicles, and nodules are much more common in infants and may be more diffusely distributed. The face and scalp usually are spared in adults and older children, but these areas are usually involved in infants. Nodular lesions may represent active infection or prolonged hypersensitivity lesions following resolution of infestation. Immunocompromised or neurologically impaired persons may develop a severe form of the disease known as **Norwegian** or **crusted scabies**, with infestation of 2 million live mites at one time.

FIGURE 196.1 Scabies (hand).

The diagnosis of scabies can be confirmed by microscopic visualization of the mite, eggs, larvae, or feces in scrapings of papules or burrows examined under oil immersion. Skin biopsy is rarely necessary but may be useful if lesions have become nodular.

Curative treatment is achieved by a 12-hour (overnight) application of permethrin 5% cream applied to the entire body. Because permethrin is not effective against the eggs, the treatment should be repeated 1 week later to kill any subsequently hatched larvae. All household members and close contacts

should be treated simultaneously, even if asymptomatic. Bed linens, towels, and clothes worn for the previous 2 days before treatment should be machine-washed in hot water and machine-dried using high heat; heat is the most effective scabicide. Items that are not washable may be dry-cleaned or placed in a sealed plastic bag for 7 days.

Secondary bacterial infection may occur but is uncommon. In contrast to the pediculoses, scabies is not a vector for infections. Pruritus may persist for 7-14 days after successful therapy because of a prolonged hypersensitivity reaction, which does not indicate treatment failure. Inadequate treatment or reinfestation should be suspected if new lesions develop after treatment.

Pediculoses

Three species of lice infest humans: *Pediculus humanus capitis*, the **head louse**; *Phthirus pubis*, the **pubic louse** or **crab louse**; and *Pediculus humanus humanus* (also known as *Pediculus humanus corporis*), the **body louse**. Lice are wingless insects 2-4 mm in length that cannot fly or jump. Transmission usually occurs by direct contact with another infested individual. Indirect spread through contact with fomites or personal belongings, such as hairbrushes, combs, or caps, is much less frequent.

Pediculosis differs from scabies infestation in that the louse resides on the hair or clothing and intermittently feeds on the host by piercing the skin. The *bite* causes small urticarial papules and itching. Head lice live close to the skin and may live for 30 days, depositing 100-400 eggs as **nits** on hair shafts, usually within 6 mm of the scalp.

Head lice are seen most frequently in early school-age children. Head lice infestations are unrelated to hygiene and are not more common among children with long hair or with dirty hair. It is estimated that 6-12 million persons in the United States and 1-3% of persons in developed countries are infested with head lice each year. In the United States, head lice infestation is rare among African Americans and may be more common in girls, which is attributed to their tendency to play more closely with one another than boys do.

Pubic lice are transmitted by sexual contact. Their presence in children may be a sign of child abuse. Body lice are firm evidence of poor hygiene, such as infrequent washing and clothing changes.

Itching, if present, is the primary symptom. Pediculosis capitis usually causes pruritus behind the ears or on the nape of the neck, or a crawling sensation in the

scalp. Pediculosis pubis usually causes pruritus in the groin. Eyelash involvement in children may cause crusting and blepharitis. Pediculosis corporis causes pruritus that, because of repeated scratching, may result in lichenification or secondary bacterial infection. Excoriations and crusting, with or without associated regional lymphadenopathy, may be present.

Infestation with the head louse may be asymptomatic and has little morbidity. The diagnosis can be confirmed by visualizing a live louse. A fine-toothed comb to trap lice is more effective than simply looking at the hair. Wet combing is more time-consuming, but dry combing produces static that may propel the lice away from the comb.

Nits represent the outer casing of the louse ova. Viable nits have an intact operculum (cap) on the nonattached end and a developing louse within the egg. **Brown nits** located on the proximal hair shaft suggest active infestation. **White nits** located on the hair shaft 4 cm or farther from the scalp indicate previous infestation. Because nonviable nits can remain stuck in the hair for weeks to months after an infestation has resolved, many children with nits do not have active lice infestation.

The treatment of head lice is controversial because of resistance to many established options. Permethrin (1%) and pyrethrin-based products (0.17-0.33%) (pyrethroids) are over-the-counter options. Because 20-30% of eggs may survive one treatment, a second treatment should be applied in 9-10 days. Drug resistance to pyrethroids is on the rise. Malathion (0.5%) lotion, benzyl alcohol (5%) lotion, spinosad (0.9%) topical suspension, and ivermectin (0.5%) lotion may be used as alternatives for resistant cases.

Everyone in the family should be checked for head lice and treated if live lice are found to reduce the risk of reinfestation. Bed linens, towels, and clothes worn for the previous 2 days before treatment should be machine-washed in hot water and machine-dried using high heat. Items that are not washable may be dry-cleaned or placed in a sealed plastic bag for 2 weeks. Brushes and combs should be soaked in dish detergent or rubbing alcohol for 1 hour. Rugs, furniture, mattresses, and car seats should be vacuumed thoroughly.

Manual removal of nits after treatment is not necessary to prevent spread. Children treated for head lice should return to school immediately after completion of the first effective treatment or first wet combing, regardless of the presence of remaining nits. There is no evidence that *no nit* or *nit-free* policies reduce transmission of head lice. If required for return to school, nit removal is best achieved by wetting the hair and combing with a fine-toothed metal comb.

Excoriations can become secondarily infected with skin bacteria, usually *Staphylococcus* and *Streptococcus*. The body louse functions as a vector for potentially serious infectious diseases, including **epidemic typhus**, caused by *Rickettsia prowazekii*; **louse-borne relapsing fever**, caused by *Borrelia recurrentis*; and **trench fever**, caused by *Bartonella quintana*. These louse-borne infections are rare in the United States. In contrast to body lice, head lice and pubic lice are not associated with transmission of other infections.

Pearls for Practitioners

Chapter 188

Dermatology Assessment

- Common cutaneous conditions in pediatrics include atopic dermatitis, impetigo, tinea capitis, acne vulgaris, verrucae vulgaris, and seborrheic dermatitis.
- Obtaining a thorough history with regard to the age of the patient, onset, duration, progression, associated cutaneous symptoms (pain, pruritus), previous treatments, and associated systemic signs or symptoms (fever, malaise, weight loss) is important.
- Characterizing and describing the primary and secondary skin lesions is important for diagnosis and communication with other health care providers.

Chapter 189

Acne

- Acne vulgaris is the most common skin condition in adolescents.
- The pathogenesis of acne involves increased sebum production, hyperkeratosis, and bacterial proliferation. Treatment is aimed at decreasing these factors.

Chapter 190

Atopic Dermatitis

- Atopic dermatitis is the most common skin disease in children and is associated with allergic rhinitis, asthma, and food allergies. Both genetic and environmental factors play a role in the development of atopic dermatitis.
- Treatment of atopic dermatitis is aimed at decreasing inflammation.
- Complications of atopic dermatitis include secondary impetigo and eczema herpeticum.

Chapter 191

Contact Dermatitis

- Contact dermatitis is a delayed type IV hypersensitivity reaction that occurs when the skin is directly exposed to irritating chemicals or substances (irritant contact dermatitis) or allergens in predisposed individuals.
- Diaper dermatitis is commonly due to irritant contact dermatitis from urine and feces, frequently complicated by secondary candida and bacterial infections.
 - Differential diagnosis for diaper dermatitis includes psoriasis, seborrheic dermatitis, and Langerhans cell histiocytosis. Referral to a pediatric dermatologist should be made in recalcitrant, difficult-to-treat cases.
- Treatment of contact dermatitis is generally avoidance of irritating substances, allergens, barriers, and topical corticosteroids.

Chapter 192

Seborrheic Dermatitis

- Seborrheic dermatitis is a common, chronic inflammatory disease that presents as cradle cap or dermatitis in intertriginous areas in infants and dandruff in adolescents.
- The pathogenesis of seborrheic dermatitis is unclear, but it is theorized that there is an abnormal inflammatory response to commensal *Malassezia* species in sebum-rich areas.
- Treatment for seborrheic dermatitis is generally not needed, but oils, shampoos, and topical steroids can be used if needed.
- Pityriasis rosea is a benign, self-limited eruption that starts with a herald patch, which precedes a generalized eruption on the torso and extremities in a Christmas-tree pattern.

- Psoriasis is a common papulosquamous disorder with various subtypes, including plaque-type psoriasis (psoriasis vulgaris), guttate, erythrodermic, and pustular.
 - Treatments for psoriasis include topical corticosteroids, topical vitamin D analog, salicylic acid, tar preparations, phototherapy, and systemic immunosuppressants.

Chapter 193

Pigmented Lesions

- Dermal melanosis is the most frequently encountered pigmented lesion. The gray-blue lesions are typically found in the lumbosacral area, buttocks, flank, extremities, or rarely, the face.
- Café-au-lait macules are light- to chocolate-brown pigmented macules or patches that can be found in normal newborns and children.
 - Children with six or more café-au-lait macules (0.5 cm in diameter before puberty or greater than 1.5 cm in diameter after puberty), especially when accompanied by axillary or inguinal freckling, should be evaluated carefully for additional stigmata of neurofibromatosis type 1.
 - Other disorders also associated with café-au-lait macules include the other forms of neurofibromatosis, Legius syndrome, tuberous sclerosis, McCune-Albright syndrome, Noonan syndrome, and Russell-Silver syndrome.
- There is an increased risk of neuromelanosis and malignant melanoma when congenital melanocytic nevi are giant (>20 cm in length in adulthood, or 9 cm on the head and neck and 6 cm on the rest of the body in a neonate).

Chapter 194

Vascular Anomalies

- Infantile hemangiomas are the most common soft tissue tumors of infancy and present as superficial, deep, or mixed types.
 - They undergo spontaneous involution after a rapid growth phase.
 - They do not need to be treated unless they are symptomatic and/or pose risks that can lead to functional compromise or permanent disfigurement, in which case oral propranolol is the mainstay of therapy.
- Infantile hemangiomas can have visceral involvement and be associated with other underlying anomalies.
 - Evaluation for airway hemangiomas should be undertaken in infants with a beard hemangioma.
 - Large lumbosacral hemangiomas should be investigated with a magnetic resonance imaging (MRI) of the spine.

Chapter 195

Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis

- Erythema multiforme (EM) is a common, self-limiting, acute hypersensitivity syndrome characterized by the abrupt onset of round, deep red, well-demarcated macules and papules with a dusky gray or bullous center (targetoid).
 - EM can be precipitated by infections (most commonly herpes simplex virus) or medications.
- Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), and SJS/TEN overlap are severe, life-threatening disorders thought to represent the same disease continuum. They are precipitated by medications.

- SJS is defined as epidermal detachment of less than 10% of the body surface area, whereas SJS/TEN overlap has 10-30% and TEN has greater than 30% body surface area involvement.

Chapter 196

Cutaneous Infestations

- Scabies is caused by the mite *Sarcoptes scabiei*.
 - Curative treatment for scabies is achieved by a 12-hour (overnight) application of permethrin 5% cream applied to the entire body and repeated in 1 week. All household members and close contacts should be treated for scabies simultaneously, even if asymptomatic.
- Household treatment for scabies and pediculosis includes machine washing (in hot water) and machine drying (using high heat) all bed linens, towels, and clothes worn in the previous 2 days. Items that are not washable may be dry-cleaned or placed in a sealed plastic bag for 7 days (scabies) and 14 days (pediculosis).

SECTION 26

Orthopedics

Kevin D. Walter, J. Channing Tassone

Keywords for Section 26

Pediatric orthopedics; pediatric sports medicine; scoliosis; developmental dysplasia of the hip; fracture

CHAPTER 197

Orthopedics Assessment

To care for the pediatric patient, one must understand the growth and development of the musculoskeletal system as well as common orthopedic terms (Table 197.1). Providers should recognize common mechanisms for congenital and acquired orthopedic disorders (Table 197.2).

TABLE 197.1

Common Orthopedic Terminology

Abduction	Movement away from midline
Adduction	Movement toward or across midline
Apophysis	Bone growth center that has a muscular insertion but is not considered a growth plate (e.g., tibial tubercle)
Arthroscopy	Surgical exploration of a joint using an arthroscope
Arthroplasty	Surgical reconstruction of a joint
Arthrotomy	Surgical incision into a joint; an “open” procedure
Deformation	Changes in limb, trunk, or head due to mechanical force
Dislocation	Displacement of bones at a joint

Equinus	Plantar flexion of the forefoot, hindfoot, or entire foot
Femoral anteversion	Increased angulation of the femoral head and neck with respect to the frontal plane
Malformation	Defect in development that occurs during fetal life (e.g., syndactyly)
Osteotomy	Surgical division of a bone
Pes cavus	High medial arch of the foot
Pes planus	Flat foot
Rotation, internal	Inward rotation (toward midline)
Rotation, external	Outward rotation (away from midline)
Subluxation	Incomplete loss of contact between two joint surfaces
Tibial torsion	Rotation of the tibia in an internal or external fashion
Valgus/valgum	Angulation of a bone or joint in which the apex is toward the midline (e.g., knock-knee)
Varus/varum	Angulation of a bone or joint in which the apex is away from the midline (e.g., bowlegs)

TABLE 197.2

Mechanisms of Common Pediatric Orthopedic Problems

CATEGORY	MECHANISM	EXAMPLE(S)
CONGENITAL		
Malformation	Teratogenesis before 12 wk of gestation	Spina bifida
Disruption	Amniotic band constriction	Extremity amputation
	Fetal varicella infection	Limb scar/atrophy
Deformation	Neck compression	Torticollis
Dysplasia	Abnormal cell growth or metabolism	Osteogenesis imperfecta Skeletal dysplasias
ACQUIRED		
Infection	Pyogenic-hematogenous spread	Septic arthritis, osteomyelitis
Inflammation	Antigen-antibody reaction Immune mediated	Systemic lupus erythematosus Juvenile idiopathic arthritis
Trauma	Mechanical forces, overuse	Child abuse, sports injuries, unintentional injury, fractures, dislocations, tendinitis
Tumor	Primary bone tumor	Osteosarcoma
	Metastasis to bone from other site	Neuroblastoma
	Bone marrow tumor	Leukemia, lymphoma

Growth and Development

The ends of the long bones contain a much higher proportion of cartilage in the skeletally immature child than in an adult (Figs. 197.1 and 197.2). The high cartilage content allows for a unique vulnerability to trauma and infection (particularly in the metaphysis).

FIGURE 197.1 Schematic of long bone structure.

FIGURE 197.2 The ends of long bones at various ages. Lightly stippled areas represent cartilage composition, whereas heavily darkened areas are zones of ossification. (From Tachjidan MO. *Congenital Dislocation of the Hip*. New York: Churchill Livingstone; 1982:105.)

The physis is responsible for the longitudinal growth of the long bones. Articular cartilage allows the ends of the bone to enlarge and accounts for growth of smaller bones, such as the tarsals. The periosteum provides for

circumferential growth. Trauma, infection, nutritional deficiency (rickets), inborn errors of metabolism (mucopolysaccharidoses), and other disorders (renal tubular acidosis, hypothyroid) may affect each of the growth processes and produce distinct aberrations.

Developmental Milestones

Neurological maturation, marked by achievement of developmental motor milestones, is important for normal musculoskeletal development (see [Section 2](#)). A neurological disorder may cause a secondary musculoskeletal abnormality (e.g., extremity contractures in Duchenne muscular dystrophy). Thus normal motor development must be included in the definition of a normal musculoskeletal system.

Infants

Decision-Making Algorithms

In-Toeing, Out-Toeing, and Toe-Walking
Bowlegs and Knock-Knees

In utero positioning of the fetus may affect the angular and torsional alignment (temporary or permanent) of the skeletal system, especially of the lower extremity ([Fig. 197.3](#)). The newborn's hips are externally rotated. Pes planus and genu varum are common. Infants are usually born with a flexed posture, which usually decreases to neutral within the first 4-6 months. The foot is often flat and *tucked under* at birth; the ankle will be inverted, and the forefoot is adducted when compared with the hindfoot. The lateral border of the foot must straighten out, even with dorsiflexion, to be considered secondary to in utero positioning.

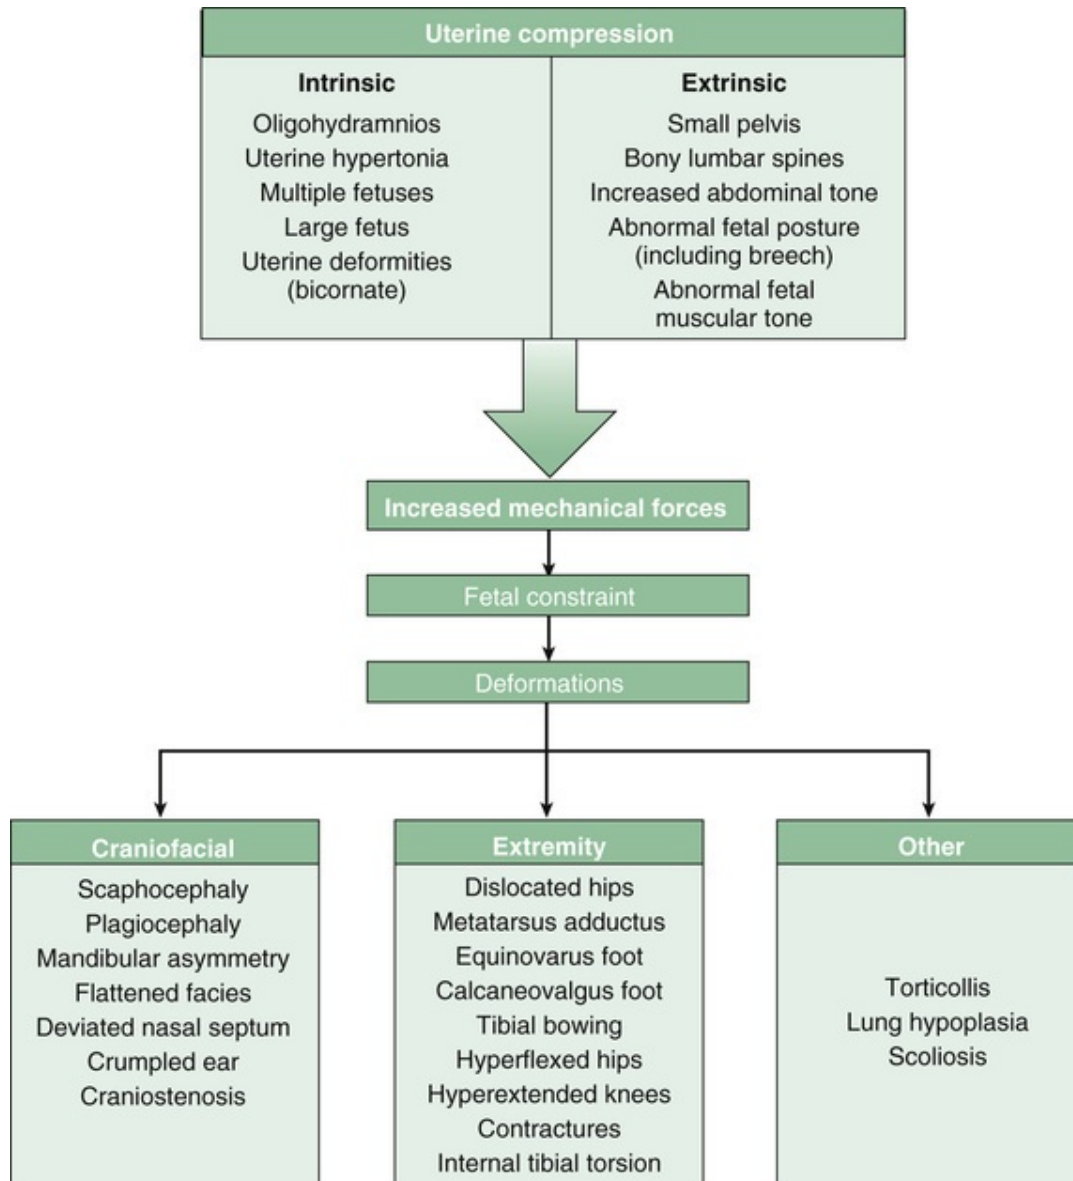

FIGURE 197.3 Deformation abnormalities resulting from uterine compression.

The head and neck may also be distorted by in utero positioning. The spine and upper extremities are less likely to be affected. By the age of 3-4 years, the effects of in utero positioning have usually resolved.

Gait

Normal gait has a stance phase and swing phase; each leg should have symmetrical timing with each phase. The stance phase represents 60% of the gait and begins with foot contact (usually the heel strike) and ends with the toe-off.

During the swing phase (40%), the foot is off the ground. The gait cycle is the interval between stance phases on the same limb.

Toddlers will generally walk independently by 18 months of age. Their externally rotated gait is usually inconsistent, is characterized by short, rapid steps, and does not have the reciprocal arm swing. Gait coordination improves over time, with a normal gait usually achieved by the time a child enters elementary school.

Decision-Making Algorithms

Limp
In-Toeing, Out-Toeing, and Toe-Walking

Limping Child

The differential diagnosis for a limping child is often categorized by age and presence or absence of a painful limp (Table 197.3). The gluteus medius muscle stabilizes the pelvis during the stance phase, preventing the pelvis from dropping toward the leg in swing phase. An **antalgic gait** is a painful limp; the stance phase and stride of the affected limb are shortened to decrease the discomfort of weight bearing on the affected limb. The **Trendelenburg gait** has a normal stance phase but excessive swaying of the trunk. **Waddling gait** refers to a bilateral decrease in function of the gluteus muscles.

TABLE 197.3

Differential Diagnosis of Limping in Children

AGE GROUP	DIAGNOSTIC CONSIDERATIONS
Early walker: 1-3 yr of age	<p><i>Painful limp</i></p> <ul style="list-style-type: none"> Septic arthritis and osteomyelitis Transient monoarticular synovitis Occult trauma (“toddler’s fracture”) Intervertebral diskitis Malignancy <p><i>Painless limp</i></p> <ul style="list-style-type: none"> Developmental dysplasia of the hip Neuromuscular disorder Cerebral palsy Lower extremity length inequality

Child: 3-10 yr of age	<p><i>Painful limp</i></p> <ul style="list-style-type: none"> Septic arthritis, osteomyelitis, myositis Transient monarticular synovitis Trauma Rheumatological disorders Juvenile idiopathic arthritis Intervertebral diskitis Malignancy <p><i>Painless limp</i></p> <ul style="list-style-type: none"> Developmental dysplasia of the hip Legg-Calve-Perthes disease Lower extremity length inequality Neuromuscular disorder Cerebral palsy Muscular dystrophy (Duchenne)
Adolescent: 11 yr of age to maturity	<p><i>Painful limp</i></p> <ul style="list-style-type: none"> Septic arthritis, osteomyelitis, myositis Trauma Rheumatological disorder Slipped capital femoral epiphysis: acute; unstable Malignancy <p><i>Painless limp</i></p> <ul style="list-style-type: none"> Slipped capital femoral epiphysis: chronic; stable Developmental dysplasia of the hip: acetabular dysplasia Lower extremity length inequality Neuromuscular disorder

Toe walking is a common complaint in early walkers. A physician should evaluate any child older than 3 years of age who still toe walks. Although this is most likely habit, a neuromuscular disorder (cerebral palsy, tethered cord), Achilles tendon contracture (heel cord tightness), or a leg-length discrepancy should be considered.

CHAPTER 198

Fractures

Fractures account for 10-15% of all childhood injuries. The anatomical, biomechanical, and physiological differences in children account for unique fracture patterns and management. Fracture terminology helps describe fractures ([Table 198.1](#)).

TABLE 198.1

Useful Fracture Terminology

Complete	The bone fragments separate completely
Incomplete	The bone fragments are still partially joined
Linear	Referring to a fracture line that is parallel to the bone's long axis
Transverse	Referring to a fracture line that is at a right angle to the bone's long axis
Oblique	Referring to a fracture line that is diagonal to the bone's long axis
Spiral	Referring to a twisting fracture
Comminution	A fracture that results in several fragments
Compaction	The bone fragments are driven into each other
Angulation	The fragments have angular malalignment
Rotation	The fragments have rotational malalignment
Shortening	The fractured ends of the bones overlap
Open	A fracture in which the bone has pierced the skin

The pediatric skeleton has a higher proportion of cartilage and a thicker, stronger, and more active periosteum capable of producing a larger callus more rapidly than in an adult. The thick periosteum may decrease the rate of displaced fractures and stabilize fractures after reduction. Because of the higher proportion of cartilage, the skeletally immature patient can withstand more force before deformation or fracture than adult bone. As children mature into adolescence, the rate of healing slows and approaches that of adults.

Pediatric Fracture Patterns

Buckle or torus fractures occur after compression of the bone; the bony cortex does not truly break. These fractures will typically occur in the metaphysis and are stable fractures that heal in approximately 4 weeks with immobilization. A common example is a fall onto an outstretched arm causing a buckle fracture in the distal radius.

Complete fractures occur when both sides of bony cortex are fractured. This is the most common fracture and may be classified as comminuted, oblique, transverse, or spiral, depending on the direction of the fracture line.

Greenstick fractures occur when a bone is angulated beyond the limits of plastic deformation. The bone fails on the tension side and sustains a bend deformity on the compression side. The force is insufficient to cause a complete fracture (Fig. 198.1).

FIGURE 198.1 The greenstick fracture is an incomplete fracture. (Modified from White N, Sty R. Radiological evaluation and classification of pediatric fractures. *Clin Pediatr Emerg Med.* 2002;3:94–105.)

Bowing fractures demonstrate no fracture line evident on radiographs, but the bone is bent beyond its limit of plastic deformation. This is not a true fracture but will heal with periosteal reaction.

Physeal Fractures

Decision-Making Algorithms

Limp
Extremity Pain

Fractures involving the growth plate constitute about 20% of all fractures in the skeletally immature patient. These fractures are more common in males (2 : 1 male-female ratio). The peak incidence is 13-14 years in boys and 11-12 years in girls. The distal radius, distal tibia, and distal fibula are the most common locations.

Ligaments frequently insert onto epiphyses. Thus traumatic forces to an extremity may be transmitted to the physis, which is not as biomechanically strong as the metaphysis; it may fracture with mechanisms of injury that may cause sprains in the adult. The growth plate is most susceptible to torsional and

angular forces.

Physeal fractures are described using **Salter-Harris classification**, which allows for prognostic information regarding premature closure of the growth plate and poor functional outcomes. The higher the type number, the more likely the patient will have complications. There are five main groups (Fig. 198.2):

FIGURE 198.2 The types of growth plate injury as classified by Salter and Harris. See text for descriptions of types I to V. (From Salter RB, Harris WR. Injuries involving the epiphyseal plate. *J Bone Joint Surg Am.* 1963;45:587–622.)

- Type I: transverse fracture through the physis; growth disturbance is unusual
- Type II: fracture through a portion of the physis and metaphysis; most common type of Salter-Harris fracture (75%)
- Type III: fracture through a portion of the physis and epiphysis into the joint that may result in complication because of intraarticular component and because of disruption of the growing or hypertrophic zone of the physis
- Type IV: fracture through the metaphysis, physis, and epiphysis with a high risk of complication
- Type V: a crush injury to the physis with a poor functional prognosis

Types I and II fractures can often be managed by closed reduction and do not require perfect alignment. A major exception is the type II fracture of the distal femur, which is associated with a poor outcome unless proper anatomical alignment is obtained. Types III and IV fractures require anatomical alignment

for successful treatment. Type V fractures are rare and often result in premature closure of the physis.

Management of Pediatric Fractures

The majority of pediatric fractures can be managed with closed methods. Some fractures need closed reduction to improve alignment. Approximately 4% of pediatric fractures require internal fixation. Patients with open physes are more likely to require internal fixation if they have one of the following fractures:

- Displaced epiphyseal fractures
- Displaced intraarticular fractures
- Fractures in a child with multiple injuries
- Open fractures
- Unstable fractures

The goal of internal fixation is to improve and maintain anatomical alignment. This is usually done with Kirschner wires, Steinmann pins, and cortical screws with subsequent external immobilization in a cast until healing is satisfactory. After healing, the hardware is frequently removed to prevent incorporation into the callus and prevent physeal damage.

External fixation without casting may be necessary for pelvic fractures causing hemodynamic instability. Fractures associated with soft tissue loss, burns, and neurovascular damage may benefit from external fixation.

Special Concerns

Remodeling

Fracture remodeling occurs because of a combination of periosteal resorption and new bone formation. Many pediatric fractures do not need perfect anatomical alignment for proper healing. Younger patients have greater potential for fracture remodeling. Fractures that occur in the metaphysis, near the growth plate, may undergo more remodeling. Fractures angulated in the plane of motion also remodel very well. Intraarticular fractures, angulated or displaced diaphyseal fractures, rotated fractures, and fracture deformity not in the plane of motion tend not to remodel as well.

Overgrowth

Overgrowth occurs in long bones as the result of increased blood flow associated with fracture healing. Femoral fractures in children younger than 10 years of age will frequently overgrow 1-3 cm. This is the reason end-to-end alignment for femur and long-bone fractures may not be indicated. After 10 years of age, overgrowth is less of a problem, so end-to-end alignment is recommended.

Progressive Deformity

Fractures and injuries to the physis can result in premature closure. If it is a partial closure, the consequence may be an angular deformity. If it is a complete closure, limb shortening may occur. The most commonly affected locations are the distal femur and the distal and proximal tibia.

Neurovascular Injury

Fractures and dislocations may damage adjacent blood vessels and nerves. The most common location is the distal humerus (**supracondylar fracture**) and the knee (dislocation and physeal fracture). It is necessary to perform and document a careful neurovascular examination distal to the fracture (pulse, sensory, and motor function).

Compartment Syndrome

Compartment syndrome is an **orthopedic emergency** that results from hemorrhage and soft tissue swelling within the tight fascial compartments of an extremity. This can result in muscle ischemia and neurovascular compromise unless it is surgically decompressed. The most common sites are the lower leg (tibial fracture) and arm (supracondylar fracture).

Affected patients have severe pain and will eventually have decreased sensation in the dermatomes supplied by the nerves located in the compartment. Swollen and tight compartments and pain with passive stretching are present. This can happen underneath a cast and may actually occur when a cast is applied too tightly. It is important to educate all patients with fractures on the signs of compartment syndrome and ensure that they realize it is an emergency.

Toddler's Fracture

This is an oblique fracture of the distal tibia without a fibula fracture. There is often no significant trauma. Patients are usually 1-3 years old but can be as old as 6 and present with limping and pain with weight bearing. There may be minimal swelling and pain. Initial radiographs do not always show the fracture; if symptoms persist, a repeat x-ray in 7-10 days may be helpful.

Child Abuse

Decision-Making Algorithm

Extremity Pain

Child abuse must always be considered in the differential diagnosis of a child with fractures, especially in those younger than 3 years (see [Chapter 22](#)). Common fracture patterns that should increase the index of suspicion include multiple fractures in different stages of radiographic healing, metaphyseal corner fractures (twisting and shaking), fractures too severe for the history, or fractures in nonambulatory infants. Although spiral fractures of long bones were historically considered pathognomonic for abuse, they can be seen in nonabuse situations.

When there is concern for child abuse, the child should have a full evaluation, which may include admission to the hospital. A thorough and well-documented physical examination should focus on soft tissue injuries, the cranium, and a fundoscopic examination for retinal hemorrhages or detachment. A skeletal survey or a bone scan may be helpful in identifying other fractures.

CHAPTER 199

Hip

The hip is a ball (femoral head) and socket (acetabulum) joint that is important

for skeletal stability. The femoral head and acetabulum are interdependent for normal growth and development. The femoral neck and head, which contain the capital femoral epiphysis, are intraarticular. The blood supply to this region is unique because the blood vessels are extraosseous and lie on the surface of the femoral neck, entering the epiphysis peripherally. Thus the blood supply to the femoral head is vulnerable to trauma, infection, and other causes that may increase intraarticular pressure. Damage to the blood supply can lead to **avascular necrosis**.

Developmental Dysplasia of the Hip

In developmental dysplasia of the hip (DDH), the hips may be dislocated or dislocatable at birth. The femoral head and acetabulum develop from the same mesenchymal cells; by 11 weeks' gestation, the hip joint is formed. There are two types of DDH: teratological and typical. **Teratological dislocations** occur early in utero and are usually associated with neuromuscular disorders (spina bifida, arthrogryposis). **Typical dislocations** occur in the neurologically normal infant and can occur before or after birth. The true incidence of DDH is unknown, but it may be as high as 1.5 cases per 1,000 infants.

Etiology

Newborn infants have ligamentous laxity that, if significant enough in the hip, may lead to spontaneous dislocation and reduction of the femoral head. Persistence of this spontaneous pattern can lead to pathological changes, such as flattening of the acetabulum, muscle contractures that limit motion, and joint capsule tightening. The left hip is affected three times as often as the right hip, possibly because of in utero positioning.

Physiological risk factors for DDH include a generalized ligamentous laxity, perhaps from maternal hormones that are associated with pelvic ligament relaxation (estrogen and relaxin). Female infants are at higher risk (9 : 1); family history is positive in 20% of all patients with DDH.

Other risk factors include breech presentation, firstborn child (60%), oligohydramnios, and postnatal infant positioning. In breech presentations, the fetal pelvis is situated in the maternal pelvis. This can increase hip flexion and limit overall fetal hip motion, causing further stretching of the already lax joint capsule and exposing the posterior aspect of the femoral head. The altered

relationship between the acetabulum and femoral head causes abnormal acetabular development. Postnatal positioning of the hips in a tight swaddle with the hips adducted and extended can displace the hip joint.

Congenital muscular torticollis, metatarsus adductus, and clubfoot are associated with DDH. An infant with any of these three conditions should receive a careful examination of the hips.

Clinical Manifestations

Every newborn requires a screening physical examination for DDH; further evaluation through at least the first 18 months of life is part of the physical examination for toddlers. DDH evolves over time, so the examination may change as the patient ages. The examination starts with inspection for asymmetrical thigh and gluteal folds with the hips and knees flexed. A relative shortening of the femur with asymmetrical skin folds is a positive **Galeazzi sign** and indicates DDH. Range of motion should be assessed with the pelvis stabilized and the child supine on the examining table, not in the parent's lap ([Fig. 199.1](#)). Hip abduction should easily reach or exceed 75 degrees, and hip adduction should reach 30 degrees. Limitations may indicate contractures associated with DDH, especially decreased abduction.

FIGURE 199.1 Hip abduction test. Place the infant supine, flex the hips 90 degrees, and fully abduct the hips. Although the normal abduction range

is broad, hip disease should be suspected in any patient who lacks more than 30-45 degrees of abduction. (From Chung SMK. *Hip Disorders in Infants and Children*. Philadelphia: Lea & Febiger; 1981:69.)

The **Barlow test** attempts to dislocate an unstable hip (Fig. 199.2). The examiner should stabilize the infant's pelvis with one hand and grasp the abducted and flexed thigh in the other hand. The hip should be flexed to 90 degrees. Next, begin to adduct the hip while applying a posterior force to the anterior hip. A hip that can be dislocated in this method is readily felt (clunk feeling) and is a positive test. It may reduce spontaneously once the posterior force is removed, or the examiner may need to perform the Ortolani test.

FIGURE 199.2 Barlow (dislocation) test. Reverse of Ortolani test. If the femoral head is in the acetabulum at the time of examination, the Barlow test is performed to discover any hip instability. **(A)** The infant's thigh is grasped as shown and adducted with gentle downward pressure. **(B)** Dislocation is palpable as the femoral head slips out of the acetabulum. Diagnosis is confirmed with the Ortolani test.

The **Ortolani test** may reduce a dislocated hip (Fig. 199.3). The examiner should stabilize the pelvis and hold the leg in the same method as for the Barlow test. The infant's hip should be in 90 degrees of flexion. Abduct the hip while applying anterior pressure to the posterior thigh. A positive test is the palpable reduction of the dislocation, which may be felt (clunk). After 2 months of age, the hip may develop muscular contractures, preventing positive Ortolani tests.

FIGURE 199.3 Ortolani (reduction) test. With the infant relaxed and content on a firm surface, the hips and knees are flexed to 90 degrees. The hips are examined one at a time. The examiner grasps the infant's thigh with the middle finger over the greater trochanter and lifts the thigh to bring the femoral head from its dislocated posterior position to opposite the acetabulum. Simultaneously the thigh is gently abducted, reducing the femoral head in the acetabulum. In a positive finding, the examiner senses reduction by a palpable, nearly audible *clunk*.

These tests should be performed with only gentle force and done one hip at a time. The test may need to be repeated multiple times, as they can be difficult to interpret. A click, which is not pathological, may occur from breaking the surface tension of the hip joint or snapping gluteal tendons.

Bilateral fixed dislocations present a diagnostic dilemma because of the symmetry on exam. The **Kliscic test** is useful in this situation; it is done by placing the third finger over the greater trochanter and the index finger over the anterior superior iliac spine, then drawing an imaginary line between the two. The line should point to the umbilicus in a normal child. However, in a dislocated hip, the greater trochanter is elevated, which causes the line to project lower (between the umbilicus and pubis). This test is helpful in identifying bilateral DDH, which can otherwise be difficult to diagnose because of the symmetry found on examination.

Older children with unrecognized DDH may present with limping. A patient with increased lumbar lordosis and a waddling gait may have an unrecognized bilateral DDH.

Radiographic Evaluation

Ultrasound is used for initial evaluation of infants with DDH. Ultrasonography is

necessary for girls with a positive family history or breech presentation in both sexes. This should be obtained after 6 weeks of age to avoid confusion with physiological laxity. Because the femoral head begins to ossify at 4-6 months of age, plain radiographs can be misleading until patients are older.

Treatment

The treatment of DDH is individualized and depends on the child's age at diagnosis. The goal of treatment is a stable reduction that results in normal growth and development of the hip. If DDH is suspected, the child should be sent to a pediatric orthopedic specialist.

The **Pavlik harness** is an effective treatment up to 6 months of age. It provides hip flexion to just over 90 degrees and limits adduction to no more than neutral. This positioning redirects the femoral head toward the acetabulum. The hip must be reduced within 1-2 weeks of beginning the Pavlik harness, although the infant will need more time in the device. The Pavlik harness is successful in treating approximately 95% of dysplastic or subluxated hips, and 80% successful for treatment of true dislocations. Persistently dislocated hips should not remain in a Pavlik harness for more than 2 weeks for fear of iatrogenic acetabular damage. Patients failing the Pavlik harness warrant treatment with an abduction orthosis.

Children over 6 months or those who have failed nonoperative treatment should undergo closed reduction using a hip spica cast. This is done under general anesthesia; reduction is evaluated with an intraoperative arthrogram then confirmed by postoperative computed tomography (CT) or magnetic resonance imaging (MRI). If closed reduction fails, open reduction is indicated. Patients over 18 months of age may require a pelvic and femoral osteotomy.

Complications

The most important and severe complication of DDH is iatrogenic avascular necrosis of the femoral head. This can occur from excessive flexion or abduction during positioning of the Pavlik harness or hip spica cast. Infants under 6 months of age are at highest risk. Pressure ulcers can occur with prolonged casting. Redislocation or subluxation of the femoral head and residual acetabular dysplasia can occur.

Transient Monoarticular Synovitis

Decision-Making Algorithm

Limp

Transient synovitis, also known as **toxic synovitis**, is a common cause of limping in children. It is a diagnosis of exclusion because **septic arthritis** and **osteomyelitis** of the hip must be excluded (see [Chapters 117](#) and [118](#)).

Etiology and Epidemiology

The etiology of transient synovitis is uncertain, but possible causes are viral illness and hypersensitivity. Approximately 70% of children diagnosed with transient synovitis have an upper respiratory tract viral infection in the preceding 7-14 days. Biopsies have revealed nonspecific synovial hypertrophy. Hip joint aspirations, when necessary, are negative for bacterial culture or signs of bacterial infection.

The mean age at onset is 6 years, with a range of 3-8 years. It is twice as common in male children.

Clinical Manifestations and Evaluation

The patient or family will describe an acute onset of pain in the groin/hip, anterior thigh, or knee. Irritation of the obturator nerve can cause referred pain in the thigh and knee when the pathology is at the hip. Patients with transient synovitis are often afebrile, walk with a painful limp, and have normal to minimally elevated white blood cell count, C-reactive protein, and erythrocyte sedimentation rate compared with bacterial diseases of the hip ([Table 199.1](#)). [Table 197.3](#) lists the differential diagnosis of a limping child.

TABLE 199.1

Differences Between Bacterial Infection and Transient Synovitis

BACTERIAL INFECTION*	TRANSIENT SYNOVITIS

Elevated joint fluid cell count Fever—temperature >38.5°C	Afebrile
Leukocytosis	Normal WBC count
ESR >20 mm/hr	Normal ESR and CRP
Refusal to walk	Painful limp
Hip held in external rotation, abduction, and flexion	Hip held normally
Severe pain and tenderness	Moderate pain and mild tenderness

Examples: Septic arthritis, osteomyelitis of hip.

CRP, C-reactive protein; *ESR*, erythrocyte sedimentation rate; *WBC*, white blood cell.

Anteroposterior and frog-leg radiographs of the hip are usually normal. Ultrasonography may reveal a joint effusion. It is mandatory to rule out septic arthritis in the presence of effusion with a joint aspiration and cell count.

Treatment

The mainstay of treatment is bed rest and minimal weight bearing until the pain resolves. Nonsteroidal antiinflammatory medication is usually sufficient to decrease pain. Limiting strenuous activity and exercise for 1-2 weeks following recovery is helpful. Follow-up will help ensure that there is no deterioration. Lack of improvement necessitates further evaluation for more serious disorders.

Legg-Calve-Perthes Disease

Etiology and Epidemiology

Decision-Making Algorithms

Limp
Extremity Pain

Legg-Calve-Perthes disease (LCPD) is idiopathic **avascular necrosis (osteonecrosis)** of the capital epiphysis of the femoral head. The etiology is unclear, but it is likely caused by an interruption of the blood supply to the capital femoral epiphysis. There may be an associated hypercoagulability state (factor V Leiden).

LCPD commonly presents in patients 3-12 years of age, with a mean age of 7 years. It is four to five times more common in boys.

Clinical Manifestations

Patients may not present for several weeks because of minimal discomfort; the classic presentation is a child with an atraumatic, painless limp. There may be mild or intermittent hip/groin, anterior thigh, or knee pain. Decreased internal rotation and abduction with some discomfort, thigh muscle spasm, and anterior thigh muscular atrophy may be present. Patients have delayed bone age.

Radiological Evaluation

Anteroposterior and frog-leg radiographs of both hips are usually adequate for diagnosis and management. It is necessary to document the extent of the disease and follow its progression. MRI and bone scan are helpful to diagnose early LCPD.

Treatment and Prognosis

LCPD is usually a self-limited disorder that should be followed by a pediatric orthopedist. Initial treatment focuses on pain control and restoration of hip range of motion. The goal of treatment is prevention of complications, such as femoral head deformity and secondary osteoarthritis (OA).

Containment is important in treating LCPD; the femoral head is contained inside the acetabulum, which acts like a mold for the capital femoral epiphysis as it reossifies. Nonsurgical containment uses abduction casts and orthoses, whereas surgical containment is accomplished with osteotomies of the proximal femur and pelvis.

The short-term prognosis is determined by the magnitude of the femoral head deformity after healing has completed. It is improved by early diagnosis, good follow-up, and compliance with the treatment plan. Older children and children with a residual femoral head deformity are more likely to develop OA. The incidence of OA in patients who developed LCPD after 10 years of age is close to 100%; it is negligible in children with onset before 5 years of age. Patients between 6 and 9 years of age have a risk of OA of less than 40%.

Slipped Capital Femoral Epiphysis

Decision-Making Algorithms

Limp
Extremity Pain

Etiology and Epidemiology

Slipped capital femoral epiphysis (SCFE) is an adolescent hip disorder that is an orthopedic emergency. The incidence is 10.8 per 100,000, and it is slightly higher in males. African-American and Hispanic populations are at higher risk. Approximately 20% of patients with SCFE will have bilateral involvement at presentation, and another 20-40% may progress to bilateral involvement. The average age is 10-16 years, with a mean of 12 years in boys and 11 years in girls. Additional risk factors for SCFE include obesity, trisomy 21, and endocrine disorders (hypothyroid, pituitary tumor, growth hormone deficiency).

Classification

SCFE is classified as stable or unstable. Unstable patients refuse to ambulate even with crutches. Stable patients have an antalgic gait. SCFE can also be characterized as acute (symptoms <3 weeks) or chronic (symptoms >3 weeks). Acute-on-chronic SCFE is seen when more than 3 weeks of symptoms are accompanied by an acute exacerbation of pain and difficulty/inability to bear weight.

Clinical Manifestation

The presentation is variable, based on severity and type of slip. Patients will often report hip or knee pain, limp or inability to ambulate, and decreased hip range of motion. There may or may not be a traumatic event. *Any knee pain mandates an examination of the hip, as hip pathology can cause referred pain to the anterior thigh and knee along the obturator nerve.* The patient usually holds the affected extremity in external rotation. As the hip is flexed, it will progressively externally rotate. There is usually a limitation of internal rotation,

but there may also be a loss of flexion and abduction. If the patient can bear weight, it is typically an antalgic gait with the affected leg in external rotation. It is important to examine both hips to determine bilateral involvement.

Radiological Evaluation

Anteroposterior and frog-leg radiographs are indicated. Patients with known SCFE or with a high index of suspicion should not undergo frog-leg lateral radiographs. Instead, a cross table lateral radiograph reduces the risk of iatrogenic progression. The earliest sign of SCFE is widening of the physis without slippage (**preslip condition**). Klein's line (Fig. 199.4) is helpful in assessing the anteroposterior radiograph for SCFE. The slippage can be classified radiographically as type I (0-33% displacement), type II (34-50%), or type III (>50%). The likelihood of complications increases with degree of displacement.

FIGURE 199.4 Slipped capital femoral epiphysis. **(A)** Anteroposterior radiograph reveals a widened physis (*small arrows*) and decreased height of the epiphysis on the left. In addition, there is loss (*large arrow*) of the Capener triangle (*c*) (normal double density of the medial metaphysis superimposed on the posterior acetabular rim on *right*) and an abnormal lateral femoral neck line (normal on *right*). **(B)** Frog, lateral view confirms the inferomedial position of the slipped capital femoral epiphysis. (From Blickman H. *Pediatric Radiology, the Requisites*. 2nd ed. St Louis: Mosby; 1998:244.)

Treatment

Patients with SCFE should be immediately made non-weight bearing and referred to a pediatric orthopedist. The goal is to prevent further slippage, enhance physeal closure, and minimize complications, which is usually

accomplished with internal fixation in situ with a single cannulated screw. More severe cases may require surgical hip dislocation and reduction to realign the epiphysis. There is controversy surrounding the prophylactic fixation of the nonaffected side. Assessment for endocrine disorders is important, particularly in children outside the range of 10-16 years of age.

Complications

The two most serious complications of SCFE are **chondrolysis** and **avascular necrosis**. Chondrolysis is destruction of the articular cartilage. It is associated with more severe slips and with intraarticular penetration of operative hardware. This can lead to severe OA and disability. Avascular necrosis occurs when there is a disruption of the blood supply to the capital femoral epiphysis. This usually happens at the time of injury but may occur during forced manipulation of an unstable slip. Avascular necrosis may occur in up to 50% of unstable SCFEs and may lead to OA.

CHAPTER 200

Lower Extremity and Knee

Torsional (in-toeing and out-toeing) and angular (physiological bowlegs and knock knees) variations in the legs are common reasons that parents seek medical attention for their child. Most of these concerns are physiological and resolve with normal growth. Understanding the natural history allows physicians to reassure the family and to identify nonphysiological disorders that necessitate further intervention. Physiological disturbances are referred to as variations; pathological disturbances are called deformities.

Torsional Variations

The femur is internally rotated (anteversion) about 30 degrees at birth, decreasing to about 10 degrees at maturity. The tibia begins with up to 30 degrees of internal rotation at birth and can decrease to a mean of 15 degrees at maturity.

Torsional variations should not cause a limp or pain. Unilateral torsion raises the index of suspicion for a neurological (hemiplegia) or neuromuscular disorder.

In-Toeing

Decision-Making Algorithm

In-Toeing, Out-Toeing, and Toe-Walking

Femoral Anteversion

Internal femoral torsion or femoral anteversion is the most common cause of in-toeing in children 2 years or older (Table 200.1). It is at its worst between 4 and 6 years of age, and then resolves. It occurs twice as often in girls. Many cases are associated with generalized ligamentous laxity. The etiology of femoral anteversion is likely congenital and is common in individuals with abnormal sitting habits such as *W-sitting*.

TABLE 200.1

Common Causes of In-Toeing and Out-Toeing

IN-TOEING	OUT-TOEING
<ul style="list-style-type: none"> Internal femoral torsion or anteversion Internal tibial torsion Metatarsus adductus Talipes equinovarus (clubfoot) Developmental dysplasia 	<ul style="list-style-type: none"> External femoral torsion or retroversion External tibial torsion Calcaneovalgus feet Hypermobility pes planus (flatfoot) Slipped capital femoral epiphysis

Clinical Manifestations. The family may give a history of *W-sitting*, and there may be a family history of similar concerns when the parents were younger. The child may have *kissing kneecaps* due to increased internal rotation of the femur. While walking, the entire leg will appear internally rotated, and with running, the child may appear to have an *egg-beater* gait where the legs flip laterally. The flexed hip will have internal rotation increased to 80-90 degrees (normal 60-70 degrees) and external rotation limited to about 10 degrees. Radiographic evaluation is usually not indicated.

Internal Tibial Torsion

Decision-Making Algorithm

In-Toeing, Out-Toeing, and Toe-Walking

This is the most common cause of in-toeing in a child *younger* than 2 years old. When it is the result of in utero positioning, it may be associated with metatarsus adductus.

Clinical Manifestations. The child will present with a history of in-toeing. The degree of tibial torsion may be measured using the **thigh-foot angle** (Fig. 200.1). The patient lies prone on a table with the knee flexed to 90 degrees. The long axis of the foot is compared with the long axis of the thigh. An inwardly rotated foot represents a negative angle and internal tibial torsion. If follow-up is warranted, measurements should be done at each visit to document improvement.

FIGURE 200.1 Thigh-foot angle measurement. The thigh-foot angle is useful for assessment of tibial torsion. The patient lies prone, with knees flexed to 90 degrees. The long axis of the thigh is compared to the long

axis of the foot to determine the thigh-foot angle. Negative angles are associated with internal tibial torsion, and positive angles are associated with external tibial torsion.

Treatment of In-Toeing

The mainstay of management is to identify patients who have pathological reasons for in-toeing and reassurance and follow-up to document improvement for patients with femoral anteversion and internal tibial torsion. It can take until 7-8 years of age for correction, so it is important to inform families of the appropriate timeline. Braces (Denis Browne splint) do not improve these conditions. Fewer than 1% of all patients with in-toeing will need surgical intervention because of functional disability or cosmetic appearance.

Out-Toeing

Decision-Making Algorithm

In-Toeing, Out-Toeing, and Toe-Walking

External Tibial Torsion

External tibial torsion is the most common cause of out-toeing and may be associated with a calcaneovalgus foot (see [Chapter 201](#)). This is often related to in utero positioning. It may improve over time, but because the tibia rotates externally with age, external tibial torsion can worsen. It may be an etiological factor for patellofemoral syndrome, especially when combined with femoral anteversion. Treatment is usually observation and reassurance, but patients with dysfunction and cosmetic concerns may benefit from surgical intervention.

Angular Variations

Decision-Making Algorithm

Bowlegs and Knock-Knees

The majority of patients who present with knock-knees (**genu valgum**) or bowlegs (**genu varum**) are normal ([Fig. 200.2](#)). Infants are born with maximum genu varum. The lower extremity straightens out around 18 months of age. Children typically progress to maximal genu valgum around 4 years. The legs are usually straight to a slight genu valgum in adulthood.

FIGURE 200.2 Bowleg and knock-knee deformities. **(A)** Bowleg deformity. Bowlegs are referred to as varus angulation (genu varum) because the knees are tilted away from the midline of the body. **(B)** Knock-knee or valgus deformity of the knees. The knee is tilted toward the midline. (From Scoles P. *Pediatric Orthopedics in Clinical Practice*. Chicago: Year Book Medical Publishers; 1982:84.)

It is important to inquire about family history and assess overall height. A child who is two standard deviations below normal with angular deformities may have skeletal dysplasia. Dietary history should be obtained, as rickets (see [Chapter 31](#)) may cause angular deformities. For genu valgum, following the intermalleolar distance (distance between the two tibial medial malleoli with the knees touching) is used. Measurement of the intercondylar distance (the distance between the medial femoral condyles with the medial malleoli touching) is used for genu varum. These measurements track improvement or progression. When obtaining radiographs, it is important to have the patella, not the feet, facing forward. In the child with external tibial torsion, having the feet facing forward

gives the false appearance of bowlegs.

Genu Valgum

Decision-Making Algorithm

Bowlegs and Knock-Knees

Physiological knock-knees are most common in 3- to 4-year-olds and usually resolve between 5 and 8 years of age. Patients with asymmetrical genu valgum or severe deformity may have underlying disease causing their knock-knees (e.g., renal osteodystrophy, skeletal dysplasia). Treatment is based on reassurance of the family and patient. Surgical intervention may be indicated for severe deformities, gait dysfunction, pain, and cosmesis.

Genu Varum

Decision-Making Algorithm

Bowlegs and Knock-Knees

Physiological bowlegs are most common in children older than 18 months with symmetrical genu varum. This will generally improve as the child approaches 2 years of age. The most important consideration for genu varum is differentiating between physiological genu varum and Blount disease (tibia vara).

Tibia Vara (Blount Disease)

Decision-Making Algorithms

Extremity Pain
Bowlegs and Knock-Knees

Tibia vara is the most common pathological disorder associated with genu varum. It is characterized by abnormal growth of the medial aspect of the proximal tibial epiphysis, resulting in a progressive varus deformity. Blount disease is classified according to age of onset:

- Infantile (1-3 years)
- Juvenile (4-10 years)
- Adolescent (>11 years)

Late-onset Blount disease is less common than infantile disease. The cause is unknown, but it is felt to be secondary to growth suppression from increased compressive forces across the medial knee.

Clinical Manifestations

Infantile tibia vara is more common in African Americans, females, and obese patients. Many patients were early walkers. Nearly 80% of patients with infantile Blount disease have bilateral involvement. It is usually painless. The patients will often have significant internal tibial torsion and lower extremity leg-length discrepancy (LLD). There may also be a palpable medial tibial metaphyseal beak.

Late-onset Blount disease is more common in African Americans, males, and markedly obese patients. Only 50% have bilateral involvement. The initial presentation is usually painful bowlegs. Late-onset Blount disease is usually not associated with palpable metaphyseal beaking, significant internal tibial torsion, or significant LLD.

Radiological Evaluation

Weight-bearing anteroposterior and lateral radiographs of both legs are necessary for the diagnosis of tibia vara. Fragmentation, wedging, and beak deformities of the proximal medial tibia are the major radiological features of infantile Blount disease. In late-onset Blount disease, the medial deformity may not be as readily noticeable. It can be very difficult to tell the difference between physiological genu varum and infantile Blount disease on radiographs in patients younger than 2 years of age.

Treatment

Once the diagnosis of Blount disease is confirmed, treatment should begin immediately. Orthotics to unload the medial compressive forces can be used in children younger than 3 years of age with a mild deformity. Compliance with this regimen can be difficult. Nonoperative management of more severe Blount disease is contraindicated. Any patient older than 4 years should undergo surgical intervention. Patients with moderate to severe deformity and patients who fail orthotic treatment also require surgical intervention. Proximal tibial valgus osteotomy with fibular diaphyseal osteotomy is the usual procedure performed.

Leg-Length Discrepancy

Decision-Making Algorithm

In-Toeing, Out-Toeing, and Toe-Walking

LLD is common and may be due to differences in the femur, tibia, or both bones. The differential diagnosis is extensive, but common causes are listed in [Table 200.2](#). The majority of the lower extremity growth comes from the distal femur (38%) and the proximal tibia (27%).

TABLE 200.2

Common Causes of Leg-Length Discrepancy

Congenital	Coxa vara Clubfoot Hypoplasia
Developmental	Developmental dysplasia of the hip (DDH) Legg-Calve-Perthes disease (LCPD)
Neuromuscular	Hemiplegia Disuse secondary to developmental delay
Infectious	Physeal injury secondary to osteomyelitis
Tumors	Fibrous dysplasia Physeal injury secondary to irradiation or neoplastic infiltration Overgrowth

Trauma	Physeal injury with premature closure Malunion (shortening of extremity) Overgrowth of healing fracture
Syndrome	Neurofibromatosis Beckwith-Wiedemann syndrome Klippel-Trenaunay syndrome

Measuring Leg-Length Discrepancy

Clinical measurements using bony landmarks (anterior superior iliac spine to medial malleolus) are inaccurate. The **teloradiograph** is a single radiograph of both legs that can be done in very young children. The **orthoradiograph** consists of three slightly overlapping exposures of the hips, knees, and ankles. The **scanogram** consists of three standard radiographs of the hips, knees, and ankles with a ruler next to the extremities. A **computed tomography (CT) scanogram** is the most accurate measure of LLD but also has the highest radiation exposure. Technology such as EOS/slot scanning is an extremely accurate, reduced-radiation alternative to CT scan. The measured discrepancy is followed using Moseley and Green-Anderson graphs.

Treatment

Treating LLD is complex. The physician must take into account the estimated adult height, discrepancy measurements, skeletal maturity, and the psychological aspects of the patient and family. LLD greater than 2 cm usually requires treatment. Shoe lifts can be used, but they will often cause psychosocial problems for the child and may make the shoes heavier and less stable. Surgical options include shortening of the longer extremity, lengthening of the shorter extremity, or a combination of the two procedures. Discrepancies less than 5 cm are treated by epiphysiodesis (surgical physeal closure) of the affected side, whereas discrepancies greater than 5 cm are treated by lengthening. Current use of removable implants, which permit growth modulation without permanent impact on growth plates, has allowed for early and more accurate treatment.

Knee

Decision-Making Algorithm

Knee Pain

The knee joint is constrained by soft tissues rather than the usual geometric fit of articulating bones. The medial and lateral collateral ligaments as well as the anterior and posterior cruciate ligaments maintain knee stability. Weight and force transmission can cross articular cartilage and the meniscus. The patellofemoral joint is the extensor mechanism of the knee and a common site of injury in the adolescent (Fig. 200.3).

FIGURE 200.3 Diagram of the knee extensor mechanism. The major force exerted by the quadriceps muscle tends to pull the patella laterally out of the intercondylar sulcus. The vastus medialis muscle pulls medially to keep the patella centralized. (Modified from Smith JB. Knee problems in children. *Pediatr Clin North Am.* 1986;33:1439.)

Knee effusion or swelling is a common sign of injury. When the fluid accumulates rapidly after an injury, it is usually a hemarthrosis (blood in the joint) and may indicate a fracture, ligamentous disruption (often of the anterior cruciate ligament [ACL]), or meniscus tear. Unexplained knee effusion may occur with arthritis (septic, Lyme disease, viral, postinfectious, juvenile idiopathic arthritis, systemic lupus erythematosus). It may also occur as a result of overactivity and hypermobile joint syndrome (ligamentous laxity). An aspiration and laboratory evaluation of unexplained effusion can help expedite a diagnosis.

Discoid Lateral Meniscus

Each meniscus is normally semilunar in shape; rarely the lateral meniscus will be disk shaped. A normal meniscus is attached at the periphery and glides anteriorly and posteriorly with knee motion. The discoid meniscus is less mobile and may tear more easily. When there is inadequate posterolateral attachment, the discoid meniscus can displace anteriorly with knee flexion, causing an audible click. Most commonly, patients will present in late childhood or early adolescence after an injury with knee pain and swelling. The anteroposterior radiographs can show increased joint space and a squared-off appearance of the lateral femoral condyle; magnetic resonance imaging (MRI) can confirm the diagnosis. Treatment is usually arthroscopic excision of tears and reshaping of the meniscus.

Popliteal Cyst

A popliteal cyst (**Baker cyst**) is commonly seen in the middle childhood years. The cause is the distension of the gastrocnemius and semimembranous bursa along the posteromedial aspect of the knee by synovial fluid. In adults, Baker cysts are associated with meniscus tears. In childhood, the cysts are usually painless and benign. They often spontaneously resolve, but it may take several years. Knee radiographs are normal. The diagnosis can be confirmed by ultrasound. Treatment is reassurance because surgical excision is indicated only for progressive cysts or cysts that cause disability.

Osteochondritis Dissecans

Decision-Making Algorithms

Knee Pain
Extremity Pain

Osteochondritis dissecans (OCD) occurs when an area of bone adjacent to the articular cartilage suffers a vascular insult and separates from the adjacent bone. It most commonly affects the lateral aspect of the medial femoral condyle. Patients may complain of knee pain or swelling. The lesions can be seen on

anteroposterior, lateral, and tunnel view radiographs. MRI can be helpful in determining the extent of the injury. In young patients with intact articular cartilage, the lesion will often revascularize and heal with rest from activities. The healing process may take several months and requires radiographic follow-up to document healing. With increasing age, the risk for articular cartilage damage and separation of the bony fragment increases. Older patients are more likely to need surgical intervention. Any patient with a fracture of the articular cartilage is unlikely to improve without surgical intervention. Patients with OCD should be referred to a specialist.

Osgood-Schlatter Disease

Decision-Making Algorithm

Knee Pain

Osgood-Schlatter disease is a common cause of knee pain at the insertion of the patellar tendon on the tibial tubercle. The stress from a contracting quadriceps muscle is transmitted through the developing tibial tubercle, which can cause microfractures and apophysitis. It usually occurs after a growth spurt and is more common in boys. The age at onset is typically 11 years for girls and 13-14 years for boys.

Patients will present with pain during and after activity as well as have tenderness and local swelling over the tibial tubercle. Radiographs may be necessary to rule out infection, tumor, or avulsion fracture.

Rest and activity modification are paramount for treatment. Pain control medications and icing may be helpful. Lower extremity flexibility and strengthening exercise programs are important. The course is usually benign, but symptoms frequently last 1-2 years. Complications can include bony enlargement of the tibial tubercle and avulsion fracture of the tibial tubercle.

Patellofemoral Disorders

Decision-Making Algorithm

Knee Pain

The patellofemoral joint is a complex joint that depends on a balance between restraining ligaments of the patella, muscular forces around the knee, and alignment for normal function. The interior surface of the patella has a V-shaped bottom that moves through a matching groove in the femur called the trochlea. When the knee is flexed, the patellar ligaments and the majority of the muscular forces pulling through the quadriceps tendon move the patella in a lateral direction. The vastus medialis muscle counteracts the lateral motion, pulling the patella toward the midline. Problems with function of this joint usually result in anterior knee pain.

Idiopathic anterior knee pain is a common complaint in adolescents. It is particularly prevalent in adolescent female athletes. Previously, this was referred to as chondromalacia of the patella, but this term is incorrect as the joint surfaces of the patella are normal. It is now known as **patellofemoral pain syndrome (PFPS)**. The patient will present with anterior knee pain that worsens with activity, going up and down stairs, and soreness after sitting in one position for an extended time. There is usually no associated swelling. The patient may complain of a grinding sensation under the kneecap. Palpating and compressing the patellofemoral joint with the knee extended elicits pain. Patients often have weak hip musculature or poor flexibility in the lower extremities. Radiographs are rarely helpful but may be indicated to rule out other diagnoses such as OCD.

Treatment is focused on correcting the biomechanical problems that are causing the pain. This is usually done using an exercise program emphasizing hip girdle and vastus medialis strengthening with lower extremity flexibility. Antiinflammatory medication, ice, and activity modifications may also be helpful. Persistent cases should be referred to an orthopedic or sports medicine specialist.

One must exclude **recurrent patellar subluxation** and **dislocation** when evaluating a patient with PFPS. Acute traumatic dislocation will usually cause significant disability, swelling, and pain. Patients with recurrent dislocations often have associated ligamentous laxity, genu valgum, and femoral anteversion. The initial treatment is nonoperative and may involve a brief period of immobilization, followed by an aggressive physical therapy program designed to strengthen the quadriceps and improve function of the patellofemoral joint. Continued subluxation or recurrent dislocation is failure of this treatment plan,

and surgical repair is usually necessary.

CHAPTER 201

Foot

In newborns and non-weight-bearing infants, the difference between posturing and deformity is important. Posturing is the habitual position in which the infant holds the foot; passive range of motion is normal. Deformity produces an appearance similar to posturing, but passive motion is restricted. Most pediatric foot disorders are painless. Foot pain is more common in older children ([Table 201.1](#)).

TABLE 201.1

Differential Diagnosis of Foot Pain by Age

AGE GROUP	DIAGNOSTIC CONSIDERATIONS
0-6 years	Poorly fitting shoes Fracture Puncture wound Foreign body Osteomyelitis Cellulitis Juvenile idiopathic arthritis Hair tourniquet Leukemia
6-12 years	Poorly fitting shoes Trauma (fracture, sprain) Juvenile idiopathic arthritis Puncture wound Sever disease Accessory tarsal navicular Hypermobility flatfoot Oncological (Ewing sarcoma, leukemia)
12-18 years	Poorly fitting shoes Stress fracture Trauma (fracture, sprain) Foreign body Ingrown toenail Metatarsalgia Plantar fasciitis Achilles tendinopathy Accessory ossicles (navicular, os trigonum) Tarsal coalition

Clubfoot (Talipes Equinovarus)

Decision-Making Algorithm

In-Toeing, Out-Toeing, and Toe-Walking

A clubfoot deformity involves the entire leg, not just the foot. It affects 1 in 1,000 newborns and is bilateral in one half of cases. The tarsals in the affected foot are hypoplastic; the talus is most affected. The muscles of the limb are hypoplastic because of the abnormal tarsal interactions, which leads to a generalized limb hypoplasia, mainly affecting and shortening the foot. There is usually atrophy of the calf musculature.

Etiology

Family history is important. Clubfoot can be congenital, teratological, or positional. Although congenital clubfoot (75% of all cases) is usually an isolated abnormality, every infant should be assessed for developmental dysplasia of the hip. Teratological clubfoot is associated with a neuromuscular disorder, such as myelomeningocele, arthrogryposis, or other syndromes. Positional clubfoot is a normal foot that was held in the deformed position in utero.

Clinical Manifestations

The diagnosis is seldom confused with other disorders ([Fig. 201.1](#)). The presence of clubfoot should prompt a careful search for other abnormalities. The infant will have hindfoot equinus and varus, forefoot adduction, and varying degrees of rigidity. All are secondary to the abnormalities of the talonavicular joint. Calf atrophy and foot shortening are more noticeable in older children.

FIGURE 201.1 Clinical picture demonstrating clubfoot deformity. (From Kliegman RM, Behrman RE, Jenson HB, et al. *Nelson's Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders; 2007:2778.)

Radiological Evaluation

In infants, radiographs and advanced imaging are rarely necessary for assessment because their tarsals have incomplete ossification. The navicular ossifies at about 3 years of age for girls and 4 years for boys. As children age, radiographs can be used to follow the tibial calcaneal and lateral talocalcaneal angles and to assess navicular positioning.

Treatment

The goal of treatment is to correct the deformity and preserve mobility. Nonoperative treatment involves the Ponseti method of serial casting. The Ponseti method also relies on a percutaneous tenotomy of the Achilles tendon to help correct the equinus deformity.

About 20% of patients will require an anterior tibialis tendon transfer in early childhood. Rarely, more aggressive surgical procedures may need to be done.

Complications of untreated clubfoot include severe disability. Complications of treated clubfoot include recurrence and stiffness.

Metatarsus Adductus

Decision-Making Algorithm

In-Toeing, Out-Toeing, and Toe-Walking

Metatarsus adductus is the most common foot disorder in infants. It is characterized by a convexity of the lateral foot (Fig. 201.2) and is caused by in utero positioning. It is bilateral in half of cases. Occurring equally in boys and girls, it is more common in first-born children because of the smaller primigravid uterus. Two percent of infants with metatarsus adductus have **developmental dysplasia of the hip**.

FIGURE 201.2 Clinical picture of metatarsus adductus with a normal foot on opposite side. (From Kliegman RM, Behrman RE, Jenson HB, et al. *Nelson's Textbook of Pediatrics*. 18th ed. Philadelphia: Saunders; 2007:2777.)

Clinical Manifestations

The forefoot is adducted and sometimes supinated, but the midfoot and hindfoot are normal. The lateral border of the foot is convex, while the medial border is

concave. Ankle dorsiflexion and plantar flexion are normal. With the midfoot and hindfoot stabilized, the deformity can be pushed beyond a neutral position (into abduction). Older children may present with an in-toeing gait.

Treatment

True metatarsus adductus resolves spontaneously over 90% of the time without treatment, so reassurance is all that is needed. Metatarsus adductus that does not improve within 2 years needs evaluation by a pediatric orthopedist. Persistent cases may benefit from serial casting or bracing, and potentially surgery. The deformity is not associated with a disability.

It is important to differentiate among metatarsus adductus, **metatarsus varus**, and **skewfoot**. Metatarsus varus looks like metatarsus adductus, but it is an uncommon rigid deformity that will need serial casting. Skewfoot is an uncommon deformity that is characterized by hindfoot plantar flexion, midfoot abduction, and forefoot adduction, giving the foot a Z or serpentine appearance. This needs to be managed very carefully with serial casting and surgery to help reduce the risk of disability in adulthood.

Calcaneovalgus Foot

The calcaneovalgus foot is another common foot disorder in newborns that is secondary to in utero positioning. It is characterized by a hyperdorsiflexed foot with forefoot abduction and heel valgus. It is usually unilateral. The appearance may be quite severe dorsiflexion, but it is not a rigid deformity like congenital vertical talus. Simulated weight-bearing radiographs may be necessary for questionable diagnoses. The calcaneovalgus foot will appear normal or have minimal hindfoot valgus.

This disorder requires no treatment beyond reassurance. Parents can be taught passive stretching exercises for their infant's foot. Most affected infants realign by 2 years. A calcaneovalgus foot can be associated with bowing of the tibia, which resolves spontaneously, but a leg length discrepancy may exist.

Hypermobile Pes Planus (Flexible Flatfoot)

Hypermobile or pronated feet are seen in 15% of adults. The child with flatfeet is usually asymptomatic and has no activity limitations. Newborn and toddler

flatfoot is the result of ligamentous laxity and fat in the medial longitudinal arch. This is called **developmental flatfoot** and usually improves by 6 years of age. In older children, flatfoot is typically the result of generalized ligamentous laxity, and there is often a positive family history. Hypermobile flatfoot can be thought of as a normal variant.

Clinical Manifestations

In the non-weight-bearing position, the older child with a flexible flatfoot will have a medial longitudinal arch. When weight bearing, the foot pronates (arch collapse) with varying degrees of hindfoot valgus. Subtalar motion (essentially all ankle motion except plantar and dorsiflexion) is normal. Any loss of subtalar motion may indicate a rigid flatfoot, which can be related to tarsal coalition, neuromuscular disorders (cerebral palsy), and heel cord contractures. Radiographs of hypermobile flatfeet are usually not indicated.

Treatment

Hypermobile pes planus cannot be diagnosed until after 6 years of age; before that, it is developmental pes planus. Reassurance that this is a normal variant is very important. Patients who are symptomatic with activity may require education on proper, supportive footwear, orthotics/arch supports, and heel cord stretching.

Tarsal Coalition

Patients with tarsal coalition will usually present with a **rigid flatfoot** (loss of inversion and eversion at the subtalar joint). Coalition is produced by a congenital fusion or failure of segmentation of two or more tarsal bones. The attachment may be fibrous, cartilaginous, or osseous. Tarsal coalition can be unilateral or bilateral and will often become symptomatic in early adolescence. The most common forms of tarsal coalition are **calcaneonavicular** and **talocalcaneal**.

Clinical Manifestations

Decision-Making Algorithms

Limp Extremity Pain

The patient will usually present with hindfoot pain, which may radiate laterally because of peroneal muscle spasm. Symptoms are exacerbated by sports, and young athletes can present with frequent *ankle sprains*. There is a familial component. Pes planus is usually present in both weight-bearing and non-weight-bearing positions. There is usually a loss of subtalar motion, and passive attempts at joint motion may produce pain.

Radiological Evaluation

Anteroposterior, lateral, and oblique radiographs should be obtained, but they may not always clearly identify the disorder. The oblique view often identifies the calcaneonavicular coalition. Computed tomography (CT) is the gold standard for diagnosis of tarsal coalition. Even patients with obvious calcaneonavicular coalition on plain radiographs should have a CT scan to rule out a second coalition.

Treatment

Coalitions that are asymptomatic (the majority) do not need treatment. Nonoperative treatment for patients with pain consists of cast immobilization for a few weeks and foot orthotics. The symptoms will often return, necessitating surgery. Surgical excision of the coalition and soft tissue interposition to prevent reossification can be very effective.

Cavus Foot

Cavus foot is characterized by increased height of the medial longitudinal arch (**high arch**) and frequently hindfoot varus. It can be classified as physiological or neuromuscular. Most patients with physiological cavus foot are asymptomatic. A thorough neurological examination on all patients with a cavus foot is important. Patients with painful high arches have a high risk of neurological (tethered cord) and neuromuscular disease, and there is a strong association with **Charcot-Marie-Tooth disease**, a familial neuropathy. The

underlying disorder should be treated first. Nonoperative treatment using orthotics is usually not helpful. Progressive, symptomatic cavus foot will likely need surgical reconstruction.

Idiopathic Avascular Necrosis

Decision-Making Algorithms

Limp
Extremity Pain

Kohler disease (tarsal navicular) and **Freiberg disease** (head of the second metatarsal) are uncommon and due to avascular necrosis. Patients will present with pain at the affected site with activity and weight bearing. Infection, fracture, and neoplasm should be excluded. Treatment consists of immobilization and activity restriction. The majority of the patients will improve upon subsequent revascularization and re-formation of bone.

Sever Disease (Calcaneal Apophysitis)

Decision-Making Algorithm

Extremity Pain

Sever disease is a common cause of heel pain among active young people. The mean age of presentation for girls is about 9 years of age and for boys about 11-12 years. Approximately 60% of cases are bilateral. Sever disease is caused by the forces of the calf musculature through the Achilles tendon at the calcaneal apophysis, causing microfracture. As the child ages and the apophysis begins to close, the pain disappears.

Clinical Manifestations

The common presentation is a young athlete who develops heel pain with activity that decreases with rest. Swelling is rare, but limping may be associated with Sever disease. The child will have pain to palpation of the posterior calcaneus and often tight heel cords. Radiographs are rarely indicated, but with persistent pain they should be done to exclude infection or tumor.

Treatment

Activity modification, icing, and antiinflammatory medications can be helpful. A program designed to improve heel cord flexibility and overall ankle strength may decrease symptoms. Heel elevation using heel wedges or heel cups can be helpful.

Toe Deformities

Curly toes are the most common deformity of the lesser toes. The fourth and fifth toes are most commonly affected. Curly toes are characterized by flexion at the proximal interphalangeal joint with lateral rotation of the toe. It is caused by contractures of the flexor digitorum brevis and longus tendons. Some curly toes will spontaneously resolve by 3-4 years of age. Persistent deformity may be treated by surgical tenotomy.

Polydactyly (extra toes) is usually found on the initial newborn physical examination. When the extra toe is adjacent to the fifth toe and attached by only a stalk of soft tissue or skin, simple ligation or amputation is effective. When the deformity involves the great toe or middle toes, or when the extra digit has cartilage or bone, delayed surgical intervention is indicated. **Syndactyly** (fusion of toes) is more common than polydactyly. It is usually a benign cosmetic problem. Both syndactyly and polydactyly may be associated with malformation syndromes ([Table 201.2](#)).

CHAPTER 202

Spine

Spinal Deformities

A simplified classification of the common spinal abnormalities, scoliosis and kyphosis, is presented in [Table 202.1](#).

TABLE 202.1

Classification of Spinal Deformities

SCOLIOSIS
Idiopathic
Infantile Juvenile Adolescent
Congenital
Failure of formation Wedge vertebrae Hemivertebrae Failure of segmentation Unilateral bar Bilateral bar Mixed
Neuromuscular
Neuropathic diseases Upper motor neuron disease Cerebral palsy Spinocerebellar degeneration Friedreich ataxia Syringomyelia Spinal cord tumor Spinal cord trauma Lower motor neuron disease

Myelodysplasia Poliomyelitis Spinal muscular atrophy Charcot-Marie-Tooth disease Myopathic diseases Duchenne muscular dystrophy Arthrogryposis Other muscular dystrophies
Syndromes
Neurofibromatosis Marfan syndrome
Compensatory
Leg-length inequality
KYPHOSIS
Postural roundback Scheuermann disease Congenital kyphosis

Modified from the Terminology Committee of the Scoliosis Research Society, 1975.

Clinical Manifestations

Decision-Making Algorithm

Back Pain

Most patients will present for evaluation of an asymmetrical spine, which is usually pain free. A complete physical examination is necessary for any patient with a spinal deformity because the deformity can indicate an underlying disease. The back is examined from behind ([Fig. 202.1](#)). First, the levelness of the pelvis is assessed. Leg-length discrepancy produces pelvic obliquity, which often results in **compensatory scoliosis**. When the pelvis is level, the spine is examined for symmetry and spinal curvature with the patient upright. Cutaneous lesions (hemangioma, skin dimple, or hair tuft) should be noted. The spine should be palpated for areas of tenderness.

FIGURE 202.1 Clinical evaluation of a patient with scoliosis.

The patient is then asked to bend forward with the hands directed between the feet (**Adams forward bend test**). The examiner should inspect for asymmetry in the spine. The presence of the hump in this position is the hallmark for scoliosis. The area opposite the hump is usually depressed because of spinal rotation. Scoliosis is a rotational malalignment of one vertebra on another, resulting in rib elevation in the thoracic spine and paravertebral muscle elevation in the lumbar

spine. With the patient still in the forward flexed position, inspection from the side can reveal the degree of roundback. A sharp forward angulation in the thoracolumbar region indicates a **kyphotic deformity**. It is important to examine the skin for café-au-lait spots (**neurofibromatosis**), hairy patches, and nevi (**spinal dysraphism**). Abnormal extremities may indicate skeletal dysplasia, whereas heart murmurs can be associated with Marfan syndrome. It is essential to do a full neurological examination to determine whether the scoliosis is idiopathic or secondary to an underlying neuromuscular disease, and to assess whether the scoliosis is producing any neurological sequelae.

Radiological Evaluation

Initial radiographs should include a posteroanterior and lateral standing film of the entire spine. The iliac crests should be visible to help determine skeletal maturity. The degree of curvature is measured from the most tilted or end vertebra of the curve superiorly and inferiorly to determine the Cobb angle (Fig. 202.2). Newer imaging modalities such as slot scanning or EOS provide the ability to obtain accurate measurements with much lower radiation than radiographs.

FIGURE 202.2 Cobb method of scoliotic curve measurement. Determine the end vertebrae of the curve: they are at the upper and lower limits of the curve and tilt most severely toward the concavity of the curve. Draw two perpendicular lines, one from the bottom of the lower body and one from

the top of the upper body. Measure the angle formed. This is the accepted method of curve measurement according to the Scoliosis Research Society. Curves of 0-20 degrees are mild; 20-40 degrees, moderate; and greater than 40 degrees, severe.

Scoliosis

Alterations in normal spinal alignment that occur in the anteroposterior plane are termed scoliosis. Most scoliotic deformities are idiopathic. Scoliosis may also be congenital, neuromuscular, or compensatory from a leg-length discrepancy.

Idiopathic Scoliosis

Etiology and Epidemiology

Idiopathic scoliosis is the most common form of scoliosis. It occurs in healthy, neurologically normal children. Approximately 20% of patients have a positive family history. The incidence is slightly higher in girls than boys, and the condition is more likely to progress and require treatment in females. There is some evidence that progressive scoliosis may have a genetic component as well.

Idiopathic scoliosis can be classified in three categories: **infantile** (birth to 3 years), **juvenile** (4-10 years), and **adolescent** (>11 years). Idiopathic adolescent scoliosis is the most common cause (80%) of spinal deformity. The right thoracic curve is the most common pattern. Juvenile scoliosis is uncommon but may be underrepresented because many patients do not seek treatment until they are adolescents. In any patient younger than 11 years of age, there is a greater likelihood that scoliosis is not idiopathic. The prevalence of an intraspinal abnormality in a child with congenital scoliosis is approximately 40%.

Clinical Manifestations

Idiopathic scoliosis is a painless disorder 70% of the time. A patient with pain requires a careful evaluation. Any patient presenting with a left-sided curve has a high incidence of intraspinal pathology (syrinx or tumor). Evaluation of the spine with magnetic resonance imaging (MRI) is indicated in these cases.

Treatment

Treatment of idiopathic scoliosis is based on the skeletal maturity of the patient,

the size of the curve, and whether the spinal curvature is progressive or nonprogressive. Initial treatment for scoliosis is likely observation and repeat radiographs to assess for progression. No treatment is indicated for nonprogressive deformities. The risk factors for curve progression include gender, curve location, and curve magnitude. Girls are five times more likely to progress than boys. Younger patients are more likely to progress than older patients.

Typically, curves under 25 degrees are observed. Progressive curves between 20 degrees and 50 degrees in a skeletally immature patient are treated with bracing. A radiograph in the orthotic is important to evaluate correction. Curves greater than 50 degrees usually require surgical intervention.

Congenital Scoliosis

Abnormalities of the vertebral formation during the first trimester may lead to structural deformities of the spine that are evident at birth or early childhood. Congenital scoliosis can be classified as follows ([Fig. 202.3](#)):

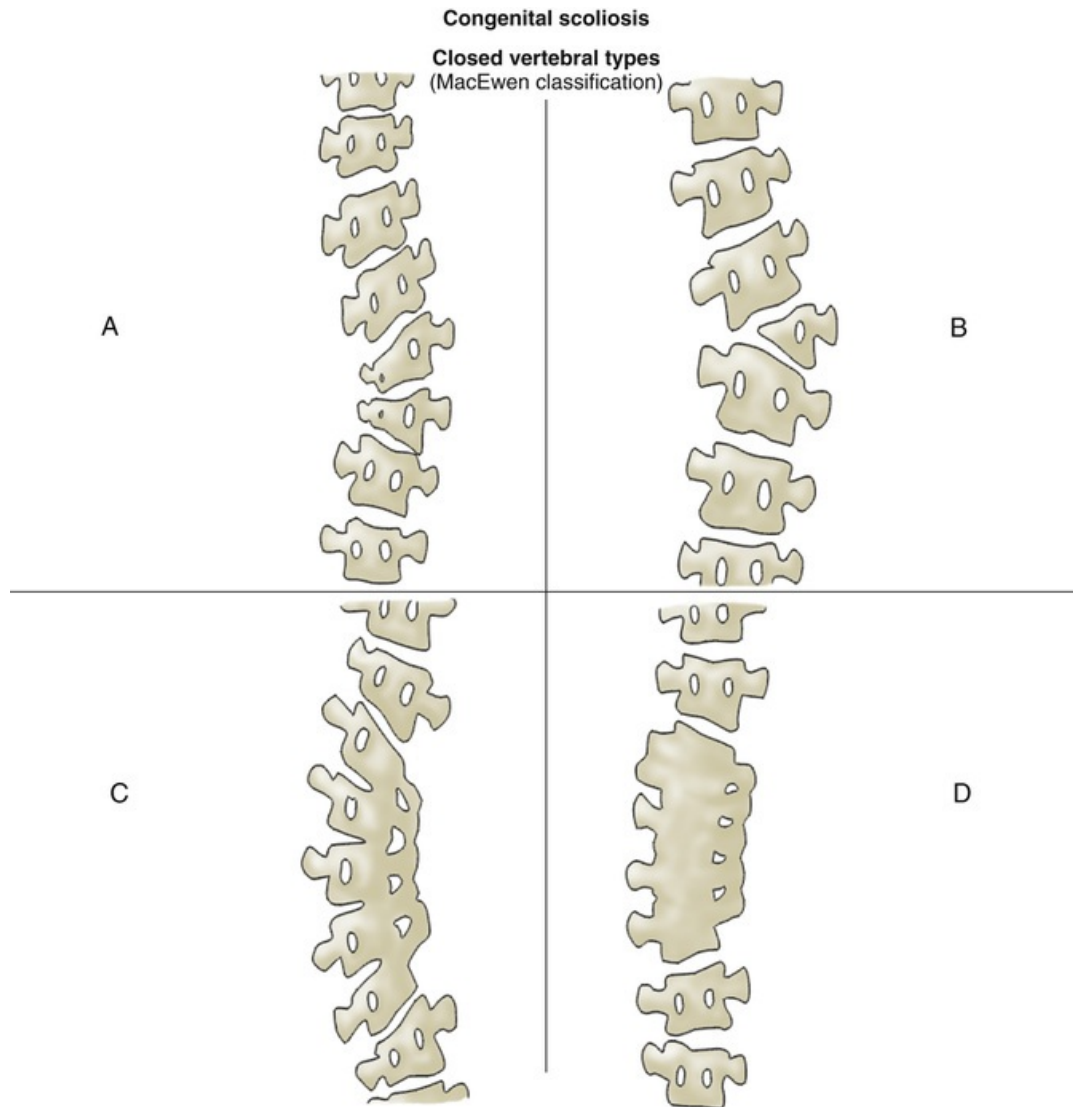

FIGURE 202.3 Types of closed vertebral and extravertebral spinal anomalies that result in congenital scoliosis. **(A)** Partial unilateral failure of formation (wedge vertebra). **(B)** Complete unilateral failure of formation (hemivertebra). **(C)** Unilateral failure of segmentation (congenital bar). **(D)** Bilateral failure of segmentation (block vertebra).

Partial or complete failure of vertebral formation (wedge vertebra or hemivertebra)

Partial or complete failure of segmentation (unsegmented bars)

Mixed

More than 60% of patients have other associated abnormalities, such as VACTERL association (vertebral defects, imperforate anus, cardiac anomalies,

tracheoesophageal fistula, renal anomalies, limb abnormalities such as radial agenesis) or Klippel-Feil syndrome. Renal anomalies occur in 20% of children with congenital scoliosis, with renal agenesis being the most common; 6% of children have a silent, obstructive uropathy suggesting the need for evaluation with ultrasonography. Congenital heart disease occurs in about 12% of patients. **Spinal dysraphism** (tethered cord, intradural lipoma, syringomyelia, diplomyelia, and diastematomyelia) occurs in approximately 20% of children with congenital scoliosis. These disorders are frequently associated with cutaneous lesions on the back and abnormalities of the legs and feet (e.g., cavus foot, neurological changes, calf atrophy). MRI is indicated in evaluation of spinal dysraphism.

The risk of spinal deformity progression in congenital scoliosis is variable and depends on the growth potential of the malformed vertebrae. A unilateral unsegmented bar typically progresses, but a block vertebra has little growth potential. About 75% of patients with congenital scoliosis will show some progression that continues until skeletal growth is complete, and about 50% will require some type of treatment. Progression can be expected during periods of rapid growth (before 2 years and after 10 years).

Treatment of congenital scoliosis hinges on early diagnosis and identification of progressive curves. Orthotic treatment is not helpful in congenital scoliosis. Early spinal surgery should be performed once progression has been documented. This can help prevent major deformities. Patients with large curves that cause thoracic insufficiency should undergo surgery immediately.

Neuromuscular Scoliosis

Progressive spinal deformity is a common and potentially serious problem associated with many neuromuscular disorders, such as cerebral palsy, Duchenne muscular dystrophy, spinal muscular atrophy, and spina bifida. Spinal alignment must be part of the routine examination for a patient with neuromuscular disease. Once scoliosis begins, progression is usually continuous. The magnitude of the deformity depends on the severity and pattern of weakness, whether the underlying disease process is progressive, and the amount of remaining musculoskeletal growth. Nonambulatory patients have a higher incidence of spinal deformity than ambulatory patients. In nonambulatory patients, the curves tend to be long and sweeping, produce pelvic obliquity, involve the cervical spine, and also produce restrictive lung disease. If the child cannot stand, then a

supine or seated anteroposterior radiograph of the entire spine, rather than a standing posteroanterior view, is indicated.

The goal of **treatment** is to prevent progression and loss of function. Nonambulatory patients are more comfortable and independent when they can sit in a wheelchair without external support. Progressive curves can impair sitting balance, which affects quality of life. Orthotic treatment is usually ineffective in neuromuscular scoliosis. Surgical intervention may be necessary with frequent fusion to the pelvis.

Compensatory Scoliosis

Adolescents with a leg-length discrepancy ([Chapter 200](#)) may have a positive screening examination for scoliosis. Before correction of the pelvic obliquity, the spine curves in the same direction as the obliquity. However, with identification and correction of any pelvic obliquity, the curvature should resolve, and treatment should be directed at the leg-length discrepancy. Thus it is important to distinguish between a structural and compensatory spinal deformity.

Kyphosis

Decision-Making Algorithm

Back Pain

Kyphosis refers to a roundback deformity or to increased angulation of the thoracic or thoracolumbar spine in the sagittal plane. Kyphosis can be postural, structural (Scheuermann kyphosis), or congenital.

Postural Roundback

Postural kyphosis is secondary to poor posture. It is voluntarily corrected in the standing and prone positions. The patient may also have increased lumbar lordosis. Radiographs are usually unnecessary if the kyphosis fully corrects. If not, radiographs will reveal no vertebral abnormalities. Treatment, if needed, is aimed at improving the child's posture.

Scheuermann Kyphosis

Scheuermann disease is the second most common cause of pediatric spinal deformity. It occurs equally in males and females. The etiology is unknown, but there may be hereditary factors. Scheuermann kyphosis is differentiated from postural roundback on physical examination and by radiographs.

A patient with Scheuermann disease cannot correct the kyphosis with standing or lying prone. When viewed from the side in the forward flexed position, patients with Scheuermann disease will have an abrupt angulation in the mid to lower thoracic region (Fig. 202.4), and patients with postural roundback show a smooth, symmetrical contour. In both conditions, lumbar lordosis is increased. However, half of patients with Scheuermann disease will have atypical back pain, especially with thoracolumbar kyphosis. The **classic radiological findings** of Scheuermann kyphosis include the following:

FIGURE 202.4 Note the sharp break in the contour of a child with kyphosis. (From Behrman RE. *Nelson Textbook of Pediatrics*. 14th ed. Philadelphia: WB Saunders; 1992.)

Narrowing of disk space

Loss of anterior height of the involved vertebrae producing wedging of 5 degrees or more in at least three consecutive vertebrae

Irregularities of the vertebral endplates

Schmorl nodes

Treatment of Scheuermann kyphosis is similar to idiopathic scoliosis. It is dependent on the degree of deformity, skeletal maturity, and the presence or absence of pain. Nonoperative treatment begins with bracing. Surgical fusion is done for patients who have completed growth, have a severe deformity, or have intractable pain.

Congenital Kyphosis

Congenital kyphosis is a failure of the formation of all or part of the vertebral body (with preservation of posterior elements) or failure of anterior segmentation of the spine, or both. Severe deformities are found at birth and tend to rapidly progress. Progression will not cease until the end of skeletal growth. A progressive spine deformity may result in neurological deficit. Treatment of congenital kyphosis is often surgical.

Torticollis

Etiology and Epidemiology

Torticollis is usually first identified in newborns because of a head tilt. Torticollis is usually secondary to a shortened sternocleidomastoid muscle (muscular torticollis). This may result from in utero positioning or birth trauma. Acquired torticollis may be related to upper cervical spine abnormalities or central nervous system pathology (mass lesion). It can also occur in older children during a respiratory infection (potentially secondary to lymphadenitis) or local head or neck infection, and it may herald psychiatric diagnoses.

Clinical Manifestations and Evaluation

Decision-Making Algorithms

Neck Masses
Stiff or Painful Neck

Infants with muscular torticollis have the ear tilted toward the clavicle on the ipsilateral side. The face will look upward toward the contralateral side. There

may be a palpable swelling or fibrosis in the body of the sternocleidomastoid shortly after birth, which is often the precursor of a contracture. Congenital muscular torticollis is associated with skull and facial asymmetry (**plagiocephaly**) and developmental dysplasia of the hip.

After a thorough neurological examination, anteroposterior and lateral radiographs should be obtained. The goal is to rule out a nonmuscular etiology. A computed tomography (CT) scan or MRI of the head and neck is necessary for persistent neck pain, neurological symptoms, and persistent deformity.

Treatment

Treatment of muscular torticollis is aimed at increasing the range of motion of the neck and correcting the cosmetic deformity. Stretching exercises of the neck can be very beneficial for infants. Surgical management is indicated if patients do not improve with adequate stretching exercises in physical therapy. Postoperative physical therapy is needed to decrease the risk of recurrence. Treatment in patients with underlying disorders should target the disorder.

Back Pain in Children

Etiology and Epidemiology

Back pain in the pediatric population should always be approached with concern. In contrast to adults, in whom back pain is frequently mechanical or psychological, back pain in children may be the result of organic causes, especially in preadolescents. Back pain lasting longer than a week requires a detailed investigation. In the pediatric population, approximately 85% of children with back pain for greater than 2 months have a specific lesion: 33% are post-traumatic (spondylolysis, occult fracture), 33% are developmental (kyphosis, scoliosis), and 18% have an infection or tumor. In the remaining 15%, the diagnosis is undetermined.

Clinical Manifestations and Management

Decision-Making Algorithm

Back Pain

The history must include the onset and duration of symptoms. The location, character, and radiation of pain are important. Neurological symptoms (muscle weakness, sensory changes, and bowel or bladder dysfunction) must be reviewed. Medical history and family history should be obtained, with a focus on back pain, rheumatological disorders, and neoplastic processes. The review of systems should include detailed questions on overall health, fever, chills, recent weight loss, and recent illnesses. Physical examination should include a complete musculoskeletal and neurological evaluation. Spinal alignment, range of motion, areas of tenderness, and muscle spasm should be noted. **Red flags** for childhood back pain include persistent or increasing pain, systemic findings (e.g., fever, weight loss), neurological deficits, bowel or bladder dysfunction, young age (under 4 is strongly associated with tumor), night waking, pain that restricts activity, and a painful left thoracic spinal curvature.

Anteroposterior and lateral standing films of the entire spine with bilateral oblique views of the affected area should be obtained. Secondary imaging with bone scan, CT scan, or MRI may be necessary for diagnosis. MRI is very useful for suspected intraspinal pathology. Laboratory studies, such as a complete blood count, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and specialized testing for juvenile idiopathic arthritis and ankylosing spondylitis, may be indicated.

The differential diagnosis of pediatric back pain is extensive ([Table 202.2](#)). Treatment depends on the specific diagnosis. If serious pathology has been ruled out and no definite diagnosis has been established, an initial trial of physical therapy with close follow-up for reevaluation is recommended.

TABLE 202.2

Differential Diagnosis of Back Pain

INFECTIOUS DISEASES
Diskitis (most common before the age of 6 years) Vertebral osteomyelitis (pyogenic or tuberculous) Spinal epidural abscess Pyelonephritis Pancreatitis

NEOPLASTIC DISEASES
Primary vertebral tumors (osteogenic sarcoma) Metastatic tumor (neuroblastoma) Primary spinal tumor (astrocytoma) Bone marrow malignancy (leukemia, lymphoma) Benign tumors (eosinophilic granuloma, osteoid osteoma)
OTHER
Conversion disorder Juvenile osteoporosis

Spondylolysis and Spondylolisthesis

Etiology and Epidemiology

Spondylolysis is a defect in the pars interarticularis. Spondylolisthesis refers to bilateral defects with anterior slippage of the superior vertebra on the inferior vertebra. The lesions are not present at birth, but about 5% of children will have the lesion by 6 years of age. It is most common in adolescent athletes, especially those involved in sports that involve repetitive back extension. Classically, this was an injury seen in gymnasts and divers. However, with increased intensity and year-round sports, the incidence is increasing. Football interior linemen (extension while blocking), soccer players (extension while shooting), and basketball players (extension while rebounding) are examples of athletes at higher risk. The most common location of spondylolysis is L5, followed by L4.

Spondylolisthesis is classified according to the degree of slippage:

- Grade 1: less than 25%
- Grade 2: 25-50%

- Grade 3: 50-75%
- Grade 4: 75-99%
- Grade 5: complete displacement or spondyloptosis

The most common location of spondylolisthesis is L5 on S1.

Clinical Manifestations

Decision-Making Algorithm

Back Pain

Patients will often complain of an insidious onset of low back pain persisting over 2 weeks. The pain tends to worsen with activity and with extension of the back and improves with rest. There may be some radiation of pain to the buttocks. A loss of lumbar lordosis may occur due to muscular spasm. Pain is present with extension of lumbar spine and with palpation over the lesion. Patients with spondylolisthesis may have a palpable *step off* at the lumbosacral area. A detailed neurological examination should be done, especially because spondylolisthesis can have nerve root involvement.

Radiological Evaluation

Anteroposterior, lateral, and oblique radiographs of the spine should be obtained. The oblique views may show the classic *Scotty dog* findings associated with spondylolysis. The lateral view will allow measurement of spondylolisthesis. Unfortunately, plain radiographs do not regularly reveal spondylolysis, so advanced imaging may be needed. The most helpful form of advanced imaging among CT, bone scan, single photon emission CT (SPECT), or MRI continues to be debated. MRI should be considered in patients with neurological deficits.

Treatment

Spondylolysis

Painful spondylolysis requires activity restriction. Bracing is controversial but

may help with pain relief. Patients benefit from an aggressive physical therapy plan to improve lower extremity flexibility and increase core strength and spinal stability. There is evidence that some patients with an acute spondylolysis can achieve bony union and that these patients have a decreased incidence of low back pain and degenerative change in the low back as they age when compared with spondylolysis patients with nonunion. Rarely, surgery is indicated for intractable pain and disability.

Spondylolisthesis

Decision-Making Algorithm

Back Pain

Patients with spondylolisthesis require periodic evaluation for progression of their slippage. Treatment of spondylolisthesis is based on grading:

- Grade 1: Same treatment as spondylolysis. Failure of nonoperative management may lead to surgical fusion.
- Grade 2: Reasonable to try nonoperative management, but if the slippage is progressing, surgical intervention may be needed. Any patient with neurological symptoms requires surgical intervention.
- Grades 3-5: Spinal fusion is usually required to prevent further slippage or damage.

Diskitis

Decision-Making Algorithms

Back Pain
Stiff or Painful Neck

Diskitis is an intervertebral disk space infection that does not cause associated vertebral osteomyelitis (see [Chapter 117](#)). The most common organism is *Staphylococcus aureus*. The infection can occur at any age but is more common in patients under 6 years of age.

Clinical Manifestations

Children may present with back pain, abdominal pain, pelvic pain, irritability, and refusal to walk or sit. Fever is an inconsistent symptom. The child typically holds the spine in a straight or stiff position, generally has a loss of lumbar lordosis due to paravertebral muscular spasm, and refuses to flex the lumbar spine. The white blood cell count is normal or elevated, but the ESR and CRP are usually high.

Radiological Evaluation

Radiographic findings vary according to the duration of symptoms before diagnosis. Anteroposterior, lateral, and oblique radiographs of the lumbar or thoracic spine will typically show a narrow disk space with irregularity of the adjacent vertebral body end plates. In early cases, bone scan or MRI may be helpful because they will be positive before findings are noticeable on plain radiographs. MRI can also be used to differentiate between diskitis and the more serious condition of vertebral osteomyelitis.

Treatment

Intravenous antibiotic therapy is the mainstay of treatment. Blood cultures may occasionally be positive and identify the infectious agent. Aspiration and needle biopsy are reserved for children who are not responding to empirical antibiotic treatment. Symptoms should resolve rapidly with antibiotics, but intravenous antibiotics should be continued for 1-2 weeks and be followed by 4 weeks of oral antibiotics. Pain control can be obtained with medications and temporary orthotic immobilization of the back.

Upper Extremity

Shoulder

The shoulder actually comprises four joints:

- Glenohumeral joint (commonly referred to as the shoulder joint)
- Acromioclavicular joint
- Sternoclavicular joint
- Scapulothoracic joint

The glenohumeral joint has minimal geometric stability because the relatively small glenoid fossa articulates with the proportionately larger head of the humerus. The low level of intrinsic stability allows for a large range of motion. The rotator cuff muscles help give the glenohumeral joint more stability, but they need normal contact of the glenohumeral joint to be successful. The scapulothoracic movement also expands the range of motion of the shoulder, but like the glenohumeral joint, it requires strong, coordinated musculature to function efficiently.

Sprengel Deformity

Sprengel deformity is the congenital elevation of the scapula. There are varying degrees of severity; it is usually unilateral. There is restricted scapulothoracic motion (especially with abduction), so most of the shoulder motion is through the glenohumeral joint. There is usually associated hypoplasia of the periscapular muscles. Webbing of the neck and low posterior hairline can be associated problems. There is an association with congenital syndromes, such as Klippel-Feil anomaly, so a thorough history and examination are necessary. Mild forms with a cosmetic deformity and mild loss of shoulder motion do not need surgical correction. Severe forms may have a bony connection (omovertebral) between the scapula and lower cervical spine. Moderate and severe forms may need surgical repositioning of the scapula in early childhood to improve cosmesis and function.

Brachial Plexus Injuries

Obstetric brachial plexus palsy is discussed in [Section 11](#). **Brachial plexopathy** is an athletic injury, commonly referred to as a **stinger** or **burner**. The symptoms are often likened to a *dead arm*. There is pain (often burning), weakness, and numbness in a single upper extremity. There are three mechanisms of injury:

1. Traction caused by lateral flexion of the neck away from the involved upper extremity
2. Direct impact to the brachial plexus at Erb's point
3. Compression caused by neck extension and rotation toward the involved extremity

Symptoms are always unilateral and should resolve within 15 minutes. It is paramount to assess the *cervical spine* for serious injury. Bilateral symptoms, lower extremity symptoms, persistent symptoms, or recurrent injury are all signs of more serious disease and may need a more extensive work-up and cervical spine stabilization. Athletes may return to activity if there are no red flags on history or physical examination and the athlete has full pain-free range of motion and strength in the neck and affected extremity.

Glenohumeral Dislocation

Shoulder dislocation is uncommon in childhood but becomes more frequent in adolescence. The younger the patient is at presentation, the more likely it is that the patient will have recurrent dislocation. Anterior dislocation is the most common. If assessment of the neurovascular status of the affected extremity reveals any compromise, urgent reduction is needed to prevent further complications. Patients will need radiographs to assess for fractures of the glenoid (Bankhart lesion) and humeral head (Hill-Sachs lesion). Most patients will require a brief period of protection in a sling or shoulder immobilizer, as well as pain control. As symptoms resolve, a gentle range-of-motion program, followed by an aggressive strengthening program, should be done. Recurrence rate may be nearly 90% for contact sport athletes, so there is controversy surrounding early surgical intervention at the first dislocation.

Overuse Injuries

The incidence of overuse injuries is increasing because of increased opportunities for athletic participation as well as higher levels of intensity during sports. Overuse injuries are inflammatory responses in tendons and bursae that are subjected to repetitive motions and trauma (e.g., rotator cuff tendinitis in swimmers). These injuries are uncommon in children but may be seen in adolescents. Bony injury, such as physal fractures and apophysitis, must be ruled out before making the diagnosis of a soft tissue overuse injury. Overuse injuries in the shoulder can be provoked by joint laxity.

The patient will often present with discomfort over the affected area that worsens with activity. Physical examination usually reveals tenderness to palpation and often weakness of the associated muscles due to pain. It is important to assess for glenohumeral stability. Radiographs may be indicated for acute trauma or when symptoms are not improving. Treatment consists of activity modification, icing, antiinflammatory medication, and a physical therapy program aimed at strengthening, increasing flexibility, and improving posture.

Proximal Humeral Epiphysiolysis

Proximal humeral epiphysiolysis is commonly referred to as **Little Leaguer's shoulder**. It most commonly occurs in 9–14 year olds who participate in overhead (tennis, volleyball) and throwing sports, particularly baseball pitchers. It is a stress injury that potentially can be a fracture (epiphysiolysis) of the proximal humeral physis. Most patients present with pain during or after throwing. There may be tenderness to palpation over the proximal humerus; if the athlete has been resting for a few days, examination may be normal. Radiographs should include comparison views to assess the physis. There may be widening of the proximal humeral physis in the affected arm, but the films may be normal. Treatment is rest from the offending activity, followed by a rehabilitation program designed to improve strength in the shoulder muscles. Pitchers should also be encouraged to follow youth pitching guidelines published by Little League baseball.

Elbow

The elbow consists of three articulations:

1. Ulnar-humeral joint
2. Radial-humeral joint
3. Proximal radioulnar joint

Collectively, these joints produce a hinge-type joint that allows for supination (palm up) and pronation (palm down) positioning of the hand. The elbow has excellent geometric stability, and the musculature around the elbow primarily produces flexion and extension.

Radial Head Subluxation

Decision-Making Algorithm

Extremity Pain

Radial head subluxation is more commonly known as **nursemaid's elbow**. Because the radial head is not as bulbous in infants and young children, the annular ligament that passes around it can partially slip off the radial head with traction across the elbow ([Fig. 203.1](#)). The subluxation is usually caused by a quick pull on the extended elbow when a child is forcefully lifted by the hand or when the child falls while holding hands with an adult. After a subluxation, the child usually holds the hand in a pronated position and will refuse to use the hand or move the elbow. Moving the hand into the supinated position while applying pressure to the radial head will usually reduce the injury. Usually radiographs are not necessary unless reduction cannot be obtained or there is concern for fracture (swelling and bruising). Once the injury is reduced, the child will begin using the arm again without complaint. Parents should be educated about the mechanism of injury and encouraged to avoid that position. There is a high rate of recurrence for this injury. The problem generally resolves with maturation, but some children with high recurrence rates may benefit from casting or, rarely, surgical intervention.

FIGURE 203.1 Nursemaid's elbow. The annular ligament is torn when the arm is pulled. The radial head moves distally, and when traction is discontinued, the ligament is carried into the joint. (From Rang M. *Children's Fractures*. Philadelphia: JB Lippincott; 1974:121.)

Panner Disease

Decision-Making Algorithm

Extremity Pain

Panner disease is an osteochondritis of the capitellum (lateral portion of distal humeral epiphysis) that occurs spontaneously in late childhood. Clinical features include elbow pain, decreased range of motion, and tenderness to palpation over the capitellum. Radiographs reveal fragmentation of the capitellum. Treatment is activity restriction and follow-up radiographs to demonstrate spontaneous reossification of the capitellum over several months. There is usually no need for further treatment or imaging studies. This is not to be confused with osteochondritis dissecans of the capitellum, which usually will occur in adolescents involved with throwing sports.

Throwing Injuries

The elbow is especially vulnerable to throwing injuries in the skeletally

immature athlete. These occur from excessive and repetitive tension forces across the radial aspect of the elbow and compression forces across the lateral aspect of the elbow. These injuries are commonly known as Little Leaguer's elbow.

Decision-Making Algorithm

Extremity Pain

Although this injury is most common in baseball players who throw frequently (pitcher, catcher, third base, and shortstop), it also occurs in football quarterbacks and tennis players. Patients will usually complain of pain over the medial elbow with throwing that may last for a few days afterward. There may be associated swelling and lateral or posterior elbow pain. Radiation of pain may be secondary to ulnar neuropathy. There is often a flexion contracture of the elbow when compared to the opposite side. Palpation of the medial epicondyle, radial head, capitellum, lateral epicondyle, and olecranon process often reveals tenderness. Ulnar (medial) collateral ligament stability should be assessed. Radiographs should include the contralateral elbow for comparison. Radiographic findings in Little Leaguer's elbow can vary and may include normal anatomy, medial humeral epicondyle apophyseal avulsion fracture, osteochondritis dissecans of the capitellum, radial head abnormalities, and foreign bodies in the elbow. MRI may be helpful.

Treatment depends on the underlying diagnosis but always includes pain control and rest from activity. *Classic Little Leaguer's elbow* refers to medial humeral epicondyle apophysitis. These athletes benefit from rest, ice, antiinflammatory medication, and a physical therapy program aimed at upper body strengthening. Throwing mechanics and the pitching guidelines published by Little League Baseball/Softball should be reviewed with these players. Switching players to a lower throwing position (e.g., first base) after rehabilitation, to avoid pitching for the remainder of the season, is often recommended.

Wrist and Hand

Multiple small joints, a delicately balanced intrinsic muscle system, a powerful

extrinsic muscle system, dense sensory innervation, and specialized skin combine to make the hand a highly mobile and sensitive yet powerful anatomical part. The extrinsic muscles originate in the forearm and the intrinsic muscles are located in the hand and coordinate small, delicate movements. The movements of opening the hand, extending and spreading the fingers, and then clenching the hand into a fist requires coordinated function of the intrinsic and extrinsic muscles. Tenderness of direct palpation of the bones raises the concern for fracture. **Scaphoid fracture** is the most common carpal bone fracture in the pediatric population. It requires immobilization in a thumb spica cast, whereas displaced fractures require surgical intervention. **Salter-Harris fractures of the distal radius** are also very common. In young gymnasts, there is increased risk for injury at the distal radial physis from repetitive impact and upper extremity weight bearing. This is commonly called **gymnast's wrist** and requires absolute rest from impact and weight bearing to prevent premature closure of the growth plate.

Ganglion cysts are synovial fluid-filled cysts about the wrist. The most common location is the dorsum of the wrist near the radiocarpal joint, followed by the volar radial aspect of the wrist. The defect is in the joint capsule, which allows synovial fluid into the soft tissues with wrist use, where it can become walled off with fibrous tissue. Often, in skeletally immature patients, the process is benign and disappears over time. Large ganglion cysts or cysts that are painful and interfere with function may require more aggressive therapy. Aspiration and steroid injection into the cyst may be helpful, but many will recur. Surgical excision will remove the tract that attaches to the wrist joint, so it is usually curative.

Finger Abnormalities

Polydactyly (extra digits) occurs in simple and complex varieties (see [Table 201.2](#)). Skin tags and digit remnants that occur near the metacarpophalangeal joint of the fifth digit and thumb that do not have palpable bones or possess voluntary motion are simple varieties. These may be excised or ligated in the nursery. Complex deformities should be referred to a pediatric orthopedist for amputation. **Syndactyly** (fused digits) are concerning because of the possibility of shared structures and the tethering effects on bone growth (see [Table 201.2](#)). All patients with syndactyly should be referred for treatment options.

Trigger thumb and **trigger finger** are secondary to isolated thickening of the

flexor tendons. As the thickened nodule enlarges, it may catch in a bent position, then snap or *trigger* straight as it passes through the first pulley that anchors the tendon. Ultimately, as it enlarges, it cannot pass through at all and produces a flexion deformity at the interphalangeal joints. The nodule may be palpable near the metacarpophalangeal joint. These children should be referred for surgical correction.

CHAPTER 204

Benign Bone Tumors and Cystic Lesions

Benign bone tumors and cystic lesions are common in childhood. Some represent fibrous dysplasia. Others are benign bone cysts (unicameral) or benign bone tumors (osteoid osteoma). Subacute osteomyelitis (**Brodie abscess**) and eosinophilic granulomas are lesions not associated with abnormal bone or cartilage growth. Some of these lesions can produce pain, limp, and pathological fractures. Others can be incidental findings on radiographs. The prognosis is usually excellent. A brief differential diagnosis of bone tumors and their management is listed in [Table 204.1](#). Malignant bone tumors are discussed in [Section 21](#).

TABLE 204.1

Benign Bone Tumors and Cysts

DISEASE	CHARACTERISTICS	RADIOGRAPHIC FINDINGS	TREATMENT	PROG
Osteochondroma (osteocartilaginous exostosis)	Common; distal metaphysis of femur, proximal humerus, proximal tibia; painless, hard, nontender mass	Bony outgrowth, sessile or pedunculated	Excision, if symptomatic	Excellent; malignant transformation rare
Multiple hereditary exostoses	Osteochondroma of long bones; bone growth disturbances	As above	As above	Recurrent
Osteoid osteoma	Pain relieved by aspirin; femur and tibia; found predominantly in boys	Dense sclerosis surrounds small radiolucent nidus, <1 cm	As above	Excellent
Osteoblastoma (giant osteoid osteoma)	As above, but more destructive	Osteolytic component; size >1 cm	As above	Excellent

Enchondroma	Tubular bones of hands and feet; pathological fractures, swollen bone; Ollier disease if multiple lesions are present	Radiolucent diaphyseal or metaphyseal lesion; may calcify	Excision or curettage	Excellent; malignancy; transferrable
Nonossifying fibroma	Silent; rare pathological fracture; late childhood, adolescence	Incidental radiographic finding; thin sclerotic border, radiolucent lesion	None or curettage with fractures	Excellent; spontaneous
Eosinophilic granuloma	Age 5-10 years; skull, jaw, long bones; pathological fracture; pain	Small, radiolucent without reactive bone; punched-out lytic lesion	Biopsy, excision rare; irradiation	Excellent; spontaneous
Brodie abscess	Insidious local pain; limp; suspected as malignancy	Circumscribed metaphyseal osteomyelitis; lytic lesions with sclerotic rim	Biopsy; antibiotics	Excellent
Unicameral bone cyst (simple bone cyst)	Metaphysis of long bone (femur, humerus); pain, pathological fracture	Cyst in medullary canal, expands cortex; fluid-filled unilocular or multilocular cavity	Curettage; steroid injection into lesion	Excellent; heal spontaneously
Aneurysmal bone cyst	As above; contains blood, fibrous tissue	Expands beyond metaphyseal cartilage	Curettage, bone graft	Excellent

Pearls for Practitioners

Chapter 197

Orthopedics Assessment

- Orthopedic rough guide to developmental milestones
 - Sit independently at 6 months
 - Pull to stand at 10 months
 - Cruising at 12 months
 - Walk at 18 months
- Lower extremity angular profile
 - Genu varum (bowlegs)—birth and begin to straighten out by 18 months
 - Genu valgum (knock knees)—maximum at 4 years old and resolve by 5-8 years of age
 - Pathological genu verum: Blount disease (Tibia Vara) and Rickets
- The limping child differential diagnosis
 - Painful
 - Septic arthritis, osteomyelitis, diskitis
 - Transient monoarticular synovitis
 - Toddler's fracture or trauma
 - Malignancy
 - Rheumatological disorders in older children
 - Acute slipped capital femoral epiphysis (SCFE) in adolescents
 - Painless
 - Development dysplasia of the hip
 - Neuromuscular disorder

- Leg length inequality
- Legg-Calve-Perthes disease in older children
- Muscular dystrophy in older children
- Chronic, stable SCFE in adolescents

Chapter 198

Fractures

- Salter-Harris Fracture Types
 - I—transverse through physis
 - II—through physis into metaphysis
 - III—through physis into epiphysis (joint)
 - IV—through both metaphysis and epiphysis
 - V—crush to the physis
- Signs/symptoms of acute compartment syndrome producing neurovascular injury
 - Pain out of proportion, exacerbated by passive stretch or muscle contraction
 - Later findings: pallor, pulselessness, paresthesia, poikilothermia (cold)
 - Common sites at risk include supracondylar and tibial fractures

Chapter 199

Hip

- Development dysplasia of the hip
 - Risk factors: first born, female, breech, family history, oligohydramnios
 - Associated lesions include congenital torticollis, metatarsus adductus, and clubfoot
 - Ortolani test reduces dislocated hip

- Barlow test dislocates unstable hip
- Galeazzi sign indicates dislocated hip
- Klisic test is helpful to diagnose bilateral dislocations
- Treatment is Pavlik harness through 6 months of age
- Legg-Calve-Perthes disease
 - Avascular necrosis of the femoral head
 - Classic presentation is painless limp in elementary school-aged boy
 - Mean age is 7 years
 - Delayed treatment increases risk of arthritis
- Transient monoarticular synovitis often follows a recent viral illness, with no fever and normal to minimally elevated white blood cell (WBC), erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP)
- Septic arthritis has elevated WBC, ESR, CRP, and elevated joint fluid cell count. Patients are usually febrile and hold hip in flexion and external rotation.
- Slipped capital femoral epiphysis
 - Mean age is 12 years in males and 11 years in females
 - Risk factors: adolescent, obese, trisomy 21, endocrine disorder
 - May present as isolated hip or knee pain
 - Hip held externally rotated, especially when moved into hip flexion
 - Treat as orthopedic emergency—non-weight bearing and immediate referral

Chapter 200

Lower Extremity and Knee

- Tarsal coalition
 - Rigid flatfoot with decreased subtalar motion

- Imaging is diagnostic (x-rays and computed tomography)
- Treat with rest and immobilization or surgical excision
- Apophysitis
 - Osgood Schlatter disease at tibial tubercle
 - Sever disease at posterior calcaneus
 - Sinding Larsen Johansson syndrome at inferior pole of patella
 - Treat with rest, stretching, and ice
 - Internal tibial torsion is the most common cause of in-toeing in children <2 years of age
 - Internal femoral torsion (anteversion) may be seen in children with W-sitting positions
 - Acute swelling of the knee joint after injury may indicate a hemarthrosis
 - Chondromalacia of the patella is an incorrect term; the proper term is patellofemoral pain syndrome

Chapter 201

Foot

- Clubfoot (talipes equinovarus) may be congenital, teratological, or positional
- Clubfoot is often seen with developmental hip dysplasia
- Metatarsus adductus is a common foot disorder in infants; it resolves spontaneously in >90% of infants
- Hypermobilable pes planus (flatfoot) are pronated feet associated with generalized ligamentous laxity, in children over 6 years of age
- A cavus foot (high arch) is associated with Charcot-Marie-Tooth disease (genetic neuropathy)

Chapter 202

Spine

- Scoliosis
 - Coronal curvature greater than 10 degrees
 - Adam's forward bend test shows trunk asymmetry
 - Congenital scoliosis has abnormal bony morphology
 - Neuromuscular scoliosis is associated with underlying disorder
 - Idiopathic scoliosis—no clear etiology
 - Treat
 - <25 degrees—observation
 - 20-50 degree curve or if progressing—bracing
 - 50+ degree curve—spinal fusion
- Kyphosis
 - Postural—normal bony structure
 - Scheuermann kyphosis
 - >5 degree anterior wedging on 3 consecutive vertebral bodies
 - Treat with bracing if skeletally immature; observation or surgical correction if skeletally mature
 - Congenital—abnormal bony structure that often requires bracing or surgery to treat

Chapter 203

Upper Extremity

- Brachial plexus birth injury
 - Moro reflex will give true neurological function
 - Differential diagnosis: clavicle or humerus fracture
- Radial head subluxation (nursemaid's elbow)
 - Mechanism—pulling the outstretched arm of a child
 - Treatment is reduction, usually with supination of

forearm and flexion of elbow

progesterone-only pill or minipill for, 280

menstrual disorders in, 275–277

abnormal uterine bleeding as, 276–277

amenorrhea as, 275–276

dysmenorrhea as, 277

irregular menses as, 274–275

pregnancy in, 277–278

continuation of, 278

diagnosis of, 278

termination of, 278

rape in, 281

Adoption, 89

Adrenal adenomas, 660

Adrenal carcinomas, 660

Adrenal cortex, 674

Adrenal corticosteroids, maternal use of, 238t

Adrenal gland, physiology of, 674

Adrenal gland dysfunction, 674–678, 680

Addison disease, 676–678

- adrenal insufficiency, [674–675](#)
- Cushing syndrome, [678](#)
- 11-hydroxylase deficiency, [676](#)
- 21-hydroxylase deficiency, [675–676](#)

Adrenal hemorrhage, [675](#)

Adrenal hyperplasia

- congenital, [Congenital adrenal hyperplasia](#)
- lipoid, [675f](#)
- mild (late-onset) or nonclassic, [675](#)

Adrenal insufficiency, [674–675](#)

- clinical and biochemical features of, [677t](#)
- clinical manifestations of, [676t](#)

Adrenarche

- in boys, [271–273](#), [272f](#)
- in girls, [270–271](#), [271f–272f](#)

Adrenoleukodystrophy (ALD), [713](#)

- genetic basis for, [174t](#)
- X-linked, [711t–712t](#), [713](#)

Adult health challenges, [2](#)

Adult tapeworm infections, [452t](#)

Advanced care, [6](#)

Adventitious breath sounds, [510t](#)

Adverse drug reactions, [338–339](#)

- accelerated, [338](#)
- classification of, [338](#)
- clinical manifestations of, [338](#)
- complications of, [339](#)
- defined, [338](#)
- differential diagnosis of, [339](#)
- epidemiology of, [338](#)
- etiology of, [338](#), [338t](#)
- immediate (anaphylactic), [338](#)

- immunological, [338](#), [338t](#)
- laboratory and imaging studies for, [338–339](#)
- late, [338](#)
- nonimmunological, [338](#), [338t](#)
- prevention of, [339](#)
- prognosis for, [339](#)
- treatment of, [339](#)

Advisory Committee on Immunization Practices (ACIP), on immunization, [364–365](#)

Advocacy, [4](#)

Aeroallergens, in asthma, [314](#)

Aerosol therapy, [512](#), [512f](#)

Afebrile pneumonia, [403](#)

Afferent pupillary defect, [683](#)

African tick-bite fever, [439t–442t](#)

African trypanosomiasis, [439t–442t](#)

Afterload, in heart failure, [553](#), [554t](#)

Afterload reduction

- for cardiomyopathies, [557t](#), [558](#)
- for heart failure, [554](#), [555t](#)
- for ventricular septal defect, [545–546](#)

Agammaglobulinemia, [294](#), [295t](#)

- autosomal recessive, [294](#)
- X-linked, [294](#)

Age, tantrums and, [43–44](#), [44f](#)

Age-related macular degeneration, [306](#)

Ages and Stages Questionnaires, [17](#)

Agonal respiration, [509t](#)

β_2 -Agonists, for asthma

- long-acting, [315](#)

short-acting, [315–316](#)

Agoraphobia, [62](#)

AH₅₀ test, [306](#)

AIRE (autoimmune regulator) gene, in chronic mucocutaneous candidiasis, [298](#)

Airway(s), endoscopic evaluation of, [511](#)

Airway hemorrhage, [525](#)

Airway hyperresponsiveness, in asthma, [313](#)

Airway management, for burns, [159](#)

Airway patency, in rapid cardiopulmonary assessment, [146t](#)

Airway remodeling, in asthma, [313](#)

Airway resistance, [508](#)

AIS (arterial ischemic stroke), [699](#)

Alagille syndrome, [494](#)

Albright hereditary osteodystrophy, [669](#)

Albuterol, for asthma, [315](#)

Alcohol

acute effects of, [284t–285t](#)

as teratogen, [237t](#)

use, during pregnancy, [90](#)

ALD (adrenoleukodystrophy), genetic basis for, [174t](#)

Alertness, assessment of, [682](#)

Alfentanil, as analgesia, [166t](#)

Algid malaria, [449](#)

Alkalemia, [139](#)

Alkali agents, ingestion of, [160–162](#)

Alkalosis

metabolic, [141–142](#), [141t](#)

respiratory, [142t](#)

Alkylating agents, for cancer, [601t–602t](#)

ALL, [Acute lymphoid/lymphoblastic leukemia](#)

Allergen, [311](#)

Allergen immunotherapy, for allergic rhinitis, [325](#)

Allergic bronchopulmonary aspergillosis (ABPA)
asthma vs., [314](#)
in cystic fibrosis, [527](#)

Allergic conjunctivitis, [433t](#)

Allergic contact dermatitis, [727](#), [728f](#)

Allergic eosinophilic esophagitis, [335t–336t](#)

Allergic eosinophilic gastroenteritis, [335t–336t](#)

Allergic proctocolitis, [335t–336t](#)

Allergic rhinitis, [323–325](#)
clinical manifestations of, [323](#)
complications of, [325](#)
differential diagnosis of, [323–324](#)
epidemiology of, [323](#)

Aplastic crisis(es)

in chronic hemolytic anemia, [574](#)

in sickle cell disease, [576](#), [577t](#)

transient, erythema infectiosum and, [377](#)

Apnea, [514–515](#)

categories of, [514t](#)

central, [246](#), [514](#), [514t](#)

defined, [246](#)

etiology of, [514–515](#)

mixed, [246](#)

obstructive, [246](#)

sleep, [514–515](#), [514t](#)

of prematurity, [246](#), [514](#), [514t](#)

Apnea-hypopnea index (AHI), [515](#)

Apneustic respiration, [509t](#)

Apophysis, [739t](#)

Apophysitis, calcaneal, [755](#)

clinical manifestations of, [755](#)

treatment of, [755](#)

Apparent life-threatening event (ALTE), [515](#)

Appearance, of newborn, [227](#)

Appendicitis, [493–494](#)

abdominal pain due to, [470t](#)

clinical manifestations of, [493](#)

etiology and epidemiology of, [493](#)

laboratory and imaging studies for, [493](#), [493t](#)

treatment of, [494](#)

vomiting due to, [473t](#)

Appendicular ataxia, [700](#)

Appetite suppression, in attention-deficit/hyperactivity disorder (ADHD), [47](#)

Arboviruses, encephalitis from, [389](#)

Arch, high, [755](#)

ARF, [Acute renal failure](#)

Argininosuccinate lyase (ASL) deficiency, [205](#)

Ariboflavinosis, [113](#)

Arm recoil, in newborn, [229f](#)

Arm span, [651](#)

Arousal, [703](#)

Arrhythmias, [Dysrhythmia\(s\)](#)

Arsenic, for cancer, [601t–602t](#)

Arterial blood gas, in respiratory failure, [150](#)

Arterial blood gas analysis, [511](#)

Arterial clots, in hemostatic disorders, [583](#)

Arterial ischemic stroke (AIS), [699](#)

Arterial switch, in transposition of great arteries, [551](#)

Artery-to-pulmonary shunt, for tricuspid atresia, [551](#)

Arthralgias, in systemic lupus erythematosus, [353](#)

Arthritis

in Henoch-Schönlein purpura, [345](#)

infectious, [428–430](#)

clinical manifestations of, [428–429](#)

complications and prognosis of, [430](#)

differential diagnosis of, [429](#), [433t](#)

epidemiology of, [428](#)

etiology of, [428](#)

- juvenile idiopathic arthritis vs., [352t](#)
- laboratory and imaging studies for, [429](#)
- pathogenic organisms causing, [428t](#)
- prevention of, [430](#)
- treatment of, [429–430](#), [430t](#)

juvenile idiopathic, [Juvenile idiopathic arthritis](#)

Lyme, [429t](#)

poststreptococcal, [352t](#)

reactive, [428](#)

- juvenile idiopathic arthritis vs., [352t](#)
- synovial fluid findings in, [429t](#)

in rheumatic diseases, [343](#)

due to rheumatic fever, [556](#)

in systemic lupus erythematosus, [353](#)

Arthritis-dermatitis syndrome, [428](#)

Arthrocentesis, for juvenile idiopathic arthritis, [351](#)

Arthrogryposis multiplex congenita, [185](#)

Arthroplasty, [739t](#)

Arthroscopy, [739t](#)

Arthrotomy, [739t](#)

Arthus reaction, [311](#)

Articular cartilage, [740f](#)

Artificial airway, [513](#)

Arylsulfatase A deficiency, [210t–212t](#)

Arytenoid cartilages, [507](#)

AS (Angelman syndrome), genetic basis for, [176](#)

Ascariasis, [450](#)

- intestinal, [450t](#)

- pulmonary, [450](#)

***Ascaris lumbricoides*, [450](#), [450t](#)**

Ascites, with chronic liver disease, [497](#), [500t](#)

Ascorbic acid deficiency, [112](#), [114t](#)

ASD, [Atrial septal defect](#)

ASD (autism spectrum disorder), [70–73](#), [70t](#)

Ash leaf spots, [715](#)

Asparaginase, for cancer, [601t–602t](#)

Aspartylglucosaminidase deficiency, [210t–212t](#)

Aspergillosis, allergic bronchopulmonary

asthma vs., [314](#)

in cystic fibrosis, [527](#)

Asphyxia

birth, etiology of, [225t](#)

effects of, [224t](#)

intrauterine, [225](#)

metabolic acidosis during, [222](#)

pallida, [233](#)

Aspiration, foreign body, [521–522](#)

bronchiolitis and, [402](#)

Aspirin

for Kawasaki disease, [348](#)

maternal use of, [238t](#)

Aspirin exacerbated respiratory disease, [324](#)

Assault, [92](#)

Association, in dysmorphology, [184](#)

Asthma, [313–321](#), [335t–336t](#), [520](#)

cardiogenic, [402](#)

clinical manifestations of, [313](#)

complications of, [316](#), [320f](#)

differential diagnosis of, [314](#), [314t](#)

epidemiology of, [313](#)

etiology of, [313](#)

factors contributing to severity of, [314](#), [315t](#)

laboratory and imaging studies of, 313–314
persistent, 316–321, 321*t*
prevention of, 321
prognosis for, 316–321, 318*t*
respiratory failure due to, 149
status asthmatic in, 316
treatment of, 314–316, 315*t*

- approach to, 316
 - stepwise, 316, 317*f*–318*f*
- for exacerbations, 320*f*
- long-term control medications in, 314–315
 - biologics as, 315
 - inhaled corticosteroids as, 314–315, 319*f*
 - leukotriene modifiers as, 315
 - long-acting β_2 -agonists as, 315
 - mepolizumab as, 315
 - omalizumab as, 315
 - theophylline as, 315
- quick-relief medications in, 315–316
 - anticholinergic agents as, 316
 - oral corticosteroids as, 316
 - short-acting β_2 -agonists as, 315–316
- rules of two for, 316
- self-management guidelines in, 321, 322*f*
 - adherence in, 321
 - peak flow monitoring in, 321

triad, 321*t*

Astroviruses, diarrhea from, 410*t*

Asymmetric tonic neck reflex, 14, 682*t*

Ataxia, 684, 700–703

due to acute labyrinthitis, 702
appendicular, 700
due to brain tumors, 701
clinical manifestations of, 700
defined, 700–702
due to drug intoxication, 700
etiologies of, 700–702, 701*t*
Friedreich, 702

- genetic basis for, 173*t*

due to inborn errors of metabolism, 702
due to neuroblastoma, 701–702
postinfectious acute cerebellar, 700–701

truncal, 700

Ataxia-telangiectasia, 298, 299t, 702

Atelectasis, 510t

in respiratory distress syndrome, 242

Atenolol, maternal use of, 238t

Athetosis, 702–703

Athlete's foot, 381t, *Tinea pedis*

Athletic amenorrhea, 658

ATM gene, in ataxia-telangiectasia, 298

Atomoxetine, for attention-deficit/hyperactivity disorder (ADHD), 47

Atonic seizures, 689

Atopic dermatitis, 325–328, 335t–336t, 724–727

with bacterial superinfection, 726, 727f

clinical manifestations of, 326, 326f, 724, 725f

complications of, 328, 726–727, 727f

differential diagnosis of, 326, 327t, 725

epidemiology of, 326, 724

etiology of, 325–326, 724

laboratory and imaging studies for, 326, 327t, 724–725

lichenified plaques in, 326, 326f

prevention of, 328, 727

prognosis for, 328, 727

treatment of, 326–328, 725–726

Atopic march, 724

Atopy, 311

Atrial contractions, premature, 543

Atrial dysrhythmias, 542–543

Atrial fibrillation, 543

Atrial flutter, 543, 544t

Atrial natriuretic peptide, in regulation of intravascular volume, [125](#)

Atrial pacemaker, wandering, [542](#)

Atrial septal defect (ASD), [546](#), [546f](#)

Atrophy, [722t](#)

Atropine

for cardiopulmonary resuscitation, [148t](#)

for organophosphate poisoning, [164t–165t](#)

Attachment, [91](#)

in infancy, [15](#)

Attention-deficit/hyperactivity disorder (ADHD), [45–47](#)

anticipatory guidance for, [47](#)

anxiety disorders and, [64](#)

clinical symptoms of, [46](#), [46t](#)

co-morbidities in, [46](#)

complications of, [47](#)

diagnosis of, [46](#)

differential diagnosis of, [46–47](#)

etiology of, [45](#)

evaluation of, [46](#)

laboratory and imaging studies in, [46](#)

physical examination for, [46](#)

treatment of, [47](#)

Atypical hemolytic uremic syndrome, [306](#)

Atypical lymphocytes

in infectious diseases, [362](#)

in lymphadenitis, [384](#)

Atypical pneumonia, [402–403](#)

Auditory brainstem response (ABR), [35](#)

Aura, migraine, [686](#)

Auscultation, in cardiovascular system assessment, [536](#)

Auspitz sign, in psoriasis, [729–730](#)

Autism, screening for, [17–18](#)

Autism spectrum disorder (ASD), [70–73](#), [70t](#)

Autoantibodies

manifestations of, [345t](#)

in systemic lupus erythematosus, [353](#)

Autocrine action, of hormones, [637](#), [637f](#)

Autoimmune encephalitis, [389](#)

Autoimmune hemolytic anemia, [580](#)

Autoimmune hepatitis, [500](#), [500t](#)

Autoimmune polyglandular syndrome type I, [667](#)

Autoimmune polyglandular syndrome type II, [667](#)

Autoimmune regulator (*AIRE*) gene, in chronic mucocutaneous candidiasis, [298](#)

Autoimmune thrombocytopenic purpura of childhood (childhood ITP), [584–585](#)

Autonomic nerves, dysfunction of, in Guillain-Barré syndrome, [695](#)

Autonomy, [4](#)

in early childhood, [15](#)

in end-of-life decision making, [8](#)

Autosomal dominant disorders, [170–171](#)

achondroplasia due to, [170t](#)

Crouzon syndrome with acanthosis nigricans due to, [170t](#)

hereditary angioneurotic edema due to, [170t](#)

Marfan syndrome due to, [170t](#)

myotonic dystrophy due to, [170t](#)

neurofibromatosis 1 due to, [170t](#)

neurofibromatosis 2 due to, [170t](#)

nonsyndromic craniosynostosis due to, [170t](#)

pedigree drawing of, [170f](#)

penetrance in, [170](#), [170f](#)

thanatophoric dysplasia due to, [170t](#)

variable expressivity of, [171](#)

Autosomal dominant (AD) inheritance

pedigree of, [173f](#)

rules of, [171t](#)

Autosomal recessive agammaglobulinemia, [294](#)

Autosomal recessive disorders, [171](#)

consanguinity and, [177](#)

cystic fibrosis due to, [173t](#)

Friedreich ataxia due to, [173t](#)

Gaucher disease due to, [173t](#)

phenylketonuria due to, [173t](#)

sickle cell disease due to, [173t](#)

Autosomal recessive (AR) inheritance, rules of, [173t](#)

Autosomes, [169](#)

Avascular necrosis, [747–748](#)

idiopathic, [755](#)

Avian influenza (bird flu), [403](#)

Azathioprine, for ulcerative colitis, [491](#)

Azelaic acid, for acne, [723](#)

Azithromycin

for *Chlamydia* infection, [423](#)

for pertussis, [401](#)

for streptococcal pharyngitis, [393–394](#)

B

B cells, [289–290](#)

Babesia, [439](#), [439t–442t](#)

Babesiosis, [439t–442t](#)

Babinski reflex, [682t](#)

Babinski response, [684](#)

Babinski sign, [231–232](#)

Baby bottle caries, [479](#)

Baby-cereals, as complementary food, [101](#)

Bacille Calmette-Guérin (BCG) vaccine, [454](#), [457](#)

Bacillus anthracis, [439t–442t](#)

Back pain, [761](#), [761t](#)

Back to Sleep initiative, [22](#)

Back-to-sleep program, [515–516](#)

Bacteremia, [417](#)

 catheter-associated, [437–438](#)

 fever and, [368](#)

 in nephrotic syndrome, [621](#)

 occult, [369](#)

Bacterial colonization, of newborn, [222](#)

Bacterial conjunctivitis, [433t](#)

Bacterial diarrhea, fever due to, [368](#)

Bacterial diseases, zoonotic, [439t–442t](#)

Bacterial enteritis, gastrointestinal bleeding due to, [477t](#)

Bacterial gastroenteritis, vomiting due to, [473t](#)

Bacterial infections

 in immunocompromised person, [434–435](#)

 superficial, [379–380](#)

 cellulitis as, [380](#)

 folliculitis as, [380](#)

 impetigo as, [379–380](#)

 perianal dermatitis as, [380](#)

 viral infections vs., [363t](#), [368–369](#)

Bacterial meningitis, [707](#)

 causes of, [386t](#)

Bacterial tracheitis, [399](#)

upper airway obstruction due to, [517t](#)

Bacterial vaginosis, [417–418](#), [418t](#), [422t](#)

Bag/mask ventilation, for respiratory failure, [150](#)

Baker cyst, [751](#)

Balloon angioplasty, for coarctation of aorta, [548](#)

Balloon atrial septostomy, for transposition of great arteries, [551](#)

Balloon valvuloplasty

- for aortic stenosis, [548](#)
- for pulmonary stenosis, [548](#)

Barbiturates, maternal use of, [238t](#)

Bardet-Biedl syndrome, obesity in, [106t](#)

Bare lymphocyte syndrome, [297t](#), [298](#)

Barium enema, for Hirschsprung disease, [489–490](#)

Barium esophagram, [511](#)

Barium upper gastrointestinal (GI) series, for gastroesophageal reflux, [481](#)

Barlow test, [231](#), [745f](#)

Bart hemoglobin, [575](#)

Bartonella henselae, [383](#), [439t–442t](#)

- conjunctivitis from, [430](#)

Bartter syndrome, [135–136](#), [136t](#)

Basophilic stippling, [571](#)

Batten disease, [210t–212t](#)

Batteries, ingestion of, [162](#)

Battle sign, [710](#)

Baylisascaris procyonis, [450–451](#), [450t](#)

Becker muscular dystrophy, [696](#)

Beckwith-Wiedemann syndrome, [184](#), [648](#)

Beclomethasone HFA, for asthma, [319f](#)

Bed bug bites, allergic reactions to, [333](#)

Bed rest, for rheumatic fever, [556](#)

Bee stings, allergic reactions to, [333](#)

Behavioral assessment, issues in, [18–19](#), [18t](#)

Behavioral disorders, [41–58](#)

attention-deficit/hyperactivity disorder (ADHD), [45–47](#)

crying, [41–43](#)

colic and, [41–43](#)

normal development, [41](#), [41f](#)

elimination, control of, [47–51](#)

pediatric sleep disorders, [52–56](#)

temper tantrums, [43–45](#)

Behavioral insomnia of childhood, pediatric sleep disorders and, [55](#)

Behavioral issues, screening for, [18t](#), [19](#)

Behavioral management, in attention-deficit/hyperactivity disorder (ADHD), [47](#)

Behavioral sleep disorders, [54t–55t](#)

Behavioral training, for functional constipation, [50](#)

Bell palsy, [683](#)

Belt-positioning booster seat, [22](#)

Beneficence, [4](#)

in end-of-life decision making, [8](#)

Benign fibroadenomas, [274](#)

Benzathine penicillin

for rheumatic fever, [556](#)

for streptococcal pharyngitis, [394t](#)

Benzodiazepines

for anxiety disorders, [64](#)

maternal use of, [238t](#)

for status epilepticus, [691](#), [691t](#)

Benzoyl peroxide, for acne, [723](#)

Bereavement, [95–96](#)

Bernard-Soulier syndrome, [586](#)

Beta cells, in insulin-dependent diabetes mellitus, [640](#)

Beta-chain hemoglobinopathies, [575](#)

Beta-chain synthesis, in β -thalassemia major, [575](#)

Bi-level positive airway pressure (BiPAP), [515](#)

Bicarbonate, for cardiopulmonary resuscitation, [148t](#)

Bidirectional cavopulmonary shunt, for tricuspid atresia, [551](#)

Bidirectional Glenn procedure, for tricuspid atresia, [551](#)

Biernard syndrome, obesity in, [106t](#)

Bilateral renal agenesis, [629](#)

Bilateral Wilms tumor, [611](#)

Bilharziasis, [451](#)

Biliary atresia, extrahepatic, [494](#)

Bilirubin

- in breast-fed infants, [100](#)
- in fetus, [251](#)

Bilirubin diglucuronide, [250](#)

Bilirubin encephalopathy, [251](#)

Biliverdin, [249–250](#)

Biophysical profile, of fetus, [220](#)

Biopsy

- lung, [512](#)
- rectal, for Hirschsprung disease, [489–490](#)
- small bowel, for celiac disease, [489–490](#)

Biopsychosocial influences, on health and illness, [3](#)

Biopterin metabolism, disorders, [201–202](#)

Biot respiration, [509t](#)

Biotinidase deficiency, [206](#)

neonatal screening for, [197](#)

Bipolar and related disorders, [66–68](#)

anxiety disorders and, [67–68](#)

bipolar I disorder, [66](#), [67t](#)

bipolar II disorder, [66](#)

cyclothymic disorder, [66–67](#)

specifiers for, [67](#)

treatment of, [68](#)

unspecified, [66](#)

Bipolar I disorder (BD), [66](#), [67t](#)

Bipolar II disorder, [66](#)

Bird flu, [403](#)

Birth(s)

history of, in genetic assessment, [178](#)

preterm, [1](#), [218](#)

Birth injury, [233–234](#)

Birth weight

low, [218–219](#)

very low, [219](#)

Birthmarks, [730](#), [730t](#)

Birthrate, in adolescent, [2](#)

Bisacodyl, for functional constipation, [52t](#)

Bisacodyl suppository, for functional constipation, [51t](#)

Bisacodyl tablet, for functional constipation, [51t](#)

Black-legged tick, [443](#), [Deer tick](#)

Western, [443](#)

Blackfly bites, allergic reactions to, [333](#)

Blackhead, [723](#)

Blackwater fever, [449](#)

Bladder outlet obstruction, [630](#)

Blalock-Taussig procedure, for tricuspid atresia, [551](#)

Bleeding

- causes of, [583f](#)
- gastrointestinal, [476–478](#)
- in hematological disorders, [563](#)
- rectal, evaluation of, [478t](#)
- spontaneous, [587](#)

Bleeding disorders, [Hemostatic disorders](#)

Bleeding time, [583](#), [584t](#)

Blepharitis, [431](#), [433t](#)

Blinatumomab, for cancer, [601t–602t](#)

β -blockers

- for cardiomyopathies, [557t](#)
- for heart failure, [554](#)

Blood-brain barrier, in chemotherapy, [601](#)

Blood component therapy, [589–590](#), [593](#)

Blood cultures, [362](#)

Blood gas analysis, for respiratory distress in newborns, [241](#)

Blood glucose testing, for type 1 diabetes, [645](#)

Blood group sensitization, maternal, [236t](#)

Blood loss, anemia and, [567–568](#)

- in newborn, [249](#)

Blood pressure

- in cardiovascular system assessment, [535](#)
- classification of, [627t](#)

Blood smear, [584t](#)

Blood urea nitrogen (BUN)

- in acute renal failure, [619](#)
- in dehydration, [128](#)

Blood volume, [125](#)

of newborn, [247](#)

Bloodstream infection, catheter-related, [437](#)

Blount disease, [750](#)

Blue cohosh herbal tea, maternal use of, [238t](#)

BMI, [Body mass index](#)

Body composition, fluid in, [125](#), [126f](#)

Body lice, [736](#)

Body mass index (BMI)

defined, [11](#)

growth charts of, [12f](#)

obesity and, [105–107](#), [107t](#)

Body plethysmography, [511](#)

Body temperature

instability of, in infants younger than 3 months of age, [368](#)

normal, [368](#)

regulatory system for, [368](#)

Boils, [380](#)

Bonding, in infancy, [15](#)

Bone(s)

growth and development of, [739](#), [740f](#)

structure of, [740f](#)

Bone and mineral diseases, important physiological changes in, [670t](#)

Bone cyst

aneurysmal, [765t–766t](#)

unicameral, [765t–766t](#)

Bone destruction, in osteomyelitis, [426](#)

Bone marrow

biopsy, in aplastic anemia, [574](#)

infiltration, by malignant cells, [573](#)

Bone marrow abnormalities, due to lysosomal storage diseases, [210t–212t](#)

Bone marrow aspiration (BMA), for cancer, [599t](#)

Bone marrow examination, in hematological disorders, [563](#)

Bone marrow failure, [574](#)
pancytopenia resulting from, [584](#)

Bone marrow replacement, in aplastic anemia, [575](#)

Bone mineral accretion, [119](#)

Bone morphogenetic receptor-2 (*BMPR2*) gene, [524](#)

Bone scan, for cancer, [599t](#)

Bone tumors, [765](#), [765t–766t](#)

Bordetella holmesii, [401](#)

Bordetella parapertussis, [401](#)

Bordetella pertussis, [400](#)

Borrelia, [439t–442t](#)

Borrelia burgdorferi, [439t–442t](#)
infection from, [443–444](#)

Bottle mouth, [479](#)

Botulism, infant, [696](#)

Boutonneuse fever, [439t–442t](#)

Bowing fractures, [742](#)

Bowleg, [749](#), [749f](#)

Boys, growth and development of, [271–273](#)

BPD (bronchopulmonary dysplasia), [244–245](#)

Brachial plexopathy, [763](#)

Brachial plexus injuries, [763](#)
in newborn, [233](#)

Brachycephaly, [183t](#), [185](#)

Brachydactyly, [183t](#)

Bradycardia, fetal, [220](#)

Bradypnea, [509t](#)

Brain, congenital anomalies of, [716–717](#)

Brain cancers, risk factors for, [597t](#)

Brain cell swelling, in hyponatremia, [133](#)

Brain hemorrhage, due to hypernatremia, [134](#)

Brain herniations, [705–706](#), [705t](#)

foremen magnum, [705t](#)

subfalcian, [705t](#)

transtentorial (central), [705–706](#), [705t](#)

uncal, [705–706](#), [705t](#)

Brain tumors

ataxia due to, [701](#)

vomiting due to, [473t](#)

Branched chain amino acids, metabolism of, [203f](#)

Branched chain ketoaciduria, [203](#)

Branching enzyme, [200t](#)

Break bone fever, [446](#)

Breast, of newborn, [228f](#)

Breast abscess, [100](#)

Breast-feeding, [99–100](#), [100f](#)

adequacy of, [99–100](#)

common problems with, [100](#)

maternal contraindications and recommendations for, [101t](#)

maternal drug use and, [100](#)

Breast-feeding jaundice, [100](#)

Breast milk, composition of, [102t](#)

Breast milk jaundice, [100](#)

Breast tenderness, [100](#)

Breastfeeding, initiation and maintenance of, [2](#)

Breath holding spells, [514](#), [514t](#)

Breath sounds, [510t](#)

Breathing

control of, [513–516](#), [514f](#)

disorders of

apnea as, [514–515](#), [514t](#)

brief resolved unexplained event as, [515](#)

sudden infant death syndrome as, [515–516](#), [516t](#)

in newborn resuscitation, [225–226](#)

in rapid cardiopulmonary assessment, [146t](#)

work of, [509–510](#)

Breathing patterns, abnormal, [509t](#)

Brentuximab, for cancer, [601t–602t](#)

Bridging therapy, in juvenile idiopathic arthritis, [352](#)

Brief psychotic disorder, [72](#), [72t](#)

Brief resolved unexplained event (BRUE), [515](#)

Broca aphasia, [682](#)

Brodie abscess, [426](#), [765](#), [765t–766t](#)

Bromides, maternal use of, [238t](#)

Bronchi, mainstem, [507](#)

Bronchiectasis, [405–407](#), [520](#)

Bronchiolitis, [401–402](#), [522](#)

clinical manifestations of, [401–402](#)

complications and prognosis of, [402](#)

differential diagnosis of, [402](#)

epidemiology of, [401](#)

etiology of, [401](#)

laboratory and imaging studies for, [402](#)

prevention of, [402](#)

treatment of, [402](#)

viral, [401](#)

Bronchiolitis obliterans, [407](#)

Bronchoalveolar lavage, [511](#)

Bronchopneumonia, [402–403](#)

Bronchopulmonary dysplasia (BPD), [244–245](#), [522](#)

Bronchoscopy, rigid, [511](#)

Bronchospasm, [510t](#)

Broviac catheters, [437](#)

Brown dog tick, [444](#)

Brucella, [439t–442t](#)

Brucellosis, [439t–442t](#)

BRUE, [Brief resolved unexplained event](#)

Bruises, due to child abuse, [80–81](#), [81f](#)

Buckle fracture, [742](#)

Budesonide DPI, for asthma, [319f](#)

Budesonide inhaled, for asthma, [319f](#)

Bulbar weakness, [694t](#)

Bulimia nervosa, [282–283](#), [283t](#)

Bulla, [721t](#), [722f](#)

Bullous impetigo, [379](#), [734t](#)

Bullous rash, infections with fever and, [373t–374t](#)

Bullying, [92](#)

Bumblebee stings, allergic reactions to, [333](#)

Burkitt lymphoma

- clinical manifestations of, [605](#)
- endemic (African) form of, [605](#)
- etiology of, [605](#), [606t](#)

sporadic (North American) form of, [605](#)

Burner, [763](#)

Burns, [158–160](#)

- due to child abuse, [81](#), [81f](#)
- clinical manifestations of, [158–159](#), [159f](#)
- complications of, [159](#), [160t](#)
- deep partial-thickness, [158](#)
- epidemiology of, [158](#)
- etiology of, [158](#)
- first-degree, [158](#)
- full-thickness, [158](#)
- inhalation injuries, [158](#)
- laboratory and imaging studies of, [159](#)
- prevention of, [160](#)
- prognosis for, [160](#)
- second-degree, [158](#)
- superficial, [158](#)
- superficial partial-thickness, [158](#)
- third-degree, [158](#)
- treatment of, [159](#)
- vesiculobullous eruptions due to, [734t](#)

Burrow, [722f](#)

Bursitis, suppurative, [429](#)

Button batteries, ingestion of, [162](#)

C

C1-esterase inhibitor deficiency, acquired, [331t](#)

C1-inhibitor, laboratory studies of, [306](#)

C1-inhibitor deficiency, [306](#)

- treatment of, [306](#)

C3 deficiency, [306](#)

Café au lait macules, [681](#), [731](#), [731f](#)

differential diagnosis pf, [730t](#)

Café-au-lait spots, [714](#), [714f](#)

with developmental disabilities, [30t](#)

CAH, [Congenital adrenal hyperplasia](#)

Calcaneal apophysitis, [755](#)

clinical manifestations of, [755](#)

treatment of, [755](#)

Calcaneovalgus foot, [754](#)

Calcidiol, [118](#)

Calcineurin inhibitors, topical, for atopic dermatitis, [726](#)

Calcinosis, in juvenile dermatomyositis, [356](#)

Calcinosis universalis, in juvenile dermatomyositis, [356](#)

Calcitriol, [118](#)

in renal function, [617](#)

Calcium, [669](#)

Calcium chloride, for cardiopulmonary resuscitation, [148t](#)

Calcium deficiency, [119–120](#)

Caliciviruses (noroviruses), diarrhea from, [410t](#)

Caloric intake, growth and, [11](#)

Calories, in parenteral nutrition, [131](#)

CAM (complementary and alternative medicine), [3](#)

Camptodactyly, [183t](#)

Campylobacter jejuni, [439t–442t](#)

diarrhea from, [410t](#), [411](#)

and Guillain-Barré syndrome, [695](#)

Campylobacteriosis, [439t–442t](#)

Cancer

assessment of, [595–596](#), [596f](#)
 common manifestations in, [595](#), [598t](#)
 differential diagnosis in, [596](#)
 history in, [595](#), [597t](#)
 initial diagnostic evaluation in, [596](#)
 diagnostic imaging in, [596](#), [599t](#)
 screening tests in, [596](#)
 physical examination in, [595](#)

childhood

 incidence of, [595](#), [596f](#)
 risk factors for, [597t](#)

common manifestations of, [595](#), [598t](#)

differential diagnosis of, [596](#)

emergencies with, [599](#), [600t](#)

prevention of, [599](#)

Cancer treatment, [599–601](#), [613–614](#)

 adverse effects of, [601](#), [603t](#)

 chemotherapy as, [601](#), [601t–602t](#)

 for oncological emergencies, [599](#), [600t](#)

 other therapies for, [601](#)

 radiation therapy as, [601](#)

 surgery for, [599](#)

Candida albicans infection, oropharyngeal, [480](#)

Candidal diaper dermatitis, [728](#)

Candidiasis, [381t](#)

 chronic mucocutaneous, [298](#), [299t](#)

 vulvovaginal, [423t](#)

Canthus, [183t](#)

Capillary hemangiomas, [228–229](#)

Capillary leak, systemic, due to burns, [159](#)

Capnocytophaga canimorsus, [439t–442t](#)

Captopril

 for heart failure, [555t](#)

 maternal use of, [238t](#)

Caput succedaneum, [233](#)

Carbohydrate disorder, [199–201](#)

fructosuria as, [201](#)

galactokinase deficiency as, [201](#)

galactosemia as, [201](#)

glycogen storage diseases as, [199–201](#), [200f](#), [200t](#)

hereditary fructose intolerance as, [201](#)

Carbon dioxide

end-tidal, [511](#)

in pulmonary physiology, [507](#)

Carbon monoxide

in bilirubin production, [249–250](#)

toxicity, [162t](#)

Carboplatin, for cancer, [601t–602t](#)

Carboxyhemoglobin assessment, for burns, [159](#)

Carbuncle, [380](#), [722f](#)

Carcinoma, of thyroid, [668](#)

Cardiac arrhythmias, [Dysrhythmia\(s\)](#)

Cardiac catheterization, in cardiovascular system assessment, [540](#), [540f](#)

Cardiac murmurs, [Heart murmurs](#)

Cardiac output

cardiopulmonary arrest and, [147](#)

oxygen delivery and, [149](#)

Cardiac silhouette, [539](#), [539f](#)

Cardiac syncope, [541t](#)

Cardiac transplantation, for cardiomyopathies, [557t](#), [558](#)

Cardiogenic asthma, [402](#)

Cardiomegaly

in coarctation of aorta, [548](#)

in hypoplastic left heart syndrome, [553](#)

in truncus arteriosus, 552

Cardiomyopathies, 213–214, 556–558

clinical manifestations of, 558

etiology of, 556, 557*t*

imaging studies for, 558

in sickle cell disease, 577*t*

treatment of, 558

Cardiopulmonary assessment, rapid, 146*t*

Cardiovascular support, for shock, 153, 153*t*

Cardiovascular system, 535–560

assessment of, 535–540

history in, 535, 536*t*

laboratory and imaging tests in, 538–540

cardiac catheterization as, 540, 540*f*

chest radiography as, 539, 539*f*

echocardiography as, 539–540, 540*f*

electrocardiography as, 538–539, 538*f*

pulse oximetry as, 538

physical examination in, 535–538

auscultation in, 536

clicks in, 536

heart murmurs in, 536–538

heart sounds in, 536, 537*t*

inspection in, 535

palpation in, 535

Cardioversion

in cardiopulmonary resuscitation, 148–149, 148*t*

synchronized, for dysrhythmias, 543–544

Carditis, due to heart failure, 556, 556*t*

Care coordination, for anxiety disorders, 64

Caries, dental, 479–480

Carmustine, for cancer, 601*t*–602*t*

Carnitine(s), plasma, 199*t*

Carotid bruit, 538*t*

Carotid sinus syncope, 541*t*

Carpenter syndrome, obesity in, 106*t*

Carriers, for genetic disorders, [170](#)

Carvedilol, for heart failure, [555t](#)

Caseous lymph node, skeletal tuberculosis and, [454](#)

Cat eye syndrome, [183](#)

Cat-scratch disease, [384](#), [439t–442t](#)

Cataract, in galactosemia, [201](#)

Catarrhal stage, of pertussis, [400](#)

CATCH 22 syndrome, [298](#)

Catch-down growth, [13](#)

Catch-up growth, [11–13](#), [112](#)

Catecholamines, in neuroblastoma, [609](#)

Cathartic, for poisoning, [164](#)

Catheter-related infections, [437t](#)
 bloodstream, [437](#)

Catheter-related sepsis, due to parenteral nutrition, [131](#)

Catheter-related thrombosis, [437](#)

Cations, in body fluids, [125](#)

Caustic ingestions, [160–162](#)

Caustic injuries, [484](#)

Cavernous hemangiomas, [228–229](#)

Cavopulmonary shunt, bidirectional, for tricuspid atresia, [551](#)

Cavus foot, [755](#)

CD, [Crohn disease](#)

Cefdinir, for otitis media, [396–397](#)

Cefixime, after rape, [281](#)

Cefotaxime, for meningitis, [388](#)

Ceftriaxone

- after rape, [281](#)
- for gonorrhea, [422](#)
- for Lyme disease, [444](#)
- for meningitis, [388](#)
- for otitis media, [396–397](#)

Celiac disease, [335t–336t](#), [492](#)

- clinical manifestations of, [492](#)
- constipation due to, [476t](#)
- etiology and epidemiology of, [492](#)
- laboratory and imaging studies for, [492](#)
- treatment of, [492](#)

Cellular compartment disorders, due to inborn errors of metabolism, [193t](#)

Cellular immune-mediated hypersensitivity, [311–312](#), [311t](#)

Cellulitis, [380](#)

- orbital, [395](#), [433t](#)
- periorbital, [433t](#)
- preseptal (periorbital), [395](#)

Central apnea, [514](#), [514t](#)

Central catheter, peripherally inserted, for parenteral nutrition, [131](#)

Central chemoreceptors, in control of ventilation, [513](#), [514f](#)

Central diabetes insipidus, [133–134](#)

Central line associated bloodstream infection (CLABSI), [437](#)

Central nervous system (CNS)

- congenital malformations of, [716–717](#)
 - of brain, [716–717](#)
 - of spinal cord, [716](#)
- due to lysosomal storage diseases, [210t–212t](#)
- of newborn, [14](#)

Central nervous system abnormalities, delayed puberty due to, [657](#)

Central nervous system depression, in newborn, [227](#)

Central nervous system perfusion, in rapid cardiopulmonary assessment, [146t](#)

Central nervous system reflexes

- of child, [684](#)
- of infancy, [682t](#)

Central nervous system shunts, infections associated with, [438–439](#)

Central nervous system tumors, [607–608](#), [614](#)

- clinical manifestations of, [607](#)
- complications of, [608](#)
- differential diagnosis of, [608](#)
- epidemiology of, [607](#)
- etiology of, [607](#)
- laboratory/imaging studies in, [607](#), [608f](#)
- prognosis for, [608](#), [608t](#)
- treatment of, [608](#)

Central pontine myelinolysis

- hyponatremia and, [133](#)
- rehydration and, [129](#)

Central venous catheters, infections associated with, [437](#)

Central wheal, in allergen-specific IgE in vivo skin testing, [312–313](#)

Cephalexin, for streptococcal pharyngitis, [394t](#)

Cephalhematoma, [730t](#)

- in newborn, [233](#)

Cephalosporins

- allergic reaction to, [338](#)
- for streptococcal pharyngitis, [393–394](#)

Cephalothin, maternal use of, [238t](#)

Cerebellar ataxia, postinfectious acute, [700–701](#)

Cerebellar mutism, central nervous system and, [608](#)

Cerebral aneurysms, in autosomal dominant polycystic kidney disease, [630](#)

Cerebral edema, [129](#)

- due to diabetic ketoacidosis, [641](#)

Cerebral palsy (CP), [37–38](#), [37t–38t](#)

Cerebrohepatorenal syndrome, [208–209](#)

Cerebrosidase, nephropathic, [210t–212t](#)

Cerebrospinal fluid (CSF) analysis, [684–685](#), [685t](#)
for cancer, [599t](#)
for neonatal meningitis, [256](#)

Cerebrospinal fluid rhinorrhea, [324t](#)

Cerebrospinal leak, [710](#)

Cerebrovascular accidents, in sickle cell disease, [577t](#)

Cervical cancer, [382](#)

Cervical lymphadenitis
etiology of, [383](#)
suppurative, [384](#)

Cervical lymphadenopathy, in Kawasaki disease, [347](#)

Cervical spine injuries, [710](#)

Cervicitis, nongonococcal, [423](#)

Cestodes, parasitic, pediatric syndrome caused by, [452t](#)

Cetirizine, for allergic rhinitis, [325](#)

CFTR gene, pancreatic insufficiency and, [501](#)

CH₅₀ test, [306](#)

Chagas disease, congenital infection with, [260t](#)

Chalasia, vomiting vs., [472](#)

Chalazion, [431](#)

Chancre, [423](#)

Chancroid, [419](#), [421t](#)

Charcoal, activated, for poisoning, [164](#)

Charcot-Marie-Tooth disease, [695](#)

cavus foot in, [755](#)

CHARGE association, choanal atresia in, [324](#)

CHCs, [Combined hormonal contraceptives](#)

Chédiak-Higashi syndrome (CHS), [301t](#)

Chelation therapy, for β -thalassemia major, [575–576](#)

Chemical(s), as teratogens, [176](#)

Chemoprophylaxis

for malaria, [449](#)

for meningitis, [388–389](#)

Chemoreceptors, in control of ventilation

central, [513](#), [514f](#)

peripheral, [513](#), [514f](#)

Chemotherapy, [601](#), [601t–602t](#)

adjuvant, [601](#)

adverse effects of, [601](#), [603t](#)

in blood-brain barrier, [601](#)

high-dose, [609](#)

for leukemia, [604](#)

neoadjuvant, [601](#)

resistance to, [601](#)

vomiting due to, [473t](#)

Cherub appearance, in GH deficiency, [655](#)

Chest

anemia and, [569t](#)

of newborn, [230](#)

Chest compressions, [147](#)

Chest motion, [510t](#)

Chest pain, [541–542](#), [542t](#)

Chest percussion, [513](#)

Chest physiotherapy, [513](#)

for cystic fibrosis, [529](#)

Chest radiography, [510–511](#)

Chest tubes, for pleural effusion, [532](#)

Chest wall disorders, [529–532](#)

pectus carinatum as, [530](#)

pectus excavatum as, [529](#)

Chest x-ray (CXR)

for asthma, [314](#)

for cancer, [596](#), [599t](#)

in cardiovascular system assessment, [539](#), [539f](#)

Cheyne-Stokes respiration, [509t](#)

Chiari type II malformation, [716](#)

Chickenpox, [378–379](#)

clinical manifestations of, [378](#)

complications and prognosis of, [379](#)

differential diagnosis of, [378–379](#)

epidemiology of, [378](#)

etiology of, [378](#)

laboratory and imaging studies for, [378](#)

prevention of, [379](#)

treatment of, [379](#)

Chikungunya virus, [446–447](#)

Child abuse, [80–84](#)

fracture due to, [744](#)

management of, [84](#), [85f](#)

physical, [80–82](#), [80t](#)

abdominal trauma due to, [81](#)

bruises due to, [80–81](#), [81f](#)

burns due to, [81](#), [81f](#)

differential diagnosis of, [81–82](#), [83t](#)

fractures due to, [81](#), [82f](#)

head trauma due to, [81](#), [82f](#)

subdural hemorrhage due to, [256–257](#)

sexual, [82–84](#)

Child-centered approach, in elimination, [47–48](#)

Child neglect, [80](#)

Child Protective Services (CPS), [83](#)

Child with special needs, [28–38](#)

 cerebral palsy, [37–38](#), [37t–38t](#)

 hearing impairment, [34–36](#), [35t](#)

 management of, [31–32](#)

 counseling principles for, [32](#)

 interdisciplinary team intervention for, [32](#)

 intervention in primary care setting for, [31–32](#), [32t](#)

 mental retardation, [33](#), [33t–34t](#)

 multifaceted team assessment of, [28–31](#)

 educational, [29–31](#)

 medical, [28](#), [29t–30t](#)

 motor, [28](#)

 psychological, [28–29](#), [31t](#)

 of social environment, [31](#)

 speech-language impairment, [36–37](#), [36t](#)

 vision impairment, [33–34](#)

Childhood antecedents, of adult health conditions, [1](#)

Childhood extreme obesity, [104–105](#)

Childhood-onset schizophrenia, [72](#)

Childhood thrombocytopenic syndromes, differential diagnosis of, [585f](#)

Children

 ethical principles related to, [4–5](#)

 laboratory results in various types of thyroid function in, [665t](#)

Children with special health care needs (SHCN), [28](#)

Children's Somatization Inventory, for somatic symptom and related disorders (SSRDs), [61](#)

Chinese liver fluke, [451t](#)

Chlamydia trachomatis, [422–423](#)

 clinical features of infections caused by, [420t](#)

 congenital infection with, [260t](#), [263](#)

pelvic inflammatory disease due to, [420–421](#)

pneumonia from, [403](#), [407t](#)

Chlamydial conjunctivitis, [431](#)

Chlamydomphila pneumoniae, pneumonia from, [403](#), [407t](#)

Chlamydomphila psittaci, [439t–442t](#)

Chloral hydrate, for sedation, [166t](#)

Chloroquine, for malaria, [449](#)

Choanal atresia (stenosis), [227t](#), [324](#), [324t](#)

upper airway obstruction due to, [518](#)

Cholangiopancreatography, endoscopic retrograde, [503](#)

Cholecalciferol, [118](#)

Cholecystitis, abdominal pain due to, [470t](#)

Cholelithiasis, abdominal pain due to, [470t](#)

Cholera-like enterotoxin, [411](#)

Cholestasis, [494](#)

chronic, [498](#)

clinical manifestations of, [494](#)

etiology and epidemiology, [494](#)

laboratory and imaging studies for, [494](#), [497t](#), [498f](#)

treatment of, [494](#)

Cholestatic liver disease, due to parenteral nutrition, [131](#)

Cholinergics, toxicity, [162t](#)

Chondritis, *Pseudomonas*, [425–426](#)

Chondrolysis, [747–748](#)

“ChooseMyPlate,” [103–104](#), [103f](#), [103t](#)

Chordee, [632](#)

Chorea, [702](#)

due to heart failure, [556](#), [556t](#)

Choriomeningitis, lymphocytic, [439t–442t](#)

Chorionic villus sampling (CVS), [179](#)

Choroiditis, [433t](#)

Chromatin, [169](#)

Chromium deficiency, [119t](#)

Chromosomal deletion syndrome, [182–183](#)

of chromosome 22q11.2 deletion syndromes, [182–183](#)

cri du chat syndrome as, [182](#)

Williams syndrome as, [182](#)

Chromosomal disorder, [179–183](#)

due to abnormalities in number (aneuploidy), [179–182](#)

monosomies as, [179–182](#)

monosomies as, [181–182](#)

Turner syndrome as, [181–182](#)

trisomies as, [180–181](#)

Down syndrome as, [180](#)

Klinefelter syndrome as, [181](#)

trisomy 13 as, [180–181](#)

trisomy 18 as, [180, 181t](#)

due to chromosomal deletions, [182–183](#)

aniridia Wilms tumor association as, [182](#)

of chromosome 22q11.2 deletion syndromes, [182–183](#)

cri du chat syndrome as, [182](#)

Williams syndrome as, [182](#)

due to chromosome duplication, [183](#)

cat eye syndrome as, [183](#)

inverted duplication chromosome 15 as, [183](#)

Chromosome(s), sex, [169](#)

Chromosome 15, inverted duplication, [183](#)

Chromosome 22q11.2 deletion syndromes, [182–183](#)

Chromosome analysis, in genetic assessment, [179](#)

Chromosome duplication syndromes, [183](#)

cat eye syndrome as, [183](#)

inverted duplication chromosome 15 as, [183](#)

Chronic autoimmune lymphocytic thyroiditis, [645](#)

Chronic blood loss, in iron deficiency anemia, [570](#)

Chronic granulomatous disease (CGD), [301t](#), [303](#)

Chronic idiopathic thrombocytopenic purpura, [585](#)

Chronic illnesses

in children and adolescents, [267](#), [267t](#)

in hospital admission, [1](#)

Chronic kidney disease (CKD), [626–627](#)

complications and treatments of, [627t](#)

etiology and epidemiology of, [626](#)

prognosis for, [627](#)

treatment of, [627](#)

Chronic kidney disease-mineral bone disorder (CKD-MBD), [626–627](#)

Chronic lung disease, [244–245](#)

in sickle cell disease, [577t](#)

Chronic major depressive disorder, [Persistent depressive disorder](#)

Chronic mucocutaneous candidiasis, [298](#), [299t](#)

Chronic myeloid leukemia (CML), [603](#)

Chronic respiratory failure, [149](#)

Chvostek sign, [235](#)

Cigarette smoke, around children, [91](#)

Ciliary dyskinesia, primary, [523](#)

Ciliary elevator system, in pneumonia, [403](#)

Ciliated epithelium, as lung defense mechanism, [508](#)

Circadian rhythm disorders, [54t–55t](#)

pediatric sleep disorders and, [55](#)

treatment of, [56](#)

Circulating toxins, [580](#)

Circulation

in cardiopulmonary resuscitation, [147](#)

in rapid cardiopulmonary assessment, [146t](#)

transition from fetal to neonatal, [222](#)

Cis-retinoic acid, for neuroblastoma, [609](#)

Cisgender, [84t](#)

Cisplatin, for cancer, [601t–602t](#)

CKD, [Chronic kidney disease](#)

Classical pathway, of complement activation, [304–305](#), [305f](#)

Cleft lip and palate, [480](#)

Clicks, [536](#)

Clindamycin

for acne, [723](#)

for streptococcal pharyngitis, [394t](#)

Clinodactyly, [183t](#)

Clitoral enlargement, in newborn, [231](#)

Clonidine, for attention-deficit/hyperactivity disorder (ADHD), [47](#)

Clonorchiasis, [451t](#)

Clonorchis sinensis, [451t](#)

C-loop, in midgut malrotation, [488](#)

Clostridium difficile, diarrhea from, [410t](#), [411](#)

Clot retraction, [580](#)

Congenital diaphragmatic hernia, [246](#), [522](#)

Congenital heart disease, [180](#)

acyanotic, [545–548](#)

aortic stenosis as, [548](#)

atrial septal defect as, [546](#), [546f](#)

coarctation of aorta as, [548](#)

endocardial cushion defect as, [547](#), [547f](#)

etiology and epidemiology of, [545](#), [545t](#)

patent ductus arteriosus as, [546–547](#), [546f](#)

pulmonary stenosis as, [547–548](#)

ventricular septal defect as, [545–546](#), [545f](#)

congenital malformation syndromes associated with, [536t](#)

cyanotic, [549–553](#)

extracardiac complications of, [553t](#)

hypoplastic left heart syndrome as, [552–553](#), [552f](#)

with polycythemia, [584](#)

presenting symptoms in, [549t](#)

tetralogy of Fallot as, [549–550](#), [550f](#)

total anomalous pulmonary venous return as, [552](#), [552f](#)

transposition of great arteries as, [550–551](#), [550f](#)

tricuspid atresia as, [551](#), [551f](#)

truncus arteriosus as, [551–552](#), [551f](#)

ductal-dependent, [227t](#)

Congenital hemolytic disorders, [567–568](#)

Congenital hypopituitarism, [639](#)

Congenital hypoplastic anemia, [573](#), [573t](#)

Congenital hypotonia, benign, [699](#)

Congenital infections, [259–264](#), [260t](#)

Congenital lobar emphysema, [522](#)

Congenital malformation syndromes, with congenital heart disease, [536t](#)

Congenital malformations, [169](#)

association in, [184](#)

defined, [184](#)

- diagnosis of, [186](#)
- due to disruptions of development, [184](#)
- due to extrinsic factors, [184](#)
- history for
 - family, [184](#)
 - pregnancy, [184](#)
- due to inborn errors of metabolism, [195–196](#)
- due to intrinsic factors, [184](#)
- laboratory evaluation of, [186](#)
- minor, [184](#)
- multiple, [184](#)
- physical examination of, [184–186](#)
 - craniofacial, [185](#)
 - of extremities, [185](#)
 - of genitalia, [185–186](#)
 - growth in, [184–185](#)
 - of neck, [185](#)
 - of trunk, [185](#)
- sequence in, [184](#)

Congenital melanocytic nevi, [228–229](#), [731–732](#), [731f](#)

- differential diagnosis of, [730t](#)

- giant, [730t](#), [732](#)

- hairy, [731–732](#), [731f](#)

Congenital myasthenic syndromes, [696](#)

Congenital myopathies, [697–698](#)

Congenital pulmonary airway malformations (CPAMs), [522](#), [523f](#)

Congenital rubella syndrome, [375](#)

Congenital scoliosis, [758](#)

Congenital thyroxine-binding globulin deficiency, [665–666](#)

Congenital tuberculosis, [454](#)

Congestive heart failure, [Heart failure](#)

Conjunctival erythema, in Kawasaki disease, [347](#)

Conjunctivitis

- acute, [430](#)
- allergic, [433t](#)
- bacterial, [431](#), [433t](#)
- chlamydial, [431](#)
- epidemiology of, [431](#)
- gonococcal, [431](#)
- hyperpurulent, [431](#)
- inclusion, [431](#)
- neonatal, [430](#), [432t–433t](#)
- viral, [430](#), [433t](#)

Connective tissue disease

- assessment of, [343](#), [344t](#)
 - common manifestations in, [343–345](#), [345t](#)
 - diagnostic imaging in, [345](#)
 - history in, [343](#)
 - initial diagnostic evaluation in, [345](#)
 - laboratory testing in, [345](#)
 - physical examination in, [343](#)
- juvenile idiopathic arthritis vs., [352t](#)

Conotruncal anomaly face syndrome, [182–183](#)

Consanguinity, and autosomal recessive inheritance, [177](#)

Consciousness

- depression of, transient, recurrent, [706](#)
- disorders of, [703–706](#)
 - acute, [703–706](#)
 - assessment of, [703–705](#)
 - clinical manifestations of, [705–706](#), [705t](#)
 - etiology of, [705](#)
 - laboratory and diagnostic imaging of, [706](#)
 - prognosis for, [706](#)
 - treatment of, [706](#)

Consolidation, of lung, [510t](#)

Constipation, [475–476](#)

- defined, [49](#)
- differential diagnosis of, [475](#), [476t](#)
- distinguishing features of, [475–476](#)
- functional, [49–51](#)
 - clinical manifestations of, [49–50](#)

- complications of, 51
- defined, 475
- differential diagnosis of, 50, 475, 476*t*
- epidemiology of, 49
- etiology of, 49
- evaluation of, 476
- prevention of, 51
- treatment of, 50–51, 50*t*–52*t*, 476

Constitutional delay, short stature due to, 653

Constitutional short stature, 13

Contact allergies, 311–312, 728*f*

Contact dermatitis, 335*t*–336*t*, 725, 727–728

- allergic, 727, 728*f*
- atopic vs., 725
- clinical manifestations of, 727–728, 727*f*–728*f*
- complications of, 728
- differential diagnosis of, 728
- etiology and epidemiology of, 727
- irritant, 727–728
- laboratory and imaging studies for, 728
- prevention of, 728
- treatment of, 728
- vesiculobullous eruptions due to, 734*t*

Containment, 747

Continuous, machine-like murmur, with patent ductus arteriosus, 546–547

Continuous murmurs, 538

Continuous positive airway pressure (CPAP), 515, 521

Contraception, 278–281

- barrier methods for, 280–281
 - condoms as, 280
 - sponge, caps, and diaphragm as, 280
- coitus interruptus for, 281
- emergency postcoital, 280–281, 281*t*
- intrauterine devices for, 279

oral and anal for, [281](#)

rhythm method (periodic coital abstinence) for, [281](#)

steroidal, [278–281](#)

combined hormonal contraceptives for, [279–280](#), [279t–280t](#)

contraceptive patch for, [279–280](#)

contraceptive vaginal ring for, [279–280](#)

hormonal injections and implants for, [278–279](#)

long-acting reversible contraceptives for, [278–279](#)

progesterone-only pill or minipill for, [280](#)

Contraceptive patch, [279–280](#)

Contraceptive vaginal ring, [279–280](#)

Contrast-enhanced CT, for infectious diseases, [362–363](#)

Convalescent stage, of pertussis, [400](#)

Convection, heat loss via, [234](#)

Conversion disorder, [59](#), [60t](#)

Convulsion(s), [Seizure\(s\)](#)

benign neonatal, [690](#)

simple febrile, [689](#)

Cooley anemia, [575–576](#)

Coombs test, [579f](#)

Coordination, of movement, [684](#)

Copper deficiency, [119t](#)

Cor pulmonale, [524–525](#)

Cordocentesis, [220](#)

Corn syrup, for functional constipation, [52t](#)

Corneal reflex, [683](#)

Coronary artery aneurysms, in Kawasaki disease, [347](#)

Coronary artery disease, syncope due to, [541t](#)

Corpus callosum, agenesis of, [716–717](#)

Corrin ring, [117](#)

Corticospinal tract, [693](#)

Corticosteroids, [725–726](#)

for asthma

inhaled, [314–315](#), [319f](#)

oral, [316](#)

for atopic dermatitis

systemic, [726](#)

topical, [327](#), [725–726](#)

for autoimmune hemolysis, [580](#)

intranasal, for allergic rhinitis, [324–325](#)

for juvenile dermatomyositis, [356](#)

for juvenile idiopathic arthritis, [352](#)

for systemic lupus erythematosus, [355](#)

topical, [726](#)

for atopic dermatitis, [725–726](#)

complications of, [726](#)

for urticaria and angioedema, [331](#)

Cortisol deficiency, hypoglycemia due to, [649](#)

Cough

evaluation of, [509](#)

as lung defense mechanism, [509](#)

whooping, [400](#)

Cough syncope, [541t](#)

Coumarin, as teratogen, [237t](#)

Counter-regulatory hormones, defects in, [649](#)

Cow's milk-based formulas, [100–101](#)

Coxiella burnetii, [439t–442t](#)

Coxsackievirus infection, vesiculobullous eruptions due to, [734t](#)

Coxsackieviruses, conjunctivitis from, [430](#)

CP, [Cerebral palsy](#)

CPAP, [Continuous positive airway pressure](#)

CPS (Child Protective Services), [83](#)

Crab louse, [425](#)

Cracked lips, in Kawasaki disease, [347](#)

Crackles, [510](#)

Cradle cap, [728](#), [729f](#)

of cranial nerve I, [683](#)

of cranial nerve II, [683](#)

of cranial nerves III, IV, and VI, [683](#)

of cranial nerve V, [683](#)

of cranial nerve VII, [683](#)

of cranial nerve VIII, [683](#)

of cranial nerves IX and X, [683](#)

of cranial nerve XII, [683](#)

Cranial nerve palsies, [708](#)

Craniopharyngioma, [639](#)

delayed puberty due to, [657](#)

Craniosynostosis, [681](#)

Craniotabes, [118](#), [229](#)

Creatine biosynthesis, disorders of, [199t](#)

Creatinine clearance, [619](#)

Creatinine concentration, in dehydration, [128](#)

Cri du chat syndrome, [182](#)

Cricoid ring, [507](#)

Crigler-Najjar syndrome, hyperbilirubinemia due to, [250](#)

Crohn disease (CD), [490t](#), [491](#)

Croup (laryngotracheobronchitis), [398–400](#), [518](#)

clinical manifestations of, [399](#)

complications and prognosis of, [400](#)

differential diagnosis of, [399](#)

etiology and epidemiology of, [398–399](#)

laboratory and imaging studies for, [399](#), [399f](#)

spasmodic, [399](#)

upper airway obstruction due to, [517t](#)

treatment of, [399–400](#)

upper airway obstruction due to, [517t](#)

Crouzon syndrome, with acanthosis nigricans, genetic basis for, [170t](#)

Crust, [722t](#)

Crusted impetigo, [379](#)

Crying, [41–43](#)

colic and, [41–43](#)

anticipatory guidance and management of, [43](#)

clinical manifestations of, [42](#), [42f](#)

differential diagnosis of, [43](#)

epidemiology of, [41–42](#)

etiology of, [41](#)

medications for, [43](#)

physical examination of, [42](#)

prognosis for, [43](#)

duration of, [41](#)

frequency of, [41](#)

intensity of, [41](#)

normal development, [41](#), [41f](#)

Cryoprecipitate, [590t](#)

Cryptosporidium parvum, diarrhea from, [410t](#), [411–412](#)

CT, [Computed tomography](#)

Cullen sign, [502](#)

Cultures, [3](#), [8–9](#)

for infectious diseases, [362](#)

Cushing syndrome, [678](#)

obesity in, [106t](#)

Cushing triad, [708](#)

Custody, [94](#)

Cutaneous infections, [379–383](#)

Cutaneous infestation(s), [735–737](#)

pediculoses as, [736–737](#)

scabies as, [735–736](#)

Cutaneous larva migrans, [450t](#)

CVID (common variable immunodeficiency), [294–295](#), [295t](#)

CVS (chorionic villus sampling), [179](#)

CXR, [Chest x-ray](#)

Cyanide, toxicity, [162t](#)

Cyanosis

central, [232](#)

in newborn, [232](#), [232t](#), [241](#)

perioral, [535](#)

peripheral, [535](#)

with respiratory distress, [549t](#)

due to respiratory failure, [149](#)

without respiratory distress, [549t](#)

Cyanotic congenital heart disease, with polycythemia, [584](#)

Cyanotic heart disease, maternal, [236t](#)

Cyclic antidepressants, toxicity, [162t](#)

Cyclic vomiting syndrome, [472](#), [473t](#), [486–487](#)

clinical manifestations of, [487](#)

epidemiology of, [486–487](#)

etiology of, [486–487](#)

laboratory and imaging studies for, [487](#)

treatment of, [487](#)

Cyclophosphamide

for cancer, [601t–602t](#)

for juvenile dermatomyositis, [356](#)

for systemic lupus erythematosus, [355](#)

Cyclospora cayatanensis, diarrhea from, [410t](#)

Cyclosporine

for atopic dermatitis, [726](#)

for juvenile dermatomyositis, [356](#)

Cyclothymic disorder, [66–67](#)

Cyst(s), [722f](#)

bone

aneurysmal, [765t–766t](#)

unicameral, [765t–766t](#)

duplication

gastrointestinal bleeding due to, [477t](#)

vomiting due to, [473t](#)

ganglion, [765](#)

laryngeal, [519](#)

leptomeningeal, [710](#)

ovarian, [662](#)

pancreatic pseudocyst, [502](#)

popliteal (Baker), [751](#)

Cystathionine β -synthase deficiency, [203](#)

Cysteinyl leukotriene receptor antagonists, for asthma, [315](#)

Cystic acne, [723](#)

Cystic fibrosis (CF), [526–529](#)

clinical manifestations of, [526–528](#), [527t](#)

complications of, [527t](#)

constipation due to, [476t](#)

diagnostic studies for, [528–529](#), [528t](#)

etiology and epidemiology of, [526](#)

genetic basis for, [173t](#)

intestinal atresia in, [488](#)

pancreatic insufficiency due to, [501](#)

treatment of, [529](#)

Cystic fibrosis transmembrane conductance regulator (CFTR), [526](#)

Cystinosis, in Fanconi syndrome, [140](#)

Cystinuria, [205](#)

Cystitis, [416](#)

Cystourethrogram, voiding, for urinary tract infection, [417](#)

Cytogenetic analysis, for leukemia, [603–604](#)

Cytokine, in hematopoiesis, [564f](#)

Cytokine synthesis, test for, [293](#)

Cytomegalovirus (CMV)

congenital infection with, [260t](#), [261–262](#)

in immunocompromised person, [435](#)

pneumonia and, [403](#)

Cytosine arabinoside (Ara-C), for cancer, [601t–602t](#)

D

Dacryoadenitis, [433t](#)

Dacryocystitis, [431](#), [433t](#)

Dactinomycin, for cancer, [601t–602t](#)

Dactylitis, in sickle cell disease, [577t](#)

Danazol, for C1-inhibitor deficiency, [306](#)

Dander, asthma and, [315t](#)

Dandruff, [728](#)

Dandy-Walker malformation, [716–717](#)

Danon disease, [210t–212t](#)

- mechanism of, [739t](#)
- due to uterine compression, [741f](#)

Degenerative disorders, [711–714](#), [711t–712t](#)

- acquired illnesses mimicking, [714](#)
- with focal manifestations, [713](#)
- gray matter (neuronal), [711](#)
- hereditary and metabolic, [711–713](#)
- white matter (leukodystrophies), [711](#)

Deglutition syncope, [541t](#)

Degree of effort, [509–510](#)

Dehydration, 127–128

- approach to, 128
- assessment of degree of, 128t
- calculation of fluid deficit in, 128
- from diarrhea, 412
- fluid management of, 129t
- hypernatremic, 129, 130f
- hyponatremic, 129
- laboratory evaluation of, 128
- mild, 127–128
- moderate, 127–128
- monitoring and adjusting therapy for, 129, 129t
- oral rehydration for, 129
- severe, 127–128

Dehydroepiandrosterone (DHEA), 656

Delayed hemolytic transfusion reaction, 590t

Delayed sleep phase disorder, 54t–55t

Delayed-type hypersensitivity, 293, 311–312, 311t

Deletion 9q34, obesity in, 106t

Delivery, history of, in genetic assessment, 178

Delivery room care

- resuscitation in, 225, 226f
 - algorithm for, 226f
 - breathing in, 225–226
 - specific conditions requiring, 232–234
 - cyanosis as, 232, 232t
 - shock as, 233
- routine, 222–227
 - vitamin K prophylaxis in, 222

Delta agent, 413

Dementia

- acquired illnesses mimicking, 714
- with focal manifestations, 713
- gray matter (neuronal), 711

hereditary and metabolic, 711–713
white matter (leukodystrophies), 711

Dengue fever, 446

Dennie lines, 312

in atopic dermatitis, 326

Dennie-Morgan folds, 312

in atopic dermatitis, 326

Dental caries, 479–480

Denver Developmental Screening Test II, 17

Depression, somatic symptom and related disorders (SSRDs) and, 59

Depressive disorders, 64–68

disruptive mood dysregulation disorder (DMDD), 65

major depressive disorder (MDD), 64, 65t

persistent depressive disorder, 65

premenstrual dysphoric disorder (PDD), 65

specifiers for, 65

Emotional aspects, of pediatric practice, [3](#)

Empathy, [4](#)

Empirical antiinfective therapy, [367](#)

Empyema, [405](#), [530–531](#)

Enalapril

- for heart failure, [555t](#)
- maternal use of, [238t](#)

Encephalitis, [389–391](#)

- autoimmune, [389](#)
- causes of, [389t](#)
- clinical manifestations of, [389–390](#)
- complications and prognosis of, [390–391](#)
- differential diagnosis of, [390](#)
- epidemiology of, [389](#)
- etiology of, [389](#)
- laboratory and imaging studies for, [390](#)
- prevention of, [391](#)
- treatment for, [390](#)

Encephalomyelitis

- acute disseminated, [389](#)
- due to measles, [375](#)

Encephalomyelopathy, subacute necrotizing, [711t–712t](#)

Encephalopathy

bilirubin, [251](#)

hepatic, [497–498](#)

stages of, [499t](#)

treatment of, [500t](#)

hypoxic-ischemic, in newborn, [257–258](#)

clinical manifestations of, [257–258](#), [257t](#)

prognosis for, [257](#)

seizures due to, [255–256](#)

due to inborn errors of metabolism, [192](#), [193t](#)

Encephalotrigeminal angiomatosis, port-wine stain in, [733](#)

Enchondroma, [765t–766t](#)

Encopresis, [49](#), [475–476](#)

End-of-life care, [6–7](#)

End-of-life issues, [6–9](#)

access to comprehensive and compassionate palliative care, [6–7](#)

acknowledgment and support provisions for caregivers, [7](#)

bereavement in, [7](#)

cognitive issues in, [7](#)

commitment to quality improvement in, [7](#)

cultural, religious, and spiritual concerns about, [7–8](#)

in dignity of patients and families, [6](#)

interdisciplinary resources in, [7](#)

End-tidal carbon dioxide, [511](#)

Endocardial cushion defect, [547](#), [547f](#)

Endocardial cushion tissue, [545](#)

Endocarditis, infective, [408–410](#)

causes of, [408t](#)

clinical manifestations of, [408](#)

complications and prognosis of, [410](#)

culture-negative, [409](#)

differential diagnosis of, [409](#)

etiology of, [408](#)

- laboratory studies and imaging of, 409
- modified Duke clinical criteria for, 409, 409t
- prevention of, 410
- subacute, 408
- treatment of, 409

Endocervicitis, 419

Endocrine disorders, manifestations of, 637

Endocrine evaluation, of growth hormone secretion, 651

Endocrine system, 637

Endocrinology assessment, 637–639, 678

Endometriosis, dysmenorrhea due to, 277

Endophthalmitis, 431–432, 433t

Endoscopic evaluation, of airways, 511

Endoscopic retrograde cholangiopancreatography (ERCP), 503

Endoscopy

- for gastroesophageal reflux, 481
- for gastrointestinal symptoms, 467, 468f

Endotracheal tubes, 513

Endovascular infections, 408

Enema, for functional constipation, 51t

Energy deficiency, due to inborn errors of metabolism, 193

Engorgement, 100

ENPP1 gene mutations, obesity in, 106t

Entamoeba histolytica, diarrhea from, 410t

Enteric adenoviruses, diarrhea from, 410t

Enteritis, [Gastroenteritis](#)

Enterogastric *E. coli* (EAEC), 410t, 411

Enterobiasis, 451

Enterobius vermicularis, [450t](#), [451](#)

Enterocolitis

- food protein-induced, [335t–336t](#)
- due to Hirschsprung disease, [489–490](#)
- necrotizing, [254–255](#)
 - gastrointestinal bleeding due to, [477t](#)

Enterohemorrhagic *E. coli* (EHEC), [410t](#), [411](#)

Enteroinvasive *E. coli* (EIEC), [410t](#), [411](#)

Enteropathogenic *E. coli* (EPEC), [410t](#), [411](#)

Enteropathy, dietary protein-induced, [335t–336t](#)

Enterotoxigenic *E. coli* (ETEC), [410t](#), [411](#)

Enteroviruses

- conjunctivitis from, [431t](#)
- meningitis from, [387](#)

Enthesitis, in rheumatic diseases, [343](#)

Enuresis, [48–49](#)

- clinical manifestations of, [48](#)
- complications of, [49](#)
- differential diagnosis of, [48](#)
- epidemiology of, [48](#)
- etiology of, [48](#)
- prevention of, [49](#)
- treatment of, [49](#)

Enuresis alarm, [49](#)

Environmental control, for asthma, [314](#), [315t](#)

Environmental sleep disorders, [54t–55t](#)

Enzootic cycle, [439](#)

Enzyme defects, [676](#)

Enzymes, for cancer, [601t–602t](#)

Enzymopathies, in hemolytic anemia, [567f](#), [578](#), [592](#)

- clinical manifestations of, [578](#)
- epidemiology of, [578](#)
- etiology of, [578](#)
- glucose-6-phosphate dehydrogenase (G6PD) deficiency as, [566](#), [578](#)
- laboratory studies of, [578](#)
- prevention of, [578](#)
- pyruvate kinase deficiency as, [566](#), [578](#)
- treatment of, [578](#)

Eosinophil(s), values of, [565t](#)

Eosinophilia

- disorders associated with, [312](#), [312t](#)
- in infectious diseases, [362](#)
- nonallergic rhinitis with, [323](#), [324t](#)

Eosinophilic esophagitis, [482–483](#)

- clinical manifestations of, [482](#)
- complications with, [483](#)
- etiology and epidemiology of, [482](#)
- laboratory and imaging studies for, [482](#), [482f](#)
- treatment and prognosis for, [482](#)
- vomiting due to, [473t](#)

Eosinophilic granuloma, [765t–766t](#)

Eosinophilic meningitis, [450t](#)

Eotaxins, functions of, [290t](#)

EPEC (enteropathogenic *E. coli*), [410t](#), [411](#)

Epidemic keratoconjunctivitis, [430](#)

Epidemic typhus, [737](#)

Epidermal nevus, [730t](#)

Epidural analgesia, [166](#)

Epidural hemorrhages, [709–710](#)

Epiglottitis, [507](#)

Epiglottitis

croup and, [399](#)

upper airway obstruction due to, [517t](#), [518](#)

Epilepsy, [Seizure\(s\)](#)

benign childhood, with centrotemporal spikes, [690](#)

defined, [687](#)

myoclonic, [689](#)

 juvenile, [690](#)

rolandic, [690](#)

status epilepticus in, [690–691](#)

 management of, [691t](#)

Epilepsy syndrome, [688t](#), [690](#)

Epinephrine

for anaphylaxis, [331](#)

for cardiopulmonary resuscitation, [148](#), [148t](#)

for croup, [399–400](#)

deficiencies in, [649](#)

for food allergies, [337](#)

in newborn resuscitation, [227](#)

for shock, [153t](#)

Epiphyseal cartilage, [740f](#)

Epiphyseal growth plate, [425](#)

Epiphysiolysis, proximal humeral, [763](#)

Epiphysis, [740f](#)

Episcleritis, [433t](#)

Episodic disorders, [681](#)

Episodic rhinitis, [323](#)

Epstein-Barr virus (EBV) infection, [573t](#)

infectious mononucleosis due to, [384](#), [385f](#)

in X-linked lymphoproliferative disease, [298–299](#)

Equinus, [739t](#)

Erb-Duchenne paralysis, in newborn, [233](#)

Ergocalciferol, [118](#)

Erosion, [722t](#)

Erysipelas, [380](#)

Erysipeloid, [439t–442t](#)

Erysipelothrix rhusiopathiae, [439t–442t](#)

Erythema infectiosum (fifth disease), [377–378](#)

- clinical manifestations of, [377](#)
- complications and prognosis of, [378](#)
- differential diagnosis of, [377](#)
- epidemiology of, [377](#)
- etiology of, [377](#)
- laboratory and imaging studies in, [377](#)
- prevention of, [378](#)
- treatment of, [377](#)

Erythema marginatum, due to heart failure, [556](#), [556t](#)

Erythema migrans, [443](#)

Erythema multiforme (EM), [331](#), [733–735](#), [734t](#)

- vesiculobullous eruptions due to, [734t](#)

Erythema nodosum, infections with fever and, [373t–374t](#)

Erythema toxicum, [228–229](#)

Erythematous flare, in allergen-specific IgE in vivo skin testing, [312–313](#)

Erythroblastosis fetalis

- newborn anemia due to, [247](#)
- predicting severity of, [247–248](#)

Erythrocyte P antigen, erythema infectiosum and, [377](#)

Erythrocytic phase, of *Plasmodium* life cycle, [447](#)

Erythroderma, diffuse, infections with fever and, [373t–374t](#)

Erythroid cells, in hematopoiesis, [563](#)

Erythroid colony-forming unit, [563–566](#)

Erythromycin, for acne, [723](#)

Erythropoiesis, [563–566](#)

embryonic, [247](#)

ineffective, [575](#)

Erythropoietin, [563–566](#), [617–618](#)

Escherichia coli

diarrhea from, [410t](#), [411](#)

urinary tract infections due to, [416](#)

Esophageal atresia, [483](#)

Esophageal disorders, [480–487](#)

caustic injuries as, [484](#)

eosinophilic esophagitis as, [482–483](#), [482f](#)

esophageal atresia as, [483](#)

due to foreign bodies, [483–484](#)

gastroesophageal reflux as, [480–482](#), [481t](#)

pill ulcers as, [484](#)

tracheoesophageal fistula as, [483](#), [483f](#)

Esophageal foreign bodies, [483–484](#)

Esophageal impedance monitoring, for gastroesophageal reflux, [481](#)

Esophageal pH probe monitoring, 24-hour, for gastroesophageal reflux, [481](#)

Esophageal reflux, abdominal pain due to, [470t](#)

Esophageal varices, [497](#)

gastrointestinal bleeding due to, [477t](#)

Esophagitis, [485–486](#), [486t](#)

allergic eosinophilic, [335t–336t](#)

Esophagram, barium, [511](#)

Etanercept, for juvenile idiopathic arthritis, [352](#)

ETEC (enterotoxigenic *E. coli*), [410t](#), [411](#)

Ethical decision making, [4](#)

Ethical issues

- in end-of-life decision making, 8
- in genetic testing and screening, 5–6
- in practice, 5–6

Ethical principles, related to infants, children, and adolescents, 4–5

Ethics, 4–6, 9

- in health care, 4
- religious issues and, 6

Ethylene glycol, 140

- toxicity, 162*t*

Etonogestrel implant, 278–279

Etoposide, for cancer, 601*t*–602*t*

Eunuchoid proportions, 656

Euphoria, in bipolar I disorder (BD), 66

Euvolemic hyponatremia, 132

Evaporation, heat loss via, 234

Ewing sarcoma, 611

- clinical manifestations of, 612
- diagnosis of, 612
- differential diagnosis of, 612
- epidemiology of, 611
- laboratory/imaging studies in, 612
- prognosis for, 613
- risk factors for, 597*t*
- treatment of, 612

Exchange transfusion, for indirect hyperbilirubinemia, 252

Excoriation, 722*t*

Exercise intolerance, due to heart failure, 535

Exertional dyspnea, due to pulmonary stenosis, 547

Exhalation, 507

Exit site infection, [437](#)

Exocrine pancreatic insufficiency, in cystic fibrosis, [527](#), [529](#)

Exons, [169](#)

Exostoses

multiple hereditary, [765t–766t](#)

osteocartilaginous, [765t–766t](#)

Expiratory reserve volume, [508f](#)

Extensor plantar reflex, [684](#)

External cardiac massage, in newborn resuscitation, [226–227](#)

External genitalia, differentiation of male and female, [671f](#)

External intercostal muscles, during inspiration, [507](#)

External tibial torsion, [749](#)

Extinction, [16](#), [25](#)

Extracellular fluid (ECF), [125](#)

Extracorporeal membrane oxygenation (ECMO)

for heart failure, [555t](#)

for meconium aspiration syndrome, [245](#)

for primary pulmonary hypertension of the newborn, [245](#)

Extrahepatic biliary atresia, [494](#)

Extramedullary hematopoiesis, in hematological disorders, [563](#)

Extrapulmonary shunt, hypoxemia due to, [508t](#)

Extrapulmonary tuberculosis, [455](#)

Extremities

anemia and, [569t](#)

congenital malformations of, [185](#)

of newborn, [231](#)

Extremity fractures, in newborn, [234](#)

Extrinsic pathways, in coagulation, [580](#)

Extrinsic tracheal compression, [521](#), [521f](#)

Exudates, [530–531](#)

Eye(s)

anemia and, [569t](#)

with developmental disabilities, [30t](#)

dysmorphology of, [185](#)

of newborn, [228f](#)

Eye movements, assessment of, [683](#)

Eyelid scrub, for blepharitis, [431](#)

F

FA (Friedreich ataxia), [702](#)

genetic basis for, [173t](#)

Fabry disease, [210t–212t](#)

Face

congenital malformations of, [183t](#)

with developmental disabilities, [30t](#)

of newborn, [230](#)

Facial nerve, assessment of, [683](#)

Facial nerve injury, in newborn, [233](#)

Facial weakness, [694t](#)

Facioscapulohumeral dystrophy, [697](#)

Factitious disorder, [60–61](#), [61t](#)

Factitious hyperinsulinemia, [649](#)

Factor 5 Leiden, [589](#)

Factor VIII deficiency, [586–587](#)

genetic basis for, [174t](#)

Factor 9 deficiency, [586–587](#)

Failure to thrive, [77–79](#), [109](#)

- clinical manifestations of, [77–79](#)
- complications of, [79](#)
- diagnosis of, [77–79](#)
- etiology of, [77](#), [78t](#)
- malnutrition and, [109](#)
- treatment of, [79](#), [79t](#)

Famciclovir

- for herpes simplex virus infection, [424](#)
- for varicella zoster virus, [379](#)

Familial hemophagocytic lymphohistiocytosis, [573t](#)

Familial hypophosphatemic rickets, [670](#), [670t](#)

Familial male-limited precocious puberty, [662](#)

Familial short stature, [13](#)

Family

- defined, [87](#)
- functions of, [87–88](#), [88t](#)
- single-parent, [88](#)
- traditional, [88](#)

Family dysfunction

- defined, [87](#)
- for emotional support, education, and socialization, [91](#)
- for physical needs, [90–91](#)

Family history

- for dysmorphology, [184](#)
- in genetic assessment, [178](#)

Family structure, [88–90](#)

- adoption as, [89](#)
- foster care as, [89–90](#)
- with sexual minority parents, [88–89](#)
- single-parent families as, [88](#)

Fanconi anemia, [573t](#), [574–575](#)

- clinical manifestations of, [574](#)

etiology and epidemiology of, 574
marrow replacement in, 575
treatment of, 575

Fanconi syndrome, 621

proximal renal tubular acidosis and, 140

Farber lipogranulomatosis, 210t–212t

Fasciculations, 684

spinal muscular atrophy, 694

Fasciitis, necrotizing, 380

Fascioliasis, 451t

Fasciolopsiasis, 451t

Fasciolopsis buski, 451t

Fat metabolic disorder(s), 207–208

Fat-soluble vitamins, 114t, 117–119

Fatal injuries, 154

Fatigability, due to pulmonary stenosis, 547

Fatigue, due to heart failure, 535

Fatty acid(s), catabolism of, 207, 207f

Fatty acid disorder(s)

carnitine deficiency as, 208

of fatty acid oxidation, 207–208

glutaric aciduria type II, 208

Fatty acid oxidation disorders, 207–208

of ketogenesis, 649–650

Fatty liver disease, nonalcoholic, 501

FBN1 gene, in Marfan syndrome, 171

Febrile nonhemolytic transfusion reaction, 590t

Febrile paroxysms, 447

Febrile seizures, [689](#)

 complex, [689](#)

 simple, [689](#)

Fecalith, in appendicitis, [493](#)

Feeding jejunostomy, for gastroesophageal reflux, [481t](#)

Femoral anteversion, [739t](#), [748](#)

 clinical manifestations of, [748](#)

Femoral pulses, in coarctation of aorta, [548](#)

Femur, [751f](#)

Fentanyl, as analgesia, [166t](#)

Ferrous sulfate, for iron deficiency anemia, [120](#)

Fetal acidosis, [220](#)

Fetal alcohol spectrum disorder (FASD), [90](#), [176–177](#)

Fetal alcohol syndrome (FAS), [90](#)

Fetal aorta, Doppler examination of, [220](#)

Fetal growth, [219](#), [220t](#)

Fetal heart rate monitoring, [220](#)

Fetal hemoglobin, [220–221](#), [247](#), [566](#)

Fetal hydrops, [240](#)

 respiratory distress in newborn due to, [240](#)

Fetal-maternal hemorrhage, [249](#)

Fetal maturity, [219](#)

Fetal size, [219](#)

Fetal well-being, [220](#)

Fetus

 assessment of, [219–220](#), [220t](#)

 diseases of, [239–240](#)

 hydrops fetalis as, [240](#)

 intrauterine growth restriction and small for gestational age as, [239–240](#), [239t](#)

Fever

- blackwater, [449](#)
- dengue, [446](#)
- factitious, [371](#)
- in immunocompromised person, [434–435](#), [435f](#), [436t](#)
- infections with rash and, [373–379](#)
 - differential diagnosis of, [373t–374t](#)
 - erythema infectiosum (fifth disease) as, [377–378](#)
 - measles (rubeola) as, [373–375](#)
 - roseola infantum (exanthem subitum), [376–377](#)
 - rubella (German or 3-day measles), [375–376](#)
 - varicella-zoster virus infection (chickenpox and zoster), [378–379](#)
- in infectious diseases, [361](#)
- in Kawasaki disease, [347](#)
- normal body temperature and, [368](#)
- Q, [439t–442t](#)
- rat-bite, [439t–442t](#)
- relapsing, [439t–442t](#)
 - louse-borne, [737](#)
- rheumatic, [556](#), [556t](#)
- in rheumatic diseases, [343](#)
- scarlet, [393](#)
- of short duration, [368](#)
- trench, [737](#)
- of unknown origin, [368](#), [370f](#)
 - causes of, in children, [371t–372t](#)
 - screening tests for, [371](#)
- without a focus, [368–371](#)
 - bacteremia and, [368](#)
 - in children 3 months to 3 years of age, [369–370](#), [369f](#)
 - in infants younger than 3 months of age, [368–369](#)
 - pattern of, [368](#)
 - sepsis and, [368](#)

Fever blisters, [382](#)

Fexofenadine, for allergic rhinitis, [325](#)

FGFR3 gene, in achondroplasia, [171](#)

Fiber supplements, for irritable bowel syndrome, [471–472](#)

Fibrillation(s), [685](#)

atrial, [543](#)

ventricular, [544t](#)

Fibrinogen, [583](#)

Fibrinolysis, in hemostasis, [581](#)

Fibrinolytic agents, for thrombosis, [589](#)

Fibroma, nonossifying, [765t–766t](#)

Fibromyalgia, [358](#)

Fibrosing colonopathy, due to lipase, [529](#)

Fibrous periosteum, [740f](#)

Fibula, [751f](#)

Filiform warts, [382](#)

Fine motor-adaptive development, milestones of, [17t](#)

Finger

abnormalities of, [765](#)

trigger, [765](#)

Fire ant bites, allergic reactions to, [333](#)

First-degree heart block, [543](#), [544t](#)

First heart sound (S₁), [536](#)

FISH (fluorescent in situ hybridization), [179](#)

Fissure, [722t](#)

Fitz-Hugh-Curtis syndrome, [420–421](#)

Flat warts (verruca plana), [382](#)

Flatfoot

developmental, [754](#)

flexible, [754](#)

rigid, [754–755](#)

Flavoprotein metabolism, [207f](#)

Flea bites, allergic reactions to, [333](#)

Flexible bronchoscopy, [511](#)

Flexible flatfoot, [754](#)

Floppy infant, [698](#)

Fluid

in body composition, [125](#), [126f](#)

in cardiopulmonary resuscitation, [148t](#)

Fluid deficit, calculation of, [128](#)

Fluid management, for burns, [159](#)

Fluid restriction, for heart failure, [555t](#)

Fluid resuscitation

for dehydration, [128](#)

for intussusception, [493](#)

Fluid therapy, maintenance, [125–126](#), [126t](#)

Flumazenil, for benzodiazepine poisoning, [164t–165t](#)

Flunisolide, for asthma, [319f](#)

Flunitrazepam, acute effects of, [284t–285t](#)

Fluorescent in situ hybridization (FISH), [179](#)

Fluorescent treponemal antibody-absorption (FTA-ABS) test, [424](#)

Fluoride deficiency, [119t](#), [121](#)

Fluoride supplementation, [479](#)

Fluorosis, [121](#), [479](#)

Fluoxetine

maternal use of, [238t](#)

as teratogens, [237t](#)

Fluticasone HFA/MDI/DPI, for asthma, [319f](#)

Flutter, atrial, [543](#), [544t](#)

Fly bites, allergic reactions to, [333](#)

FMR-1 gene, in fragile X syndrome, [176](#)

FMRP (fragile X mental retardation protein), [176](#)

Focal segmental glomerulosclerosis (FSGS), [620](#)

Folate deficiency, [114–116](#), [114t](#)
in anemia, [567f](#)

Folic acid antagonists, as teratogens, [237t](#)

Folliculitis, [380](#)
hot tub, [380](#)

Fontan procedure, for tricuspid atresia, [551](#)

Fontanelles, [229](#)

Food(s), adverse reactions to, [334–338](#)
clinical manifestations of, [335](#), [335t–336t](#)
complications of, [337](#)
diagnosis of, [335–337](#)
etiology and epidemiology of, [334–335](#)
laboratory and imaging studies for, [335](#)
prognosis and prevention of, [337–338](#)
treatment of, [337](#)

Food-borne causes, of diarrhea, [410–411](#)

Food protein-induced enterocolitis syndrome, [335t–336t](#)

Foot, [752–755](#)
calcaneovalgus, [754](#)
cavus, [755](#)
club, [753–754](#), [753f](#)
deformity, posturing vs., [752](#)
hypermobile pes planus (flexible flatfoot), [754](#)
idiopathic avascular necrosis of, [755](#)
metatarsus adductus, [754](#), [754f](#)
Sever disease (calcaneal apophysitis) of, [755](#)
skew, [754](#)
tarsal coalition of, [754–755](#)

- toe deformities of, [755](#), [756t](#)
- Foot pain, differential diagnosis of, [752](#), [753t](#)
- Forced expiratory flow (FEF), [511](#)
- Forced expired volume in first second (FEV₁), [511](#)
- Forced vital capacity (FVC), [511](#)
- Forchheimer spots, in rubella, [375](#)
- Forehead, dysmorphology of, [185](#)
- Foreign bodies
 - esophageal, [483–484](#)
 - in nose, [324](#)
 - upper airway obstruction due to, [517t](#)

Idiopathic pulmonary hemosiderosis, [525](#)
Idiopathic scoliosis, [758](#)
Idiopathic thrombocytopenic purpura (ITP), [584–585](#)
 bleeding disorder in newborn due to, [254](#)
 clinical manifestations of, [585](#)
 diagnosis of, [585](#)
 etiology of, [584–585](#)

- maternal, [235–236](#), [236t](#), [584](#)
 - neonatal thrombocytopenia due to, [254](#)
- prognosis for, [585](#)
- treatment of, [585](#)

Iduronate 2-sulfatase deficiency, [210t–212t](#)

α -L-Iduronidase deficiency, [210t–212t](#)

Ifosfamide, for cancer, [601t–602t](#)

Ig replacement therapy, for severe combined immunodeficiency, [299–300](#)

IgA nephropathy, [622](#)

Ileal atresia, [227t](#)

Illness, [54t–55t](#)

Illness anxiety disorder, [59](#), [60t](#)

Illness Attitude Scales and Soma Assessment Interview, for somatic symptom and related disorders (SSRDs), [61](#)

Imatinib, for cancer, [601t–602t](#)

Imipramine

- for enuresis, [49](#)
- maternal use of, [238t](#)

Immobilization, physiological changes due to, [670t](#)

Immotile cilia syndrome, [523](#)

Immune-mediated mechanisms, in thrombocytopenia resulting from peripheral destruction, [584](#)

Immunization, [363–366](#)

- active, [363](#)
- administration of, [365](#)
- adverse events after, [366](#)
- catch-up, [364–365](#)
 - schedules for, [365f](#)
- contraindications to, [365–366](#)
- informed consent for, [365](#)
- passive, [363](#)

and prophylaxis, 363–366

recommended schedules for, 364*f*

Immunocompromised person, infection in, 434–437

clinical manifestations of, 436

differential diagnosis of, 436

epidemiology of, 435, 435*f*

etiology of, 434–435, 434*t*

laboratory tests and imaging for, 436

prevention of, 436–437

treatment of, 436

Immunodeficiency, 117

common variable, 294–295, 295*t*

fever due to, 371

general management of, 299, 300*t*

severe combined, 297, 297*t*

 autosomal recessive, 297–298

 clinical manifestations of, 297–298

 due to deficiencies in adenosine deaminase and purine nucleoside phosphorylase, 298

 X-linked, 297–298

Immunodeficiency diseases

antibody deficiency disease, 294–295, 294*f*, 295*t*

 agammaglobulinemia as, 294, 295*t*

 autosomal recessive, 294

 X-linked, 294

 antibody deficiency syndrome as, 295, 295*t*

 common variable immunodeficiency as, 294–295, 295*t*

 IgA deficiency as, 295, 295*t*

 IgG subclass deficiency as, 295, 295*t*

 transient hypogammaglobulinemia of infancy as, 295, 295*t*

assessment, 289–293

 adaptive immune system and, 289

 clinical characteristics of, 291*t*

 due to defects in anatomic-mucociliary barrier, 289, 289*t*

 diagnostic evaluation of, 292–293, 292*f*

 imaging in, 293

 laboratory tests in, 292–293, 293*t*

 differential diagnosis of, 291–292, 291*t*

 history of, 290–291

 innate immune system and, 289, 290*t*

 physical examination for, 291

combined, [296–299](#), [297t](#)

autosomal recessive, [297–298](#)

bare lymphocyte syndrome as, [297t](#), [298](#)

clinical manifestations of, [297](#)

DiGeorge syndrome as, [297t](#), [298](#)

hyper-IgM syndrome as, [297t](#)

autosomal recessive, [296](#)

due to defects in NEMO, [296](#)

X-linked, [296](#), [296f](#)

Omenn syndrome as, [297–298](#), [297t](#)

reticular dysgenesis as, [297t](#)

severe, [297](#), [297t](#)

autosomal recessive, [297–298](#)

clinical manifestations of, [297–298](#)

due to deficiencies in adenosine deaminase and purine nucleoside phosphorylase, [298](#)

X-linked, [297–298](#)

due to lymphocyte disorders, [Lymphocyte disorders](#)

secondary, [291t](#)

Immunoglobulin, intravenous, for autoimmune hemolysis, [580](#)

Immunoglobulin A (IgA) deficiency, [295](#), [295t](#)

Immunoglobulin E (IgE)

disorders associated with elevated, [312](#), [312t](#)

in food allergies, [337t](#)

Immunoglobulin G (IgG) subclass deficiency, [295](#), [295t](#)

Immunomodulating drugs, topical, for atopic dermatitis, [327–328](#)

Immunophenotype, of leukemia, [603–604](#)

Immunosuppression, immunization and, [366](#)

Immunotherapy, for allergic rhinitis, [325](#)

Impact seizures, [710](#)

Imperforate anus, [489](#)

constipation due to, [476t](#)

Impetigo, [379–380](#)

bullous, [379](#)

nonbullous, [379](#)

Impetigo, bullous, [734t](#)

Implanted venous access systems (Port-a-Cath), [437](#)

In-toeing, 748–749

- common causes of, 748t
- due to femoral anteversion, 748
- due to internal tibial torsion, 748–749
- treatment of, 749

In vitro serum testing, for antigen-specific IgE, 312–313, 313t

In vivo skin testing, for allergen-specific IgE, 313, 313t

Inactivated poliovirus (IPV) vaccine, 364f–365f

Inborn errors of metabolism

- assessment of, 191
 - clinical, and laboratory findings, 196, 196t
- ataxia due to, 702
- clinical presentation of, 191–196
 - congenital malformations or dysmorphic features in, 195–196
 - energy deficiency in, 193
 - ketosis and ketotic hypoglycemia in, 193–195
 - specific organ, 192–193, 195t
 - storage disorders, 196
 - toxic, 191–192
- genetic aspects of, 196–197
 - identification of molecular pathology as, 197
 - mechanisms of inheritance as, 196–197
- hyperammonemia in
 - etiology of, 195t
 - in later infancy and childhood, 192, 194f
 - metabolic acidosis in, 192, 196t
 - neonatal
 - moderate, 192
 - severe, 192
- incidence of, 192t
- metabolic acidosis due to, 140
- neonatal screening for, 197–199
 - confirmatory testing principles of, 197
 - disorders identified by, 197
 - specialized laboratory and clinical testing after, 197–199, 199t
 - strategy of, 197
- overview of treatment for, 199
- signs and symptoms of, 191

Inclusion conjunctivitis, [431](#)

Incontinentia pigmenti, [173](#)

Individualized educational plan (IEP), [28](#)

Indomethacin, maternal use of, [238t](#)

Induction chemotherapy, for leukemia, [604](#)

Infancy

bonding and attachment in, [15](#)

obesity and, [107–108](#)

physical development in later, [14](#)

Infant(s)

crying, [41](#), [Crying](#)

ethical principles related to, [4–5](#)

genetic assessment of, [178](#)

hearing and vision screening of, [20](#)

low birth weight of, [218–219](#)

mortality, [2](#), [218](#)

very low birth weight of, [219](#)

Infant botulism, [696](#)

Infantile beriberi, [113](#)

Infantile hypotonia, [698–699](#), [698f](#)

Infantile spasms, [690](#)

Infantometer, [651](#)

Infection(s)

assessment, [289–293](#)

adaptive immune system and, [289](#)

clinical characteristics of, [291t](#)

due to defects in anatomic-mucociliary barrier, [289](#), [289t](#)

diagnostic evaluation of, [292–293](#), [292f](#)

imaging in, [293](#)

laboratory tests in, [292–293](#), [293t](#)

differential diagnosis of, [291–292](#), [291t](#)

history of, [290–291](#)

innate immune system and, [289](#), [290t](#)

physical examination for, [291](#)

congenital (TORCH), 259–264, 260t

- with chlamydia, 263–264
- with *Chlamydia trachomatis*, 260t
- with cytomegalovirus, 261–262
- with herpes simplex virus, 260t, 262
- with HIV, 260t
- with *Mycobacterium tuberculosis*, 260t
- with *Neisseria gonorrhoeae*, 260t, 263
- with parvovirus, 260t
- with rubella, 260t, 261
- with toxoplasmosis, 261
- with *Trypanosoma cruzi*, 260t
- with varicella-zoster virus, 260t
- with Zika virus, 264

cutaneous (superficial)

- bacterial, 379–380
 - cellulitis as, 380
 - folliculitis as, 380
 - impetigo as, 379–380
 - perianal dermatitis as, 380
- fungal, 380–381, 381t
- viral, 381–383
 - from herpes simplex virus, 381–382
 - from human papillomaviruses (warts), 382
 - molluscum contagiosum as, 383

with fever and rash, 373–379

- differential diagnosis of, 373t–374t
- erythema infectiosum (fifth disease) as, 377–378
- measles (rubeola) as, 373–375
- roseola infantum (exanthem subitum), 376–377
- rubella (German or 3-day measles), 375–376
- varicella-zoster virus infection (chickenpox and zoster), 378–379

in immunocompromised person, 434–437

- clinical manifestations of, 436
- differential diagnosis of, 436
- epidemiology of, 435, 435f
- etiology of, 434–435, 434t
- laboratory tests and imaging for, 436
- prevention of, 436–437
- treatment of, 436

maternal

- effect on fetus or newborn, 236t
- as teratogens, 176

medical devices-associated, 437–439

- from central nervous system shunts, 438–439
- peritoneal dialysis-associated infections as, 438

from urinary catheters, [438](#)
from vascular devices, [437–438](#)
ventilator-associated pneumonia as, [438](#)

with neutropenia, [302t](#)

orthopedic problems due to, [739t](#)

in sickle cell disease, [577t](#)

Infectious arthritis, juvenile idiopathic arthritis vs., [352t](#)

Infectious diseases, [361–461](#)

- assessment of, [361–363](#)
 - diagnostic imaging in, [362–363](#)
 - differential diagnosis in, [361](#)
 - history in, [362t](#)
 - initial diagnostic evaluation in, [361](#)
 - physical examination in, [361](#)
 - screening tests in, [361–362](#)
- localizing manifestations of, [363t](#)
- in transfusion reactions, [590](#)
- viral vs. bacterial, [363t](#), [368–369](#)

Infectious mononucleosis, [384](#)

Infectious pyogenic infection, synovial fluid findings in, [429t](#)

Infectious rhinitis, [323–324](#)

Infective endocarditis, [408–410](#)

- causes of, [408t](#)
- clinical manifestations of, [408](#)
- complications and prognosis of, [410](#)
- culture-negative, [409](#)
- differential diagnosis of, [409](#)
- etiology of, [408](#)
- laboratory studies and imaging of, [409](#)
- modified Duke clinical criteria for, [409](#)
- prevention of, [410](#)
- subacute, [408](#)
- treatment of, [409](#)

Inflammation, orthopedic problems due to, [739t](#)

Inflammatory bowel disease (IBD), [490–491](#)

- abdominal pain due to, [470t](#)
- clinical manifestations of, [490](#), [490t](#)
- epidemiology and etiology of, [490–491](#)
- gastrointestinal bleeding due to, [477t](#)
- juvenile idiopathic arthritis vs., [351t](#)
- laboratory and imaging studies for, [491](#), [491t](#)

synovial fluid findings in, [429t](#)

treatment of, [491](#)

Inflammatory diseases, fever due to, [371](#)

Infliximab, for juvenile idiopathic arthritis, [352](#)

Influenza, avian, [403](#)

Influenza A (H5N1), [403](#)

Influenza vaccines, [364f](#)

for prevention of pneumonia, [407–408](#)

Infuse-a-Port (implanted venous access systems), infections associated with, [437](#)

Inhalants, acute effects of, [284t–285t](#)

Inhalation challenge tests, [511](#)

Inheritance patterns

autosomal dominant disorders, [170–171](#), [170t](#)

autosomal recessive disorders, [171](#)

 vomiting due to, [473t](#)
Intestinal injury, [157](#)

Intestinal obstruction

- abdominal pain due to, [470t](#)
- due to congenital anomaly, [227t](#)

Intestinal tract disorders, [487–494](#)

- anorectal malformations as, [489](#)
- appendicitis as, [493–494](#), [493t](#)
- celiac disease as, [492](#)
- gastroschisis as, [489](#)
- Hirschsprung disease as, [489–490](#)
- inflammatory bowel disease as, [490–491](#), [491t](#)
- intestinal atresia as, [488–489](#), [489f](#)
- intussusception as, [492–493](#)
- Meckel diverticulum as, [490](#)
- midgut malrotation as, [487–488](#), [487f–488f](#)
- omphalocele as, [489](#)

Intimate partner violence, [91](#), [92t](#)

Intracellular fluid (ICF), [125](#)

Intracranial hemorrhage

- in NATP, [584](#)
- in newborn, [256–257](#)

Intracranial pressure (ICP), increased, [706–708](#)

- due to bacterial meningitis, [707](#)
- causes of, [707t](#)
- in central nervous system, [607](#)
- clinical manifestations of, [708](#)
- etiology of, [706–708](#), [707t](#)
- due to hydrocephalus, [707](#), [707t](#)
- due to idiopathic intracranial hypertension, [707–708](#)
- laboratory and diagnostic studies for, [708](#)
- oncological emergencies, [600t](#)
- treatment of, [708](#)

Intramedullary destruction, in pancytopenia, [575](#)

Intramuscular influenza vaccine, [363–364](#)

Intrapulmonary shunting, [523–524](#)

hypoxemia due to, [508t](#)

Intrauterine growth restriction (IUGR), [239–240](#)

complications of, [219](#)

management of, [239–240](#)

Intravascular volume, regulation of, [125](#)

Intravenous (IV) fluids, during labor, [238t](#)

Intravenous immunoglobulin (IVIG)

for autoimmune hemolysis, [580](#)

complications of, [299–300](#)

for Guillain-Barré syndrome, [695](#)

Intraventricular hemorrhage (IVH), in newborn

diagnosis of, [257](#)

seizures due to, [255](#)

Intrinsic factor, [117](#)

Intrinsic pathways, in coagulation, [580](#)

Introns, [169](#)

Intubation, [513](#)

Intussusception, [492–493](#)

abdominal pain due to, [470t](#)

clinical manifestations of, [492](#)

etiology and epidemiology of, [492](#)

gastrointestinal bleeding due to, [477t](#)

ileocolonic, [492](#)

laboratory and imaging studies for, [492–493](#)

treatment of, [493](#)

vomiting due to, [473t](#)

Inverse psoriasis, [729–730](#)

Inverted duplication chromosome 15, [183](#)

Involucrum, [426](#)

Iodides, maternal use of, [238t](#)

radioactive, [238t](#)

Iodine, radioactive

maternal use of, [238t](#)

as teratogens, [237t](#)

Iodine deficiency, [119t](#)

IP-10, functions of, [290t](#)

Ipecac syrup, for poisoning, [164](#)

Ipratropium bromide

for allergic rhinitis, [325](#)

for asthma, [316](#)

IPV (inactivated poliovirus) vaccine, [364f–365f](#)

Iridocyclitis, [433t](#)

in juvenile idiopathic arthritis, [350](#)

Iris coloboma, in cat eye syndrome, [183](#)

Iron, toxicity of, [162t](#)

Iron deficiency, [119t](#), [120](#)

hookworm, [450t](#)

Iron deficiency anemia, [568–571](#), [591](#)

clinical manifestations of, [570](#)

diagnosis of, [120](#)

epidemiology of, [570](#), [570t](#)

etiology of, [570](#)

prevention of, [571](#)

treatment of, [120](#), [571](#), [571t](#)

Iron-fortified cereals, as complementary food, [101](#)

Iron intake, for toddlers and older children, [104](#)

Irregular sleep-wake pattern, [54t–55t](#)

Irritable bowel syndrome, abdominal pain due to, [468–471](#), [470t](#)

Irritant contact dermatitis, [727](#)

Irritant diaper dermatitis, [727f](#)

Isoelectric focusing, for hemoglobinopathies, [577](#)

Isoimmune hemolysis, [579](#)

Isolation effect, with inborn errors of metabolism, [196–197](#)

Isoleucine, metabolism of, [203f](#)

Isoniazid (INH), for tuberculosis, [455–456](#), [457t](#)

Isospora belli, diarrhea from, [410t](#)

Isotonic crystalloids, [146](#)

Isotonic fluid, for third space losses, [127](#)

Isotretinoin

- for acne, [723](#)
- for cancer, [601t–602t](#)
- as teratogens, [237t](#)

Isovaleric acidemia, [206](#), [206f](#)

- neonatal screening for, [198t](#)

ITP, [Idiopathic thrombocytopenic purpura](#)

IUGR, [Intrauterine growth restriction](#)

IV (intravenous) fluids, during labor, [238t](#)

IVIG (intravenous immunoglobulin)

- for autoimmune hemolysis, [580](#)
- complications of, [299–300](#)
- for Guillain-Barré syndrome, [695](#)

Ixodes pacificus, [443](#)

Ixodes scapularis, [443](#), [445](#)

J

Jarisch-Herxheimer reaction, [424](#)

JAS (juvenile ankylosing spondylitis), [351t](#)

Jaundice, [649](#)

- due to anemia, [567–568](#)
- breast-feeding, [100](#)
- breast milk, [100](#), [250](#)
- differential diagnosis of, [494](#), [495f](#)
- on first day of life, [250](#)
- in hematological disorders, [563](#)
- due to inborn errors of metabolism, [195t](#)
- physiological, [250](#)
- in pyloric stenosis, [485](#)

JDM, [Juvenile dermatomyositis](#)

Jejunostomy, feeding, for gastroesophageal reflux, [481t](#)

JIA, [Juvenile idiopathic arthritis](#)

Jock itch, [381t](#)

Joint custody, [94](#)

Joint hypermobility, [357](#)

Joint space, [740f](#)

Jones criteria, for rheumatic fever, [556](#), [556t](#)

Juice intake, for toddlers and older children, [103](#)

Justice, [4](#)

- distributive, [6](#)

Juvenile ankylosing spondylitis (JAS), [351t](#)

Juvenile dermatomyositis (JDM), [355–356](#)

- clinical manifestations of, [355–356](#)
- complications of, [356](#)
- diagnostic criteria for, [356t](#)
- differential diagnosis of, [356](#)
- epidemiology of, [355](#)
- etiology of, [355](#)
- laboratory and imaging studies of, [356](#)
- prognosis for, [356](#)

treatment of, [356](#)

Juvenile idiopathic arthritis (JIA), [349–353](#)

clinical presentation of, [349–351](#), [350f](#), [350t](#)

complications of, [352](#)

differential diagnosis of, [344t](#), [351–352](#), [352t](#)

epidemiology of, [349](#)

etiology of, [349](#)

laboratory and imaging studies for, [351](#)

oligoarticular, [350](#)

polyarticular, [350–351](#)

prognosis for, [352–353](#)

spondyloarthropathies and, [351](#), [351t](#)

systemic, [351](#)

treatment of, [352](#)

Juvenile laryngeal papillomatosis, [519](#)

Juvenile pernicious anemia, [117](#)

Juvenile polyp, gastrointestinal bleeding due to, [477t](#)

Juvenile rheumatoid arthritis, [Juvenile idiopathic arthritis](#)

K

Kallmann syndrome, [657](#)

Kaposi varicelliform eruption

in atopic dermatitis, [328](#), [726](#), [727f](#)

herpes zoster virus and, [382](#)

varicella zoster virus and, [378–379](#)

Karyotype, [180](#)

Kasabach-Merritt syndrome, [253](#), [580](#)

Kasai procedure, [494](#)

Katayama fever, [452](#)

Kawasaki disease (KD), [347–349](#), [735](#)

clinical manifestations of, [347–348](#)

- in acute phase, [347](#), [348f](#)
- in convalescent phase, [347–348](#)
- incomplete (atypical), [348](#)
- in subacute phase, [347](#)

- complications of, [348](#), [349t](#)
- differential diagnosis of, [344t](#), [348](#), [348t–349t](#)
- epidemiology of, [347](#)
- etiology of, [347](#)
- laboratory and imaging studies for, [348](#)
- prognosis for, [349](#)
- Stevens-Johnson syndrome vs., [735](#)
- treatment of, [348](#)

Kehr sign, [156](#)

Keratitis, [202–203](#), [430](#), [433t](#)

Keratoconjunctivitis, epidemic, [430](#)

Keratolytic agents, for acne, [723](#)

Keratosis pilaris, [312](#)

- in atopic dermatitis, [326](#)

Kerion, [381t](#)

Kerley B lines, in pulmonary edema, [524](#)

Kernicterus, [251](#)

Ketamine, for sedation, [166t](#)

Ketoacidosis, diabetic, [641–645](#)

Ketoaciduria, branched chain, [203](#)

Ketogenesis

- fatty acid oxidation disorders of, [649–650](#)

- in insulin-dependent diabetes mellitus, [640–641](#)

Ketone bodies

- in diabetic ketoacidosis, [641](#)

- formation of, [207f](#)

Ketosis

due to defects in propionate pathway, [205](#)

due to inborn errors of metabolism, [195](#)

Ketotic hypoglycemia, due to inborn errors of metabolism, [195](#)

Kidney disease(s)

chronic, [626–627](#)

complications and treatments of, [627t](#)

etiology and epidemiology of, [626](#)

prognosis for, [627](#)

treatment of, [627](#)

polycystic, [629–630](#)

autosomal dominant, [630](#)

autosomal recessive, [630](#)

Kindergarten readiness, [15](#)

Kingella kingae, osteomyelitis from, [425](#)

Kissing kneecaps, [748](#)

Klinefelter syndrome (KS), [181](#), [659](#), [673](#)

gynecomastia and, [663](#)

Klippel-Trénaunay-Weber syndrome, port-wine stain in, [733](#)

Klisic test, [745](#)

Klumpke paralysis, [233](#)

Knee(s), [751–752](#)

discoid lateral meniscus, [751](#)

effusion or swelling, [751](#)

extensor mechanism of, [751](#), [751f](#)

knock-, [749](#), [749f](#)

Osgood-Schlatter disease of, [752](#)

osteochondritis dissecans of, [752](#)

patellofemoral disorders of, [752](#)

popliteal cyst of, [751](#)

Knee pain, idiopathic anterior, [752](#)

Kneecaps, kissing, [748](#)

Knock-knee deformities, [749](#), [749f](#)

Knowledge of limits, [4](#)
Kohler disease, [755](#)
Koplik spots, [373–374](#)
Kostmann syndrome, neutropenia in, [301](#)
Krabbe disease, [210t–212t](#), [712](#)
KS, [Klinefelter syndrome](#)
Kugelberg-Welander syndrome, [694](#)
Kussmaul respirations, [509t](#)
 in diabetic ketoacidosis, [641](#)
Kwashiorkor, [110–111](#)
Kyphosis, [760](#)
 classification of, [756t](#)
 congenital, [760](#)
 postural roundback, [760](#)
 Scheuermann, [760](#), [760f](#)

L

L/S (lecithin to sphingomyelin) ratio, [248](#)
La belle indifference, [59](#)
La Crosse encephalitis, [389](#)
Laboratory studies, for obesity, [107](#)
Labyrinthitis
 acute, ataxia due to, [702](#)
 vomiting due to, [473t](#)
Lactate, metabolism of, [214f](#)
Lactic acidosis, [140](#)
 due to mitochondrial disorders, [214](#)
Lactose intolerance, abdominal pain due to, [470t](#)

Lactulose, for functional constipation, [52t](#)

Lacy, reticulated rash, in erythema infectiosum, [377](#)

LAD-I (leukocyte adhesion deficiency type I), [302–303](#)

LAD-II (leukocyte adhesion deficiency type II), [303](#)

Ladd bands, in midgut malrotation, [487–488](#), [487f](#)

Lamina papyracea, [395](#)

Lamp-2 deficiency, [210t–212t](#)

Landau-Kleffner syndrome, [690](#)

Landau posture, [698](#)

Langerhans cell histiocytosis, [326](#), [729](#)

Language development, milestones of, [17t](#)

Language function, assessment of, [682](#)

Lanugo, [228f](#)

Lap and shoulder seat belts, [22](#)

Large for gestational age, [228](#)

Laron dwarfism, [651](#)

Laron syndrome, [655](#)

Laryngeal cysts, [519](#)

Laryngeal hemangioma, upper airway obstruction due to, [519](#)

Laryngeal mask airway (LMA), [513](#)

Laryngeal webs, [519](#)

Laryngomalacia, [518](#)

- clinical manifestations of, [518](#)
- diagnostic studies for, [518](#)
- etiology of, [517t](#), [518](#)
- treatment of, [518](#)

Laryngotracheobronchitis, [398–400](#)

- clinical manifestations of, [399](#)

- complications and prognosis of, [400](#)
- differential diagnosis of, [399](#)
- etiology and epidemiology of, [398–399](#)
- laboratory and imaging studies for, [399](#), [399f](#)
- spasmodic, [399](#)
- treatment of, [399–400](#)
- upper airway obstruction due to, [517t](#), [518](#)

Lateral meniscus, discoid, [751](#)

Laurence-Moon-Bardet-Biedl syndrome, [653](#)

LBW (low birth weight) infants, [218–219](#)

LCHAD (long-chain hydroxyacyl-CoA dehydrogenase) deficiency, [207](#), [207f](#)

- neonatal screening for, [198t](#)

Lead, maternal ingestion of, [238t](#)

Lead poisoning, in hypochromic, microcytic anemia, [571](#), [591](#)

Lecithin to sphingomyelin (L/S) ratio, [248](#)

Lectin pathway, of complement activation, [304–305](#), [305f](#)

Leflunomide, for juvenile idiopathic arthritis, [352](#)

Left-shift, in infectious diseases, [362](#)

Left-to-right shunts, [545](#)

Left ventricular diastolic volume, in heart failure, [554t](#)

Left ventricular hypertrophy

- due to aortic stenosis, [548](#)

- due to tricuspid atresia, [551](#)

Left ventricular outflow tract (LVOT) obstruction, syncope due to, [541t](#)

Leg discomfort, in coarctation of aorta, [548](#)

Leg-length discrepancy (LLD), [750–751](#)

- common causes of, [751t](#)

- measuring, [750](#)

- treatment of, [751](#)

Leg ulceration, in sickle cell disease, [577t](#)

Legal blindness, [33](#)

Legal issues, [5](#), [9](#)

Legg-Calvé-Perthes disease (LCPD), [746–747](#)

clinical manifestations of, [747](#)

etiology and epidemiology of, [746–747](#)

radiological evaluation for, [747](#)

treatment and prognosis for, [747](#)

Legionella pneumophila, [405](#)

Legionnaires disease, [405](#)

Leigh disease, [213–214](#)

Leishmania, [439t–442t](#)

Leishmania donovani complex, [439t–442t](#)

Leishmaniasis, [439t–442t](#)

visceral, [439t–442t](#)

Lemierre syndrome, [393](#)

Length, growth chart of, [12f](#)

Lennox-Gastaut syndrome, [690](#)

Leptin receptor gene deficiency, obesity in, [106t](#)

Leptomeningeal cyst, [710](#)

Leptospira spp., [439t–442t](#)

Leptospirosis, [439t–442t](#)

Lethargy, [703](#)

due to intussusception, [492](#)

Leucine, metabolism of, [203f](#)

Leukemia, [180](#), [603–605](#), [614](#)

acute lymphoid/lymphoblastic, [Acute lymphoid/lymphoblastic leukemia](#)

acute myeloid, [Acute myeloid leukemia](#)

chronic myeloid, [603](#)

- clinical manifestations of, [603](#)
- complications of, [604](#)
- differential diagnosis of, [344t](#), [604](#)
- epidemiology of, [603](#)
- etiology of, [603](#)
- laboratory and imaging studies for, [603–604](#)
- prognosis for, [604–605](#), [605t](#)
- treatment of, [604](#)

Leukocyte adhesion deficiency, [301t](#)

- type I (LAD-I), [302–303](#)

- type II (LAD-II), [303](#)

Leukocyte esterase, in urine, [619–620](#)

Leukocytes, values of, [565t](#)

Leukocytosis, [362](#)

Leukodystrophy

- adreno-, genetic basis for, [174t](#)

- metachromatic, [210t–212t](#)

Leukokoria, in newborn, [230](#)

Leukomalacia, periventricular, in newborn, [257](#)

Leukorrhea, physiological, vs. sexually transmitted infections, [422t](#)

Leukotriene modifiers, for asthma, [315](#)

Levalbuterol, for, for asthma, [315–316](#)

Levocetirizine, for allergic rhinitis, [325](#)

Lichenification, [722t](#)

Liddle syndrome, [136](#)

Lidocaine, for cardiopulmonary resuscitation, [148t](#)

Lifestyle modifications, for migraines, [687](#)

Ligament of Treitz, in midgut malrotation, [487–488](#)

Limb-girdle muscular dystrophy, [697](#)

Limb weakness

distal, [694t](#)

ophthalmoplegia and, [694t](#)

Limit-setting subtype, behavioral insomnia of childhood, [55](#)

Limits, knowledge of, [4](#)

Limping child, [740](#), [741t](#)

Lipase, fibrosing colonopathy due to, [529](#)

Lipid emulsion, in parenteral nutrition, [131](#)

Lipidoses, [210t–212t](#)

Lipoma, sacral, constipation due to, [476t](#)

Lisch nodules, [714](#)

Lissencephaly, [717](#)

Listeria monocytogenes, [439t–442t](#)

Listeriosis, [439t–442t](#)

Lithium

for bipolar disorders, [68](#)

as teratogens, [237t](#)

Little Leaguer's elbow, [764](#)

Little Leaguer's shoulder, [763](#)

Liver disease, [494–501](#)

cholestasis as, [494](#), [497t](#), [498f](#)

chronic, [497–498](#)

clinical manifestations of, [497–498](#)

etiology and epidemiology of, [497](#)

laboratory and imaging studies for, [498](#), [500t](#)

treatment of, [498](#), [501t](#)

fulminant liver failure as, [494–497](#), [499t–500t](#)

Liver failure

fulminant, [494–497](#)

clinical manifestations of, [497](#)

etiology and epidemiology of, [494](#), [499t](#)

laboratory and imaging studies for, [497](#)

treatment of, [497](#), [500t](#)

in galactosemia, [201](#)

Liver function tests

for chronic liver disease, [500t](#)

for gastrointestinal symptoms, [467](#)

Liver phosphorylase deficiency, [200t](#)

LLD, [Leg-length discrepancy](#)

Lobar pneumonia, [402–403](#)

Local anesthetics, [166](#)

Lomustine, for cancer, [601t–602t](#)

Long-chain hydroxyl-CoA dehydrogenase (LCHAD) deficiency, [207](#), [207f](#)

neonatal screening for, [198t](#)

Long-term penicillin prophylaxis, for rheumatic fever, [556](#)

Loop of Henle, [617](#), [619f](#)

Loratadine, for allergic rhinitis, [325](#)

Lorazepam

for sedation, [166t](#)

for status epilepticus, [691](#), [691t](#)

Loss-of-function mutation, [176](#)

Louse-borne infections, [737](#)

Louse-borne relapsing fever, [737](#)

Low birth weight (LBW) infants, [218–219](#)

Lower airway disease, [519–526](#)

acute respiratory distress syndrome, [524](#)

asthma as, [Asthma](#)

bronchiolitis as, [Bronchiolitis](#)

bronchopulmonary dysplasia as, [522](#)

clinical manifestations of, [520](#)

congenital lung anomalies, [522](#)

- cor pulmonale as, [524–525](#)
- diagnostic studies for, [520](#)
- differential diagnosis of, [520–526](#)
- etiology of, [519–520](#), [520t](#)
- due to extrinsic tracheal compression, [521](#), [521f](#)
- due to foreign body aspiration, [521–522](#)
- pneumonia as, [Pneumonia](#)
- primary ciliary dyskinesia as, [523](#)
- pulmonary arterial hypertension as, [524–525](#)
- pulmonary edema as, [523–524](#)
- pulmonary embolism as, [526](#)
- pulmonary hemorrhage as, [525–526](#), [525t](#)
- tracheoesophageal fistula as, [Tracheoesophageal fistula](#)
- tracheomalacia as, [520–521](#)

Lower extremity, [748–752](#)

- angular variations in, [749–750](#)
 - genu valgum as, [749f](#), [750](#)
 - genu varum as, [749f](#), [750](#)
 - tibia vara (Blount disease) as, [750](#)
- leg-length discrepancy in, [750–751](#), [751t](#)
- torsional variations in, [748–749](#)
 - common causes of, [748t](#)
 - due to external tibial torsion, [749](#)
 - in-toeing as, [748–749](#)
 - common causes of, [748t](#)
 - due to femoral anteversion, [748](#)
 - due to internal tibial torsion, [748–749](#), [749f](#)
 - treatment of, [749](#)
 - out-toeing as, [749](#)
 - common causes of, [748t](#)
 - due to external tibial torsion, [749](#)

Lower motor neuron disease, [694–698](#), [694t](#)

- of anterior horn cells, [693t](#), [694](#)
- Duchenne muscular dystrophy as, [696–697](#)
- infant botulism as, [696](#)
- laboratory and diagnostic studies for, [698](#)
- malignant hyperthermia with, [698](#)
- muscle diseases as, [697–698](#), [Muscular disease\(s\)](#)
- myasthenia gravis as, [696](#)

- myotonic dystrophy as, [697](#)
- peripheral neuropathy as, [695–696](#)
- spinal muscular atrophy as, [694–695](#)
- topography of, [694t](#)
- upper motor neuron lesions and, [693t](#)

Lower motor neurons, [692–693](#)

Lower motor unit, [693](#)

Lower respiratory tract infection, [402–403](#)

LP, [Lumbar puncture](#)

LSD (lysergic acid diethylamide), acute effects of, [284t–285t](#)

Lubricant, for functional constipation, [52t](#)

Ludwig angina, [393](#)

Lumbar puncture (LP)

- for increased intracranial pressure, [708](#)
- for infectious diseases, [362](#)
- for leukemia, [603–604](#)
- traumatic, [684–685](#)

Lumbosacral hemangioma, [732–733](#)

Lumbosacral spine, hair tufts over, [228](#)

Lung(s)

- anatomy of, [507](#)
- of newborn, [230](#)
- physiology, [507–509](#)
 - defense mechanisms in, [508–509](#)
 - pulmonary mechanics in, [507–508](#), [508f](#)
 - respiratory gas exchange in, [508](#), [508t](#)
- unilateral hyperlucent, [407](#)

Lung abscess, [405–407](#)

Lung biopsy, [512](#)

Lung capacities, [508f](#)

Lung compliance, [508](#)

Lung defense mechanisms, [508–509](#)

Lung development, [241](#)

Lung disease

chronic, [244–245](#)

restrictive, [508](#)

Lung volumes, [508f](#)

Lupus, discoid, [353](#)

Lupus nephritis, [355](#)

Luteinizing hormone, in puberty, [656](#)

LVOT (left ventricular outflow tract) obstruction, syncope due to, [541t](#)

Lyme disease, [429](#), [439t–442t](#), [443–444](#)

clinical manifestations of, [443](#), [443f](#)

complications and prognosis, [444](#)

differential diagnosis of, [344t](#), [444](#)

early disseminated, [443](#)

epidemiology of, [443](#), [443f](#)

etiology of, [443](#)

laboratory and imaging studies for, [443–444](#)

late, [443](#)

prevention of, [444](#)

synovial fluid findings in, [429t](#)

treatment of, [444](#)

Lymphadenitis, [383](#)

cervical

etiology of, [383](#)

suppurative, [384](#)

Lymphadenopathy, [383–386](#)

clinical manifestations of, [383–384](#)

complications and prognosis for, [385–386](#)

differential diagnosis for, [385](#)

epidemiology of, [383](#)

etiology of, [383](#)

- generalized, [383](#), [383t](#)

laboratory and imaging studies for, [447–449](#)

prevention of, [449](#)

treatment of, [449](#)

Male sex determination, [672f](#)

Malformations, [169](#), [183–184](#)

association in, [184](#)

congenital, [169](#)

defined, [183–184](#), [739t](#)

- diagnosis of, [186](#)
- due to disruptions of development, [184](#)
- due to extrinsic factors, [184](#)
- history for
 - family, [184](#)
 - pregnancy, [184](#)
- due to inborn errors of metabolism, [195–196](#)
- due to intrinsic factors, [184](#)
- laboratory evaluation of, [186](#)
- life-threatening, [232–233](#)
- mechanisms of, [739t](#)
- minor, [184](#)
- multiple, [184](#)
- physical examination of, [184–186](#)
 - craniofacial, [185](#)
 - of extremities, [185](#)
 - of genitalia, [185–186](#)
 - growth in, [184–185](#)
 - of neck, [185](#)
 - of trunk, [185](#)
- sequence of, [184](#)

Malignancies, fever due to, [371](#)

Malignant germ cell tumors, risk factors for, [597t](#)

Malignant hypertension, in thrombotic microangiopathy, [580](#)

malignant hyperthermia, [698](#)

Malignant melanoma, [732](#)

- giant congenital nevi and, [732](#)

Malignant melanoma, maternal, [236t](#)

Malingering, in somatic symptom and related disorders (SSRDs), [61](#)

Mallory-Weiss syndrome, gastrointestinal bleeding due to, [477t](#)

Malnutrition

- definitions of, [110t](#)

- in failure to thrive, [78t](#), [109](#), [Failure to thrive](#)

- kwashiorkor as, [110–111](#)

marasmus as, [110](#)

maternal, effect on infants, [1](#)

Malnutrition-infection cycle, [79](#)

Maltreatment, [2](#)

Mandibular region, dysmorphology of, [185](#)

α -Mannosidase deficiency, [210t–212t](#)

Mannosyl phosphotransferase deficiency, [210t–212t](#)

Mantoux test, [454](#)

Maple syrup urine disease (MSUD), [203–204](#)

clinical manifestations of, [203](#)

definitive diagnosis of, [204](#)

laboratory manifestations of, [204](#)

neonatal screening for, [198t](#)

Marasmus, [110](#)

Marcus Gunn pupil, [683](#)

Marfan syndrome (MS), [171](#)

diagnostic criteria for, [171](#)

genetic basis for, [170t](#)

hypermobility in, [357](#)

hypotonia in, [699](#)

Marijuana, acute effects of, [284t–285t](#)

Markers, for cancer, [599t](#)

Maroteaux-Lamy syndrome, [210t–212t](#)

Marrow failure, in macrocytic anemia, [574](#)

Masculinization, in male, [673t](#)

Mass lesions, [706–707](#)

upper airway obstruction due to, [519](#)

Mastocytoma, [730t](#)

Mastoiditis, acute, otitis media and, [397](#)

Maternal assessment, [217–218](#)

Maternal blood, ingested, gastrointestinal bleeding due to, [477t](#)

Maternal deprivation, growth failure due to, [653](#)

Maternal disease, affecting newborn, [235–237](#), [236t](#)

antiphospholipid syndrome as, [235](#)

diabetes mellitus as, [236t–237t](#), [237](#)

hyperthyroidism as, [236](#), [236t](#)

idiopathic thrombocytopenia as, [235–236](#), [236t](#)

other, [237](#)

systemic lupus erythematosus as, [236](#), [236t](#)

teratogens, [176](#)

Maternal history, in cardiovascular system assessment, [535](#)

Maternal hyperphenylalaninemia, [202](#)

Maternal infections, as teratogens, [176](#)

Maternal medications

small for gestational age due to, [239t](#)

that may adversely affect newborn, [238t](#)

Mature minors, [5](#)

Maturity

fetal, [219](#)

pulmonary, [219–220](#)

of newborn

neurological criteria in, [227–228](#)

physical criteria for, [227–228](#)

Maturity-onset diabetes of youth, [646](#)

MCAD (medium-chain acyl-CoA dehydrogenase) deficiency, [207–208](#)

McArdle disease, [200t](#)

McCune-Albright syndrome, [660](#)

MCD (multicystic renal dysplasia), [629](#)

MDI (metered dose inhaler), [512](#)

Mean mid-expiratory flow rate (FEF_{25-75%}), [511](#)

Measles, mumps, and rubella (MMR) vaccine, [363–364](#), [364f–365f](#), [375](#)

Measles (rubeola), [373–375](#)

black, [373–374](#)

clinical manifestations of, [373–374](#)

complications and prognosis of, [375](#)

differential diagnosis of, [374](#)

epidemiology of, [373](#)

etiology of, [373](#)

laboratory and imaging studies in, [374](#)

modified, [374](#)

mumps, and rubella (MMR) vaccine, [363–364](#), [364f–365f](#), [375](#)

prevention of, [375](#)

treatment of, [374–375](#)

Mechanical counterpulsation, for heart failure, [555t](#)

Mechanical ventilation, [513](#)

for bronchopulmonary dysplasia, [245](#)

pulmonary air leaks due to, [244](#)

for respiratory failure, [150](#)

Meckel diverticulum, [490](#)

abdominal pain due to, [470t](#)

gastrointestinal bleeding due to, [477t](#)

Meconium aspiration pneumonia, [245](#)

Meconium aspiration syndrome, [245–246](#)

Meconium ileus

in cystic fibrosis, [527](#), [529](#)

intestinal atresia in, [488](#)

Meconium-stained amniotic fluid, [226](#)

Mediastinal deviation, [510t](#)

Mediastinal lymphadenopathy, [605](#)

Medical conditions

psychological factors in, [59–60](#), [60t](#)

psychotic disorder due to, [72](#)

Medical decision making, [4](#)

Medical devices, infections associated with, [437–439](#)

Medical history, in genetic assessment, [178](#)

Medications, [Drug\(s\)](#)

Mediterranean spotted fever, [439t–442t](#)

Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency, [207–208](#)

neonatal screening for, [198t](#)

Mefloquine, for malaria, [449](#)

Megacolon, toxic, [490](#)

Megakaryocytes, [566](#)

Megakaryocytic cells, in hematopoiesis, [563](#)

Melanocortin 4 receptor gene mutation, obesity in, [106t](#)

Melanocytic nevi, [730t](#)

acquired, [732](#)

congenital, [228–229](#), [731–732](#), [731f](#)

differential diagnosis of, [730t](#)

giant, [730t](#), [732](#)

hairy, [731–732](#), [731f](#)

Melanoma, malignant, [732](#)

giant congenital nevi and, [732](#)

maternal, [236t](#)

Melanosis

dermal, [730](#), [730t](#), [731f](#)

pustular, [228–229](#)

MELAS (mitochondrial encephalomyopathy with lactic acidosis and strokelike episodes), [175](#)

Melia, [183t](#)

Membrane attack complex (MAC), [304–305](#), [305f](#)

Membrane disorders, in hemolytic anemia, [578–579](#), [592](#)

clinical manifestations of, [579](#)

etiology of, [578–579](#)

laboratory diagnosis of, [579](#)

treatment of, [579](#)

Membrane rupture

premature, [218](#)

prolonged, [218](#)

Membranoproliferative glomerulonephritis (MPGN), [620](#)

type II, [306](#)

- chloride responsive, [141](#)
- clinical manifestations of, [141](#)
- diagnosis of, [141](#)
- etiology of, [141](#)
- hypokalemic, in pyloric stenosis, [485](#)
- treatment of, [141–142](#)

Metabolic compensation, appropriate, [139](#)

Metabolic disorder(s), [191–215](#)

- assessment of, [191–199](#), [192f](#)
- clinical presentation of, [191–196](#)
 - congenital malformations or dysmorphic features in, [195–196](#)
 - energy deficiency in, [193](#)
 - hyperammonemia
 - etiology of, [195t](#)
 - in later infancy and childhood, [192](#), [194f](#)
 - moderate neonatal, [192](#)
 - severe neonatal, [192](#)
 - ketosis and ketotic hypoglycemia in, [193–195](#)
 - metabolic acidosis in, [192](#), [196t](#)
 - specific organ, [192–193](#), [195t](#)
 - toxic, [191–192](#)
- genetic aspects of, [196–197](#)
 - identification of molecular pathology as, [197](#)
 - mechanisms of inheritance as, [196–197](#)
- neonatal screening for, [Neonatal screening, for inborn errors of metabolism](#)
- overview of treatment for, [199](#)
- storage as, [196](#)
- vomiting due to, [473t](#)

Metabolic syndrome, [646](#)

Metabolic testing, for chronic liver disease, [500t](#)

Metachromatic leukodystrophy, [210t–212t](#), [712](#)

Metagonimiasis, [451t](#)

Metagonimus yokogawai, [451t](#)

Metaphase analysis, in genetic assessment, [179](#)

Metaphysis, [740f](#)

Metatarsal, head of the second, idiopathic avascular necrosis of, [755](#)

Metatarsus adductus, [754](#), [754f](#)

Metatarsus varus, [754](#)

Metered dose inhaler (MDI), [512](#)

Methadone, as analgesia, [166t](#)

Methanol ingestion, metabolic acidosis due to, [140](#)

Methicillin-resistant *Staphylococcus aureus*, pneumonia from, [407t](#)

Methicillin-susceptible *Staphylococcus aureus*, pneumonia from, [407t](#)

Methimazole, maternal use of, [238t](#)

Methionine, metabolism of, [203f](#)

Methotrexate

- for cancer, [601t–602t](#)
- for juvenile dermatomyositis, [356](#)
- for juvenile idiopathic arthritis, [352](#)

Methyl mercury, as teratogen, [237t](#)

Methylene blue, for nitrite poisoning, [164t–165t](#)

Methylmalonic acidemia, [205](#)

- clinical manifestations of, [205](#)
- neonatal screening for, [198t](#)
- treatment of, [205](#)

Methylprednisolone, for systemic lupus erythematosus, [355](#)

Methylxanthines, for apnea of prematurity, [246](#)

Metoclopramide, for gastroesophageal reflux, [481t](#)

Metorchiasis, [451t](#)

Metorchis conjunctus, [451t](#)

Metronidazole, for trichomoniasis, [424](#)

MHC (major histocompatibility complex) compatibility, in hematopoietic stem cell transplantation, [307](#)

Micaceous scale, in psoriasis, [729–730](#)

Microangiopathy, thrombotic, [580](#), [585–586](#)

Microarray comparative genomic hybridization, [186](#)

Microcephaly, [681](#), [717](#), [718t](#)

Microcomedo, [723](#)

Microcytic anemia, hypochromic, [566](#), [567f](#), [568–574](#)

 due to iron deficiency, [568–571](#)

 clinical manifestations of, [570](#)

 epidemiology of, [570](#), [570t](#)

 etiology of, [570](#)

 prevention of, [571](#)

 treatment of, [571](#), [571t](#)

 due to lead poisoning, [571](#)

 thalassemia minor as, [571](#)

 etiology and epidemiology of, [571](#), [572f](#), [572t](#)

 laboratory testing for, [571](#)

 treatment of, [571](#)

Microhemagglutination assay-*T. pallidum* (MHA-TP), [424](#)

Micronutrient deficiencies, [112–121](#), [113t](#)

 of fat-soluble vitamins, [114t](#), [117–119](#)

 malnutrition with, [112](#)

 of minerals, [119–121](#), [119t](#)

 of water-soluble vitamins, [112–117](#), [114t](#)

Micronutrients, [112](#)

Microphallus, [673](#)

Microscopic analysis, [619–620](#)

Microsporidia, diarrhea from, [410t](#)

Micturition syncope, [541t](#)

Mid-diastolic murmur, due to ventricular septal defect, [545](#)

Midazolam

for sedation, [166t](#)

for status epilepticus, [691](#), [691t](#)

Middle ear effusion, persistent, otitis media and, [397](#)

Midface, dysmorphology of, [185](#)

Midgut malrotation, [487–488](#)

clinical manifestations of, [488](#)

etiology and epidemiology of, [487–488](#), [487f](#)

laboratory and imaging studies for, [488](#)

treatment of, [488](#)

with volvulus, [487–488](#), [488f](#)

vomiting due to, [473t](#)

Midparental height determination, growth chart and, [13](#)

Migraine, [685–687](#)

clinical manifestations of, [686](#), [686f](#), [686t](#)

confusional, [706](#)

diagnostic studies for, [686–687](#)

etiology and epidemiology of, [685–686](#)

treatment of, [687](#)

vomiting due to, [473t](#)

Mild to moderate visual impairment, [34](#)

Milia, [228–229](#), [721t](#), [722f](#)

Miliaria, [228–229](#)

crystallina, vesiculobullous eruptions due to, [734t](#)

Miliary tuberculosis, [453](#)

Military deployment, [3](#)

Milk intake

adequacy of, [99–100](#)

for toddlers and older children, [103](#)

Milk intolerance, vomiting due to, [473t](#)

Milk of molasses, for functional constipation, [51t](#)

Miller Fisher variant, of Guillain-Barré syndrome, [695](#)

Milrinone

for heart failure, [555t](#)

for shock, [153t](#)

Mineral, in parenteral nutrition, [131](#)

Mineral bone disorder, chronic kidney disease, [626–627](#)

Mineral deficiencies, [119–121](#), [119t](#)

Mineral endocrinology, [669–670](#), [680](#)

Mineral oil, for functional constipation, [51t–52t](#)

Minimal change nephrotic syndrome, [620](#)

Minor determinant, in skin testing for penicillin allergy, [339](#)

Minors

emancipated, [5](#)

mature, [5](#)

Minute dog tapeworm, [452](#)

Minute ventilation, [513](#)

MIP-1 α , functions of, [290t](#)

MiraLAX (polyethylene glycol powder), for functional constipation, [52t](#)

Misoprostol, as teratogen, [237t](#)

Missense mutation, [169](#)

Mitochondrial disorders, [213–214](#), [713](#)

genetics of, [214](#)

inborn errors of metabolism due to, [196t](#)

MELAS as, [175](#)

signs and symptoms of, [213–214](#)

treatment of, [214](#)

Mitochondrial DNA (mtDNA), [175](#)

Mitochondrial encephalomyopathy with lactic acidosis and strokelike episodes (MELAS), [175](#)

Mitochondrial function, biochemical abnormalities in, [214](#)

Mitochondrial genome, [213f](#)

Mitochondrial inheritance, [175](#)

- heteroplasmy in, [175](#)
- MELAS as, [175](#)

Mitochondrion(ia), function of, [214](#)

Mixed malformation, differential diagnosis of, [730t](#)

Mixed marasmus-kwashiorkor, [111](#)

Mixed venous oxygen saturation, in shock, [152–153](#)

ML (mucopolidosis[es]), [210t–212t](#)

Mobitz type I heart block, [544t](#)

Mobitz type II heart block, [544t](#)

Möbius syndrome, in newborn, [233](#)

Modified Checklist for Autism in Toddlers-Revised (M-CHAT-R), [17–18](#)

Mold, asthma and, [315t](#)

Molecular tests, [362](#)

Molluscum contagiosum, [383](#)

Mometasone DPI, for asthma, [319f](#)

Mongolian spots, [228](#), [730](#), [730t](#), [731f](#)

Monkeypox, [439t–442t](#)

Monoclonal antibodies, for cancer, [601t–602t](#)

Monocytes, values of, [565t](#)

Monosomy(ies), [181–182](#)

- Turner syndrome as, [181–182](#)

Montelukast, for asthma, [315](#)

Morbidity, changing, [3](#)

Morbilliform rash, in juvenile idiopathic arthritis, [351](#)

Moro reflex, [14](#), [233](#), [682t](#)

Morphine

as analgesia, [166t](#)

maternal use of, [238t](#)

Mortality, infant, [2](#)

Mosaicism, [180](#)

Motion sickness, vomiting due to, [473t](#)

Motor examination, [682](#), [684](#)

of bulk, [684](#)

of coordination, [684](#)

of gait, [684](#)

in neonate, [682](#)

of reflexes, [684](#)

of strength, [684](#)

of tone, [684](#)

Motor intervention, for child with special needs, [32](#)

Motor sensory neuropathy, hereditary, [695](#)

Motor vehicle accidents, [2](#)

Motor vehicle crashes, [22](#)

Mouth, [Oral cavity](#)

anemia and, [569t](#)

bottle, [479](#)

of newborn, [230](#)

Mouth sores, in systemic lupus erythematosus, [353](#)

Movement disorders, [702–703](#)

causes of, [702t](#)

MPS (mucopolysaccharidoses), [210t–212t](#)

MRI, [Magnetic resonance imaging](#)

MS, [Marfan syndrome](#)

MSUD, [Maple syrup urine disease](#)

mtDNA (mitochondrial DNA), [175](#)

MTTL1 gene, in MELAS, [175](#)

Muckle-Wells syndrome, [331](#)

Mucopolidosis(es) (ML), [210t–212t](#)

Mucopolysaccharidoses (MPS), [210t–212t](#), [713](#)

Mucopurulent cervicitis, [420t](#)

Multicystic renal dysplasia (MCD), [629](#)

Multifactorial disorders

- hypertrophic pyloric stenosis due to, [174–175](#)
- neural tube defects due to, [175](#)

Multiple acyl-CoA dehydrogenase deficiency, [208](#)

Multiple gestation, [217](#)

Multiple hereditary exostoses, [765t–766t](#)

Multiple malformation syndrome, [184](#)

Multiple organ dysfunction, in respiratory failure, [150](#)

Multiple sulfatase deficiency, [210t–212t](#)

Multisystem disease, constipation due to, [476t](#)

Munchausen syndrome, [649](#)

- fever due to, [371](#)

Munchausen syndrome by proxy, fever due to, [371](#)

Murine typhus-like illness, [439t–442t](#)

Murmurs, [Heart murmurs](#)

Muscle bulk, in motor examination, [684](#)

Muscle fasciculations, [684–685](#)

- in spinal muscular atrophy, [694](#)

Muscle fibrillations, [685](#)

Muscle phosphofructokinase deficiency, [200t](#)

Muscle phosphorylase deficiency, [200t](#)

Muscle tone

in motor examination, [684](#)

in neonate, [682](#)

Muscular disease(s)

congenital myopathies as, [697–698](#)

Duchenne muscular dystrophy as, [696–697](#)

Emery-Dreifuss muscular dystrophy as, [697](#)

facioscapulohumeral dystrophy as, [697](#)

limb-girdle muscular dystrophy as, [697](#)

metabolic myopathies as, [698](#)

myotonic dystrophy as, [697](#)

Muscular dystrophy, 693t

- Becker, 696
- congenital, 697
- constipation due to, 476t
- Duchenne, 696–697
 - clinical manifestations of, 696–697
 - etiology of, 696
 - laboratory and diagnostic studies of, 697
 - treatment of, 697
- facioscapulohumeral, 697
- limb-girdle, 697
- myotonic, 697

Muscular septum, 545

Musculoskeletal pain syndromes, 356–358

- benign hypermobility as, 357, 357f, 357t
- defined, 343
- growing pain as, 356–357
- juvenile idiopathic arthritis vs., 352t
- myofascial pain syndrome and fibromyalgia as, 358

Mutation, 169

- frameshift, 169
- hot spot, 171

Myofascial pain syndrome, [358](#)

Myonecrosis, [380](#)

Myopathies

congenital, [697–698](#)

endocrine, [698](#)

metabolic, [698](#)

mitochondrial, [698](#)

Myositis, in rheumatic diseases, [343](#)

Myotonia, [697](#)

Myotonic dystrophy, [697](#)

clinical manifestations of, [697](#)

etiology and epidemiology of, [697](#)

genetic basis for, [170t](#)

maternal, [236t](#)

N

N-acetylcysteine, for acetaminophen poisoning, [164t–165t](#)

N-acetylgalactosamine-4-sulfatase deficiency, [210t–212t](#)

Nail, hypoplastic, [183t](#)

Nail-fold capillaries, dilated, in juvenile dermatomyositis, [355–356](#)

Naloxone

in newborn resuscitation, [227](#)

for opiate poisoning, [164t–165t](#)

Naltrexone, for autism spectrum disorder (ASD), [71](#)

Nanophyiasis, [451t](#)

Nanophyetus salmincola, [451t](#)

Naphthalene, maternal use of, [238t](#)

Narcotics

constipation due to, [476t](#)

maternal use of, [238t](#)

toxicity, [162t](#)

Nasal alae, [183t](#)

Nasal cannula, [512](#)

Nasal flaring, [509–510](#)

Nasal influenza vaccine, [363–364](#)

Nasal polyposis, in cystic fibrosis, [527](#)

Nasal polyps, [324](#)

Nasal smear, for upper respiratory tract infection, [391](#)

Nasal sores, in systemic lupus erythematosus, [353](#)

Nasal turbinates, [507](#)

Nasolabial fold, [183t](#)

Nasopharyngoscopy, [511](#)

National Childhood Vaccine Injury Act, [366](#)

National Practitioner Data Bank, [3–4](#)

National Vaccine Injury Compensation Program, [366](#)

NBS (New Ballard Score), [229f](#)

NCL (neuronal ceroid lipofuscinosis), [210t–212t](#)

NCVs (nerve conduction velocities), [685](#)

Nebulizer, [512](#)

Necator americanus, [450](#), [450t](#)

Neck

- congenital malformations of, [185](#)
- of newborn, [230](#)

Necrotic eschar, infections with fever and, [373t–374t](#)

Necrotizing enterocolitis (NEC), [254–255](#)

- gastrointestinal bleeding due to, [477t](#)

Necrotizing fasciitis, [380](#)

Needle biopsy, [512](#)

Negative-pressure ventilation, for tuberculosis, [457](#)

Negative reinforcement, [16](#)

Neglect, [80](#)

Neisseria gonorrhoeae

- clinical features of infections caused by, [420t](#)
- congenital infection with, [260t](#), [263](#)
- conjunctivitis from, [430](#)
- disseminated gonococcal infections from, [421–422](#)
- pelvic inflammatory disease from, [420–421](#)

Neisseria meningitidis, prophylaxis for, [366](#)

Neisseria meningitidis vaccine, [363–364](#)

NEMO (nuclear factor κ B essential modulator), in hyper-IgM syndrome, [296](#)

Neoadjuvant chemotherapy, [601](#)

Neonatal alloimmune thrombocytopenic purpura (NATP), [584](#)

Neonatal conjunctivitis, [432t–433t](#)

Neonatal drug addiction and withdrawal, [235](#)

- from cocaine, [235](#)

- from opiates, [235](#)

Neonatal hepatitis, [494](#)

Neonatal hypotonia, [698–699](#)

Neonatal mortality, [218](#), [219t](#)

Neonatal physiology, transition from fetal to, [218](#), [221t](#)

Neonatal screening, for inborn errors of metabolism, [198t](#)

- subtypes of, [606t](#)
- treatment of, [606–607](#)

Non-nucleoside reverse transcriptase inhibitor (NNRTI), for HIV, [460](#)

Non-REM (NREM) sleep, [52](#)

Nonadherence, in tuberculosis, [456](#)

Nonalcoholic fatty liver disease, [501](#)

Nonallergic, noninfectious rhinitis, [324](#), [324t](#)

Nonallergic rhinitis with eosinophilia syndrome, [323](#), [324t](#)

Nonbullous impetigo, [379](#)

Noncompliance, in tuberculosis, [456](#)

Nongonococcal urethritis and cervicitis, [423](#)

Nonheme iron, [120](#)

Noninvasive ventilation, [150](#), [513](#)

Nonmaleficence, [4](#)

- in end-of-life decision making, [8](#)

Nonossifying fibroma, [765t–766t](#)

Nonsense mutation, [169](#)

Nonsteroidal antiinflammatory drugs (NSAIDs)

- as analgesia, [166t](#)
- gastrointestinal bleeding due to, [477t](#)
- for juvenile idiopathic arthritis, [352](#)

Nonstress test, of fetal well-being, [220](#)

Nonsyndromic craniosynostosis, genetic basis for, [170t](#)

Nontreponemal antibody tests, [424](#)

Nontuberculous mycobacteria, lymphadenitis and, [384](#)

Nonulcer dyspepsia, [485–486](#), [486t](#)

Norepinephrine, for shock, [153t](#)

Normal saline, for functional constipation, [51t](#)

Normal temper tantrums, [44t](#)

Normocytic anemia, [571–574](#), [591](#)

North American liver fluke, [451t](#)

Nose, [507](#)

- as filter, [508](#)
- foreign bodies in, [324](#)
- skier's, [324](#)

Nosocomial infections, [437](#)

NSAIDs, [Nonsteroidal antiinflammatory drugs](#)

NTDs, [Neural tube defects](#)

Nucleated red cells, values of, [565t](#)

Nucleic acid amplification test (NAAT), [412](#)

Nucleotide reverse transcriptase inhibitor (NRTI) , for HIV, [460](#)

Nucleotides, [169](#)

Nursemaid's elbow, [764](#), [764f](#)

Nutrition

of adolescent, [102–104](#)

and growth, [653](#)

of normal infant, [99–102](#)

breast-feeding in, [99–100](#), [100f](#)

complementary foods for, [101–102](#)

formula feeding in, [100–101](#)

parenteral, [Parenteral nutrition](#)

recommendations to, [103–104](#), [103t](#)

of toddlers and older children, [103](#)

for type 1 diabetes mellitus, [644](#)

Nutritional counseling, [23t–24t](#)

Nutritional evaluation, for chronic liver disease, [500t](#)

Nutritional management, for failure to thrive, [79](#)

Nutritional rehabilitation, [112](#)

Nutritional support, for burns, [159](#)

Nystagmus, [683](#)

O

Obesity, [2–3](#), [104–109](#)

assessment of, [107](#)

clinical manifestations of, [105–107](#), [106t](#)

complications of, [105t](#)

- definitions of, [104–105](#)
- epidemiology of, [105](#)
- prevention of, [107–109](#), [108t](#)
- treatment of, [109](#)

Obsessions, in OCD, [68](#)

Obsessive-compulsive disorder (OCD), [68–70](#), [69t](#)

Obstructive hydrocephalus, [707](#)

Obstructive sleep apnea (OSA), [54t–55t](#)

- pediatric sleep disorders and, [56](#)
- syndrome, [514–515](#), [514t](#)

Obstructive stenotic lesions, congenital heart disease due to, [545](#)

Obtunded patients, [703](#)

Occult blood, [568](#)

OCD (osteochondritis dissecans), [752](#)

Ocular examination, in neurology assessment, [681](#)

Ocular hypertelorism, [183t](#)

Ocular infections, [430–432](#)

- clinical manifestations of, [431](#)
- complications and prognosis of, [432](#)
- differential diagnosis of, [431–432](#)
- epidemiology of, [431](#)
- etiology of, [430](#)
- laboratory and imaging studies for, [431](#)
- prevention of, [432](#)
- treatment of, [432](#), [432t](#)

Ocular larva migrans, [450–451](#), [450t](#)

Oculocephalic vestibular reflexes, [683](#), [703–704](#)

Oculomotor nerve, assessment of, [683](#)

Oculovestibular response, [703–704](#)

OI (oxygenation index), for primary pulmonary hypertension of the newborn,

Oligodactyly, [185](#)

Oligohydramnios, [217–218](#)

Oligosaccharide chromatography, urine, [199t](#)

Oliguria, fluid therapy for, [127](#), [127t](#)

Omalizumab, for asthma, [315](#)

Omenn syndrome, [297–298](#), [297t](#)

Omphalitis, [231](#)

Omphalocele, [227t](#), [231](#), [489](#)

Oncological disorders, juvenile idiopathic arthritis vs., [352t](#)

Oncology assessment, [595–596](#), [596f](#), [613](#)

common manifestations in, [595](#), [598t](#)

differential diagnosis in, [596](#)

history in, [595](#), [597t](#)

initial diagnostic evaluation in, [596](#)

diagnostic imaging in, [596](#), [599t](#)

screening tests in, [596](#)

physical examination in, [595](#)

Oncospheres, in echinococcosis, [452](#)

Onychomycosis, [380](#), [381t](#)

Open adoptions, [89](#)

Ophthalmia neonatorum, [430](#)

treatment of, [432](#)

Ophthalmoplegia

and limb weakness, [694t](#)

progressive external, [213–214](#)

Opiate

acute effects of, [284t–285t](#)

neonatal addiction to and withdrawal from, [235](#)

use, during pregnancy, [90](#)

Opioids, as analgesia, [166t](#)

Opisthorchiasis, [451t](#)

Opisthorchis viverrini, [451t](#)

Opsoclonus-myoclonus, neuroblastoma and, [701–702](#)

Opsomyoclonus, neuroblastoma and, [609](#)

Optic gliomas, [662](#)

Optic nerve, assessment of, [683](#)

Optic nerve hypoplasia, [639](#)

Optimal educational settings, in attention-deficit/hyperactivity disorder (ADHD), [47](#)

Oral allergy syndrome, [335t–336t](#)

Oral cavity, [479–480](#)

- cleft lip and palate of, [480](#)
- deciduous and primary teeth in, [479](#), [479t](#)
- dental caries in, [479–480](#)
- effects of systemic disease on, [479](#)
- thrush of, [480](#)

Oral glucose tolerance test (OGTT), [639](#)

Oral iron, therapeutic trial of, for iron deficiency anemia, [571](#)

Oral rehydration solution (ORS), [129](#), [413](#)

Oral tolerance, [334](#)

Orbital cellulitis, [395](#), [433t](#)

Orchidopexy, [633](#)

Orf, [439t–442t](#)

Organ-directed therapeutics, for shock, [153–154](#)

Organ donation, [8](#)

Organic acid disorders, [205–206](#)

- biotinidase deficiency as, [206](#)

- glutaric acidemia I as, [206](#), [207f](#), [208](#)
- holocarboxylase deficiency as, [206](#)
- isovaleric acidemia as, [206](#), [206f](#)
- methylmalonic acidemia as, [205](#), [206f](#)
- neonatal screening for, [197–198](#), [198t](#)
- propionic acidemia as, [205](#), [206f](#)
- treatment of, [206](#)

Organic acid metabolism, disorders of, hypoglycemia due to, [650](#)

Organic acid profile, urine, [199t](#)

Organic sleep disorders, [54t–55t](#)

Orientia tsutsugamushi, [439t–442t](#)

Ornithine carbamoyltransferase (OTC) deficiency, [204](#)

ORS, [Oral rehydration solution](#)

Orthopedic disorders

- juvenile idiopathic arthritis vs., [352t](#)
- mechanisms of, [739t](#)

Orthopedics, common terminology in, [739t](#)

Orthopedics assessment, [739–740](#)

- developmental milestones in, [740](#)
 - for infants, [740](#), [741f](#)
- of gait, [740](#)
- growth and development in, [739–740](#), [740f](#)
- of limping child, [740](#), [741t](#)
- of toe walking, [740](#)

Orthoradiograph, of leg-length discrepancy, [750](#)

Ortolani (reduction) test, [744–745](#), [745f](#)

OSA, [Obstructive sleep apnea](#)

Osgood-Schlatter disease, [752](#)

Osmolality, regulation of, [125](#)

Osmotic fragility test, [579](#)

Osmotic gap, in diarrhea, [475](#)

Osmotics, for functional constipation, [52t](#)

Ossification center, secondary, [740f](#)

Osteoblastoma, [765t–766t](#)

Osteochondritis dissecans, [752](#)

Osteochondroma, [765t–766t](#)

Osteoid osteoma, [765t–766t](#)

Osteomalacia, [118](#), [670](#)

Osteomyelitis, [425–428](#)

- acute hematogenous, [425](#)
- chronic, [425](#)
- clinical manifestations of, [426](#)
- complications and prognosis of, [427–428](#)
- culture-negative, [425](#)
- differential diagnosis for, [427](#)
- epidemiology of, [426](#)
- etiology of, [425–426](#), [426f](#)
- fever due to, [368](#)
- hematogenous, complications and prognosis of, [427–428](#)
- laboratory and imaging studies in, [426–427](#), [427f](#)
- multifocal, recurrent, [425–426](#)
- prevention of, [428](#)
- subacute, [425](#)
 - focal, [425–426](#)
- treatment for, [427](#), [427t](#)
- vertebral, [426](#)

Osteoporosis, [119](#)

Osteosarcoma, [611](#)

- clinical manifestations of, [612](#)
- epidemiology of, [611](#)
- etiology of, [611](#)
- laboratory/imaging studies in, [612](#)

- prognosis for, [613](#)
- risk factors for, [597t](#)
- treatment of, [612](#)

Osteotomy, [739t](#)

Ostiomeatal complex, [394](#)

Otalgia, in otitis media, [396](#)

Otitis externa, [397–398](#)

- clinical manifestations of, [398](#)
- complications and prognosis of, [398](#)
- differential diagnosis of, [398](#)
- epidemiology of, [398](#)
- etiology of, [397–398](#)
- laboratory and imaging studies of, [398](#)
- malignant, [397–398](#)

Otitis media, [395–397](#)

- clinical manifestations of, [395–396](#), [397f](#)
- due to common cold, [391–392](#)
- complications and prognosis of, [397](#)
- definition of, [396t](#)
- differential diagnosis of, [396](#)
- with effusion, [396](#)
- epidemiology of, [395](#)
- etiology of, [395](#)
- laboratory and imaging studies, [396](#)
- prevention of, [397](#)
- recurrent, [395](#)
- treatment of, [396–397](#), [396t](#)
- with tympanic perforation, [398](#)
- vomiting due to, [473t](#)

Otitis prone, [395](#)

Otoacoustic emission, [35](#)

Otorrhea

in otitis media, [396](#)
tympanostomy tube, [398](#)

Out-toeing, [749](#)

common causes of, [748t](#)
due to external tibial torsion, [749](#)

Ovarian cysts, [662](#)

Ovarian failure, [659](#)

Overgrowth syndrome, [184–185](#)

Overuse injuries, of shoulder, [763](#)

Oxycodone, acute effects of, [284t–285t](#)

Oxygen

administration of, [512](#)
for carbon monoxide poisoning, [164t–165t](#)
delivery, [145](#)
for heart failure, [555t](#)
in pulmonary physiology, [507](#)
supplemental, [512](#)
supplementation, [146](#)

Oxygenation index (OI), for primary pulmonary hypertension of the newborn, [246](#)

Oxytocin, maternal use of, [238t](#)

Oxytocin challenge test, [220](#)

P

P wave, [539](#)

Pachygyria, [717](#)

Packed RBCs, [589–590](#), [590t](#)

PAH, [Pulmonary arterial hypertension](#)

PAH (phenylalanine hydroxylase) deficiency, [173t](#)

Pain

analgesia for, 166

back, 761

clinical manifestations and management of, 761

differential diagnosis of, 761, 761*t*

etiology and epidemiology of, 761

red flags in, 761

chest, 541–542, 542*t*

in sickle cell disease, 577*t*

Palivizumab, for bronchiolitis, 402

Palliative care, 6–9

access to comprehensive and compassionate palliative care, 6–7

acknowledgment and support provisions for caregivers, 7

bereavement in, 7

cognitive issues in, 7

commitment to quality improvement of, 7

cultural, religious, and spiritual concerns about, 7–8

in dignity of patients and families, 6

interdisciplinary resources in, 7

Palliative shunt surgery, 550

Pallor

in anemia, 567–568

in hematological disorders, 563

Palpation, in cardiovascular system assessment, 535

Palpebral fissure, 183*t*

Pancreatic disease, 501–503

pancreatic insufficiency as, 501–502

pancreatitis as

acute, 502–503, 502*t*

chronic, 503

Pancreatic enzymes, for pancreatic insufficiency, 502

Pancreatic injury, 157

Pancreatic insufficiency, 501–502

exocrine, in cystic fibrosis, [527](#), [529](#)

Pancreatic pseudocyst, [502](#)

Pancreatitis

abdominal pain due to, [470t](#)

acute, [502–503](#)

clinical manifestations of, [502–503](#)

etiology and epidemiology of, [502](#), [502t](#)

laboratory and imaging studies for, [503](#)

treatment of, [503](#)

chronic, [503](#)

clinical manifestations of, [503](#)

etiology and epidemiology of, [503](#)

laboratory and imaging studies for, [503](#)

treatment of, [503](#)

vomiting due to, [473t](#)

Pancytopenia, [573t](#), [574](#), [591](#)

differential diagnosis of, [574](#)

etiology of, [574](#)

resulting from bone marrow failure, [584](#)

resulting from destruction of cells, [575](#)

Panencephalitis, subacute sclerosing, due to measles, [375](#)

Panic attack, [61–62](#)

Panic disorder, [61–62](#)

Panner disease, [764](#)

Pansystolic murmur, due to ventricular septal defect, [545](#)

Pantothenic acid deficiency, [114t](#)

Papilledema, [686](#), [686f](#)

Papules, [721t](#), [722f](#)

in acne, [723](#)

Papulosquamous dermatoses, [729–730](#)

Paracentesis, for peritonitis, [504](#)

Parachute reflex, [682t](#)

Paracrine action, of hormones, [637](#), [637f](#)

Paragonimiasis, [451t](#)

Paragonimus africanus, [451t](#)

Paragonimus heterotremus, [451t](#)

Paragonimus kellicotti, [451t](#)

Paragonimus skjabini, [451t](#)

Paragonimus uterobilateralis, [451t](#)

Paragonimus westermani, [451t](#)

Parainfluenza virus, croup from, [398–399](#)

Paralysis

flaccid, areflexic, [694](#)

due to hypokalemia, [136](#)

periodic, [698](#)

tick, [695–696](#)

Parameningeal infection, [387t](#)

Paraneoplastic syndromes, [609](#)

Paraphimosis, [632](#)

Parapneumonic effusion, [407](#), [530–531](#)

Parasitic diseases, [447–452](#)

ascariasis, [450](#)

helminthiasis as, [449–452](#)

enterobiasis as, [451](#)

hookworm infections of, [450](#)

neurocysticercosis, [452](#)

schistosomiasis as, [451–452](#)

visceral larva migrans, [450–451](#)

protozoal, [447–449](#)

malaria as, [447–449](#)

toxoplasmosis, [449](#)

Parasomnias, [54t–55t](#)

pediatric sleep disorders and, [55](#)

Parathyroid bone, [669–670](#), [680](#)

Parathyroid hormone, [669](#)

Parechoviruses, meningitis from, [387](#)

Parenteral nutrition, [130–131](#)

- access for, [131](#)
- for burn patients, [159](#)
- complications of, [131](#)
- composition of, [131](#)
- indications for, [130–131](#), [130t](#)

Parenteral penicillin, [263](#)

Parenting, [25](#)

Parents' Evaluation of Developmental Status (PEDS), [17](#)

Parinaud oculoglandular syndrome, [430](#)

Parinaud syndrome, [384](#)

Paronychia, viral, [382](#)

Paroxysmal disorders, [687–692](#), [687t](#), [Seizure\(s\)](#)

Paroxysmal nocturnal hemoglobinuria, [573t](#)

Paroxysmal stage, of pertussis, [400](#)

Partial thromboplastin time (PTT), [583](#)

- activated, [584t](#)
 - prolonged, in hemophilia, [587](#)
- in newborn, [253](#)

Partial vision, [33](#)

Parvovirus infection, [573t](#)

- congenital, [260t](#)

Pasteurella multocida, [439t–442t](#)

- osteomyelitis from, [425](#)

Patch, [721t](#), [722f](#)

Patella, [751f](#)

Patellar dislocation, recurrent, [752](#)

Patellar subluxation, recurrent, [752](#)

Patellofemoral disorders, [752](#)

Patellofemoral joint, [752](#)

Patellofemoral pain syndrome (PFPS), [752](#)

Patent airway, [147](#)

Patent ductus arteriosus (PDA), [221–222](#), [546–547](#), [546f](#)

- clinical manifestations of, [244](#), [546](#)
- etiology and epidemiology of, [546](#)
- imaging studies for, [547](#)
- respiratory distress syndrome and, [243–244](#)
- treatment of, [244](#), [547](#)

Paternalism, [4](#)

Pathogen-associated molecular patterns, [289](#)

Patient-controlled analgesia, [166](#)

Pavlik harness, for developmental dysplasia of the hip, [746](#)

PCD, [Primary ciliary dyskinesia](#)

PDA, [Patent ductus arteriosus](#)

Peak expiratory flow rate (PEFR), [511](#)

- in asthma, [316](#)

Peak flow monitoring, for asthma, [321](#)

Pectus carinatum, [530](#)

Pectus excavatum, [529](#)

Pediatric acute-onset neuropsychiatric syndrome (PANS), [68](#)

Pediatric advanced life support and cardiopulmonary resuscitation, [147](#)

Pediatric autoimmune neuropsychiatric disorders associated with streptococcal (PANDAS) infection, [68](#)

Pediatric sleep disorders, [52–56](#), [54t–55t](#)

clinical manifestations and evaluation of, [53–55](#)

differential diagnosis of, [55–56](#)

epidemiology of, [53](#)

prevention and treatment of, [56](#), [56t](#)

Pediculoses, [736–737](#)

capitis, [736](#)

corporis, [736](#)

pubis, [736](#)

treatment of, [736](#)

Pediculosis pubis (crabs), [423t](#)

Pediculus humanus capitis, [736](#)

Pediculus humanus corporis, [736](#)

Pediculus humanus humanus, [736](#)

Pedigree

drawing, [169–170](#), [170f](#)

for dysmorphology, [184](#)

in genetic assessment, [178](#)

in hematology assessment, [563](#)

PEFR (peak expiratory flow rate), [511](#)

in asthma, [316](#)

Pellagra, [113](#)

Pelvic inflammatory disease, [420–421](#), [420t](#)

dysmenorrhea due to, [277](#)

PEM, [Protein-energy malnutrition](#)

Penicillamine, as teratogen, [237t](#)

Penicillin

allergic reaction to, [338](#)

desensitization for, [339](#)

skin testing for, [339](#)

for streptococcal pharyngitis, [393–394](#)

Penicillin G

for Lyme disease, [444](#)

for syphilis, [424](#)

Penicillin V, for pharyngitis, [394](#)

Penicilloyl polylysine, in skin testing for penicillin allergy, [339](#)

Penis, disorders of, [632](#)

Peptic ulcer disease, [485–486](#)

clinical manifestations of, [486](#), [486t](#)

etiology and epidemiology of, [485–486](#)

gastrointestinal bleeding due to, [477t](#)

laboratory and imaging studies for, [486](#)

risk factors for, [485–486](#), [486t](#)

treatment of, [486](#)

vomiting due to, [473t](#)

Peptide hormones, [637](#)

Percussion, [510t](#)

Perennial allergic rhinitis, [323](#)

Perianal dermatitis, [380](#)

Pericardiocentesis, for pericarditis, [558](#)

Pericarditis, [558](#), [559t](#)

Perinatal care, [1](#)

Perinatal history, [221t](#)

present, [221t](#)

prior, [221t](#)

Perinatal mortality, [218](#), [219t](#)

Perinatal period, obesity and, [107–108](#)

Periodic breathing, [509t](#)

Periodic fever, aphthous stomatitis, pharyngitis, and cervical adenitis (PFAPA) syndrome, [393](#)

Periodic paralysis, [698](#)

Periorbital cellulitis, [395](#), [433t](#)

Periorbital hemangioma, [732–733](#)

Periosteal elevation, in osteomyelitis, [426](#)

Periosteal fat line, loss of, in osteomyelitis, [426](#)

Peripheral chemoreceptors, in control of ventilation, [513](#), [514f](#)

Peripheral destruction

- in pancytopenia, [575](#)
- thrombocytopenia resulting from, [584](#)

Peripheral neuropathy, [695–696](#)

- in chronic inflammatory demyelinating polyneuropathy, [695](#)
- in Guillain-Barré syndrome, [695](#)
- in hereditary motor sensory neuropathy (Charcot-Marie-Tooth disease), [695](#)
- in tick paralysis, [695–696](#)

Peripheral pulmonary stenosis murmur, [538t](#)

Peripherally inserted central catheter (PICC), [437](#)

- for parenteral nutrition, [131](#)

Peristaltic waves, in pyloric stenosis, [485](#)

Peritoneal dialysis-associated infections, [438](#)

Peritonitis, [504–505](#)

- in nephrotic syndrome, [621](#)
- tuberculous, [454](#)

Peritonsillar abscess, upper airway obstruction due to, [517t](#)

Periventricular hemorrhage, in newborn, [257](#)

Periventricular leukomalacia, in newborn, [257](#)

Permanent teeth, [479t](#)

Permethrin, for prevention of zoonoses, [439](#)

Pernicious anemia, [117](#)

Peroxisomal disorders, [208–209](#)

Peroxisomes, [208–209](#)

Persistent depressive disorder, [65](#)

Persistent middle ear effusion, otitis media and, [397](#)

Persistent pulmonary hypertension of the newborn (PPHN), [222](#), [246](#)

Personal-social development, milestones of, [17t](#)

Pertussis, [400–401](#)

 complications and prognosis of, [401](#)

 differential diagnosis of, [401](#)

 epidemiology of, [400](#)

 etiology of, [400](#)

 laboratory and imaging studies for, [400–401](#)

 prevention of, [401](#)

 treatment of, [401](#)

Pertussis vaccine, [363–364](#)

Pes cavus, [739t](#)

 in hereditary motor sensory neuropathy, [695](#)

Pes planus, [739t](#)

 hypermobile, [754](#)

Petechiae, [721t](#)

 in anemia, [568](#)

 in hematological disorders, [563](#)

 in hemostatic disorders, [583](#)

Petechial-purpuric rash, infections with fever and, [373t–374t](#)

PFPS (patellofemoral pain syndrome), [752](#)

PHACE syndrome, [732–733](#)

Phagocytic disorders, [301t](#)

Phagocytosis, [301t](#)

Pharmacodynamics, [367](#)

Pharmacokinetics, [367](#)

Pharmacotherapy

 for anxiety disorders, [63–64](#)

for enuresis, [49](#)

Pharyngitis, [392–394](#)

causes of, [392t](#)

clinical manifestations of, [392–393](#)

complications and prognosis of, [394](#)

differential diagnosis of, [393](#)

epidemiology of, [392](#)

etiology of, [392](#)

laboratory evaluation of, [393](#)

treatment of, [393–394](#), [394t](#)

Pharynx, [507](#)

Phencyclidine, acute effects of, [284t–285t](#)

Phenobarbital

maternal use of, [238t](#)

for status epilepticus, [691](#), [691t](#)

Phenylalanine, metabolism of, [202f](#)

Phenylalanine hydroxylase (PAH) deficiency, [173t](#)

Phenylephrine, for allergic rhinitis, [325](#)

Phenylketonuria (PKU), [201–202](#), [202f](#)

genetic basis for, [173t](#), [198t](#), [201–202](#)

maternal, [236t](#)

outcome of, [202](#)

as teratogens, [176](#)

treatment of, [202](#)

Phenytoin

for status epilepticus, [691](#), [691t](#)

as teratogen, [237t](#)

Philtrum, [183t](#)

Phimosis, [632](#)

Phlebitis, due to parenteral nutrition, [131](#)

Phobias, [63](#)

Phosphate, [669](#)

Phosphorylase kinase deficiency, [200t](#)

Photosensitivity, in systemic lupus erythematosus, [353](#)

Phototherapy, for indirect hyperbilirubinemia, [252](#)

PHOX2B gene, in congenital central hypoventilation syndrome, [514](#)

Phrenic nerve palsy, [233](#)

Phthirus pubis, [425](#)

Phylloquinone, [118](#)

Physeal fractures, [742–743](#)

Physical abuse, [80–82](#), [80t](#)

abdominal trauma due to, [81](#)

bruises due to, [80–81](#), [81f](#)

burns due to, [81](#), [81f](#)

differential diagnosis of, [81–82](#), [83t](#)

fractures due to, [81](#), [82f](#)

head trauma due to, [81](#), [82f](#)

Physical activity history, for obesity, [107](#)

Physical criteria, for newborn maturity and gestational age, [227–228](#), [228f](#)

Physical examination

for cancer, [595](#)

in cardiovascular system assessment, [535–538](#)

in hematology assessment, [563](#), [564t](#)

in hemostatic disorders, [583](#)

in neurology assessment, [681](#)

of newborn, [227–231](#)

for obesity, [107](#)

for skin disorders, [721](#)

Physical maturation, changes associated with, [273](#)

Physiological nadir, [566](#)

Physiological stability, in anemia, [568](#)

Physis, [740f](#)

Pica, [571](#)

Pierre Robin sequence, [184](#)

Pierre Robin syndrome, [227t](#)

Pigmented lesions, [730–732](#)

- acquired nevi as, [732](#)
- café au lait macules as, [731](#), [731f](#)
- congenital melanocytic nevi as, [731–732](#), [731f](#)
 - giant, [732](#)
 - hairy, [731–732](#), [731f](#)
- dermal melanosis as, [730](#), [731f](#)
- differential diagnosis of, [730](#), [730t](#)

Pigmented nevi, giant, [731–732](#)

Pill ulcers, [484](#)

Pimecrolimus, for atopic dermatitis, [327–328](#)

Pinworm, [450t](#), [451](#)

Pituitary function, assessment of, [638](#)

Pituitary hormone, [637–638](#), [638f](#)

Pituitary thyroid-stimulating hormone (TSH), [663](#)

Pityriasis rosea, [729](#)

PKU, [Phenylketonuria](#)

Placenta previa, [217](#)

Placental abruption, [217](#)

Placing reflex, [682t](#)

Plagiocephaly, [183t](#), [185](#)

- and torticollis, [760](#)

Plague, [439t–442t](#)

Plain x-rays, for infectious diseases, [362–363](#)

Plantar surface, of newborn, [228f](#)

Plantar warts, [382](#)

Plaque, [721t](#), [722f](#)

Plasma, fresh frozen, [590t](#)

Plasma creatinine, [619](#)

Plasma lipids, alterations in, [580](#)

Plasma osmolality, [125](#)

Plasma water, [125](#)

Plasminogen, [589](#)

Plasmodium, [447](#), [448t](#)

 life cycle of, [447](#), [448f](#)

Plasmodium falciparum, [448t](#)

Plasmodium knowlesi, [448t](#)

Plasmodium malariae, [448t](#)

Plasmodium ovale, [448t](#)

Plasmodium vivax, [448t](#)

Platelet concentrate, [590t](#)

Platelet count, [583](#), [584t](#)

Platelet function, disorders of, [586](#)

Platelet function analyzer (PFA), [584t](#)

Platelet plug, in hemostasis, [580](#)

Platelets

 activated, [580](#)

 disorders of, [583](#), [592](#)

 production, decreased, thrombocytopenia resulting from, [584](#)

Pleiotropy, [171](#)

Pleura disorders, [529–532](#)

 pleural effusion as, [530–532](#)

 pneumomediastinum as, [530](#)

pneumothorax as, [530](#)

Pleural effusion, [405](#), [510t](#), [530–532](#)

clinical manifestations of, [531](#)

diagnostic studies for, [531–532](#), [531t](#)

etiology of, [530–531](#), [531f](#)

treatment of, [532](#)

Plexiform neurofibroma, [730t](#)

Pluripotential progenitor stem cells, [563](#)

Pneumatic otoscopic examination, [36](#)

Pneumatic otoscopy, in otitis media, [396](#)

Pneumatic vests, [513](#)

Pneumatocele, [407](#)

Pneumatosis intestinalis, due to necrotizing enterocolitis, [254–255](#)

Pneumococcal polysaccharide vaccines, [364f–365f](#)

Pneumocystis jiroveci, in immunocompromised person, [434–435](#)

Pneumomediastinum, [530](#)

Pneumonia, [120–121](#), [402–408](#), [523](#)

afebrile, [403](#), [404t](#)

atypical, [402–403](#)

broncho-, [402–403](#)

clinical manifestations of, [403–405](#)

complications and prognosis for, [407](#)

differential diagnosis of, [406](#), [406t](#)

epidemiology of, [403](#)

etiology of, [402–403](#), [404t](#)

fever due to, [368](#)

giant cell (Hecht), due to measles, [375](#)

in immunocompromised persons, [403](#)

laboratory and imaging studies for, [405–406](#), [405f–406f](#)

lobar, [402–403](#)

meconium aspiration, [245](#)

- in neonates, [403](#), [404t](#)
- prevention of, [407–408](#)
- treatment of, [406](#), [407t](#)
- ventilator-associated, [438](#)
- viral, [403](#)
- vomiting due to, [473t](#)

Pneumonitis, [402–403](#)

- interstitial, [402–403](#)

Pneumothorax, [244f](#), [510t](#), [530](#)

- due to assisted ventilation in newborn, [244](#)
- clinical manifestations of, [530](#)
- diagnostic studies for, [530](#)
- etiology of, [530](#)
- in newborn, [227](#)
- secondary, [530](#)
- spontaneous primary, [530](#)
- tension, [530](#)
- treatment of, [530](#)

Point mutation, [169](#)

Poisoning, [160–165](#)

- clinical manifestations of, [160](#), [161t](#)
- complications of, [160–163](#)
 - coma as, [160](#)
 - direct toxicity as, [160–162](#)
 - dysrhythmias as, [162](#), [163t](#)
 - gastrointestinal symptoms as, [163](#)
 - metabolic acidosis as, [162](#), [162t](#)
 - seizures as, [163](#)
- epidemiology of, [160](#)
- etiology of, [160](#)
- laboratory and imaging studies of, [163](#), [164t](#)
- prevention of, [165](#)
- prognosis for, [165](#)
- treatment of, [163–164](#)
 - enhanced elimination for, [164](#)
 - gastrointestinal decontamination for, [164](#)

specific antidotes for, [164](#), [164t–165t](#)

supportive care for, [163–164](#)

Polio vaccine, [363–364](#)

Pollen-food allergy syndrome, [335t–336t](#)

Polyarthritis, due to heart failure, [556t](#)

Polycystic kidney disease (PKD), [629–630](#)

autosomal dominant, [630](#)

autosomal recessive, [630](#)

Polycystic ovary syndrome, amenorrhea due to, [275](#)

Polycythemia

cyanotic congenital heart disease with, [584](#)

in newborn, [252](#)

presentation of, [564t](#)

Polydactyly, [183t](#), [185](#)

of digits, [765](#)

of toes, [755](#), [756t](#)

Polydipsia, in insulin-dependent diabetes mellitus, [641](#)

Polyethylene glycol (GoLYTELY), for poisoning, [164](#)

Polyethylene glycol electrolyte solution, for functional constipation, [51t](#)

Polygenic inheritance, [173–174](#)

hypertrophic pyloric stenosis due to, [174–175](#)

neural tube defects due to, [175](#)

Polyhydramnios, [218](#)

Polymerase chain reaction (PCR), [362](#)

for HIV, [460](#)

Polymicrogyria, [717](#)

Polymorphonuclear cells, as lung defense mechanisms, [508](#)

Polyp, juvenile, gastrointestinal bleeding due to, [477t](#)

Polysomnography, [55](#), [515](#)

Polyuria, fluid therapy for, [127](#), [127t](#)

Pompe disease, [200t](#), [698](#)

Popliteal angle, in newborn, [229f](#)

Popliteal cyst, [751](#)

Population, [1–3](#), [8–9](#)

 changing morbidity and, [3](#)

 culture and, [3](#)

 current challenges in, [1](#)

 health disparities in, [3](#)

 landscape of, [1–2](#), [2t](#)

 other health issues affecting, [2–3](#)

 in society, [1](#)

Pork tapeworm, [452](#)

Port-a-Cath (implanted venous access systems), infections associated with, [437](#)

Port-wine stain, [228](#), [733](#), [733f](#)

 differential diagnosis of, [730t](#)

 in Klippel-Trénaunay-Weber syndrome, [733](#)

 in Sturge-Weber syndrome, [715](#), [733](#)

Portal hypertension, [497](#)

Portion sizes, age-appropriate, [108–109](#)

Portosystemic shunts, [498](#)

Positive reinforcement, [16](#)

Positron emission tomography (PET), for cancer, [596](#), [599t](#)

Post-traumatic stress disorder, due to domestic violence, [91](#)

Posterior fossa, tumors in, ataxia due to, [701](#)

Posterior fossa syndrome, central nervous system and, [608](#)

Posterior urethral valves, [630](#)

Posterior uveitis, [433t](#)

Postexposure prophylaxis, for measles, [375](#)

Postherpetic neuralgia, [379](#)
 varicella zoster virus and, [378](#)

Postmenopausal osteoporosis, [119](#)

Postmitotic maturing cells, [563](#)

Postnatal genetic assessment, [178](#)

Postobstructive pulmonary edema, [524](#)

Postpericardiotomy syndrome, [558](#)

Postseptal cellulitis, [395](#), [433t](#)

Poststreptococcal arthritis (PsA), [352t](#)

Poststreptococcal glomerulonephritis (PSGN)
 clinical manifestations of, [622–623](#)
 etiology and epidemiology of, [622](#)
 therapy for, [623](#)

Posttransplant lymphoproliferative disorder (PTLD), [435](#)

Posttraumatic seizures, [710](#)

Postural roundback, [760](#)

Posture
 assessment of, [683](#)
 of newborn, [229f](#), [682](#)
 vs. foot deformity, [752](#)

Potassium, for diabetic ketoacidosis, [642–643](#)

Potassium disorders, [134–138](#)
 hyperkalemia as, [137–138](#)
 hypokalemia as, [134–137](#), [135t](#)

Pott disease, [454](#)

Pott puffy tumor, [395](#)

Potter syndrome, [217–218](#), [227t](#), [629](#)

Poverty, health disparities and, [3](#)

PPD-S (purified protein derivative standard), [454](#)

PPHN (persistent pulmonary hypertension of the newborn), [222](#)

PR interval, [539](#)

Prader-Willi syndrome (PWS), [653](#)

genetic basis for, [175–176](#), [183–184](#)

hypotonia in, [698–699](#)

obesity in, [106t](#)

Pralidoxime, for organophosphate poisoning, [164t–165t](#)

Preadoption visit, [89](#)

Precocious puberty, [659–663](#)

central, [660](#)

classification of, [659–660](#)

differential diagnosis of, [661t](#)

familial male-limited, [662](#)

GnRH-dependent, [660](#)

GnRH-independent, [660–662](#)

Preconception genetic assessment, [177–178](#)

adolescent and adult, [178](#)

familial factors in, [177](#)

maternal factors in, [177–178](#)

postnatal, [178](#)

screening in, [177](#)

Precordium, hyperdynamic, with patent ductus arteriosus, [546–547](#)

Prednisolone, for croup, [399–400](#)

Prednisone, [527](#)

for asthma, [316](#)

for cancer, [601t–602t](#)

for Henoch-Schönlein purpura, [347](#)

for idiopathic thrombocytopenic purpura, [585](#)

for nephrotic syndrome, [621](#)

for serum sickness, [333](#)

Preeclampsia, [218](#)

Pregnancy

adolescent, [277–278](#)

continuation of, [278](#)

- diagnosis of, 278
- termination of, 278
- assessment during, 217
- complications of, 217
 - hydrops fetalis as, 218
 - maternal medical, 217
 - with multiple gestations, 218
 - obstetric, 217
 - oligohydramnios as, 217–218
 - placenta previa as, 217
 - placental abruption as, 217
 - polyhydramnios as, 218
 - preeclampsia/eclampsia as, 218
 - premature rupture of membranes as, 218
 - prolonged rupture of membranes as, 218
 - vaginal bleeding as, 217
- genetic assessment during, 177–179
 - familial factors in, 177
 - maternal factors, 177–178
 - postnatal, 178
 - screening in, 177
- high-risk, 217
- maternal diseases during, 235
 - antiphospholipid syndrome as, 235
 - diabetes mellitus as, 236t–237t, 237
 - hyperthyroidism as, 236
 - idiopathic thrombocytopenic purpura as, 235–236, 236t
 - other, 237
 - systemic lupus erythematosus as, 236, 236t
- toxemia of, 218
- vomiting due to, 473t

Pregnancy history

- for dysmorphology, 184
- in genetic assessment, 184

Prehospital trauma care, 155

Preicteric phase, of viral hepatitis, 413

Preload, in heart failure, 553, 554t

Premature atrial contractions, 543

Premature pubarche, [663](#)

Premature rupture of membranes, [218](#)

Premature ventricular contractions (PVCs), [543](#), [544t](#)

Prematurity

apnea of, [246](#), [514](#), [514t](#)

retinopathy of, [245](#)

Premenstrual dysphoric disorder (PDD), [65](#)

Premutation carriers, in fragile X syndrome, [176](#)

Prenatal care, [1](#)

Prenatal genetic assessment, [177–178](#)

adolescent and adult, [178](#)

familial factors in, [177](#)

maternal factors in, [177–178](#)

postnatal, [178](#)

screening in, [177](#)

Prenatal history, in cardiovascular system assessment, [535](#)

Prerenal azotemia, [625](#)

due to shock, [154](#)

Preschool children

obesity in, [107–108](#)

reaction to divorce by, [94](#)

Preschool readiness, [15](#)

Preseptal (periorbital) cellulitis, [395](#)

Preslip condition, [747](#)

Presumptive antiinfective therapy, [367](#)

Preterm births, [1](#), [218](#)

Preterm infants, sepsis in, [258](#)

Priapism, in sickle cell disease, [577](#), [577t](#)

Primaquine, maternal use of, [238t](#)

Primary ciliary dyskinesia (PCD), [523](#)

Primary enuresis, [48](#)

Primary hypoparathyroidism, [669](#), [670t](#)

Primary survey, of trauma patient, [155](#)

Primary teeth, [479](#), [479t](#)

Primitive neonatal reflexes, [14](#)

Procedural sedation, [165](#)

Proctocolitis, allergic, [335t–336t](#)

Professionalism, [3–4](#)

Progesterone withdrawal test, for amenorrhea, [275](#)

Progressive primary disease, [453](#)

Progressive symptoms, in neurology assessment, [681](#)

Prolonged QT syndrome, [539](#)

Prolonged rupture of membranes, [218](#)

Promoter sequence, [169](#)

Pronator drift, [684](#)

Proopiomelanocortin deficiency, obesity in, [106t](#)

Properdin, [304–305](#)
deficiency of, [306](#)

Prophase analysis, in genetic assessment, [179](#)

Prophylaxis, [366](#)
immunization and, [363–366](#)
for meningococcus, [366](#)
postexposure, for measles, [375](#)
primary, [366](#)
for rabies, [366](#)
secondary, [366](#)
for tetanus, [366](#), [367t](#)

Propionate pathway, [206f](#)

Propionibacterium acnes, [723](#)

Propionic acidemia, [205](#), [206f](#)

clinical manifestations of, [206](#)

neonatal screening for, [198t](#), [205](#)

treatment of, [206](#)

Propofol, for sedation, [166t](#)

Propranolol, maternal use of, [238t](#)

Propylthiouracil, maternal use of, [238t](#)

Prostaglandin E₁

for coarctation of aorta, [548](#)

for hypoplastic left heart syndrome, [553](#)

for transposition of great arteries, [551](#)

Protein C, [581](#), [589](#)

Protein carrier, [363–364](#)

Protein-energy malnutrition (PEM), [109](#)

Protein S, [581](#), [589](#)

Proteinuria, [620–622](#)

asymptomatic, [620](#)

clinical manifestations of, [621](#)

complications of, [621](#)

diagnostic studies of, [621](#)

differential diagnosis of, [621](#)

etiology and epidemiology of, [620–621](#)

fixed, [620](#)

glomerular, [620](#)

persistent, [620](#)

postural, [621](#)

prognosis for, [622](#)

symptomatic, [620](#)

transient, [620](#)

treatment of, [621](#)

tubular, [620](#)

Prothrombin time (PT), [583](#), [584t](#)

in newborn, [253](#)

Proton-pump inhibitor, for gastroesophageal reflux, [481t](#)

Protozoal disease, [447–449](#)

malaria as, [447–449](#)

toxoplasmosis, [449](#)

zoonotic, [439t–442t](#)

Proximal humeral epiphysiolysis, [763](#)

Proximal tubule, [617](#), [619f](#)

Pruritus ani, [451](#)

PsA (poststreptococcal arthritis), [352t](#)

Pseudo-Hurler polydystrophy, [210t–212t](#)

Pseudocyst, pancreatic, [502](#)

Pseudoephedrine, for allergic rhinitis, [325](#)

Pseudohypertrophy, [684](#)

Pseudohypoaldosteronism (PHA) type 1, [138](#)

Pseudohyponatremia, [131–132](#)

Pseudohypoparathyroidism, [653](#), [669](#), [670t](#)

obesity in, [106t](#)

Pseudomembranous colitis, gastrointestinal bleeding due to, [477t](#)

Pseudomonas aeruginosa

conjunctivitis from, [430](#)

in cystic fibrosis, [527](#)

folliculitis due to, [380](#)

osteomyelitis from, [425–426](#)

otitis externa from, [397–398](#)

pneumonia from, [407t](#)

Pseudomonas chondritis, [425–426](#)

Pseudoparalysis, from osteomyelitis, [426](#)

Pseudoseizures, [689–690](#)

Pseudotumor cerebri, [707–708](#)

PSGN, [Poststreptococcal glomerulonephritis](#)

Psilocybin, acute effects of, [284t–285t](#)

Psittacosis, [439t–442t](#)

Psoriasis, [729–730](#)

plaque-type, [729–730](#)

treatment of, [730](#)

vs. atopic dermatitis, [725](#)

vulgaris, [729–730](#)

Psychiatric disorders, [59–73](#)

anxiety disorders, [61–64](#)

autism spectrum disorder and schizophrenia spectrum disorders, [70–73](#)

depressive disorders and bipolar disorders, [64–68](#)

in medical conditions, [59–60](#), [60t](#)

obsessive-compulsive disorder (OCD), [68–70](#), [69t](#)

somatic symptom and related disorders (SSRDs), [59–61](#), [60t](#)

Psychogenic nonepileptic seizures, [689–690](#)

Psychological development, of adolescent, [270t](#)

Psychological intervention, for child with special needs, [32](#)

Psychological problems, in sickle cell disease, [577t](#)

Psychosocial assessment, [15–16](#)

of adolescence, [15–16](#)

of bonding and attachment in infancy, [15](#)

of developing autonomy in early childhood, [15](#)

of early childhood, [15](#)

of infancy, [15](#)

of school readiness, [15](#), [15t](#)

Psychosocial behaviors, modification of, [16](#)

Psychosocial dwarfism, [653](#)

Psychosocial issues, [77–96](#)

 bereavement as, [93–96](#)

 child abuse and neglect as, [80–84](#)

 divorce as, [93–96](#)

 failure to thrive as, [77–79](#)

 family structure and function as, [87–91](#)

 homosexuality and gender identity as, [84–87](#)

 separation as, [93–96](#)

 violence as, [91–93](#)

Psychosocial problems, [3](#)

Psychosocial short stature, [79](#)

Psychosocial treatments, for schizophrenia spectrum disorders, [73](#)

Psychotherapy, for depressive disorders, [66](#)

Psychotropics, constipation due to, [476t](#)

PT (prothrombin time), [583](#), [584t](#)

 in newborn, [253](#)

PTT (partial thromboplastin time), [583](#)

 activated, [584t](#)

 prolonged, in hemophilia, [587](#)

 in newborn, [253](#)

Pubarche, [656](#)

 in boys, [271–273](#), [272f](#)

 in girls, [270–271](#), [271f–272f](#)

 isolated premature, [663](#)

Pubertal development

 for boys, [271–273](#), [272f](#)

 for girls, [270–271](#), [271f–272f](#)

 variations in, [274–275](#), [663](#)

 breast asymmetry and masses as, [274](#), [274t](#)

 gynecomastia as, [274–275](#), [274t](#)

irregular menses as, [274](#)
physiological leukorrhea as, [274](#)

Puberty, [656–663](#), [679–680](#)

delayed, [656–659](#)

classification of, [657t](#)
due to CNS abnormalities, [657](#)
due to constitutional delay, [656](#)
differential diagnostic feature of, [658t](#)
evaluation of, [659](#)
due to hypergonadotropic hypogonadism, [658–659](#)
due to hypogonadotropic hypogonadism, [656](#), [658](#)
due to idiopathic hypopituitarism, [657](#)
due to isolated gonadotropin deficiency, [657](#)
due to Kallmann syndrome, [657](#)
primary amenorrhea as, [659](#)
treatment of, [659](#)

physiology of, [656](#)

precocious, [659–663](#)

central, [660](#)

Respiratory compensation, appropriate, [139](#), [139t](#)

Respiratory disease

assessment of

- breathing patterns in, [509t](#)
- endoscopic evaluation of airways in, [511](#)
- examination of sputum in, [511–512](#)
- history in, [509](#)
- imaging techniques in, [510–511](#)
- lung biopsy in, [512](#)
- measures of respiratory gas exchange in, [511](#)
- physical examination in, [509–510](#), [509t–510t](#), [510f](#)
- pulmonary function testing in, [511](#)

of newborn, [240–246](#)

therapeutic measures for, [512–513](#)

- aerosol therapy as, [512](#), [512f](#)
- chest physiotherapy and clearance techniques as, [513](#)
- intubation as, [513](#)
- mechanical ventilation as, [513](#)
- oxygen administration as, [512](#)
- tracheostomy as, [513](#)

Respiratory distress

cyanosis with/without, [549t](#)

with desaturation, [549t](#)

with normal saturation, [549t](#)

Respiratory distress syndrome (RDS), [241–243](#)

acute, [149](#)

bronchopulmonary dysplasia due to, [244–245](#)

clinical manifestations of, [242](#), [243f](#)

lung development and, [241](#), [242f](#)

patent ductus arteriosus due to, [221–222](#)

potential causes of, [243t](#)

prevention and treatment of, [242–243](#)

pulmonary air leaks due to, [244](#)

and retinopathy of prematurity, [245](#)

Respiratory failure, [145](#), [149–151](#)

acute, due to shock, [154](#)

chronic, [149](#)

- clinical manifestations of, [149](#)
- complications of, [150](#)
- differential diagnosis of, [150](#)
- epidemiology of, [149](#)
- etiology of, [149](#)
- hypercarbic, [149–150](#)
- hypoxemic, [149](#)
- hypoxic, [150](#)
- laboratory and imaging studies of, [149–150](#)
- mixed forms of, [150](#)
- prevention of, [150–151](#)
- prognosis for, [150](#)
- treatment of, [150](#)

Respiratory gas exchange, [508](#), [508t](#)

- measures of, [511](#)

Respiratory rate

- assessment of, [509](#), [509t](#)
- in cardiovascular system assessment, [535](#)
- of newborn, [227](#)

Respiratory support, for shock, [153–154](#)

Respiratory syncytial virus (RSV)

- bronchiolitis and, [401](#)
- croup from, [398–399](#)

Respiratory system, [507–532](#)

- anatomy of, [507](#)
- assessment of, [507–513](#)
 - breathing patterns in, [509t](#)
 - history in, [509](#)
 - physical examination in, [509–510](#), [509t–510t](#), [510f](#)
- physiology of, [507–509](#)
 - lung defense mechanisms in, [508–509](#)
 - pulmonary mechanics in, [507–508](#), [508f](#)
 - respiratory gas exchange in, [508](#), [508t](#)

Responsibility, [4](#)

Rest, for heart failure, [555t](#)

Restless legs syndrome, [54t–55t](#)

Restrictive cardiomyopathies, [557t](#)

clinical manifestations of, [558](#)

etiology of, [556](#)

imaging studies for, [558](#)

treatment of, [558](#)

Restrictive lung disease, [508](#)

Resuscitation, [146–147](#)

for drowning, [157](#)

fluid, for shock, [153](#)

of newborn, [225](#), [226f](#)

breathing in, [225–226](#)

cyanosis as, [232](#), [232t](#)

specific conditions requiring, [232–234](#)

life-threatening congenital malformations as, [232–233](#)

shock as, [233](#)

Reticular dysgenesis, neutropenia in, [301](#)

Reticulate bodies, in *Chlamydia* infection, [423](#)

Reticulocytes

count of, [568](#)

in erythropoiesis, [563–566](#)

values of, [565t](#)

Retinoblastoma, risk factors for, [597t](#)

Retinoids, topical, for acne, [723](#)

Retinol, [117](#)

Retinopathy of prematurity, [245](#)

Retrolental fibroplasia, [245](#)

Retropharyngeal abscess, upper airway obstruction due to, [517t](#)

Retroviral syndrome, acute, [384](#)

Rett syndrome, [173](#), [711t–712t](#), [713](#)

genetic basis for, [183–184](#)

Reye syndrome, hyperammonemia vs., [192](#)

Rh antigen system, [247–248](#)

Rh blood group incompatibility, erythroblastosis fetalis due to, [247–248](#)

Rh sensitization

management of, [248](#)

maternal, [236t](#)

Rhabdomyolysis, [213–214](#)

due to hypokalemia, [136](#)

Rhabdomyosarcoma (RMS), [611](#)

alveolar, [612](#)

clinical manifestations of, [612](#)

differential diagnosis of, [612](#)

embryonal, [612](#)

epidemiology of, [611](#)

laboratory/imaging studies in, [612](#)

prognosis for, [613](#)

risk factors for, [597t](#)

treatment of, [612](#)

Rheumatic diseases

assessment of, [343–345](#), [344t](#)

common manifestations in, [343–345](#), [345t](#)

diagnostic imaging in, [345](#)

differential diagnosis of, [344t](#)

history in, [343](#)

initial diagnostic evaluation in, [345](#)

laboratory testing in, [345](#)

physical examination in, [343](#)

of childhood, [343–358](#)

Rheumatic fever, [556](#), [556t](#)

differential diagnosis of, [344t](#)

Rheumatoid arthritis, synovial fluid findings in, [429t](#)

Rhinitis

- allergic, 323–325, 391

Schizoaffective disorder, [72](#)

Schizogony, of *Plasmodium* life cycle, [447](#)

Schizophrenia spectrum disorders, [71–73](#), [72t](#)

Schizophreniform disorder, [72](#)

Schnitzler syndrome, [331](#)

School-age children
obesity and, [107–108](#)
physical development in, [14](#)
reaction to divorce by, [94](#)

School readiness, [15](#), [15t](#)

Schwachman-Diamond syndrome, neutropenia in, [301](#)

SCID, [Severe combined immunodeficiency](#)

Scleritis, [433t](#)

Sclerosis, [722t](#)

Scoliosis

- adolescent, [758](#)
- classification of, [756t](#)
- clinical evaluation of, [757f](#)
- compensatory, [756](#), [759](#)
- congenital, [758](#), [759f](#)
 - treatment of, [758](#)
- idiopathic, [758](#)
 - clinical manifestations of, [758](#)
 - etiology and epidemiology of, [758](#)
 - treatment of, [758](#)
- infantile, [758](#)
- juvenile, [758](#)
- neuromuscular, [758–759](#)
 - treatment of, [759](#)
- thoracic, [529](#)

Screening

- anemia, [20–21](#)
- autism, [17–18](#)
- cholesterol, [21](#), [21t](#)
- depression, [22](#)
- developmental, [16–18](#)
- hearing, [20](#)
 - of children 3 years of age and older, [20](#)
 - of infants and toddlers, [20](#)
- language, [18](#), [18t](#)
- lead, [21](#), [21t](#)
- newborn, [20](#)
 - critical congenital heart disease (CCHD), [20](#)
 - hearing, [20](#)
 - hemoglobin electrophoresis, [20](#)
 - metabolic, [20](#)
- sexually transmitted infection, [21–22](#)
- tuberculosis, [21](#), [21t](#)
- vision, [20](#)
 - of children 3 years of age and older, [20](#)
 - of infants and toddlers, [20](#)

Screening tests

- for cancer, [596](#)
- in well child, [17](#), [20–22](#)
 - for anemia, [20–21](#)
 - for cholesterol, [21](#), [21t](#)
 - for depression, [22](#)
 - hearing and vision, [20](#)
 - for lead, [21](#), [21t](#)
 - newborn, [20](#)
 - for sexually transmitted infection, [21–22](#)
 - for tuberculosis, [21](#), [21t](#)

Screening tools, for somatic symptom and related disorders (SSRDs), [61](#)

Scrofula, [454](#)

Scrotum, abnormalities of, [632–633](#)

Scrub typhus, [439t–442t](#)

Scurvy, [112](#)

Seasonal allergic rhinitis, [323](#)

Seborrheic dermatitis, [728–730](#)

- atopic vs., [725](#), [729](#)
- clinical manifestations of, [728–729](#), [729f](#)
- differential diagnosis of, [729](#)
- etiology of, [728](#)
- laboratory and imaging studies of, [729](#)
- prevention of, [729](#)
- prognosis for, [729](#)
- treatment of, [729](#)

Second-degree heart block, [543](#), [544t](#)

Second hand cigarette smoke, [91](#)

Second heart sound (S₂), [536](#)

- abnormal, [537t](#)
- in tetralogy of Fallot, [549](#)
- in total anomalous pulmonary venous return, [552](#)
- in tricuspid atresia, [551](#)

in truncus arteriosus, [551](#)

Second impact syndrome, [709](#)

Secondary enuresis, [48](#)

Secondary ossification center, [740f](#)

Secondary pneumothorax, [530](#)

Secondary survey, of trauma patient, [155](#)

Sedation, [165–166](#), [166t](#)

Sedatives, acute effects of, [284t–285t](#)

Sedentary behavior, obesity and, [109](#)

Sedentary lifestyle, [2](#)

Seizure(s), [687–692](#), [733](#)

absence, [688–689](#)

atonic, [689](#)

atypical, [689](#)

due to inborn errors of metabolism, [195t](#)

myoclonic, [689](#)

causes of, [688t](#)

classification of, [687](#), [688t](#)

clonic, [688](#)

differential diagnosis of, [687](#), [687t](#)

in epilepsy syndrome, [688t](#), [690](#)

etiology and epidemiology of, [687](#), [687t–688t](#)

febrile, [689](#)

complex, [689](#)

simple, [689](#)

focal, [687–688](#), [689t](#)

with altered awareness, [687–688](#)

with retained awareness, [687](#)

generalized, [688–690](#)

impact, [710](#)

laboratory and diagnostic evaluation of, [691](#)

long-term therapy for, [691–692](#), [692f](#), [692t](#)

neonatal, [255–256](#)

benign familial, [255](#)

- clinical characteristics of, [256t](#)
- diagnostic evaluation of, [256](#)
- focal clonic, [256t](#)
- focal tonic, [256t](#)
- generalized tonic, [256t](#)
- myoclonic, [256t](#)
- poisoning and, [163](#)
- posttraumatic, [710](#)
- pseudo-, [689–690](#)
- psychogenic nonepileptic, [689–690](#)
- status epilepticus with, [690–691](#)
 - management of, [691t](#)
- in Sturge-Weber syndrome, [733](#)
- tonic, [688](#)
- tonic-clonic, [688](#)

Selective mutism, [63](#)

Selective serotonin reuptake inhibitors (SSRIs)

- for anxiety disorders, [64](#)
- for autism spectrum disorder (ASD), [71](#)
- for depressive disorders, [66](#)
- for OCD, [69](#)

Selenium deficiency, [119t](#)

Self-awareness, [4](#)

Self-improvement, [4](#)

Self-management strategies, for somatic symptom and related disorders (SSRDs), [61](#)

Senna, for functional constipation, [52t](#)

Sennetsu ehrlichiosis, [439t–442t](#)

Sensory and motor neuropathy, [117](#)

Sensory examination, [682](#), [684](#)

Separation anxiety disorder (SAD), [63](#), [63t](#)

Separations, [95](#)

Sepsis

- bacterial, [258](#)
- catheter-related, [131](#)
- clinical manifestations of, [259](#)
- early-onset
 - clinical manifestations of, [259](#)
 - treatment for, [259](#)
- fever and, [368](#)
- incidence of, [258](#)
- in newborn, [258–259](#)
 - acquired in utero, [258](#)

Septic arthritis, fever due to, [368](#)

Septic emboli, [410](#)

Septic thrombophlebitis, [437](#)

Septo-optic dysplasia, [639](#)

Sequence, of malformations, [184](#)

Sequestration crisis, in sickle cell disease, [577t](#)

Sequestrum, in osteomyelitis, [425–426](#)

Serological tests, [362](#)

Serositis, in rheumatic diseases, [343](#)

Serum immunoglobulin levels, for immunodeficiency disorders, [292](#)

Serum sickness, [311](#), [332–333](#)

- clinical manifestations of, [332–333](#)
- epidemiology of, [332](#)
- etiology of, [332](#)
- laboratory and imaging studies for, [333](#)
- treatment and prevention of, [333](#)

Sever disease, [755](#)

- clinical manifestations of, [755](#)
- treatment of, [755](#)

Severe acute respiratory syndrome (SARS), [403](#)

Severe combined immunodeficiency (SCID), [297](#), [297t](#)

autosomal recessive, [297–298](#)

clinical manifestations of, [297–298](#)

due to deficiencies in adenosine deaminase and purine nucleoside phosphorylase, [298](#)

hematopoietic stem cell transplantation for, [307](#)

X-linked, [297–298](#)

Severe visual impairment, [33](#)

Sex chromosomes, [169](#)

Sex steroids, in puberty, [656](#)

Sexual abuse, [82–84](#)

Sexual development

abnormal, [672–673](#)

classification of, [671](#)

diagnosis of, [673–674](#)

disorders of, [670–674](#), [680](#)

ovotesticular, [673](#)

sex chromosome, [673](#)

normal, [670–671](#)

treatment of, [674](#)

Sexual infantilism, [657t](#)

differential diagnostic features of, [658t](#)

Sexual maturity rating, [14](#)

Sexual phase, of *Plasmodium* life cycle, [447](#)

Sexual precocity, [659–663](#)

classification of, [659–660](#), [660t](#)

differential diagnosis of, [661t](#)

evaluation of, [662](#)

laboratory evaluation of, [662](#)

pharmacological therapy of, [662t](#)

treatment of, [662–663](#)

Sexuality, development of, [84–86](#)

Sexually transmitted infections (STIs), [274](#), [419–425](#)

abnormal uterine bleeding due to, 276

chlamydia (*Chlamydia trachomatis*) as, 422–423

- clinical features of, 420t
- pelvic inflammatory disease due to, 420–421

genital ulcers from, 419, 421t

genital warts (condylomata acuminata) as, 382, 419, 423t, 425

gonorrhea (*Neisseria gonorrhoeae*) as, 421–422

- clinical features of, 420t
- disseminated gonococcal infections due to, 421–422

granuloma inguinale as, 419, 421t

herpes simplex virus infection (genital herpes) as, 419, 424

lymphadenopathy due to, 384t

mucopurulent cervicitis as, 420t

pediculosis pubis (crabs) as, 423t

pelvic inflammatory disease, 420–421, 420t

syphilis (*Treponema pallidum*) as, 419, 421t, 423–424

trichomoniasis (*Trichomonas vaginalis*) as, 419, 422t, 424–425

urethritis as, 419

vaginal discharge from, 419

vulvovaginal candidiasis as, 423t

SGA, **Small for gestational age**

Shagreen patches, 715

Shawl sign, in juvenile dermatomyositis, 355–356

Shiga-like toxin, 411

Shiga toxin, 411

Shigella, diarrhea from, 410t

Shigella dysenteriae, 411

Shock, 145, 151–154

- cardiogenic, 152
 - clinical manifestations of, 152
- classification of, 151t
- clinical manifestations of, 152
- complications of, 154
- differential diagnosis of, 153

- dissociative, [152](#)
 - clinical manifestations of, [152](#)
- distributive, [151–152](#)
 - clinical manifestations of, [152](#)
- epidemiology of, [151](#)
- etiology of, [151](#)
- hypovolemic, [151](#)
 - clinical manifestations of, [152](#)
- laboratory and imaging studies of, [152–153](#)
- in newborn, [233](#)
- obstructive, [152](#)
 - clinical manifestations of, [152](#)
- prevention of, [154](#)
- prognosis for, [154](#)

Short bowel syndrome, parenteral nutrition for, [130–131](#)

Short-chain acyl-CoA dehydrogenase (SCAD) deficiency, [207](#), [207f](#)

Short stature, [650–656](#), [679](#)

- caused by growth hormone deficiency, [653–656](#)
- causes of, [652t](#)
- constitutional, [13](#)
- due to constitutional delay, [653](#)
- differential diagnosis and therapy of, [654t](#)
- familial, [13](#)
- genetic or familial, [653](#)
- of nonendocrine causes, [651–653](#)
- psychosocial, [79](#)

Shortness of breath, due to heart failure, [535](#)

Shoulder, [763](#)

- brachial plexus injuries of, [763](#)
- glenohumeral dislocation of, [763](#)
- Little Leaguer's, [763](#)
- overuse injuries of, [763](#)
- proximal humeral epiphysiolysis of, [763](#)
- Sprengel deformity of, [763](#)

Shoulder, drooping of, [683](#)

Shprintzen syndrome, [182–183](#)

Shunts, central nervous system, infections associated with, [438–439](#)

Shwachman-Diamond syndrome, [301t](#)

Sialidosis type I, [210t–212t](#)

Sialidosis type II, [210t–212t](#)

Sickle cell disease, [576–578](#), [592](#)

- clinical manifestations of, [576–577](#), [577t](#)
- etiology and epidemiology of, [576](#), [576t](#)
- genetic basis for, [173t](#)
- laboratory diagnosis of, [577](#)
- treatment of, [577–578](#)

SIDS, [Sudden infant death syndrome](#)

Silent stroke, in sickle cell disease, [577](#)

Silver nitrate instillation, in newborn, [222](#)

Single gene mutations, [169](#)

Single-parent families, [88](#)

Sinus arrhythmia, [542](#)

Sinus rhythm, [542](#)

Sinus tachycardia, [544t](#)

Sinus venosus defect, [546](#)

Sinusitis, [394–395](#)

- chronic, [394](#)
- clinical manifestations of, [394](#)
- complications and prognosis for, [395](#)
- epidemiology of, [394](#)
- etiology of, [394](#)
- laboratory and imaging studies for, [395](#)
- prevention of, [395](#)
- treatment for, [395](#)

Skeletal radiographs, [186](#)

Skeletal tuberculosis, [454](#)

Skewfoot, [754](#)

Skier's nose, [324](#)

Skin

anemia and, [569t](#)

of newborn, [228–229](#)

Skin color, in cardiovascular system assessment, [535](#)

Skin disorder, [721](#)

assessment of, [721](#)

history in, [721](#)

initial diagnostic evaluation and screening tests in, [722–723](#)

physical examination in, [721](#)

common manifestations of, [721–722](#)

with primary lesions, [721](#), [721t](#), [722f](#)

with secondary lesions, [721](#), [722t](#)

Skin lesions

primary, [721](#), [721t](#), [722f](#)

secondary, [721](#), [722t](#)

Skull, of newborn, [229](#)

Skull fractures, [710](#)

in newborn, [233–234](#)

Slapped cheek rash, [377](#)

SLE, [Systemic lupus erythematosus](#)

Sleep, normal, [52–56](#)

Sleep disturbances, in attention-deficit/hyperactivity disorder (ADHD), [47](#)

Sleep-onset association subtype, behavioral insomnia of childhood, [55](#)

Sleep position, [23t–24t](#)

Sleep terrors, [54t–55t](#)

Sleepwalking, [54t–55t](#)

Slipped capital femoral epiphysis, [747–748](#)

classification of, [747](#)

clinical manifestation of, [747](#)

complications of, [747–748](#)

etiology and epidemiology of, [747](#)

radiological evaluation for, [747](#), [748f](#)

treatment of, [747](#)

Slow to warm up child, [16](#)

Sly syndrome, [210t–212t](#), [711t–712t](#), [713](#)

Small bowel biopsy, for celiac disease, [489–490](#)

Small for gestational age (SGA), [239–240](#)

complications of, [220t](#), [228](#)

management of, [239–240](#)

Small molecule pathway inhibitors, for cancer, [601t–602t](#)

SMART goals, [109](#)

Smell, assessment of, [683](#)

Smooth muscle hamartoma, [730t](#)

Sniffing position, in epiglottitis, [399](#)

Social anxiety disorder, [63](#), [64t](#)

Social aspects, of pediatric practice, [3](#)

Social (pragmatic) communication disorder (SCD), [71](#)

Social disruptions, [54t–55t](#)

Social phobia, [Social anxiety disorder](#)

Social stress, [3](#)

Sodium balance, regulation of, [125](#)

Sodium benzoate, for hyperammonemia, [205](#)

Sodium bicarbonate, [148](#)

for cyclic antidepressants poisoning, [164t–165t](#)

Sodium disorders, [131–134](#)

hypernatremia as, [133–134](#), [133f](#)

hyponatremia as, [131–133](#), [132f](#)

Sodium excretion, [131](#)

Sodium intoxication, [133](#)

Sodium phenylacetate, for hyperammonemia, [205](#)

Sodium restriction, for heart failure, [555t](#)

Sudoku, [439t–442t](#)

Soiling, [49–51](#), [Encopresis](#)

Solid cereals, as complementary food, [101](#)

Somatic pain, in appendicitis, [493](#)

Somatic symptom and related disorders (SSRDs), [59–61](#), [60t](#)

prevalence of, [59](#)

screening tools for, [61](#)

treatment of, [61](#)

Somatostatin, for chronic pancreatitis, [503](#)

Somatostatin release inhibitory factor, [650–651](#)

Somnolence syndrome, central nervous system and, [608](#)

Sorbitol

for functional constipation, [52t](#)

for poisoning, [164](#)

Sotos syndrome, [184–185](#)

Southeast Asian liver fluke, [451t](#)

Southern tick-associated rash illness (STARI), [439t–442t](#), [444](#)

Soy-based formulas, [100–101](#), [102t](#)

Soy protein intolerance, vomiting due to, [473t](#)

Spasmodic croup, [399](#)

Spasms, infantile, [690](#)

Spasticity, [684](#)

Specifiers

for bipolar and related disorders, [67](#)

for depressive disorders, [65](#)

Speculum examination, for adolescents, [274](#)

Speech-language impairment, in child, with special needs, [36–37](#), [36t](#)

Spherocytosis, hereditary

clinical manifestations of, [579](#)

etiology of, [566](#), [578–579](#)

laboratory diagnosis of, [579](#)

treatment of, [579](#)

Sphingolipidoses, [712](#)

Sphingomyelin lipidosis A, [210t–212t](#)

Sphingomyelin lipidosis B, [210t–212t](#)

Sphingomyelinase deficiency, [210t–212t](#)

Spina bifida, [716](#)

occulta, [716](#)

Spinal cord, congenital anomalies of, [716](#)

Spinal cord abnormalities, constipation due to, [476t](#)

Spinal cord compression, oncological emergencies, [600t](#)

Spinal cord injuries, in newborn, [233](#)

Spinal cord injury without radiological abnormality (SCIWORA), [156](#)

Spinal cord lesions, weakness due to, [694](#)

Spinal deformities, [756–757](#)

classification of, [756t](#)

clinical manifestations of, [756–757](#)

kyphosis as, [760](#)

classification of, [756t](#)

congenital, [760](#)

postural roundback, [760](#)

Scheuermann, [760](#), [760f](#)

radiological evaluation of, [757](#), [758f](#)

scoliosis as, [Scoliosis](#)

Spinal dysraphism, [756–758](#)

Spinal muscular atrophy, [683](#), [694–695](#)

clinical manifestations of, [694](#)

etiology of, [694](#)

laboratory and diagnostic studies for, [694–695](#)

treatment for, [695](#)

Spine, [756–762](#)

back pain of, [761](#), [761t](#)

deformities of, [756–757](#)

classification of, [756t](#)

clinical manifestations of, [756–757](#)

kyphosis as, [760](#)

classification of, [756t](#)

congenital, [760](#)

postural roundback, [760](#)

Scheuermann, [760](#), [760f](#)

radiological evaluation of, [757](#), [758f](#)

scoliosis as, [Scoliosis](#)

diskitis as, [762](#)

of newborn, [231](#)

spondylolysis and spondylolisthesis of, [761–762](#)

torticollis of, [760–761](#)

Spirillum minus, [439t–442t](#)

Spirochetal diseases, zoonotic, [439t–442t](#)

Spirometry, [511](#)

for asthma, [313–314](#), [316](#)

Spitting up, [480](#)

vomiting vs., [472](#)

Spleen, injury to, [156](#)

Splenectomy, for hereditary spherocytosis, [579](#)

Splenic dysfunction, in sickle cell disease, [576](#)

Splenic infarction, in sickle cell disease, [576](#)

Splenic sequestration crisis, in sickle cell disease, [576](#)

Splenomegaly, in anemia, [567–568](#)

Spondylitis, juvenile ankylosing, [351t](#)

Spondyloarthropathies, [351](#), [351t](#)

Spondylolisthesis, [761–762](#)

classification of, [762](#)

clinical manifestations of, [762](#)

etiology and epidemiology of, [761–762](#)

radiological evaluation of, [762](#)

treatment of, [762](#)

Spondylolysis, [761–762](#)

clinical manifestations of, [762](#)

etiology and epidemiology of, [761–762](#)

radiological evaluation of, [762](#)

treatment of, [762](#)

Spontaneous bacterial peritonitis, [504](#)

Spontaneous bleeding, [587](#)

Spontaneous mutation, [171](#)

Spontaneous primary pneumothorax, [530](#)

Spore-forming intestinal protozoa, diarrhea from, [410t](#)

Sporogony, of *Plasmodium* life cycle, [447](#)

Spot urine protein/creatinine, [620](#)

Sprengel deformity, [763](#)

Spur cells, [580](#)

Sputum, examination of, [511–512](#)

Square window wrist, in newborn, [229f](#)

SSPE (subacute sclerosing panencephalitis), [375](#)

St. Vitus dance, due to rheumatic fever, [556](#)

Stage MS, neuroblastoma, [609](#)

Stanozolol, for C1-inhibitor deficiency, [306](#)

Staphylococcal scalded skin syndrome, [734t](#), [735](#)

Staphylococcus aureus

in cystic fibrosis, [527](#)

osteomyelitis from, [425](#)

subacute focal, [425–426](#)

treatment of, [427](#)

pneumonia from, [407t](#)

Starvation, [79](#)

Static neurological abnormalities, [681](#)

Stature

with developmental disabilities, [30t](#)

growth chart of, [12f](#)

Status asthmaticus, [316](#)

Status epilepticus, [690–691](#)

management of, [691t](#)

Steatorrhea, in cystic fibrosis, [527](#)

Steeple sign, in croup, [399](#)

Steinert disease, genetic basis for, [170t](#)

STEP guide, for adolescent interviewing, [267](#), [270f](#)

Stepped down therapy, for asthma, [316](#), [317f–318f](#)

Stepped up therapy, for asthma, [316](#), [317f–318f](#)

Stepwise approach, to asthma management, [316](#), [317f–318f](#)

Stereognosis, [684](#)

Sternocleidomastoid muscles, during inspiration, [507](#)

Steroid hormones, [637](#)

Steroidal contraception, [278–281](#)

combined hormonal contraceptives for, [279–280](#), [279t–280t](#)

contraceptive patch for, [279–280](#)

contraceptive vaginal ring for, [279–280](#)

hormonal injections and implants for, [278–279](#)

long-acting reversible contraceptives for, [278–279](#)

progesterone-only pill or minipill for, [280](#)

Stertor, [516](#)

Stevens-Johnson syndrome (SJS), [733–735](#), [734t](#)

Stilbestrol, as teratogen, [237t](#)

Still's murmur, [538t](#)

Stimson line, in measles, [373–374](#)

Stimulants

for attention-deficit/hyperactivity disorder (ADHD), [47](#)

for autism spectrum disorder (ASD), [71](#)

for bipolar disorders, [68](#)

for functional constipation, [52t](#)

Stimulation, appropriate, [91](#)

Stinger, [763](#)

STIs, [Sexually transmitted infections](#)

Stomach disorders, [480–487](#)

peptic disease as, [485–486](#), [486t](#)

pyloric stenosis as, [484–485](#), [485f](#)

Stool, of breast-fed infant, [99–100](#)

Stool impaction, in functional constipation, [49](#)

Stool softener, for functional constipation, [476](#)

Stop codons, [169](#)

Storage disorders, [196](#)

caused by defective synthesis of lysosomal membrane, [210t–212t](#)

caused by defects in lysosomal proteolysis, [210t–212t](#)

caused by dysfunction of lysosomal transport proteins, [210t–212t](#)

Stork bite, [733](#)

Stranger anxiety, [15](#)

Strawberry tongue

in Kawasaki disease, [347](#)

red, [393](#)

white, [393](#)

Strength, in motor examination, [684](#)

Streptobacillus moniliformis, [439t–442t](#)

Streptococcal carriage, [393](#)

Streptococcal infection

in OCD, [68](#)

in rheumatic fever, [556](#)

Streptococcal pharyngitis, [392–394](#)

causes of, [392t](#)

clinical manifestations of, [392–393](#)

complications and prognosis of, [394](#)

differential diagnosis of, [393](#)

Subconjunctival hemorrhage, in newborn, [233](#)

Subcutaneous nodules, due to heart failure, [556](#), [556t](#)

Subdural hematoma, in newborn, [256–257](#)

Subdural hemorrhages, [709–710](#)

- due to child abuse, [81](#), [82f](#)
- in newborn, [256–257](#)

Subependymal giant cell astrocytomas, [715](#)

Subependymal nodules, [715](#)

Subgaleal bleed, in newborn, [233](#)

Subglottic hemangioma, [732–733](#)

Subglottic space, [507](#)

Subglottic stenosis, [518–519](#)

Subluxation, [739t](#)

Substance abuse

- by adolescents, [2](#), [283–284](#), [284t](#)
 - acute and chronic effects of, [284](#)

acute overdose due to, [284](#), [284t–285t](#)

treatment for, [284](#)

maternal, during pregnancy, [90](#)

Substance/medication-induced psychotic disorders, [72](#)

Substernal retractions, [509–510](#)

Succimer acid, for lead poisoning, [164t–165t](#)

Succinylacetone, urine or blood, [199t](#)

Sucking reflex, [14](#)

Sudden infant death syndrome (SIDS), [515–516](#)

differential diagnosis of, [516t](#)

etiology and epidemiology of, [515](#)

with medium-chain acyl-CoA dehydrogenase deficiency, [207–208](#)

prevention of, [515–516](#)

Sufentanil, as analgesia, [166t](#)

Suffocation, fatal injury due to, [154](#)

Suicide, in bipolar disorders, [68](#)

Sulfadiazine, [449](#)

Sulfasalazine, for ulcerative colitis, [491](#)

Sulfatases deficiency, [210t–212t](#)

Sulfonamides, maternal use of, [238t](#)

Sulfonylurea, maternal use of, [238t](#)

Superficial infections

bacterial, [379–380](#)

cellulitis as, [380](#)

folliculitis as, [380](#)

impetigo as, [379–380](#)

perianal dermatitis as, [380](#)

fungal, [380–381](#), [381t](#)

viral, [381–383](#)

from herpes simplex virus as, [381–382](#)

from human papillomaviruses (warts), [382](#)

molluscum contagiosum as, [383](#)

Superior vena cava syndrome, oncological emergencies, [600t](#)

Supplemental oxygen, [512](#)

Supportive care

for cancer, [601](#)

for poisoning, [163–164](#)

for Stevens-Johnson syndrome and toxic epidermal necrolysis, [735](#)

Suppurative bursitis, [429](#)

Supraclavicular retractions, [509–510](#)

Supracondylar fracture, [743](#)

Supracristal septum, [545](#)

Supraventricular tachycardia (SVT), [543](#), [544t](#)

Surfactant, [219–220](#)

Susceptibilities, to antiinfective drugs, [367](#)

Sutures, of newborn, [229](#)

Swallowing study, videofluoroscopic, [520](#)

Sweat test, for cystic fibrosis, [528](#), [528t](#)

Swimmer's ear, [397–398](#), [Otitis externa](#)

Swinging flashlight test, [683](#)

Swyer-James syndrome, [407](#)

Sydenham chorea, due to rheumatic fever, [556](#), [556t](#)

Sympathomimetics

maternal use of, [238t](#)

toxicity, [162t](#)

Symptomatic hyponatremia, [133](#)

Synchronized cardioversion, for dysrhythmias, [543–544](#)

Syncope, [540–541](#), [706](#)

cardiac, [541t](#)

carotid sinus, [541t](#)

- clinical manifestations of, [540–541](#)
- cough (deglutition), [541t](#)
- diagnostic studies for, [541](#)
- etiology of, [540](#), [541t](#)
- micturition, [541t](#)
- neurocardiogenic (vasopressor), [541t](#)

Syndactyly, [183t](#), [185](#)

- of finger, [765](#)
- of toes, [755](#), [756t](#)

Syndrome of inappropriate antidiuretic hormone (SIADH), [132](#)

Synergism, of antimicrobial drugs, [367–368](#)

Synophrys, [183t](#)

Synovial fluid findings, in various joint diseases, [429t](#)

Synovitis

- in juvenile idiopathic arthritis, [349](#)
- in rheumatic diseases, [343](#)
- toxic or transient, [428](#)
- transient monoarticular, [746](#)
 - clinical manifestations and evaluation of, [746](#), [746t](#)
 - etiology and epidemiology of, [746](#)
 - treatment for, [746](#)

Syphilis (*Treponema pallidum*), [419](#), [423–424](#)

- clinical features of, [421t](#)
- congenital, [262–263](#), [423](#)
- latent, [423](#)
- neuro-, [424](#)
- primary, [423](#)
- secondary, [423](#)
- tertiary, [423](#)

Syrup of ipecac, for poisoning, [164](#)

Systematic ignoring, for pediatric sleep disorders, [56](#)

Systemic capillary leak, due to burns, [159](#)

Systemic diseases, cardiac manifestations of, [536t](#)

Systemic inflammatory response syndrome (SIRS), [151–152](#)

Systemic lupus erythematosus (SLE), [353–355](#)

clinical manifestations of, [353](#), [353t–354t](#)

complications of, [355](#)

differential diagnosis of, [344t](#), [355](#)

epidemiology of, [353](#)

etiology of, [353](#)

laboratory and imaging studies for, [354–355](#)

maternal, [236](#), [236t](#)

prognosis for, [355](#)

synovial fluid findings in, [429t](#)

treatment of, [355](#)

Systolic murmurs, [536](#)

ejection, [536](#)

due to aortic stenosis, [548](#)

in total anomalous pulmonary venous return, [552](#)

in truncus arteriosus, [551](#)

T

T-cell proliferation, [293](#)

T cells, [289–290](#)

Tachycardia

due to respiratory failure, [149](#)

sinus, [544t](#)

supraventricular, [543](#), [544t](#)

ventricular, [543](#), [544t](#)

Tachypnea, [509t](#)

due to heart failure, [535](#)

due to respiratory failure, [149](#)

transient, of newborn, [222](#)

Tacrolimus, for atopic dermatitis, [327–328](#)

Taenia solium, [452](#), [452t](#)

Talipes equinovarus, [753–754](#), [753f](#)

Tanner stages

in boys, [271–273](#), [272f](#)

in girls, [270–271](#), [271f–272f](#)

Tantrums, [43–45](#), Temper tantrums

anticipatory guidance and management of, [45](#)

clinical manifestations of, [43–44](#), [44f](#), [44t](#)

differential diagnosis of, [44–45](#)

epidemiology of, [43](#)

etiology of, [43](#)

physical examination for, [44](#)

Tapeworm

echinococcosis from, [452](#)

neurocysticercosis from, [452](#)

Tardive dyskinesia, [703](#)

Target lesions, in erythema multiforme, [735](#)

Targeted therapies, for cancer, [601](#)

Tarsal coalition, [754–755](#)

calcaneonavicular, [754–755](#)

clinical manifestations of, [755](#)

radiological evaluation of, [755](#)

talocalcaneal, [754–755](#)

treatment of, [755](#)

Tarsal navicular, idiopathic avascular necrosis of, [755](#)

Tarui disease, [200t](#)

Tay-Sachs disease, [210t–212t](#), [711t–712t](#), [712](#)

Tazarotene, for acne, [723](#)

Teeth

deciduous (primary), [479](#), [479t](#)

eruption of, [479](#), [479t](#)

delayed, 479

natal, 479

permanent, 479t

TEF, [Tracheoesophageal fistula](#)

Telangiectasia, [721t](#)

with developmental disabilities, [30t](#)

Telecanthus, [183t](#)

Teloradiograph, of leg-length discrepancy, [750](#)

Temper tantrums, [43–45](#)

anticipatory guidance and management of, [45](#)

clinical manifestations of, [43–44](#), [44f](#), [44t](#)

differential diagnosis of, [44–45](#)

epidemiology of, [43](#)

etiology of, [43](#)

physical examination for, [44](#)

Temperament, [16](#)

Temperature instability, in infants younger than 3 months of age, [368](#)

Temperature regulation, in newborn, [234](#)

Tender points, in myofascial pain syndromes, [358](#)

Tension pneumothorax, [530](#)

Tension-type headaches, [686](#)

Teratogenic agents, [176–177](#)

Teratoma, sacral, constipation due to, [476t](#)

Tertian periodicity, of *P. vivax* and *P. ovale*, [447](#)

Tertiary survey, of trauma patient, [155](#)

Testes

detorsion and fixation of, [633](#)

undescended, [632](#)

Testosterone-like drugs, as teratogens, [237t](#)

Tet spells, [550](#)

Tetanus, prophylaxis for, [366](#), [367t](#)

Tetanus and diphtheria toxoids and acellular pertussis (Tdap) vaccine, [364f–365f](#)

Tetanus vaccine, [363–364](#)

Tetany, neonatal, [235](#)

Tethered cord, constipation due to, [476t](#)

Tetracycline

for acne, [723](#)

as teratogen, [237t](#)

Tetralogy of Fallot, [549–550](#), [550f](#)

TGF- β (transforming growth factor- β), functions of, [290t](#)

Thalassemia(s), [591](#)

α -Thalassemia minor, [571](#), [575](#)

β -Thalassemia major, [575–576](#)

β -Thalassemia minor, [571](#)

Thalassemia minor, in hypochromic, microcytic anemia, [571](#)

etiology and epidemiology of, [571](#), [572f](#), [572t](#)

laboratory testing for, [571](#)

treatment of, [571](#)

Thalidomide, as teratogen, [237t](#)

Thanatophoric dysplasia, [170t](#)

Thelarche, [270–271](#), [656](#)

isolated premature, [663](#)

Theophylline, for asthma, [315](#)

Thermal environment, neutral, of newborn, [234](#)

Thiamine deficiency, [113](#), [114t](#)

Thiazides, maternal use of, [238t](#)

Thigh-foot angle, [749](#), [749f](#)

Thin basement membrane disease, [622–623](#)

Third-degree heart block, [543](#)

Third heart sound (S₃), [536](#)

Third space losses, [127](#)

Thoracic scoliosis, [529](#)

Thoracoscopic procedure, [512](#)

Thoracotomy, [512](#)

Threats, by parents, [25](#)

Threshold, in hypertrophic pyloric stenosis, [174–175](#)

Throat culture, for streptococcal pharyngitis, [393](#)

Thrombin, in hemostasis, [580](#)

Thrombin time, [584t](#)

Thrombocytopenia, [583](#)

- bleeding disorder in newborn due to, [254](#)
- due to decreased platelet production, [584](#)
- in hemolytic uremic syndrome, [624](#)
- isoimmune
 - maternal, [236t](#)
 - in newborn, [254](#)
- maternal
 - idiopathic purpura, [235–236, 236t](#)
 - isoimmune, [236t](#)
- oncological emergencies, [600t](#)
- due to peripheral destruction, [584](#)
- presentation of, [564t](#)

Thrombocytopenia with absent radii syndrome, [584](#)

Thrombocytopenic purpura

- idiopathic, [Idiopathic thrombocytopenic purpura](#)
- neonatal alloimmune, [584](#)
- thrombotic, [585–586, 624](#)
 - in thrombotic microangiopathy, [580](#)

Thromboembolism, in nephrotic syndrome, [621](#)

Thrombophlebitis, [437](#)

septic, [437](#)

Thrombopoietin, [566](#)

Thrombosis, [589](#), [593](#)

catheter-related, [437](#)

clinical manifestations of, [589](#)

diagnostic and imaging studies in, [589](#)

etiology of, [589](#), [589f](#)

presentation of, [564t](#)

treatment of, [589](#)

Thrombotic microangiopathy, [580](#), [585–586](#)

Thrombotic thrombocytopenic purpura, [585–586](#), [624](#)

in thrombotic microangiopathy, [580](#)

Thrush, [480](#)

Thumb, trigger, [765](#)

Thumb sign, in epiglottitis, [399](#)

Thyroid disease, [665–668](#), [680](#)

hypothyroidism, [665–667](#)

laboratory results of, [665t](#)

physiology and development of, [663–665](#)

Thyroid hormone, and GH secretion, [651](#)

Thyroid tumors, [668](#)

Thyrotropin-releasing hormone (TRH), [663](#)

Thyroxine (T₄), [663](#)

Thyroxine-binding globulin, [664](#)

Tonic neck reflex, [682](#)

Tonsillar hypertrophy, [519](#)

Tonsillitis, [393](#)

Tonsillopharyngitis, [393](#)

Toothbrush, introduction of, [102](#)

Topoisomerase inhibitors, for cancer, [601t–602t](#)

Topotecan, for cancer, [601t–602t](#)

TORCH infection(s), [259–264](#), [260t](#)

Torticollis, [760–761](#)

Torus fracture, [742](#)

Total anomalous pulmonary venous return, [552](#), [552f](#)

Total body surface area, [159](#)

Total body water (TBW), [125](#), [126f](#)

Total lung capacity (TLC), [507–508](#), [508f](#)

Tourette syndrome, [703](#)

Toxemia

- of pregnancy, [218](#)
- in thrombotic microangiopathy, [580](#)

Toxic epidermal necrolysis (TEN), [733–735](#), [734t](#)

Toxic ingestions, metabolic acidosis due to, [140](#)

Toxic megacolon, [490](#)

Toxic stress, [2](#)

Toxic syndromes, [162t](#)

Toxic synovitis, [428](#), [746](#), [746t](#)

Toxocara canis, [450–451](#), [450t](#)

Toxocara cati, [450–451](#), [450t](#)

Toxoids, for immunization, [363–364](#)

Toxoplasma gondii, [439t–442t](#), [449](#)
congenital infection with, [259–261](#)
in immunocompromised person, [434–435](#)

Toxoplasmosis, [439t–442t](#), [449](#)
congenital infection with, [260t](#), [261](#)

Trachea, [507](#)

Tracheal compression
extrinsic, [521](#), [521f](#)
oncological emergencies, [600t](#)

Tracheitis, bacterial, [399](#)
upper airway obstruction due to, [517t](#)

Tracheoesophageal fistula (TEF), [227t](#), [483](#), [521](#)
clinical manifestations of, [483](#), [483f](#)
complications with, [483](#)
etiology and epidemiology of, [483](#)
laboratory and imaging studies for, [483](#)
treatment and prognosis for, [483](#)

Tracheomalacia, [520–521](#)

Tracheostomy, [513](#)

Traffic light diet, [107–108](#)

Tranquilizers, acute effects of, [284t–285t](#)

Transcellular shift, of potassium, [135](#)

Transcription, [169](#)

Transcutaneous electrodes, for respiratory gas exchange measurements, [511](#)

Transesophageal echocardiography (TEE), in cardiovascular system assessment, [540](#)

Transforming growth factor- β (TGF- β)

functions of, [290t](#)

in Marfan syndrome, [171](#)

Transfusion, [589–590](#)

for autoimmune hemolysis, [580](#)

commonly used, [590t](#)

reactions of, evaluation of, [590t](#)

Transgender, [84t](#), [87](#)

Transient aplastic crisis, erythema infectiosum and, [377](#)

Transient erythroblastopenia, [573t](#)

of childhood, [573–574](#)

Transient hypogammaglobulinemia of infancy as, [295](#), [295t](#)

Transient hypoparathyroidism, [669](#)

Transient monoarticular synovitis, [746](#), [746t](#)

Transient myeloproliferative disorder, [604](#)

Transient neonatal hypocalcemia, [669](#)

Transient synovitis, [428](#)

Transient tachypnea of the newborn, [222](#), [245](#)

Transplantation, for heart failure, [555t](#)

Transposition, of great arteries, [550–551](#), [550f](#)

Transtentorial (central) herniation, [705–706](#)

Transudates, [530–531](#)

Transverse myelitis, [694](#)

Trauma, [155–157](#), [Injury\(ies\)](#)

abdominal, [156](#)

assessment and resuscitation for, [155](#)

clinical manifestations of, [156–157](#)

- complications of, [157](#)
- epidemiology of, [155](#)
- etiology of, [155](#)
- head, [156](#)
- informed care, [93](#)
- intestinal, [157](#)
- laboratory and imaging studies of, [155](#), [156t](#)
- liver, [156](#)
- orthopedic problem due to, [739t](#)
- pancreatic, [157](#)
- prevention of, [157](#)
- prognosis for, [157](#)
- renal, [156–157](#)
- spleen, [156](#)
- thoracic, [156](#)
- treatment of, [156–157](#)

Traumatic brain injury

- due to cervical spine injuries, [710](#)
- concussion in, [709](#), [709t](#)
- due to CSF leak, [710](#)
- disorders of consciousness due to, [703](#), [709–711](#)
- drowsiness, headache, and vomiting after, [710](#)
- evaluation and treatment for, [710](#)
- Glasgow Coma Scale for, [710](#)
- intracranial hemorrhage in, [709–711](#), [709t](#)
- due to posttraumatic seizures, [710](#)
- prognosis for, [710–711](#)
- due to skull fractures, [710](#)

Traumatic intracranial hemorrhage, [709–711](#), [709t](#)

Traveler's diarrhea, [411](#), [413](#)

Trematodes, parasitic, pediatric syndromes caused by, [451t](#)

Tremor, [703](#)

Trench fever, [737](#)

Trench mouth, [393](#)

Trendelenburg gait, [740](#)

Treponema pallidum, [419](#), [423–424](#)
congenital infection with, [260t](#)

Treponemal antibody tests, [424](#)

Tretinoin (vitamin A analog)
for acne, [723](#)
for cancer, [601t–602t](#)

Triad asthma, [321t](#)

Triamcinolone acetonide, for asthma, [319f](#)

Triatoma bites, anaphylaxis due to, [333](#)

Trichinella spiralis, [450t](#)

Trichinellosis, [450t](#)

Trichomonas vaginalis, [419](#), [424–425](#)

Trichuris dysentery, [450t](#)

Tricuspid atresia, [551](#), [551f](#)

Trifunctional protein, in fatty acid catabolism, [207](#), [207f](#)

Trigeminal nerve, assessment of, [683](#)

Triiodothyronine (T₃), [663](#)

Trimethadione, as teratogen, [237t](#)

Trimethoprim-sulfamethoxazole (TMP-SMX)
for HIV, [461](#)
for pertussis, [401](#)

Trinucleotide repeat, expansion of, [176](#)

Triptans, for migraine, [687](#)

Trisomic rescue, [180](#)

Trisomy(ies), [180–181](#)
Down syndrome as, [180](#)

Klinefelter syndrome as, [181](#)

trisomy 13 as, [180–181](#)

trisomy 18 as, [180](#), [181t](#)

Trisomy 13, [180–181](#)

Trisomy 18, [180](#), [181t](#)

Trisomy 21, newborn assessment for, [227t](#)

Trochlear nerve, assessment of, [683](#)

Trophozoite, of *Plasmodium* life cycle, [447](#)

Trousseau sign, [235](#), [669](#)

Truncal ataxia, [700](#)

Truncus arteriosus, [551–552](#), [551f](#)

Trunk, congenital malformations of, [185](#)

Trunk incurvation reflex, [682t](#)

Trypanosoma brucei gambiense, [439t–442t](#)

Trypanosoma brucei rhodesiense, [439t–442t](#)

Trypanosoma cruzi, [439t–442t](#)

congenital infection with, [260t](#)

Trypanosomiasis

African, [439t–442t](#)

American, [439t–442t](#)

Trypsin, [502](#)

Tryptophan, [113](#)

Tubercle bacilli, [453–454](#)

Tuberculin skin test, [454t–455t](#)

Tuberculosis, [452–457](#)

abdominal, [454](#)

clinical manifestations of, [453–454](#)

complications and prognosis of, [457](#)

diagnosis of

- culture for, [454–455](#)
- imaging in, [455](#), [456f](#)
- tuberculin skin test for, [454t–455t](#)
- differential diagnosis of, [455](#)
- epidemiology of, [453](#)
- etiology of, [452](#)
- extrapulmonary, [455](#)
- laboratory and imaging studies for, [454–455](#)
- latent, [453](#)
- miliary, [453](#)
- prevention of, [457](#)
- primary progressive, [453](#)
- pulmonary
 - primary, [453](#)
 - reactivation, [453](#)
- skeletal, [454](#)
- synovial fluid findings in, [429t](#)
- transmission of, [453](#)
- treatment for, [455–456](#), [457t](#)
- urogenital, [454](#)

Tuberculous meningitis, [387t](#), [453–454](#)

Tuberculous peritonitis, [454](#)

Tuberculous pleural effusion, [453](#)

Tuberous sclerosis

- complex, [715](#)

- infantile spasms due to, [690](#)

Tubers, [715](#)

Tubular function, [617](#)

Tubulin inhibitors, for cancer, [601t–602t](#)

Tularemia, [439t–442t](#)

Tumor(s), [721](#)

- orthopedic problem due to, [739t](#)

- of skin, [721t](#), [722f](#)

syncope due to, [541t](#)

of thyroid, [668](#)

Tumor lysis syndrome, [599](#), [600t](#)

Tunnel infection, [437](#)

Turner syndrome, [181–182](#), [653](#), [673](#)

amenorrhea due to, [275](#)

obesity in, [106t](#)

Twin-to-twin transfusion syndrome, [218](#)

Twinning, [218](#)

Two-point discrimination, [684](#)

TYK2 gene, in hyper-IgE syndrome, [299](#)

Tympanic membranes, of newborn, [230](#)

Tympanic perforation, otitis media with, [398](#)

Tympanocentesis, for otitis media, [396–397](#)

Tympanogram, for otitis media, [396](#)

Tympanometry, [36](#)

for otitis media, [396](#)

Tympanostomy tube otorrhea, [398](#)

Tympanostomy tubes, otitis externa and, [397–398](#)

Typhus

endemic

flea-borne, [439t–442t](#)

louse-borne, [439t–442t](#)

epidemic, [737](#)

Typical syncopal events, [540–541](#)

Tyrosinemia(s)

neonatal screening for, [198t](#)

type I, [202](#)

type II, [202–203](#)

type III, [202–203](#)

Tzanck test, [726](#)

U

UBE3A gene, in Angelman syndrome, [176](#)

UC, [Ulcerative colitis](#)

Ulcer(s), [722t](#)

duodenal, abdominal pain due to, [470t](#)

genital, [419](#), [421t](#)

peptic, [485–486](#)

pill, [484](#)

Ulcerative colitis (UC), [490t](#), [491](#)

Ultrasonography

of chest, [511](#)

for infectious diseases, [362–363](#)

for infective arthritis, [429](#)

of kidney, [620](#)

for urinary tract infection, [417](#)

Ultraviolet light therapy, for atopic dermatitis, [726](#)

Umbilical arteries, Doppler examination of, [220](#)

Umbilical cord, clamping or milking (stripping) of, [247](#)

Umbilical hernia, [231](#)

Uncal herniation, [705–706](#)

Undernutrition, pediatric, [109–112](#), [110f](#)

complications of, [112](#)

in failure to thrive, [109](#)

kwashiorkor as, [110–111](#)

marasmus as, [110](#)

mixed marasmus-kwashiorkor as, [111](#)

physical signs of, [111t](#)

treatment of, [111–112](#)

Undescended testes, [632](#)

Unicameral bone cyst, [765t–766t](#)

Unilateral hyperlucent lung, [407](#)

Unilateral renal agenesis, [629](#)

Unilocular cyst disease, [452](#)

Unintentional injury, [154](#)

Uniparental disomy, [175](#)

- Angelman syndrome due to, [176](#)
- Prader-Willi syndrome as, [175–176](#)

Unmodified extinction, for pediatric sleep disorders, [56](#)

Unspecified anxiety disorder, [62](#)

Unspecified bipolar and related disorder, [66](#)

Unspecified depressive disorder, [65](#)

Upper airway obstruction, [516–519](#)

- acute, causes of, [517t](#)
- adenoidal and tonsillar hypertrophy, [519](#)
- due to angioedema, [517t](#)
- due to bacterial tracheitis, [517t](#)
- due to choanal stenosis (atresia), [518](#)
- clinical manifestations of, [516](#)
- due to croup (laryngotracheobronchitis), [517t](#)
- diagnostic studies for, [517–518](#)
- differential diagnosis of, [518–519](#)
 - age-related, [516t](#)
- due to epiglottitis, [517t](#)
- etiology of, [516](#)
- due to foreign body, [517t](#)
- due to laryngomalacia, [518](#)
- due to mass lesions, [519](#)
- due to peritonsillar abscess, [517t](#)
- due to retropharyngeal abscess, [517t](#)

- due to spasmodic croup, [517t](#)
- due to subglottic stenosis, [518–519](#)
- supraglottic vs. subglottic, [517t](#)
- due to vocal cord paralysis, [519](#)

Upper extremity, [763–765](#)

- elbow in, [764](#)
 - Panner disease of, [764](#)
 - radial head subluxation of, [764](#), [764f](#)
 - throwing injuries of, [764](#)
- shoulder in, [763](#)
 - brachial plexus injuries of, [763](#)
 - glenohumeral dislocation of, [763](#)
 - overuse injuries of, [763](#)
 - proximal humeral epiphysiolysis of, [763](#)
 - Sprengel deformity of, [763](#)
- wrist and hand in, [765](#)
 - finger abnormalities of, [765](#)
 - fracture of, [765](#)
 - ganglion cysts of, [765](#)

Upper respiratory tract infection, [391–392](#)

- clinical manifestations of, [391](#)
- complications and prognosis for, [391–392](#)
- differential diagnosis for, [391](#)
- epidemiology of, [391](#)
- etiology of, [391](#)
- laboratory and imaging studies for, [391](#)
- prevention of, [392](#)
- treatment for, [391](#)

Upper-to-lower segment ratio, [651](#)

Urea cycle, [204f](#)

Ureaplasma urealyticum, pneumonia from, [403](#)

Urethritis, [419](#)

- nongonococcal, [423](#)

Urinalysis, [619–620](#)

- for urinary tract infection, [417](#)

Urinary anion gap, [617](#)

Urinary ascites, [630](#)

Urinary catheters, infections associated with, [438](#)

Urinary concentrating capacity, [617–618](#)

Urinary schistosomiasis, [451t](#)

Urinary tract

congenital and developmental abnormalities of, [629–630](#)

etiology and epidemiology of, [629–630](#)

and genital disorders, [631–633](#)

Urinary tract infection (UTI), [416–417](#)

clinical manifestations of, [416](#)

common manifestations of, [618](#)

complications and prognosis of, [417](#)

differential diagnosis, [417](#)

epidemiology of, [416](#)

etiology of, [416](#)

fever due to, [368](#)

laboratory and imaging studies in, [416–417](#)

prevention of, [417](#)

treatment of, [417](#)

urinary catheters and, [438](#)

vomiting due to, [473t](#)

Urinary tract obstruction, [630](#)

clinical manifestations of, [630](#)

diagnostic imaging of, [630](#)

site and etiology of, [630t](#)

treatment of, [630](#)

Urinary tract stones, [631](#)

Urine amino acid profile, [199t](#)

Urine culture, for urinary tract infection, [417](#)

Urine output, water loss and, [127](#)

Urine specific gravity, in dehydration, [128](#)

Urogenital tuberculosis, [454](#)

Urolithiasis, [623](#), [631](#)

abdominal pain due to, [470t](#)

Urology assessment, [617–620](#)

common manifestations in, [618](#), [618t](#)

history in, [617](#)

laboratory studies in, [619–620](#)

physical examination in, [617](#)

Urticaria, [328–332](#)

acute, [328](#), [329t](#), [335t–336t](#)

cholinergic, [329](#)

chronic, [328–329](#), [329t](#)

clinical manifestations of, [330](#), [330f](#)

cold, [329](#)

differential diagnosis of, [331](#)

epidemiology of, [330](#)

etiology of, [328](#), [329t](#)

laboratory and imaging studies for, [330–331](#), [331t](#)

physical, [328–329](#)

pigmentosa, vesiculobullous eruptions due to, [734t](#)

prevention of, [331–332](#)

treatment of, [331](#)

Urticarial rash, infections with fever and, [373t–374t](#)

Urticarial vasculitis, [331](#)

Uterine abnormalities, intrauterine growth restriction and small for gestational age due to, [239t](#)

Uterine compression, deformation abnormalities resulting from, [741f](#)

UTI, [Urinary tract infection](#)

Uveitis

anterior, [433t](#)

in juvenile idiopathic arthritis, [350](#)

posterior, [433t](#)

V

V/Q (ventilation-perfusion) matching, [508](#)

V/Q (ventilation-perfusion) mismatching, [508](#), [508t](#)

Vaccine Adverse Event Reporting System (VAERS), [366](#)

Vaccines and vaccinations, [363–364](#)

catch-up schedules for, [365f](#)

contraindications to, [365–366](#)

informed consent for, [365](#)

recommended schedules for, [364f](#)

VACTERL association, [184](#)

tracheoesophageal fistula and, [483](#)

VAERS (Vaccine Adverse Event Reporting System), [366](#)

Vagal maneuvers, [543–544](#)

Vaginal bleeding, during pregnancy, [217](#)

Vaginal discharge, physiological, [419](#), [422t](#)

Vaginal sponge, [280](#)

Vaginitis

due to *Gardnerella vaginalis*, [417–418](#)

nonspecific, [417–418](#)

vulvo-, [Vulvovaginitis](#)

Vaginosis, bacterial, [417–418](#), [418t](#), [422t](#)

Valacyclovir

for herpes simplex virus infection, [424](#)

for varicella zoster virus, [379](#)

Valgum, [739t](#)

Valgus, [739t](#)

Valine, metabolism of, [203f](#)

Valproate, as teratogen, [237t](#)

Valproic acid, for status epilepticus, [691](#), [691t](#)

Value differences, ethical problems due to, [4](#)

Vanillylmandelic acid, in neuroblastoma, [609](#)

Variable expressivity, [171](#)

Varicella, vesiculobullous eruptions due to, [734t](#)

Varicella vaccine, [363–364](#), [364f–365f](#)

Varicella-zoster immunoglobulin (VZIG), [379](#)
in immunocompromised person, [437](#)

Varicella-zoster virus infection (chickenpox and zoster), [378–379](#)
clinical manifestations of, [378](#)
complications and prognosis of, [379](#)
congenital infection with, [260t](#)
differential diagnosis of, [378–379](#)
epidemiology of, [378](#)
etiology of, [378](#)
in immunocompromised person, [435](#)
laboratory and imaging studies for, [378](#)
prevention of, [379](#)
treatment of, [379](#)

Varices, esophageal, [497](#)
gastrointestinal bleeding due to, [477t](#)

Varum, [739t](#)

Varus, [739t](#)

Vascular anomalies, [732–733](#)

Vascular catheters, infections associated with, [437](#)

Vascular device infections, [437–438](#)

Vascular malformation(s), [733](#)
defined, [732](#)
port-wine stain (nevus flammeus) as, [733](#), [733f](#)

pyogenic granuloma as, [733](#)
salmon patch stain (nevus simplex) as, [733](#)

Vascular ring, extrinsic tracheal compression due to, [521](#)

Vasculitis

angioedema vs., [331t](#)
in rheumatic diseases, [343](#)
urticarial, [331](#)

Vasoactive substances, [146–147](#)

Vasoconstriction, hypoxic pulmonary, [508](#)

Vasomotor rhinitis, [324](#)

Vasooclusive painful events, in sickle cell disease, [576](#)

Vasopressin, in renal function, [617](#)

Vasopressor syncope, [541t](#)

VUCUG (voiding cystourethrogram), for urinary tract infection, [417](#)

Vector borne infection, [439–447](#)

Vegetation, in infective endocarditis, [408](#)

Velocardiofacial syndrome, [182–183](#), [298](#)

Venereal Disease Research Laboratory (VDRL) test, [424](#)

Venom immunotherapy, for insect allergies, [334](#)

Venous hum, [538](#), [538t](#)

Venous malformation, differential diagnosis of, [730t](#)

Ventilation, [147](#)

Ventilation-perfusion (V/Q) matching, [508](#)

Ventilation-perfusion (V/Q) mismatching, [508](#), [508t](#)

Ventilator-associated pneumonia, [438](#)

Ventricular contractions, premature, [543](#), [544t](#)

Ventricular dysrhythmias, [543](#)

Ventricular fibrillation, [544t](#)

Ventricular function curve, [553](#), [554f](#)

Ventricular septal defect, [545–546](#), [545f](#)

clinical manifestations of, [545](#)

etiology and epidemiology of, [545](#)

imaging studies for, [545](#)

perimembranous, [545](#)

in tetralogy of Fallot, [549](#)

treatment of, [545–546](#)

tricuspid atresia with, [551f](#)

Ventricular tachycardia, [543](#), [544t](#)

Ventriculoperitoneal shunt, for hydrocephalus, [708](#)

Vernix caseosa, [228](#)

Verruca

plana, [382](#)

vulgaris, [382](#)

Vertebral osteomyelitis, [426](#)

Vertical transmission, of HIV, [458](#)

Very long chain acyl-CoA dehydrogenase (VLCAD) deficiency, [207](#), [207f](#)

neonatal screening for, [198t](#)

Very low birth weight (VLBW) infants, [219](#)

Vesicle, [721t](#), [722f](#)

Vesicoureteral reflux (VUR), [628–629](#)

classification of, [629f](#)

clinical manifestations of, [629](#)

complications of, [629](#)

diagnostic studies of, [629](#)

etiology and epidemiology of, [628–629](#)

treatment of, [629](#)

Vesicular rash, infections with fever and, [373t–374t](#)

Vesicular stomatitis, [439t–442t](#)

Vesiculobullous eruptions, [734t](#)

Vespid stings, allergic reactions to, [333](#)

Vibratory murmur, [538t](#)

Vibrio cholerae, diarrhea from, [410t](#)

Vibrio parahaemolyticus, diarrhea from, [410t](#)

Video-assisted thoracoscopic surgery (VATS), for pleural effusion, [532](#)

Video endoscopy, for gastrointestinal symptoms, [467](#)

Videofluoroscopic swallowing study, [520](#)

Vinblastine, for cancer, [601t–602t](#)

Vincent angina, [393](#)

Vincristine, for cancer, [601t–602t](#)

Violence, [3](#), [91–93](#)

- dating, [92](#)
- intimate partner, [91](#), [92t](#)
- prevention of, [23t–24t](#)
- technology and, [93](#)
- youth, [92](#)

Viral conjunctivitis, [433t](#)

Viral disease, zoonotic, [439t–442t](#)

Viral gastroenteritis, vomiting due to, [473t](#)

Viral hepatitis, [413–416](#)

- laboratory and imaging studies for, [500t](#)

Viral infections

- asthma and, [315t](#)
- bacterial infections vs., [363t](#), [368–369](#)
- superficial, [381–383](#)
 - from herpes simplex virus as, [381–382](#)
 - from human papillomaviruses (warts), [382](#)
 - molluscum contagiosum as, [383](#)

Viral meningitis, [387t](#)

Viral opportunistic infections, in immunocompromised person, [435](#)

Viral paronychia, [382](#)

Virilization, in the female, [672t](#)

Virus-associated hemophagocytic syndrome, [573t](#)

Visceral larva migrans, [450–451](#), [450t](#)

Visceral pain, in appendicitis, [493](#)

Visceral trauma, in newborn, [234](#)

Vision impairment, in child, with special needs, [33–34](#)

Vision screening, [20](#)

- of children 3 years of age and older, [20](#)
- of infants and toddlers, [20](#)

Visual acuity, [683](#)

Visual evoked response, [34](#)

Vital capacity (VC), [507–508](#), [508f](#)

Vital signs, of newborn, [227](#)

Vitamin A, as teratogen, [237t](#)

Vitamin A analog (tretinoin)

- for acne, [723](#)
- for cancer, [601t–602t](#)

Vitamin A deficiency, [114t](#), [117](#)

Vitamin B₆ deficiency, [113–114](#), [114t](#)

Vitamin B₁₂ deficiency, [114t](#), [116–117](#)

- in anemia, [567f](#)

Vitamin D, [669](#)

- as teratogen, [237t](#)

Vitamin D deficiency, [114t](#), [118](#), [670t](#)

- nutritional, [670](#)

Vitamin D₂, [118](#)

Vitamin D₃, [118](#)

Vitamin deficiencies, [113t](#)

fat-soluble, [114t](#), [117–119](#)

treatment of, [115t–116t](#)

water-soluble, [112–117](#), [114t](#)

Vitamin E deficiency, [114t](#), [117](#), [580](#)

Vitamin K deficiency, [114t](#), [118–119](#), [588](#)

coagulation disorders due to, [253](#)

Vitamin K prophylaxis, for newborn, [222](#)

Vitamin K₁, [118](#)

Vitamin K₂, [118](#)

VLBW (very low birth weight) infants, [219](#)

VLCAD (very long chain acyl-CoA dehydrogenase) deficiency, [207](#), [207f](#)

neonatal screening for, [198t](#)

Vocal cord paralysis, [519](#)

Vocal fremitus, [510t](#)

Voice signs, [510t](#)

Voiding cystourethrogram (VCUG), [620](#), [629](#)

for urinary tract infection, [417](#)

Voiding dysfunction, [631–632](#)

Volume depletion, [129](#)

Volume expansion, [125](#)

Volume overload, [125](#)

Volume status, regulation of, [125](#)

Volvulus, [227t](#)

gastrointestinal bleeding due to, [477t](#)

midgut malrotation with, [487–488](#), [488f](#)

Vomiting, [472–473](#)

- after traumatic brain injury, [710](#)
- cyclic, [472](#)
- differential diagnosis of, [472](#), [473t](#)
- distinguishing features of, [472–473](#)
- treatment of, [473](#)

von Willebrand disease, [581–582](#), [586t](#), [587–588](#)

- clinical manifestations of, [587](#)
- etiology of, [587](#)
- laboratory testing in, [587](#)
- treatment of, [588](#)

von Willebrand factor (VWF)

- antigen, [587](#)
- containing concentrate, [588](#)
- in hemostasis, [580](#)

VP-16, for cancer, [601t–602t](#)

Vulnerable child syndrome, [91](#)

Vulvovaginal candidiasis, [423t](#)

Vulvovaginitis, [417–419](#)

- characteristics of, [418t](#)
- clinical manifestations of, [419](#)
- complications and prognosis of, [419](#)
- differential diagnosis for, [419](#)
- epidemiology of, [418](#)
- etiology of, [417–418](#)
- laboratory and imaging studies for, [419](#)
- prevention of, [419](#)
- treatment for, [419](#)

VUR, [Vesicoureteral reflux](#)

VWF, [von Willebrand factor](#)

VZIG (Varicella-zoster immunoglobulin), [379](#)

- in immunocompromised person, [437](#)

W

Waddling gait, [740](#)

WAGR (Wilms tumor, aniridia, genitourinary anomalies, and mental retardation) syndrome, [182](#)

Wandering atrial pacemaker, [542](#)

Warfarin, for thrombosis, [589](#)

Warts

common, [382](#)

filiform, [382](#)

genital, [382](#), [419](#), [425](#)

clinical features of, [423t](#)

plantar, [382](#)

Wasp stings, allergic reactions to, [333](#)

Water

in body composition, [125](#), [126f](#)

plasma, [125](#)

total body, [125](#), [126f](#)

Water balance, sodium excretion and, [131](#)

Water losses

hyponatremia from, [133](#)

insensible, [126](#)

Water-soluble vitamins, [112–117](#), [114t](#)

Weakness, [692–700](#)

clinical manifestations of, [693t](#)

disorders causing, [693t](#)

etiology of, [692–693](#)

facial and bulbar, [694t](#)

hypotonia without significant, [698–699](#)

limb

distal, [694t](#)

ophthalmoplegia and, [694t](#)

due to lower motor neuron diseases, [694–698](#), [694t](#)

- Duchenne muscular dystrophy as, [696–697](#)
- infant botulism as, [696](#)
- muscle diseases as, [697–698](#)
- myasthenia gravis as, [696](#)
- myotonic dystrophy as, [697](#)
- peripheral neuropathy as, [695–696](#)
- spinal muscular atrophy as, [694–695](#)

malignant hyperthermia, [698](#)

in neonatal and infantile hypotonia, [698–699](#), [698f](#)

proximal, [694t](#)

due to spinal cord lesions, [694](#)

due to stroke, [699–700](#), [699t](#)

due to upper motor neuron diseases, [693–694](#)

- etiology and epidemiology of, [693–694](#)

Weight

- benchmarks for, [11](#), [11t](#)
- growth charts for, [12f](#)

Well child, evaluation of, [19–25](#)

- anticipatory guidance in, [22–25](#), [23t–24t](#)
- dental care in, [22](#)
- fostering optimal development in, [22–25](#)
- immunizations in, [22](#)
- nutritional assessment in, [22](#)
- safety issues in, [22](#)
- screening tests in, [17](#), [20–22](#)
 - for anemia, [20–21](#)
 - for cholesterol, [21](#), [21t](#)
 - for depression, [22](#)
 - hearing and vision, [20](#)
 - for lead, [21](#), [21t](#)
 - newborn, [20](#)
 - for sexually transmitted infection, [21–22](#)
 - for tuberculosis, [21](#), [21t](#)
- topics for, [19](#), [19t](#)

Wenckebach heart block, [543](#), [544t](#)

Werdnig-Hoffmann disease, [694](#)

Wernicke aphasia, [682](#)

Wessel's rule of threes, in colic, [41](#)

West African sleeping sickness, [439t–442t](#)

West Nile virus, encephalitis from, [389](#)

West syndrome, [690](#)

Western black-legged tick, [443](#)

Wet beriberi, [113](#)

Wheal, [721t](#), [722f](#)

Wheezing, [510](#)

- causes of, [520t](#)
- differential diagnosis of, [402](#)

White reflex, in newborn, [230](#)

White strawberry tongue, [393](#)

Whitehead, [723](#)

Whitlow, herpetic, [382](#)

Whole blood, in transfusion, [589–590](#)

Whole-bowel irrigation, for drug toxicity, [164](#)

Whole exome sequencing, in genetic assessment, [179](#)

Whooping cough, [400](#)

Williams syndrome, [182](#)

Wilms tumor, aniridia, genitourinary anomalies, and mental retardation (WAGR) syndrome, [182](#)

Wilms tumors, [610–611](#), [614](#)

- bilateral, [611](#)
- clinical manifestations of, [610](#)
- differential diagnosis of, [611](#)
- etiology and epidemiology of, [610](#)
- laboratory/imaging studies in, [611](#)
- prognosis and complications of, [611](#)
- risk factors for, [597t](#)

treatment of, [611](#)

Wilson disease, [499–500](#), [711t–712t](#), [713](#)

Window period, for hepatitis B virus, [414](#)

Wireless capsule endoscopy, for gastrointestinal symptoms, [467](#), [468f](#)

Wiskott-Aldrich syndrome, [298](#), [299t](#), [585](#)

Wolman disease, [210t–212t](#)

Wood smoke, asthma and, [315t](#)

Wood tick, [444](#)

Wound care, for burns, [159](#)

Wrist, square window, in newborn, [229f](#)

X

X chromosome, [171](#)

X-linked adrenoleukodystrophy, [711t–712t](#), [713](#)

X-linked agammaglobulinemia, [294](#)

X-linked dominant inheritance, [173](#)

G6PD deficiency due to, [174t](#)

hemophilia A due to, [174t](#)

incontinentia pigmenti due to, [173](#)

Rett syndrome due to, [173](#)

vitamin D-resistant rickets due to, [173](#)

X-linked hyper-IgM syndrome, [296](#), [296f](#)

X-linked lymphoproliferative disease, [386](#)

X-linked lymphoproliferative syndrome, [298–299](#), [299t](#)

X-linked recessive inheritance, [172](#)

pedigree of, [174f](#)

rules of, [174t](#)

X-linked thrombocytopenia, isolated, [298](#)

X-Prep (senna), for functional constipation, [51t](#)

Xanthogranuloma, juvenile, [730t](#)

Xerophthalmia, [117](#)

Xerosis, [117](#)

Y

Y chromosome, [171](#)

Yale-Brown Obsessive-Compulsive Scale (Y-BOCS), [69](#)

Yeast infections, superficial, [381t](#)

Yellow jacket stings, allergic reactions to, [333](#)

Yersinia enterocolitica, [439t–442t](#)

diarrhea from, [410t](#), [411](#)

Yersinia pestis, [439t–442t](#)

Yersinia pseudotuberculosis, [439t–442t](#)

Yersiniosis, [439t–442t](#)

Youth violence, [92](#)

Z

Zafirlukast, for asthma, [315](#)

Zellweger syndrome, [208–209](#)

Zidovudine, for HIV, [461](#)

Zika virus, [447](#)

congenital infection with, [264](#)

Zileuton, for asthma, [315](#)

Zinc deficiency, [119t](#), [120–121](#)

Zinc deficiency dwarfism, [120–121](#)

Zoonoses, [439–447](#)

- anaplasmosis as, [445–446](#)
- defined, [439](#)
- ehrlichiosis as, [445–446](#)
- Lyme disease as, [443–444](#)
- Rocky Mountain spotted fever as, [444–445](#)
- spread of, [439](#)
- West Nile virus as, [446](#)

Zoster, [378–379](#)

- clinical manifestations of, [378](#)
- complications and prognosis of, [379](#)
- differential diagnosis of, [378–379](#)
- epidemiology of, [378](#)
- etiology of, [378](#)
- laboratory and imaging studies for, [378](#)
- prevention of, [379](#)
- treatment of, [379](#)
- vesiculobullous eruptions due to, [734t](#)
