Lithium-induced alterations in gene expression may also account for recent findings of a neuroprotective effect in some cell systems. A number of groups have demonstrated a neuroprotective effect of lithium in systems both *in vivo* and *in vitro* against a variety of insults, including glutamate-induced excitatory apoptosis (130 ,131 and 132). It is well established that neuronal survival during apoptosis or programmed cell death depends on the relative expression of “executioner” proteins and “protector” proteins and the presence of neurotrophic factors. The B-cell lymphoma/leukemia 2 gene (*bcl2*), abundantly present in mammalian neurons, encodes one of the protector proteins that inhibits apoptosis and cell death under variety of circumstances. Recent studies in rat brain have demonstrated that long-term exposure to lithium or valproate increases the expression of the polyomavirus enhancer-binding protein 2ß gene (*PEBP2B*), a regulator of *bcl2* expression (133). Subsequent studies in rat brain have demonstrated an increase in cells immunoreactive for Bcl-2 in layers II and III of frontal cortex, dentate gyrus, and striatum after long-term lithium (134). In cultured cerebellar granule cells, long-term treatment with lithium induces a concentration-dependent decrease in *p53* and *bax* (apoptotic genes) mRNA and protein, with a concomitant increase in *bcl2* at both the mRNA and protein levels (135). It is of interest that these actions of lithium have been attributed to an enhancement of the PI_3 kinase pathway, in which GSK-3ß plays a prominent role (136) (Fig. 79.2). To what extent this neuroprotective effect may be related to the long-term prophylactic effect of lithium in stabilizing the course of BPD and the putative role of cellular loss in the pathophysiology of affective disorders remains to be demonstrated (137).

Neuroplasticity and Cytoskeletal Remodeling

Recent studies in a number of laboratories have provided evidence that long-term lithium treatment may alter molecular substrates underlying neuroplastic changes in brain that mediate alterations in interneuronal connectivity. As noted above, developmental studies in the *Xenopus* embryo have recently provided evidence that lithium can act as an inhibitor of GSK-3ß, a component of the wnt signaling pathway, at concentrations that may be relevant to clinical treatment (110). Several groups have reported that inhibition of GSK-3ß by lithium reduces phosphorylation of tau protein in different cell systems, the effect of which is to enhance the binding of tau to microtubules and promote microtubule assembly (110 ,138 ,139 and 140). Lithium treatment also decreases phosphorylation of MAP-1ß, a microtubule-associated protein involved in microtubule dynamics within the growth cone and axonal outgrowth (141). Lithium-induced dephosphorylation of MAP-1ß reduces its ability to bind to microtubules; in cerebellar granule neurons, this effect was accompanied by axonal spreading and increases in growth cone area and perimeter (142 ,143). Thus, it is possible under the appropriate conditions that inhibition of GSK-3ß by lithium can induce significant changes in microtubule assembly that result in changes in the association dynamics among cytoskeletal proteins mediating neuroplastic changes in regions of the brain.

The significance of actin-membrane remodeling in the long-term action of lithium is also supported by a series of studies demonstrating that long-term lithium down-regulates the expression of the PKC substrate MARCKS in brain, as noted previously. MARCKS is a complex protein

that binds calmodulin in a calcium-dependent manner; it also binds and cross-links filamentous actin, thereby conferring focal rigidity to the plasma membrane. Following phosphorylation of its phosphorylation site domain in the presence of activated PKC, MARCKS translocates from the plasma membrane and neither binds calmodulin nor cross-links actin. Thus, this protein is in a key position to transduce extracellular signals to alterations in the conformation of the actin cytoskeleton, which are critical to cellular processes underlying development and signaling, including morphogenesis and secretion. MARCKS is enriched in neuronal growth cones, developmentally regulated, and necessary for normal brain development (144 ,145 and 146). MARCKS expression remains elevated in specific regions of the hippocampus and limbic-related structures, which retain the potential for plasticity in the adult rat (147 ,148) and human brain (149), and its expression is induced in the mature central nervous system during axonal regeneration (150). Recent studies support a role for MARCKS in plastic events associated with learning and memory. Induction of long-term potentiation, thought to be a physiologic component of learning and memory, elevates MARCKS phosphorylation in hippocampus (151). Moreover, adult mutant mice expressing MARCKS at 50% exhibit significant spatial learning deficits that are reversed in the presence of a MARCKS transgene (144). These data reveal that MARCKS plays an important role in the mediation of neuroplastic processes in the developing and mature central nervous system. Thus, by virtue of its action in signaling pathways utilizing PI/PKC and GSK-3ß cascades (Fig. 79.2), long-term lithium administration may alter presynaptic and postsynaptic membrane structure to stabilize aberrant neuronal activity in critical regions of the brain involved in the regulation of mood (92).

ANTIDEPRESSANTS

Part of "79 - Mechanism of Action of Antidepressants and Mood Stabilizers "

Neurotransmitter Signaling

Antidepressants are usually classified according to structure [e.g., tricyclic antidepressants (TCAs)] or function [e.g., monoamine oxidase inhibitors (MAOIs), selective serotonin reuptake inhibitors (SSRIs)]. However, it may be more useful to classify them according to the acute pharmacologic effects that are presumed to trigger behavioral improvement. If this is done, the antidepressants can be grouped in four categories (Table 79.1). First are the drugs that selectively block the reuptake of norepinephrine (NE). These include certain TCAs and TCA-like compounds (maprotiline). Another drug that falls into this category is reboxetine, although it is distinct structurally from the TCAs and TCA-like compounds (152). It is currently available as an antidepressant in European and South American countries but is not yet marketed in the United States. Second are the SSRIs, which, as their class name implies, selectively block the reuptake of serotonin [5-hydroxytryptimine (5-HT)] *in vivo*.

Category	Mechanism	Examples	Current Classification (If Any)
I	Selective blockade of NE reuptake (SNRIs)	DMI, NT amoxapine, maprotiline reboxetine	TCAs TCA-like —
II	Selective blockade of 5-HT reuptake (SSRIs)	Citalopram, fluoxetine, paroxetine, sertraline	SSRIs
III	Nonselective enhancement of NE and 5-HT transmission	IMI, AMI phenelzine, tranylcypromine venlafaxine mirtazapine	TCAs MAOIs (sometimes with SSRIs) —
IV	Unknown potent stimulatory effects on NE or 5-HT	trimipramine bupropion nefazodone, trazodone	TCA — —

5-HT, 5-hydroxytryptamine (serotonin); AMI, amitriptyline; DMI, desipramine; IMI, imipramine; MAOI, monoamine oxidase inhibitor; NE, norepinephrine; NT, nortriptyline; SNRI, selective norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

TABLE 79.1. MECHANISM-BASED CLASSIFICATION FOR ANTIDEPRESSANTS

Third are the drugs that act nonselectively on noradrenergic and serotoninergic neurons with a resultant enhancement of synaptic transmission. Some TCAs are in this category, as are the MAOIs. Some novel drugs are also in this category. One of these is venlafaxine, discussed in more detail later. Another is mirtazapine. Mirtazapine is not a potent inhibitor of the reuptake of either NE or 5-HT (153). It is a relatively potent antagonist, though, of inhibitory α_2 autoreceptors on noradrenergic nerves. By blocking such autoreceptors, mirtazapine removes their inhibitory influence on noradrenergic transmission. Thus, even though it is not a reuptake inhibitor, mirtazapine can directly enhance NE-mediated transmission (154 ,155 and 156). In this respect, then, it might be appropriate to place mirtazapine in the first

category. However, mirtazapine may also enhance serotoninergic transmission, albeit *indirectly* (157 ,158 and 159). This enhancement is caused in part by NE activation of α_1 noradrenergic receptors located on serotoninergic soma and dendrites to increase cell firing and the release of 5-HT (160 ,161). Mirtazapine may also block inhibitory α_2 adrenoceptors located on serotoninergic terminals (i.e., heteroceptors) (154 ,162). However, some recent data call into question the likelihood that mirtazapine enhances serotoninergic transmission (163). Whether mirtazapine increases serotoninergic transmission may depend on the state of activation of the central noradrenergic system when the drug is administered. Further research is needed to clarify this point. At this time, we have placed mirtazapine in the third category.

In the fourth and final heterogeneous group are drugs without known potent, acute pharmacologic effects that result in enhancement of noradrenergic or serotoninergic transmission. In other words, their mechanisms of action are unknown. Drugs in this category include the TCA trimipramine and also bupropion, nefazodone, and trazodone. It has been speculated that bupropion acts through dopaminergic mechanisms because it is the only antidepressant that more potently blocks the reuptake of dopamine than that of either NE or 5-HT (164). However, in reality, bupropion and its metabolites are very weak inhibitors of the reuptake of all three biogenic amines, with potencies in the micromolar range (164). Perhaps this is why the data regarding whether bupropion inhibits dopamine reuptake in patients at clinically relevant doses are at best conflicting (165). Some data indicate an as yet ill-defined effect of bupropion or its hydroxylated metabolite on noradrenergic function (164), but the efficacy of bupropion cannot at this time be attributed to effects on noradrenergic transmission.

The most potent acute effect of nefazodone and trazodone on serotoninergic or noradrenergic systems is their antagonism of 5-HT_{2A} receptors (166). They are very weak inhibitors of NE reuptake and relatively weak inhibitors of 5-HT reuptake (167). If enhancement of serotoninergic transmission is a mechanism that ultimately leads to clinical efficacy, it is not clear how antagonism of the 5-HT_{2A} receptor produces such enhancement. Some data indicate that 5-HT_2-receptor antagonism enhances 5-HT_{1A}-receptor responsivity (168 ,169), or that 5-HT_2-receptor antagonists share discriminative stimulus properties with 5-HT_{1A}receptor antagonists (170). However, not everyone finds such effects (171), and whether such an effect would enhance endogenous serotoninergic transmission is uncertain. Thus, acute pharmacologic properties that contribute to the efficacy of the drugs in the fourth category remain unknown.

Originally, brain tissue from rats was used to measure the potencies of drugs *in vitro* to block the reuptake of ^{3}H-NE or ^{3}H-5-HT. Subsequently, radioligand binding techniques were developed such that the potencies of antidepressants to displace the specific binding of ligands to the norepinephrine transporter (NET) or serotonin transporter (SERT) could be measured. These studies were also carried out in brain tissue, usually from rats. The potencies of drugs to produce such effects were thought to be reflective of their potencies at blocking NE or 5-HT uptake clinically. The cloning of the SERT and NET in the early 1990s enabled many types of studies not possible heretofore (172). Among these are studies in which the human NET (*h*NET) or human SERT (*h*SERT) is transfected, often stably, into cells that normally do not have any NET or SERT. These cells can be maintained in cell culture systems and used to measure the uptake of ^{3}H-NE and ^{3}H-5-HT by the *h*NET and *h*SERT, respectively, and the binding of radioligands to the *h*NET and *h*SERT. Further, such cells can be used to measure the potencies of antidepressants to block such effects. The advantage of such systems, obviously, is that potencies are measured directly on human transporters. The disadvantages of such systems are equally obvious—namely, they are artificial, and a variety of factors can influence results (173). As Kenakin (173) has written, "Transfecting the cDNA of a receptor protein into a foreign cell and expecting a physiologic system can be likened to placing the Danish King Hamlet on the moon and expecting Shakespeare to emerge."

It might be illustrative to compare potencies of antidepressants obtained with the different preparations and approaches. This is done in Tables 79.2 and 79.3. Irrespective of the noradrenergic parameter chosen (Table 79.2), the orders of potency are almost identical, especially for the most potent compounds (i.e., desipramine > nortriptyline > amitriptyline = imipramine > paroxetine). Also, citalopram is the least potent drug on all measures. Perhaps the value that most stands out quantitatively from the others is that for ^{3}H-NE uptake by *h*NET. In general, these values tend to be sixfold to 10-fold higher (i.e., potencies are less) than those found to inhibit such uptake into rat brain synaptosomes. An interesting specific difference is seen with venlafaxine; its potency to inhibit ^{3}H-NE uptake by rat brain is five to eight times greater than its potency on the other noradrenergic parameters. For serotoninergic parameters also, the rank order of potencies appears reasonably similar irrespective of the specific parameter—namely, paroxetine > sertraline ≥ citalopram ≥ fluoxetine ≥ imipramine ≥ venlafaxine ≥ amitriptyline > nortriptyline ≥ desipramine ≥ nefazodone. However, the potencies found for most of the drugs to inhibit *h*SERT binding are greater than those to inhibit ^{3}H-5-HT uptake by the *h*SERT, oftentimes eightfold to 20-fold greater (Table 79.3).

TABLE 79.2. VALUES (nM) OF THE INHIBITION CONSTANT (K_i)

Drug	^{3}H-NE Uptake (Rat)	*r*NET Binding	^{3}H-NE Uptake (Human)	*h*NET Binding
Amitriptyline	14	9	102	27
Citalopram	>3,000[a]	>3,000	>30,000	>5,500
Desipramine	0.6	0.3	3.5	0.7
Fluoxetine	143	473	2186	508
Imipramine	14	11	142	28
Nefazodone	570	555	713	489
Nortriptyline	2	1	21	3
Paroxetine	33	59	328	62
Sertraline	220	1597	1716	618
Venlafaxine	210	1067	1644	1664

Potencies of these drugs for blocking the uptake of ^{3}H-NE or ^{3}H-5-HT into rat brain synaptosomes were taken primarily from Bolden-Watson and Richelson, 1993 (167). These values tend to be in good agreement with those reported by others. Potencies for drugs to inhibit the binding of radioligands to the NET or SERT in rat brain synaptosomes were taken from Owens et al., 1997 (175) for the same reason. Potencies of drugs to inhibit the binding of selective radioligands to the *h*NET and *h*SERT were averaged from results in Owens et al., 1997 (175) and Tatsumi et al., 1997 (176). In general, the results obtained in these two studies are in remarkably close agreement. Finally, potencies of drugs to inhibit uptake of ^{3}H-NE and ^{3}H-5-HT by the *h*NET and *h*SERT, respectively, were taken from Owens et al., 1997 (175). Such values tend to be in good agreement with those obtained by others using transfected cell systems, such as Eshleman et al., 1999 (177).
5-HT, 5-hydroxytryptamine (serotonin); NET, norepinephrine transporter; SERT, serotonin transporter.
[a]From Hyttel and Larsen, 1985 (174).

TABLE 79.3. VALUES (nM) OF THE INHIBITION CONSTANT (K_i)

Drug	^{3}H-5-HT Uptake (Rat)	*r*SERT Binding	^{3}H-5-HT Uptake (Human)	*h*SERT Binding
Amitriptyline	84	16	36	4
Citalopram	1.4[a]	0.8	9	1
Desipramine	180	129	163	20
Fluoxetine	14	2	20	0.9
Imipramine	41	9	20	1
Nefazodone	137	220	549	330
Nortriptyline	154	60	279	16
Paroxetine	0.7	0.05	0.8	0.1
Sertraline	3	0.3	3	0.2
Venlafaxine	39	19	102	8

Potencies of these drugs for blocking the uptake of ^{3}H-NE or ^{3}H-5-HT into rat brain synaptosomes were taken primarily from Bolden-Watson and Richelson, 1993 (167). These values tend to be in good agreement with those reported by others. Potencies for drugs to inhibit the binding of radioligands to the NET or SERT in rat brain synaptosomes were taken from Owens et al., 1997 (175) for the same reason. Potencies of drugs to inhibit the binding of selective radioligands to the *h*NET and *h*SERT were averaged from results in Owens et al., 1997 (175) and Tatsumi et al., 1997 (176). In general, the results obtained in these two studies are in remarkably close agreement. Finally, potencies of drugs to inhibit uptake of ^{3}H-NE and ^{3}H-5-HT by the *h*NET and *h*SERT, respectively were taken from Owens et al., 1997 (175). Such values tend to be in good agreement with those obtained by others using transfected cell systems, such as Eshleman et al., 1999 (177).
5-HT, 5-hydroxytryptamine (serotonin); NET, norepinephrine transporter; SERT, serotonin transporter.
[a]Calculated from Hyttel, 1978 (178).

It is important to recognize that potencies obtained *in vitro* for any pharmacologic effect give only some indication of whether the pharmacologic effect in question could occur clinically. High potency *in vitro* (e.g., ≤ 10 n*M*) certainly increases the likelihood that an effect will occur clinically, and low potency (e.g., > 500 n*M*) decreases the probability. However, as emphasized by others (179), whether or not a

specific effect occurs clinically depends on how much drug reaches its presumed site(s) of action (i.e., a function of pharmacokinetics). Because these drugs must act on brain to exert their beneficial effects, a factor that substantially influences how much reaches the brain is the extent to which they are protein-bound. Because of the blood–brain barrier, the amount of drug in the extracellular fluid of brain (i.e., CSF) tends to be equivalent at steady state to the concentration of non–protein-bound drug in plasma (i.e., "free" drug). Normal CSF contains so little protein that it may be regarded as an ultrafiltrate of serum. Because most, but not all, antidepressants are extensively bound to plasma proteins (180 ,181), their concentration in CSF is only a small fraction of the total concentration in serum.

Table 79.4 shows the percentages of protein binding of certain antidepressants. Also shown are steady-state total plasma concentrations of drug and concentrations in CSF. It is apparent that drug actually measured in CSF approximates what would be calculated to be the non–protein-bound concentration in plasma. For this reason, also shown in Table 79.4 are some antidepressants with concentrations in CSF that have not been reported. It is possible, then, to compare these CSF concentrations of drugs with their K_i values for the inhibition of uptake or ligand binding, shown in Table 79.2 and Table 79.3 . For a drug such as citalopram, it is obvious that its concentration in CSF is much greater than that required to inhibit serotoninergic uptake or binding to the SERT, irrespective of whether one is obtaining measurements with rat synaptosomes or *h*SERT. It is also obvious that citalopram does not reach sufficient concentration in CSF to block NE reuptake, again irrespective of the noradrenergic parameter or type of tissue. Considerable data indicate that citalopram maintains selectivity as a 5-HT uptake inhibitor *in vivo* (162). It is also apparent that desipramine reaches concentrations in CSF sufficient to block NE uptake, irrespective of the parameter or tissue used for measurement. However, the potency of desipramine to block ligand binding to the *h*SERT (20 n*M*) is sufficient to indicate that it may have a substantial effect on 5-HT uptake in the brain of patients. Although treatment with desipramine does lower concentrations of the serotonin metabolite 5-hydroxyindolacetic acid (5-H1AA) in the CSF of patients (192),

it is unlikely that this observation directly reflects the ability of the drug to block 5-HT uptake. Rather, it is more likely to be some indirect effect. The clinical efficacy of desipramine does not appear to depend on the availability of 5-HT (194). Furthermore, considerable preclinical data demonstrate little to no effect of desipramine on serotoninergic function (195 ,196 and 197). Given this, any of the other three serotoninergic values for desipramine, which are quite similar, would seem to be a better indicator of what happens clinically. The situation with nortriptyline appears to be similar to that with desipramine. Even at low concentrations, nortriptyline is likely to block NE uptake. Nortriptyline maintains reasonable selectivity *in vivo* as an inhibitor of NE reuptake (198 ,199 ,200 and 201). Because its concentration in CSF exceeds its potency to block ligand binding to the *h*SERT (and approaches its potency to inhibit binding at the *r*SERT), it seems doubtful that these potencies have relevance for functional inhibition of 5-HT uptake by nortriptyline clinically. Irrespective of the parameters used to assess the effects of fluoxetine, the interpretation would be the same—namely, levels of fluoxetine in CSF are likely sufficient to block 5-HT uptake, but not NE uptake. Again, considerable clinical and preclinical data indicate that fluoxetine maintains selectivity *in vivo* as a 5-HT reuptake inhibitor (202 ,203 and 204).

TABLE 79.4. TOTAL PLASMA AND CEREBROSPINAL FLUID CONCENTRATIONS OF SOME ANTIDEPRESSANTS

Drug	Protein Binding (%)[a]	Concentration (nM) in Plasma	CSF (measured)	CSF (estimated)	Reference
Amitriptyline	95	512	33		Hanin et al., 1985 (182)
(Nortriptyline)[b]	92	524	48		
Citalopram	50	40–750[c]	—	20–375	
Fluoxetine	95	854	26		Martensson et al., 1989 (183)
(Norfluoxetine)[b]	—	1,006	17		
Imipramine	90	433	40		Muscettola et al., 1978 (184)
(Desipramine)[b]	82–92	431	56		
Imipramine	90	475	36		Hanin et al., 1985 (182)
(Desipramine)[b]	82–92	642	79		
Nortriptyline	92	443	39		Nordin et al., 1985 (185)
Paroxetine	95	275	7		Lundmark et al., 1994 (186)
Venlafaxine[d]	27–30	370–3,000	—	100–850	

These numbers do not take into account concentrations of hydroxylated metabolites in CSF, which can have pharmacologic activity [Nordin and Bertilsson, 1995 (190); Nordin et al., 1987 (191); Potter et al., 1979 (192)]. Even though such hydrophylic metabolites may have diminished lipid solubility, the penetration of some hydroxylated metabolites into CSF may be somewhat greater than that of the parent compounds, presumably because of decreased protein binding [Nordin et al., 1985 (185); Sallee and Pollock, 1990 (181)]. Nevertheless, such metabolites more often than not are more weakly potent than their parent compounds, so it is not likely as a rule that such metabolites contribute substantially to pharmacologic activity in brain.
[a]Values taken from van Harten, 1993 (180); Sallee and Pollock, 1990 (181); and Benet et al., 1996 (187).
[b]Parentheses indicate measurements were taken of the drug as a metabolite of the parent antidepressant.
[c]Values taken from Bjerkenstedt et al., 1985 (188) and Fredricson-Overo, 1982 (189).
[d]Range of values for venlafaxine refers to venlafaxine plus *O*-desmethylvenlafaxine.

Given the great potency of paroxetine on any of the serotoninergic parameters in Table 79.3 , its concentration in CSF is sufficient to cause functional blockade of 5-HT uptake. Also, concentrations of paroxetine in CSF appear insufficient to cause much, if any, functional blockade of NE reuptake. Its greatest potency on a noradrenergic parameter (33 n*M* for inhibition of ^{3}H-NE uptake by rat brain synaptosomes) is considerably higher than its highest concentration in CSF (Table 79.2). Considerable data *in vivo* indicate that paroxetine maintains selectivity as an inhibitor of 5-HT reuptake (205 ,206 and 207). Other than its ability to decrease concentrations of methoxyhydroxyphenylglycol (MHPG) in the CSF of depressed patients (186), an effect produced by all SSRIs, including citalopram (186 ,188 ,208), no other clinical data are available from which it may be inferred that paroxetine blocks NE reuptake.

Venlafaxine (and its metabolite *O*-desmethylvenlafaxine) appears to be likely to inhibit 5-HT uptake, even at the low end of its concentration in CSF. This conclusion is reached by comparing its concentration in CSF with any of its "serotoninergic" potencies, with the exception of its potency in inhibiting ^{3}H-5-HT uptake by *h*SERT. Its low concentration in CSF is only equivalent to this potency. Interestingly, one might conclude that venlafaxine blocks NE uptake at higher concentrations only if one considers its potency in blocking ^{3}H-NE uptake by rat brain synaptosomes (210 n*M*). Even its highest concentration in CSF (850 n*M*) is only about half its potency on either of the *h*NET parameters and comparable with its potency to inhibit ligand binding to the *r*NET. Data show that venlafaxine is likely to block NE uptake *in vivo*, especially at higher doses (206 ,209). Thus, it seems reasonable to speculate that the most clinically relevant potency for venlafaxine at a noradrenergic parameter is its potency to block ^{3}H-NE uptake by rat brain synaptosomes.

For many of the drugs, then, the same conclusion is reached about selectivity (or nonselectivity) *in vivo* based on concentrations achieved in CSF and any of the noradrenergic or serotoninergic parameters. For some of the drugs, though, the parameter chosen influences the prediction of what will happen clinically. If one examines potencies to inhibit ligand binding to the *h*SERT, one might predict that both desipramine and nortriptyline are nonselective inhibitors of both NE and 5-HT reuptake *in vivo*. This does not seem to be so (194). For these drugs, then, the values for the *h*SERT should be viewed cautiously. As discussed, the clinical situation with venlafaxine causes some concern about its potency to inhibit ^{3}H-5-HT uptake by *h*SERT or to inhibit ligand binding to either *r*NET or *h*NET. This analysis demonstrates that K_i values measured *in vitro* allow only a prediction of what will occur *in vivo*—they offer no proof. Experiments must be carried out *in vivo* to prove (or disprove) the predictions.

Regulatory Effects

The pharmacologic effects of uptake inhibitors, just described in detail, are acute and direct effects of the drugs. As mentioned previously, the optimal behavioral effects of antidepressants on mood may not be evident immediately after initiation of treatment; rather, they are delayed from 2 to 3 weeks (210 ,211), although some symptoms may show early improvement (212 ,213 and 214). Furthermore, until this past decade, even though UPD was recognized as a recurrent illness in some patients, antidepressants were used primarily on a short-term basis (e.g., 2 to 4 months). However, evidence accumulated during the past several years has caused a fundamental shift in the treatment of UPD, so that prophylaxis is emphasized in addition to acute treatment. Such evidence includes the following: (a) UPD is widely recurrent, with more than 50% of patients having a recurrence sometime during their lifetime (215); (b) long-term (years) treatment of patients with recurrent UPD with different classes of antidepressants is effective in preventing depressive recurrences (215 ,216); (c) antidepressants (SSRIs, venlafaxine, mirtazapine) have been developed that have a much better side effect (and toxicity) profile than the TCAs, so that they are much better tolerated by patients (217). Such realizations have led to an extensive study of the longer-term and more slowly developing effects of antidepressants, particularly on central monoamine systems. It is beyond the scope of this chapter to review this area in detail. The interested reader can find more exhaustive reviews elsewhere (218 ,219 ,220 ,221 and 222). Rather, we emphasize the long-term effects of antidepressants that would be expected to continue or markedly

enhance the increase in serotoninergic and noradrenergic transmission initiated by the inhibition of uptake. Further, we emphasize some issues we believe to be important in long-term studies of antidepressant effects in laboratory animals such as rats.

Receptors/Transporters

Clearly, a key assumption is that an understanding of delayed pharmacologic effects and the mechanisms that produce them can lead to the development of drugs (or drug combinations) that produce such effects earlier, with consequent earlier clinical improvement. For example, early research showed that although uptake inhibitors do acutely block uptake, they also rapidly decrease the firing rate of serotoninergic or noradrenergic soma (200 ,223). For this reason, it was speculated that appreciable enhancement of neurotransmission does not occur with these drugs early in treatment. With serotonin, this was thought to be a consequence of a rise in 5-HT in the raphe nucleus during 5-HT uptake inhibition, which activates inhibitory somatodendritic autoreceptors so as to restrain the rise in serotonin in terminal fields (224 ,225 and 226). A similar mechanism was thought to underlie the decrease in firing in the locus ceruleus (227 ,228 and 229).

With time, though, regulatory changes occur that can enhance transmission, especially in the presence of continued inhibition of uptake. Perhaps chief among these is a time-dependent desensitization of inhibitory serotoninergic autoreceptors. In general, the consensus is that long-term administration of inhibitors of 5-HT uptake cause a desensitization of somatodendritic 5-HT_{1A} receptors (230 ,231 and 232), although whether terminal autoreceptors become desensitized is more controversial (233 ,234 ; see references in 235). The time-dependent desensitization of inhibitory somatodendritic autoreceptors enhances serotoninergic neurotransmission in terminal fields during the long-term administration of 5-HT uptake inhibitors (231 ,236 ,237). Such observations led to the idea that concomitant administration of pindolol, a 5-HT_{1A}-receptor antagonist, with an SSRI would enhance the rate of response. Unfortunately, data about whether this happens are controversial (232 ,238 ,239). The data are somewhat more contradictory regarding whether desensitization of inhibitory somatodendritic noradrenergic α_2 autoreceptors occurs after long-term administration of NE reuptake inhibitors (227 ,229 ,240 ,241). Less attention has been focused on whether concomitant administration of an α_2-adrenoceptor antagonist would improve the speed of response of a noradrenergic reuptake inhibitor.

Many of the studies of long-term effects of antidepressants have focused on presynaptic or postsynaptic changes in 5-HT and NE receptors (such as those just described) and their physiologic or behavioral consequences. Even though the SERT and NET are the initial cellular targets for reuptake inhibitors, few early studies examined whether such treatment has regulatory effects on these proteins. However, the cloning of the SERT and NET in the early 1990s (172) made it possible to determine whether these integral plasma membrane proteins exhibit plasticity. This work culminated in studies of mice with knockouts of these transporters. In heterozygotes, in which transporter density is reduced by 50%, the impact on transporter capacity is marginal, which suggests that powerful post-transcriptional events regulate transporter function (242). Studies of the mechanisms of such events have in general been carried out *in vitro*, either with cells that naturally express these transporters or with cells into which the transporters have been stably transfected. The realization that transporters can be regulated stimulated considerable research during the last decade to determine whether long-term treatment of rats with reuptake inhibitors produces regulatory effects on the SERT or NET. Unfortunately, no consistent picture has emerged (243). We think some of the inconsistency may be a consequence of such factors as route of drug administration and tissue preparation. Because this area has not been reviewed in detail previously, we do so here.

In 1990, Marcusson and Ross (244) reviewed the literature about the effect of antidepressants on the SERT. At that time, the approach to measuring SERT function was to measure ^{3}H-5-HT uptake *in vitro*. Factors that may contribute to regulatory effects can be lost during tissue preparation (slices, synaptosomes) and the use of artificial incubation media. Other techniques, such as binding a radioligand to the SERT or quantifying mRNA for the SERT, do not measure SERT function. Another important factor that can affect results is how the drugs are administered. Assessment of the literature and the experience of one of the authors (A. F.) with sertraline caused us to believe that sustained antagonism of the SERT throughout the day is needed to demonstrate down-regulation of the SERT. When sertraline was administered intraperitoneally to rats at a dose of 5 mg/kg twice daily for 21 days (245), quantitative autoradiographic analysis of ^{3}H-cyanoimipramine (^{3}H-CN-IMI) binding to the SERT in 23 areas of brain revealed small (15% to 21%) decreases in binding in only four areas. By contrast, when the drug was administered subcutaneously by minipump for 21 days (at a daily dose of 7.5 mg/d, which is even less than that used in the previous study), a large (70% to 75%) decrease in the binding of ^{3}H-CN-IMI was seen throughout brain (246). Given that the analytic methodology was essentially identical in the two studies, as was the time of drug administration, the factor that most likely accounts for the difference in results is the route of drug administration.

In general, the metabolism of drugs is faster in rats than in humans. Most uptake inhibitors (or their active metabolites) have half-lives in humans that average about 1 day or even longer (247). Given this, even the administration of antidepressants once a day with doses producing recommended “therapeutic” plasma concentrations (usually measured

at the trough of the daily variation in concentration) is sufficient to maintain consistent blockade of the transporter. In the rat, though, sertraline has a half-life of about 4.5 hours (248). Thus, twice-daily and especially once-daily injections of this drug may not be sufficient to maintain adequate occupancy of the SERT in brain throughout the day, and continuous adequate occupancy may be necessary to obtain regulatory effects. Such considerations are even more important with a drug such as citalopram, which has an elimination half-life in the rat of 3 to 5 hours (189 ,249), or venlafaxine (or its metabolite *O*-desmethylvenlafaxine), which has a half-life of about 1 hour (250). All these considerations are relevant in a review of effects of long-term administration of uptake inhibitors on the SERT (251).

In general, studies of long-term citalopram given intraperitoneally either once or twice daily have found little to no regulatory effects on the SERT (234 ,245 ,252 ,253 and 254). In addition to the lack of effect of long-term intraperitoneal administration of citalopram on SERT parameters, comparable administration of this drug has produced inconsistent effects on somatodendritic 5-HT_{1A}-receptor sensitivity (233 ,254 ,255 and 256). A recent report is illustrative (235). The investigators speculated that positive results with long-term citalopram administration might be obtained if the administration and dosage were adequate to maintain plasma levels in a “therapeutic” range. This was achieved by giving the drug subcutaneously by minipump at a dose of 20 mg/kg per day for 15 days. This regimen produced stable plasma citalopram levels of about 300 n*M*. After a 48-hour washout, when analytic experiments were carried out, plasma levels of citalopram had dropped to levels that were not pharmacologically active. At this time, evidence for marked subsensitivity of somatodendritic 5-HT_{1A} receptors was obtained. Their conclusion was that if a proper, pharmacokinetically validated, long-term regimen with citalopram is used, 5-HT_{1A}-autoreceptor desensitization can be observed. We think that these observations account for why those who gave long-term paroxetine by minipump consistently obtained evidence of decreases in SERT function (246 ,257 ,258 and 259).

Fluoxetine has a half-life in the rat of just 5 to 8 hours, but that of its metabolite, norfluoxetine, is about 15 hours (260). Inconsistent results have been obtained in studies of the effects of long-term administration of this drug on SERT parameters. Gobbi et al. (234) reported no effect in rats of 3 weeks of treatment with fluoxetine (15 mg/kg orally twice daily) on either ^{3}H-5-HT uptake into synaptosomes or ^{3}H-citalopram binding. In this study, measurements were made after 7 days of drug washout. Similar results were obtained by Dean et al. (261), who used homogenates; they gave the drug at a dose of 10 mg/kg per day intraperitoneally for either 10 or 28 days. By contrast, in the study of Durand et al. (262), the same dose of fluoxetine, when given for 21 days, markedly lowered ^{3}H-citalopram binding in brain homogenates. Berton et al. (263) also reported a significant but more modest (25%) reduction in ^{3}H-citalopram binding in the midbrain of rats treated once daily with 7.5 mg of fluoxetine per kilogram for 21 days. It is interesting that such dose schedules for fluoxetine produce inconsistent results on SERT measures because comparable schedules cause consistent effects on other measures of serotoninergic function, such as 5-HT_{1A}-receptor sensitivity (231 ,264 ,265). It does appear, then, that stable, nonfluctuating plasma levels of 5-HT uptake inhibitors over time are needed to show regulatory effects on the SERT, whereas this may not be so for other serotoninergic parameters.

Several investigators have examined mRNA for the SERT at different times after long-term administration of 5-HT uptake inhibitors. Here, also, the results have been inconsistent (246 ,266 ,267 ,268 ,269 ,270 and 271). This may be a consequence not only of the route of drug administration but also of the duration. Although no change in mRNA for the SERT after 21 days of treatment with paroxetine or sertraline by minipump has been reported (246 ,272), changes in mRNA are found earlier in treatment, with peak effects after about 10 days (272). It seems that only if the drugs are given in a regimen that causes decreases in SERT binding can changes in its mRNA be observed, and even then only if one looks at the proper times (i.e., early in treatment).

As with the SERT, a number of investigators have studied the effect of long-term treatment of rats with NE uptake inhibitors on NET binding sites. In more recent work, ^{3}H-nisoxetine, a radioligand that binds specifically to the NET, has been used (273 ,274). In the study of Bauer and Tejani-Butt (275), 21 days of treatment with desipramine (10 mg/kg intraperitoneally once daily) caused modest (20% to 40%) but significant decreases in ^{3}H-nisoxetine binding in some areas of brain, but not in others. More robust and widespread changes were obtained when desipramine was given by osmotic minipump for 21 days (272). We think it likely that the greater effect seen is a result of giving the drug by minipump to obtain consistent daily plasma levels in the “therapeutic” range. It does seem likely that long-term desipramine treatment can down-regulate the NET; its addition *in vitro* to PC12 cells in culture at concentrations above 100 n*M* caused a decrease in the B_{max} of (i.e., the maximum density of binding sites) ^{3}H-nisoxetine binding, with a maximum effect occurring after 3 days of exposure (276). The uptake of ^{3}H-NE was also decreased. These effects occurred after exposure of the cells to desipramine for as little as 4 hours, but always after desipramine had been removed from the incubation medium. In a follow-up study in which cells transfected with *h*NET were used, similar results were obtained with desipramine; in addition, less NET protein was measured in the desipramine-treated cells. Interestingly, desipramine did not cause any change in mRNA for the NET in these cells. In contrast, in the study of Zavosh et al. (277), addition of desipramine to the human neuroblastoma cell line SK-N-SHSY 5Y not only decreased the B_{max} of ^{3}H-nisoxetine binding by 24 hours

but also decreased message, although only after 72 hours of treatment, not after 24 hours. For this reason, Zavosh et al. (277) concluded that the decreases in ligand binding were not a consequence of changes in message. Interestingly, Szot et al. (278) found that both 2-day and 4-week treatment of rats with desipramine (10 mg/kg intraperitoneally once daily) increased mRNA for the NET in the locus ceruleus.

The antidepressant-induced loss of SERT binding sites (and presumably also NET binding sites) may have important functional consequences relevant to the behavioral improvement produced by reuptake inhibitors. The changes that acute local administration of an SSRI has on the clearance of 5-HT *in vivo*, measured by chronoamperometry, are significant but modest. Variable and quite small effects are produced on the peak amplitude of the electrochemical signal caused by 5-HT, and clearance of the indolalkylamine is inhibited by 30% to 40% (246). However, when antidepressant treatment causes a marked reduction in SERT binding sites, then the peak amplitude of the 5-HT signal is substantially increased and the clearance time is more than doubled (246). Similar effects on the 5-HT chronoamperometric signal were also observed in rats treated with a serotoninergic neurotoxin to cause more than a 70% loss of SERT binding sites (279). Thus, acute blockade of the SERT by SSRIs may not produce the same enhancement of serotoninergic transmission as that caused by the loss of SERT after longer-term administration of drug. Because sertraline treatment has been found to cause a marked loss of SERT binding sites only after 10 to 15 days of treatment (272), which corresponds to the time when drug-induced behavioral improvement becomes obvious, it may be that such loss of SERT binding sites is among the effects necessary to obtain marked enhancement of serotoninergic transmission and consequent behavioral improvement.

Signal Transduction

In recent years, there has been considerable speculation that the beneficial behavioral effects of antidepressants are a consequence of changes in the intracellular signaling pathways linked to noradrenergic or serotoninergic receptors. In other words, behavioral improvement is not a direct consequence of antidepressant-induced receptor activation (which may occur quickly); rather, it results when such receptor activation alters signaling pathways to cause more slowly developing changes in gene expression. Two major areas have been studied. One deals with effects of antidepressants on second messenger-regulated protein kinases in brain. The other deals with changes in activities of protein kinases that result in changes in gene expression and perhaps even neurogenesis. Such effects are reviewed in this section.

Protein Kinases

Phosphorylation of proteins may well be the primary regulatory mechanism for intracellular events. Such phosphorylation is controlled by protein kinases, which catalyze the binding of phosphate groups to substrate proteins, or by protein phosphatases, which catalyze the removal or release of such groups. Most often, these enzymes are the primary sites of action of the intracellular second messengers in many signaling cascades. Importantly, many kinases can regulate different and independent functions within a cell, presumably by selective co-localization with necessary substrates (280). This implies that drug effects on translocation of kinases, in addition to direct effects on their activity, may have important functional consequences.

The long-term administration of either fluoxetine or desipramine decreases the basal activity of both soluble and particulate PKC in cerebral cortex and hippocampus (281). Because PKC may be involved in the desensitization of 5-HT_{2A} receptors (282) and cell surface expression of the SERT (283), antidepressant-induced effects on PKC activity may cause changes in 5-HT_{2A}-receptor sensitivity or SERT expression (246 ,257).

Long-term, but not acute, treatment of rats with various antidepressants activates two other protein kinases in brain, namely PKA in the microtubule fraction and calcium/calmodulin-dependent protein kinase II (CaMKII) in the synaptic vesicle fraction. Such activation results in phosphate incorporation into selected substrates (284 ,285). With respect to PKA, Nestler et al. (286) had earlier reported a result consistent with the idea that antidepressants cause a translocation of PKA. They found that long-term antidepressant administration decreases the activity of PKA in the cytosol but increases enzyme activity in the nuclear fraction. Other data have also been reported suggestive of an antidepressant-induced translocation of PKA within intracellular compartments (287). Interestingly, long-term desipramine treatment increases the phosphorylation of MAP-2, a substrate for PKA (288); the increased phosphorylation is coupled to inhibition of the microtubule assembly. The effects on PKA may be caused when long-term treatment with antidepressants increases the binding of cAMP to the regulatory II subunit of PKA in brain homogenates (287 ,289).

Thus, one site affected by long-term antidepressant treatment may be cAMP-dependent phosphorylation, mediated by PKA, in microtubules. It may be speculated that such phosphorylation causes cytoskeletal changes that result in a modification of neurotransmission and antidepressantinduced changes in gene expression (see below), as PKA translocation to the nucleus is microtubule-dependent (290). Antidepressant-induced activation of PKA is interesting in light of findings of decreased PKA activity in cultured fibroblasts of melancholic patients with major depression (291), perhaps a consequence of reduced binding of cAMP to the regulatory subunit of PKA (292). Given the established facilitative function of CaMKII on neurotransmitter release (293), the effect of long-term antidepressant treatment on CMKII, with increased phosphorylation of substrates such as synapsin 1 and synaptotagmin, may underlie

the facilitation of monoamine transmitter release produced by these drugs.

Gene Expression/Neuroplasticity

Although the precise mechanism is not understood, long-term but not acute treatment with antidepressants has effects on the expression of specific genes that may be a consequence of the activation of protein kinases, particularly PKA. It is known, for example, that PKA can phosphorylate the transcription factor CREB. CREB binds to specific promoter sites (cAMP response elements) to produce changes in the expression of specific genes, such as those for brain-derived neurotrophic factor (BDNF) and its receptor, trkB. Relevant, then, to this signaling cascade is the observation that long-term but not acute administration of various types of antidepressants increases the mRNA for CREB in addition to CREB protein in brain (294 ; see 221 ,295). More recently, it was shown that such treatments increase CREB expression and CREB phosphorylation, indicative of functional activation of CREB (296). Furthermore, long-term antidepressant treatment increases BDNF and trkB expression in hippocampus (294 ,297). The increase in BDNF expression is likely to be a consequence of the increase in CREB expression (298 ,299). Finally, exogenous BDNF has been shown to have antidepressant-like activity in behavioral tests sensitive to antidepressant treatment (301).

Such results are viewed as evidence that long-term antidepressant treatment causes sustained activation of the cAMP system and the intracellular events described. The noradrenergic and serotoninergic receptors producing increases in cAMP are ß-adrenoceptors and 5-HT_4, 5-HT_6, and 5-HT_7 receptors. If such intracellular effects are responsible for clinical improvement, then these receptors may be the important ones triggering such improvement.

Finally, these slowly developing intracellular effects of antidepressants have been put into an interesting hypothesis to explain antidepressant actions (221 ,295). The hypothesis is fundamentally different from earlier views of antidepressant action, in which depression was a problem of synaptic transmission and drugs acted within the synapse to improve behavior directly (301 ,302). The new view is more morphologic in nature. It posits that depression may be caused by chronic, stress-induced atrophy of neurons in certain areas of brain, particularly the hippocampus. It is well established that such atrophy occurs (303 ,304). Further, more recent data indicate a decrease in hippocampal volume in some depressive patients (305 ,306 and 307), although this need not indicate a loss of neurons. However, postmortem studies have revealed a loss of glia and neurons in the cortex of depressed patients (137 ,308). The theory then proceeds to make use of the fact that BDNF is known to be involved not only in the differentiation and growth of neurons in the developing brain but also in neuron maintenance and survival in the adult brain (309 ,310 and 311). Thus, the antidepressant-induced increase in BDNF can oppose and perhaps overcome the stress-induced cell death pathway. Indeed, long-term antidepressant treatment has been shown recently to increase neurogenesis of dentate gyrus granule cells (312).

CONCLUSION

Part of "79 - Mechanism of Action of Antidepressants and Mood Stabilizers "

Our understanding of the mechanism of action of drugs that treat mood disorders such as depression and manic-depressive illness derives for the most part from their interaction with known signaling systems within the brain. It is evident that intracellular effects initiated by antidepressant or mood stabilizers in synaptic physiology may trigger subsequent neuroplastic changes that result in the long-term regulation of signaling in critical regions of the brain. Although much more research is needed to test this hypothesis and establish whether and how such long-term changes are of physiologic significance, current evidence suggests that such changes in brain may be quite important for the now well-established prophylactic effects of mood stabilizers and antidepressants in the treatment of recurrent mood disorders.

With the advent of new molecular biological strategies that use gene expression arrays, we have the opportunity to examine multiple targets in the brain, both known and unknown, for the action of these drugs. Within this chapter, we have tried to identify the most promising of the candidate targets of mood stabilizers and antidepressants. However, research to determine which current and future targets constitute a profile that is most relevant to the therapeutic action of these agents will continue to be hampered by a lack of animal models for these complex behavioral disorders that have strong construct and predictive validity. Although the field of antidepressant research has used animal models with some of these properties for the development of “like” agents, the development of animal models with which new mood stabilizers can be discovered has proved more challenging. We suggest that the creation of models with both construct and predictive validity to permit the discovery of novel targets directly related to therapeutic efficacy will be significantly enhanced by the identification of susceptibility and protective genes for these illnesses.

HISTORY AND MECHANISMS

Part of "80 - Hormonal and Gender Influences on mood Regulation "

Within the past 20 years, the putative role of gender and gonadal steroids in mood regulation has been transformed from the staple of stereotype to a critical locus of research in clinical neuroscience. This transformation reflects the impact of explosive advances in molecular endocrinology and basic neuroscience, both of which suggest the myriad and dramatic neuroregulatory effects of gonadal steroids. Although direct isomorphs between basic mechanisms and clinical observations are for the most part absent, our burgeoning knowledge of the cellular and central nervous system effects of gonadal steroids is offering new models for understanding the relevance of gender and gonadal steroids in mood regulation. In this chapter, we review some of the major findings in reproductive neuroscience, emphasize the context dependency of many of these findings, and suggest that similar contextual effects underlie the inability to demonstrate uniform effects of gender or gonadal steroids on mood and behavior.

Reproductive hormones have played a central historical role in the development of our understanding of the effects of hormones on brain and behavior. More than 2,000 years ago, Aristotle, in his biological treatise *Historia Animalium*, observed that castration of immature male birds prevents the development of characteristic male singing and sexual behavior (1). One hundred fifty years ago, Berthold (2) successfully transplanted testes in castrated roosters and reversed their hypogonadal symptoms, demonstrating that reproductive organs possess factors that can dramatically alter physiology and behavior. These observations culminated in the claims by nineteenth century organotherapists (e.g., Brown-Sequard) that the administration of ovarian or testicular extracts could treat a variety of mood disorders in humans, ranging from depression to the anergy of senescence (3 ,4). In the 1920s and 1930s, the active gonadal substances—testosterone, estradiol, and progesterone—were isolated and characterized.

In 1962, Jensen and Jacobsen (5) provided evidence that the effects of estradiol are mediated through a specific intracellular hormone-binding protein, the estrogen receptor (a concept originally proposed by Langley in 1905), and by 1966, the estrogen receptor became the first hormone receptor to be isolated and identified (6). An elegant scheme for the cellular effects of hormones was subsequently elaborated. As lipophilic factors, steroid hormones would diffuse into cells, where they would bind the intracytoplasmic receptor (in contrast to the membrane-bound receptors of neurotransmitters and peptide hormones); the receptor protein would then be phosphorylated to cause dissociation of a heat shock protein and uncapping of the DNA binding domain of the receptor, which would result in binding of the receptor (frequently after dimerization) to a response element on the DNA, transcription of messenger RNA (mRNA), and finally translation of the mRNA into proteins in the cell cytoplasm. Because an enormous array of proteins relevant to neural transmission (e.g., neurotransmitter synthetic and metabolic enzymes, neural peptides, receptor proteins, signal transduction proteins) were observed to be regulated by gonadal steroids, this “genomic” mechanism promised to explain at a cellular level many of the effects of reproductive steroids observed at the level of the organism. In the past 15 years, the elegant simplicity of this genomic mechanism has given way to a model for the actions of reproductive steroids that is more comprehensive, powerful, and complex. Examination of this complexity promotes both an appreciation for the rich neuroregulatory potential of reproductive steroids and a means for understanding the diverse and wide ranging behavioral responses to alterations in reproductive steroid levels.

First, as the mechanics of transcription were elucidated, it became clear that activated steroid receptors influence transcription not as solitary agents but in combination with other intracellular proteins (7). These protein–protein interactions were such that an activated receptor might enhance, reduce, initiate, or terminate transcription of a particular gene solely as a function of the specific proteins with which it interacted (and the ability of these proteins to enhance or hinder the recruitment of the general transcription factor apparatus). The expression of these proteins—co-regulators (co-activators or co-repressors)—proved to be tissue-specific, and so suggested a means by which a hormone receptor modulator (e.g., tamoxifen) could act like an (estrogen) agonist in some tissues (e.g., bone) and like an (estrogen) antagonist in others (e.g., breast) (8 ,9). Another group of intracellular proteins, the co-integrators, provided a means by which classic hormone receptors could bind to and regulate sites other than hormone response elements [e.g., estrogen receptor (ER) or glucocorticoid receptor (GR) binding cyclic adenosine monophosphate (cAMP) response element binding (CREB) protein and, subsequently, the activator protein 1 (AP-1) binding site)] (10), and competition for co-integrator or other transcriptional regulatory proteins was demonstrated as a mechanism by which even ligand-free hormone receptors could influence (e.g., squelch or interfere with) the transcriptional efficacy of other activated hormone receptors (11). Thus, both the intracellular hormone receptor environment and the extracellular hormone environment might dictate the response to hormone receptor activation.

Second, the hormone receptors were found to exist in different forms. For example, isoforms of the progesterone receptor, PR_A and PR_B (the latter of which contains a 164-amino acid N-terminal extension), have different distributions and biological actions (12). As another example, two separate forms of the estrogen receptor, ER_α and ER_β, are encoded on different chromosomes (6 and 14, respectively) and have different patterns of distribution in the brain, different affinity patterns for certain ligands, and a range of different actions (including those created by ER heterodimers) (13 ,14 and 15). Further, a variant of ER_β, ER_β, is expressed in the brain, where it can form heterodimers with the ER_α or ER_β receptors (16) and inhibit their transcriptional actions (17).

Third, a variety of substances (e.g., nerve growth factor, insulin) are capable of activating a steroid receptor even in the absence of ligand (18 ,19). This crosstalk is exemplified by the ability of dopamine to induce lordosis by activating the PR (20 ,21).

Fourth, the relatively slow “genomic” effects of gonadal steroids have been expanded in two dimensions: time, with a variety of rapid (seconds to minutes) effects observed, and targets, which now include ion channels and a variety of second-messenger systems. For example, estradiol increases the firing of neurons in the cerebral cortex and hippocampus (CA1) (22) and decreases firing in medial preoptic neurons (23). The activity of membrane receptors like the glutamate and γ-aminobutyric acid (GABA) receptors is acutely modulated by gonadal steroids (estradiol and the 5-α reduced metabolite of progesterone, allopregnanolone, respectively) (24 ,25). Estradiol binds to and modulates the maxi-K potassium channel (26), increases cAMP levels (27), activates membrane G proteins ($G_{\alpha q}$, $G_{\alpha s}$) (28), inhibits L-type calcium channels (via nonclassic receptor) (29), and immediately activates the mitogen-activated protein kinase (MAPK) pathway (albeit in a receptor-mediated fashion) (30). The effects observed are tissue- and even cell-specific (e.g., estradiol increases MAPK in neurons but decreases it in astrocytes (31) (Zhang et al., *unpublished data*). The increase in the number of described mechanisms by which gonadal steroids can affect cell function has paralleled the rapid growth in their observed effects. Consequently, with each of these newly identified actions (which are usually, but sometimes inaccurately, called *nongenomic*), one needs to examine multiple factors before inferring the mechanism of action: (a) the duration required to see the effect, (b) the impact on the effect of inhibitors of transcription and protein synthesis, (c) the presence (or absence) of intracellular hormone receptors, (d) the stereospecificity of ligand binding (to see if effects are mediated through a classic receptor), (e) the effect of hormone receptor blockers, and (f) the ability of the ligand to initiate the action from the cell membrane (i.e., when entry into the cell is blocked). This last requirement acknowledges the presence on the membrane of binding sites for gonadal steroids that appear to be physiologically relevant (32).

Fifth, gonadal steroids regulate cell survival. Neuroprotective effects of estradiol have been described in neurons grown in serum-free media or those exposed to glutamate, amyloid-β, hydrogen peroxide, or glucose deprivation (22). Some of these effects appear to lack stereospecificity (i.e., are not classic receptor-mediated) and may be attributable to the antioxidant properties of estradiol (33 ,34), although data from one report are consistent with a receptor-mediated effect (35). Gonadal steroids may also modulate cell survival through effects on cell survival proteins (e.g., Bcl-2, Bax), MAPK, or even amyloid precursor protein metabolism (31 ,36 ,37) (Zhang et al., *unpublished data*).

Sixth, some actions of gonadal steroids on brain appear to depend on context and developmental stage. ToranAllerand (38) has shown that estrogen displays reciprocal interactions with growth factors and their receptors (e.g., p51 and trkA, neurotrophins) in such a way as to regulate, throughout development, the response to estrogen stimulation; estrogen stimulates its own receptor early in development, inhibits it during adulthood, and stimulates it again

in the context of brain injury. Additionally, we have demonstrated that the ability to modulate serotonin receptor subtype and GABA receptor subunit transcription in rat brain with exogenous administration of gonadal steroids or gonadal steroid receptor blockade largely depends on the developmental stage (e.g., last prenatal week vs. fourth postnatal week) during which the intervention occurs (39 ; Zhang et al., *unpublished data*).

Finally, the effects of gonadal steroids do not occur in isolation, but rather in exquisite interaction with the environment. Juraska (40), for example, demonstrated that the rearing environment (enriched vs. impoverished) dramatically influences sex differences in dendritic branching in the rat cortex and hippocampus. Further, the size of the spinal nucleus of the bulbocavernosus and the degree of adult male sexual behavior in rats is in part regulated by the amount of anogenital licking they receive as pups from their mothers, an activity that is elicited from the dames by the androgen the pups secrete in their urine (41).

SEXUAL DIMORPHISMS IN BRAIN STRUCTURE AND FUNCTION

Part of "80 - Hormonal and Gender Influences on mood Regulation "

In a highly influential article from the laboratory of C. W. Young, Phoenix et al. (42) demonstrated that exposure of the prenatal female guinea pig to androgens leads to defeminization of reproductive behavior in adulthood and increased sensitivity to androgen-induced male mating behavior. The authors interpreted these results as demonstrating an organizational effect of perinatal steroids on structure and subsequent behavioral function of the brain. These organizational effects, permanent changes in the brain consequent to exposure to gonadal steroids during small, critical windows of development, were contrasted with activational effects, which were impermanent effects that required continued exposure to gonadal steroids. This dichotomy was not uniformly accepted (43); Beach and Holz (44), who had demonstrated the effects on adult reproductive behavior of perinatal steroid manipulation and had interpreted them as derived from changes in gonadal morphology rather than brain function, referred to organizational effects as *imaginary brain mechanisms* (45). Nonetheless, by the late 1960s and early 1970s, the evidence for sexual dimorphisms in the brain that were organized by perinatal steroids was fairly compelling. Pfaff (46) demonstrated dimorphisms in rat brain in both gross and cellular morphology, with the dimorphisms altered by perinatal castration. Nottebohm and Arnold (47) showed that male song birds, who, in contrast to females, have the capacity to sing, had song control nuclei that were five to six times larger than comparable structures in the female. In two classic articles, Raisman and Field (48 ,49) demonstrated dimorphisms in neural connections; females showed a greater proportion of spine synapses in the preoptic area (48), and this dimorphism could be altered by perinatal steroid manipulation (49). Gorski et al. (50) identified in mammals a sexually dimorphic nucleus of the preoptic area that was two to six times larger in males than in females, and Rainbow et al. (51) demonstrated sexual differences in the response to gonadal steroids, with PR induction by estrogen seen more robustly in females than in males.

In subsequent years, sexual dimorphisms have been identified at all levels of the neuraxis and include differences in the following: nuclear volume; neuron number, size, density, morphology, and gene expression; neuritic outgrowth and arborization; synapse formation; glial number, morphology, and gene expression; and capacity for certain physiologic (e.g., cyclic gonadotropin secretion) and behavioral (e.g., song) activities (see refs. 52 , 53 for review). For example, we observed that in comparison with male astrocytes, perinatal cortical astrocytes from female rats have more activated MAPK at baseline and are more sensitive to estradiol suppression of both MAPK and cell proliferation (Zhang et al., *unpublished data*). Additionally, we observed dramatic dimorphisms in the developmental pattern and amount of expression of the cell survival/death proteins Bcl-2 and Bax (Zhang et al., *unpublished data*). The wide scope of these sex differences has become less mystifying as gonadal steroids have been seen to regulate virtually all stages of brain development, from neurogenesis to neural migration, differentiation, synaptogenesis, survival, and death (53). Nonetheless, despite the elegance of sexually dimorphic brain organization as an explanation for dimorphic behaviors, the complexity of the process underlying the development of sexual dimorphisms has assumed daunting proportions. First, it is often difficult to interpret the meaning of the dimorphisms. For example, lesions of the sexually dimorphic nucleus of the preoptic area (SDN-POA) do not compromise male copulatory behavior (despite the role of the preoptic area in reproductive behavior) (54), and DeVries and Boyle (55) have suggested that sexual dimorphisms may in some cases mediate the same behavior (e.g., the same parental behavior in prairie voles is mediated by differences in vasopressin). Second, lack of parallelism across genders complicates ascription of dimorphisms to the presence or absence of a particular steroid hormone. For example, song behavior (usually seen only in males) develops in female zebra finches if they are administered androgen or estradiol perinatally, but males deprived of androgen perinatally show no disruption of song behavior as adults (56 ,57). Third, some sexual dimorphisms appear to be organized and are independent of subsequent steroid exposure (58); others are activated (i.e., are dependent on subsequent steroid exposure) but not organized (i.e., they are not permanently influenced by perinatal steroid manipulation) (59); and still others are both organized and activated (e.g., the perinatally androgenized female zebra finch requires androgen as an

adult to express song behavior) (55 ,60). Further, Reisert and Pilgrim (61) have evidence suggesting that dimorphisms in the course of development of mesencephalic and diencephalic neurons are under genetic control (i.e., they are determined well before the appearance of any differences in gonadal steroid levels), like the genetically determined pouch or scrotum in marsupials (62). Fourth, the activational–organizational dichotomy is far more fluid and plasticity is much greater than the concept of critical periods allows. In contrast to the female zebra finch (who shows no male song behavior if androgenized during adulthood only), the female canary receiving androgen during adulthood exhibits male song behavior and shows masculine morphologic changes in the vocal control nuclei, including marked dendritic branching (63 ,64). Not only is the timing of hormonal administration (and species of the animal) important in determining outcome, but the manner of administration may also dictate the response. For example, Sodersten (65) demonstrated that one can induce typical female behavior in gonadectomized adult male rats by pulsatile but not continuous administration of estradiol followed by progesterone. Complexities notwithstanding, gonadal steroids appear capable of programming gonadal steroid sensitive circuitry in the brain, behavioral capacities, and differential response to the same physiologic stimulus.

SEXUAL DIMORPHISMS IN HUMANS

Part of "80 - Hormonal and Gender Influences on mood Regulation "

Given the relative lack of access to the brain in human studies in comparison with similar investigations in animals, the existence of gender-related differences has provided a major source of inference about the role of gonadal steroids in brain function and behavior. Reported gender dimorphisms in psychiatry include the following: prevalence, phenomenology (including characteristic symptoms, age at onset, susceptibility to recurrence, stress responsivity), and treatment characteristics. Specific examples of such dimorphisms are presented below.

Depression

Studies consistently demonstrate a twofold increased prevalence of depression in women in comparison with men (66 ,67 ,68 and 69), and this increased prevalence has been observed in a variety of countries (68). A twofold to threefold increased prevalence of dysthymia and a threefold increase in seasonal affective disorder (70) in women have also been noted (71). Although bipolar illness is equally prevalent in men and women (66 ,72 ,73 ; see ref. 74 for review), prepubertal depression prevalence rates are not higher in girls (75 ,76), possibly reflecting ascertainment bias (depressed boys may be more likely to come to the attention of health care providers) or the possibility that prepubertal major depression is premonitory of bipolar illness (77). With some exceptions, fewer differences in age at onset (68 ,69 ,78 ,79 ,80 and 81 ; but see also refs. 82 ,83 ,84 and 85), type of symptoms, severity, and likelihood of chronicity and recurrence (68 ,69 ,78 ,82 ,86 ,87 and 88 ; but see also refs. 89 ,90 ,91 ,92 and 93) are seen between men and women. Women are more likely to present with anxiety, atypical symptoms, or somatic symptoms (70 ,78 ,78 ,82 ,91 ,93 ,94 and 95) and are more likely to report symptoms, particularly in self-ratings (70 ,78 ,95). They are also more likely to report antecedent stressful events (96 ,97) and manifest a more robust effect of stress on the likelihood depression developing during adolescence (98). Women display increased comorbidities of anxiety and eating disorders (83 ,99 ,100 and 101), thyroid disease (102 ,103), and migraine headaches (104), and a lower lifetime prevalence of substance abuse and dependence (82 ,83). Reported differences in treatment response characteristics in women in comparison with men include a poor response to tricyclics (105 ,106 ,107 and 108), particularly in younger women (106); a superior response to selective serotonin reuptake inhibitors or monoamine oxidase inhibitors (109 ,110); and a greater likelihood of response to triiodothyronine (T_3) augmentation (103). The extent to which these differences reflect gender-related differences in pharmacokinetics (111 ,112 ,113 ,114 ,115 ,116 and 117) remains to be determined. Finally, although the prevalence of bipolar disorder is comparable in men and women, rapid cycling is more likely to develop in women (74), and they may be more susceptible to antidepressant-induced rapid cycling (118).

Schizophrenia

Although prevalence rates of schizophrenia appear comparable in men and women, a variety of differences in phenomenology, course, and treatment response characteristics have been identified (111 ,119 ,120).

Most but not all (121) studies suggest that the onset of schizophrenia is later in women and that they have better premorbid function (20–40 vs. 17–30; 122–126). Although symptom patterns during acute psychosis do not appear to differ substantially by gender, a variety of studies suggest that deficit or negative symptoms occur more frequently in men (123 ,127 ,128 and 129), perhaps consistent with the increased incidence in men of abnormalities of brain structure (primarily the corpus callosum) (127 ,130 ,131 ,132 and 133) and cognitive impairment (134). The course of illness in women tends to be more benign, with higher levels of psychosocial function (124), less time in a psychotic state (135), fewer days of hospitalization and fewer readmissions (126 ,136 ,137), less substance abuse (126 ,135 ,137), and less violence (aggressive episodes and completed suicide) (123 ,138). Finally, consistent with a more benign course (at least until middle age), women are reported to respond to neuroleptics more quickly, more extensively, and at lower doses (123 ,139 ,140 ,141 ,142 ,143 ,144 and 145).

The extent to which this last observation reflects gender dimorphisms in pharmacokinetics (e.g., drug absorption, storage, distribution volume, clearance) versus pharmacodynamics awaits determination (112).

Physiologic Dimorphisms

The epidemiologic observations previously described are increasingly complemented by demonstrations of sexual dimorphisms in brain structure and physiology in humans. Structural and functional brain imaging studies, for example, have shown the following: (a) differences in functional organization of the brain, with brain activation response to rhyming task lateralized in men but not in women (146); (b) gender-specific decreases in regional brain volume (caudate in males and globus pallidus, putamen in females) during development (147); (c) increased neuronal density in the temporal cortex in women (148); (d) greater interhemispheric coordinated activation of brain regions in women (149); (e) larger-volume hypothalamic nucleus (INAH3) in men (150); (f) differences in both resting blood flow and the activation pattern accompanying self-induced mood change (151); (g) decreased serotonin (5-HT_2) binding in the frontal, parietal, temporal, and singular cortices in women (152); (h) differences in whole-brain serotonin synthesis (interpreted as decreased in women but possibly increased if corrected for plasma levels of free tryptophan (153); (i) greater and more symmetric cerebral blood flow in women (154 ,155 ,156 ,157 and 158); (j) greater asymmetry in the planum temporale in men (159); and (k) higher rates of brain glucose metabolism (19%) in women (160 ,161). The potential relevance of gonadal steroids in some of these differences has also been demonstrated with the same technologies. For example, Berman et al. (162) demonstrated that the normal pattern of cognitive task-activated cerebral blood flow is eliminated by induced hypogonadism and restored by replacement with estradiol or progesterone. These findings were supported by Shaywitz et al. (163), who demonstrated estrogen enhancement of cognitive task-stimulated brain regional activation on function magnetic resonance imaging (fMRI) in postmenopausal women. Additionally, Wong et al. (164) demonstrated in a small number of subjects that dopamine receptor density in the caudate (measured by positron emission tomography) varies as a function of the menstrual cycle (lower in the follicular phase). The contribution of these and other effects of gonadal steroids to observed gender dimorphisms must, obviously, await further determination.

MOOD DISORDERS RELATED TO REPRODUCTIVE ENDOCRINE FUNCTION

Part of "80 - Hormonal and Gender Influences on mood Regulation "

Given the complexity of the factors that affect gender throughout development, it is very difficult to infer the degree to which differential exposure to gonadal steroids determines gender-related behavioral differences. A better opportunity to determine the behavioral relevance of fluctuations in gonadal steroids is provided by mood disorders that appear linked to changes in levels of reproductive steroids. In the following section, we review the role of gonadal steroids in the precipitation and treatment of mood disorders by focusing on three disorders: premenstrual syndrome (PMS), postpartum depression (PPD), and perimenopausal depression.

Premenstrual Syndrome

Although Frank is credited with the first description of “premenstrual tension” in 1931, reports of mood and behavioral disturbances confined to the luteal phase of the menstrual cycle appeared earlier, in the medical literature of the nineteenth century. For example, in 1847, Dr. Ernst G. Von Feuchtersleben stated that “the menses in sensitive women is almost always attended by mental uneasiness, irritability or sadness” (165). Two years later, the organ transplantation studies of Berthold (2) demonstrated that the reproductive organs possess factors that can markedly alter physiology and behavior, an observation that culminated in the late nineteenth century in the practice by organotherapists of administering ground-up animal glands and organs to treat a wide array of diseases and ailments (4). In this context, the isolation and characterization of ovarian steroids in the early twentieth century led to the inevitable assumption that premenstrual tension is caused by an excess or deficiency of estrogen or progesterone. In the ensuing years, each new discovery in endocrinology gave rise to a new theory of PMS if the new endocrine factor could in any way be shown to influence or be influenced by the menstrual cycle or potentially mediate any of the myriad symptoms attributed to PMS. Despite the obvious appeal of hormonal excess or deficiency as an explanation for PMS, consistent demonstration of any hormonal abnormality was lacking. A major source of study inconsistency was identified in the 1980s (166)—namely, that samples of women with PMS were selected (diagnosed) with highly unreliable techniques (i.e., unconfirmed history). Without prospective demonstration of luteal phase-restricted symptom expression, samples selected were certain to include a large number of false-positives and so make it impossible to apply the data to the population with PMS (167). This requirement for prospective confirmation of luteal phase symptomatology was ultimately incorporated into diagnostic criteria for PMS (National Institute of Mental Health, *unpublished data*, 1983) and late luteal phase depressive disorder/premenstrual depressive disorder (168). Although the improved diagnostic methods used since the mid-1980s have ensured the comparability of samples selected for study, subsequent data, if anything, have provided fairly convincing evidence against

hormonal excess or deficiency as etiologically relevant in PMS.

Individual studies have identified diagnostic group-related differences in levels of reproductive hormones, but the most consistent and compelling data support the absence of such differences. We observed no diagnosis-related differences in plasma levels, areas under the curve, or patterns of hormone secretion for estradiol, progesterone, follicle-stimulating hormone (FSH), or luteinizing hormone (LH) (169), findings consistent with those of Backstrom et al. (170) in a comparison of patients with high and low degrees of cyclic mood change.

In recent additions to the conflicting literature, Wang et al. (171) observed increased estradiol and decreased progesterone levels in women with PMS, Redei and Freeman (172) reported nonsignificant increases in both estradiol and progesterone, and Facchinetti et al. (173) found no differences between subjects and controls in integrated progesterone levels. Results of studies of androgen levels have been similarly inconsistent, demonstrating both normal and decreased testosterone levels (174 ,175 and 176) and elevated and decreased free testosterone levels (175 ,176).

Recent speculations about the etiology of PMS have focused on putative abnormal neurosteroid levels. Observations central to these speculations include the following: (a) the GABA receptor (the presumed mediator of anxiolysis) is positively modulated by the 5-α and 5-ß reduced metabolites of progesterone (allopregnanolone and pregnanolone, respectively) (25); (b) withdrawal of progesterone in rats produces anxiety and insensitivity to benzodiazepines secondary to withdrawal of allopregnanolone, with consequent induction of $GABA_A$ α_4 subunit levels and inhibition of GABA currents (177 ,178); (c) decreased plasma allopregnanolone levels are seen in major depressive disorder and in depression associated with alcohol withdrawal, with increased levels seen in plasma and cerebrospinal fluid following successful antidepressant treatment (179 ,180 ,181 and 182); (d) allopregnanolone has anxiolytic effects in several animal models of anxiety (183 ,184 and 185) and may be involved in the stress response (186); (e) antidepressants may promote the reductive activity of one of the neurosteroid synthetic enzymes (3-α-hydroxysteroid oxidoreductase) and thus favor the formation of allopregnanolone (187); (f) patients with PMS show differences in pregnanolone-modulated saccadic eye velocity and sedation in the luteal phase in comparison with controls (188) (although the reported differences seem attributable to a saccadic eye velocity response to vehicle in those with PMS and a blunted sedation response in the follicular phase in controls); (g) patients with severe PMS show blunted saccadic eye velocity and sedation responses to $GABA_A$-receptor agonists—pregnanolone (188) or midazolam (189)—in comparison with patients with mild PMS. Although one investigator observed decreased serum allopregnanolone levels in women with PMS in comparison with controls on menstrual cycle day 26 (190), other studies showed no diagnosis-related differences in allopregnanolone or pregnanolone (191 ,192) nor any difference in allopregnanolone levels in women with PMS before and after successful treatment with citalopram (193). Wang et al. (192) did find that if two cycles differed in area under the curve of a hormone by more than 10%, the cycle with the lower levels of allopregnanolone and higher levels of estradiol, pregnanolone, and pregnenolone sulfate was accompanied by more severe symptoms.

In sum, then, no consistent or convincing evidence is available that PMS is characterized by abnormal circulating plasma levels of gonadal steroids or gonadotropins or by hypothalamic–pituitary–ovarian axis dysfunction. Several studies do, however, suggest that levels of estradiol, progesterone, or neurosteroids (e.g., pregnenolone sulfate) may be correlated with symptom severity in women with PMS (171 ,194 ,195).

If one treats PMS with any of a number of therapies, one is never certain that the response seen is causally related to the pharmacologic (contrasted with the nonspecific) properties of the intervention employed. Therefore, we attempted to dissociate the symptoms of PMS from the menstrual cycle phase by targeting the menstrual cycle phase rather than the symptoms (196). We administered a progesterone receptor blocker (RU 486) with or without human chorionic gonadotropin (hCG) to women with PMS during the early luteal to midluteal phase. Within 2 days of administration, RU 486 caused menses (by blocking the endometrial progesterone receptors) and luteolysis and advanced the onset of the follicular phase of the next cycle. Addition of hCG does not alter the RU 486-induced menses but “rescues” or preserves the corpus luteum and permits a luteal phase of normal length. Consequently, after women experienced an RU 486-induced menses, they did not know whether they were in the follicular phase of the next cycle (RU 486 alone) or in the preserved luteal phase of the first cycle (RU 486 plus hCG). Women in both groups experienced typical PMS symptoms despite the fact that the women receiving RU 486 were now symptomatic in the context of an experimentally advanced follicular phase. Hence, the endocrinology of the midluteal to late luteal phase is irrelevant to the symptoms of PMS, as this phase can be eliminated without influencing the appearance of PMS symptoms. This suggested two possibilities: mood symptoms in women with PMS were entrained to the menstrual cycle but not caused by it, or mood symptoms might be triggered in the luteal phase by reproductive endocrine events occurring earlier in the menstrual cycle, a possibility that was examined in a second study.

The gonadotropin-releasing hormone (GnRH) agonist leuprolide acetate (Lupron) was administered for 3 months in a double-blinded, placebo-controlled, parallel-design study to 20 women with PMS. Women receiving Lupron, but not those receiving placebo, demonstrated a significant decrease in symptom severity and cyclicity, consistent with

several earlier demonstrations of the efficacy in PMS of medical or surgical oophorectomy (197 ,198). The ovulatory cycle, therefore, appears to be necessary for the expression of PMS (199).

To determine whether gonadal steroids were the factors that when removed resulted in the elimination of PMS, we added back estradiol and progesterone separately to women who continued to take Lupron and for whom Lupron alone successfully eliminated symptoms of PMS. Both estradiol and progesterone were associated with a return of symptoms typical of PMS. Symptoms were precipitated within 7 to 10 days and largely remitted by the end of the 4-week phase of addback. It does appear, therefore, that gonadal steroids can trigger symptoms of PMS, an observation that at first glance appears discordant with the lack of differences in gonadal steroid levels between women with PMS and controls. The reconciliation of these observations is found in the second part of the aforementioned study, in which a comparison group of women with confirmed absence of PMS received the same protocol of Lupron and hormone addback. The control women showed no perturbation of mood during Lupron-induced hypogonadism or during hormone addback with either progesterone or estradiol, despite achieving hormone levels comparable with those seen in the women with PMS. Women with PMS, therefore, are differentially sensitive to gonadal steroids such that they experience mood destabilization with levels or changes in gonadal steroids that are absolutely without effect on mood in women lacking a history of PMS. Gonadal steroids, then, are necessary but not sufficient for PMS. They can trigger PMS, but only in women, who, for undetermined reasons, are otherwise vulnerable to experience mood state destabilization (199). In other words, PMS represents an abnormal response to normal hormone levels.

Postpartum Depression

The literature examining the possible role of hormone abnormalities in postpartum is more exiguous than that for PMS. This literature, however, may be similarly distilled; the evidence for a reproductive hormone abnormality in PPD is scant (200 ,201 ,202 ,203 and 204 , but see also ref. 205). Nonetheless, it is difficult to regard as irrelevant the enormous hormonal excursions occurring during the puerperium (with precipitous drops of estradiol and progesterone from levels of up to 15,000 pg/mL and 150 ng/mL, respectively, to hypogonadal levels in just 1 to 3 days). Analagous to our observations with PMS, it is possible that women with and those without PPD differ in sensitivity to puerperal hormone changes, not in the degree to which they occur. To test this hypothesis, we created a scaled-down model of the puerperium in which women received high-dose estradiol and progesterone for 2 months (superimposed on Lupron-induced gonadal suppression to permit comparability and stability of levels achieved), followed by a blinded, precipitous withdrawal of gonadal steroids and a consequent Lupron-induced hypogonadal state. This protocol was performed in two groups: euthymic women with a history of PPD occurring no more recently than 1 year before the study (PPD+) and controls lacking a history of depression (PPD-). In the first 2 weeks following withdrawal, the women with a history of PPD experienced a significant increase in measures of depression relative to baseline, with several subjects experiencing an increase in symptoms during the last few weeks of addback. No similar symptoms were experienced by the women lacking a history of PPD. Both the levels of hormones achieved and the change from peak to withdrawal-induced hypogonadism were comparable in the two groups. It appears, therefore, that like women with PMS, women with a history of PPD experience mood state destabilization in association with changes in levels of gonadal steroids that are without effect on mood in women lacking a history of PPD. The hormonal changes can trigger the mood state change, but only in a context of increased susceptibility to affective dysregulation.

Context

The differential sensitivity to gonadal steroids seen in women with a history of PMS or PPD emphasizes that the response to a biological signal cannot be inferred absent an understanding of the context in which the signal occurs. This context includes current physiologic and external environments, prior experience, past history of exposure to the stimulus, and genetic makeup. With the imminent mapping of the human genome, this last contextual determinant becomes of great practical interest as a potential explanation for the differential response to steroids. Data already exist from both animal and human studies in support of this hypothesis. Spearow et al. (206) demonstrated greater than 16-fold differences in sensitivity to estradiol (reproductive disruption) across six different mouse strains, with genotype accounting for more of the variation than the dose of estradiol. Similarly, strain/genetic (and task-dependent) differences in behavioral sensitivity to allopregnanolone were observed by Finn et al. (207). Huizenga et al. (208) demonstrated not only intraperson stability of baseline cortisol and feedback sensitivity (to dexamethasone), which suggests a genetic influence (209), but also a higher sensitivity to exogenously administered glucocorticoid (dexamethasone) in association with a polymorphism in exon 2 of the glucocorticoid receptor. Association studies suggest a progressively increased rate and severity of prostate cancer as the number of cytosine–adenine–guanosine (CAG) trinucleotide repeats in exon 1 of the androgen receptor decreases (210). This observation is accompanied by the recent observation that androgen receptors with decreased CAG repeats demonstrate increased transcriptional efficiency (211). Steroid receptor polymorphisms, then, may alter the steroid signaling pathway in such a way as to produce or

contribute to a different behavioral/phenotypic response to a hormone signal. As appealing as this explanation is for the differential sensitivity observed in PMS and PPD, the demonstrations in animal studies that perinatal steroid manipulations alter the organization of gonadal steroid-sensitive circuitry (42) and gonadal steroid-activated gene expression (212) caution us that gene–environment interactions may yield markedly different phenotypic expressions of the same genotype.

Hormones as Therapeutic Agents

An emerging area of interest is the use of gonadal steroids in the treatment of PPD (213) and the perimenopause. As in PPD, the evidence for a reproductive hormonal abnormality in perimenopausal depression is vanishingly small (214 ,215 and 216 ; Schmidt et al., *unpublished data*). Some (217 ,218 ,219 and 220) but not all (Schmidt et al., *unpublished data*) studies have observed lower plasma LH levels in postmenopausal depressed women, but no consistent group-related differences in gonadal steroids have been demonstrated. Similarly, despite claims for the antidepressant efficacy of estrogen dating back to the nineteenth century (4 ,221), reports of the effect of estradiol on mood in perimenopausal and postmenopausal women (222 ,223 ,224 ,225 and 226) have been inconsistent (227 ,228 and 229) and have been compromised by the failure to diagnose depression (as opposed to depressive symptoms, which have different causes and treatment response characteristics), the failure (with one exception; see ref. 226) to consider remediation of hot flushes as a confound in assessment of psychotropic efficacy, and the failure to assess efficacy in perimenopausal (vs. postmenopausal) women, a potentially important distinction identified by Montgomery et al. (222). These problems were addressed in a recent study that demonstrated the antidepressant efficacy of estradiol in perimenopausal women with major and minor depression (230 ,231). The antidepressant effects were further shown in the subsample of women with no hot flushes, so that the possibility that remediation of hot flush-induced sleep disturbance might indirectly improve mood was eliminated. A subsequent study has similarly demonstrated the psychotropic efficacy of estradiol in perimenopausal depression (C. Soares et al., *unpublished data*). These observations converge with *in vitro* and epidemiologic evidence for neuroprotective effects of estradiol in suggesting that gonadal steroids (and adrenal androgens) may enter the neuropsychiatric therapeutic armamentarium, either as primary or adjunctive agents. While not permitting an inference about the etiology of reproductive endocrine-related mood disorders, the psychotropic effects of hormones may help dissect neural pathways of relevance to the regulation of affect. Attempts to define the mechanisms underlying both the psychotropic effects of gonadal steroids and the differential response to endogenous gonadal steroids should help advance our efforts to illuminate the neurobiology of mood and mood disorders.

Depression and the Medically Ill

Robert G. Robinson

K. Ranga Rama Krishnan

Robert G. Robinson: Department of Psychiatry, University of Iowa, Iowa City, Iowa.

K. Ranga Rama Krishnan: Department of Psychiatry and Behavioral Sciences, Duke University Medical Center, Durham, North Carolina.

The lifetime prevalence of depression in the general U.S. population has been reported to be as high as 17% (1). The rates of depression in healthy persons are significantly lower than those among the medically ill. The rates of depression among medically ill patients range as high as 20% to 40%. Depression in the presence of medical illness, in comparison with depression in the absence of medical illness, is associated with more severely impaired physical or cognitive function. Untreated, depression can persist for many months and may complicate recovery from the medical illness.

Each year, approximately $44 billion is spent in the treatment of depression (2). Although depression associated with medical illness has been shown to increase mortality (3), the benefits of treating depression on medical morbidity and mortality have not yet been established. In this chapter, we review the relationship between depression and medical illness, with cerebrovascular and cardiovascular disease used as a prototype of medical illness.

PREVALENCE OF DEPRESSION AFTER MYOCARDIAL INFARCTION OR STROKE

Part of "81 - Depression and the Medically Ill "

The prevalence of major depression in patients after myocardial infarction (MI) has been estimated to be about 20% (3 ,4 ,5 ,6 ,7 and 8). Depressive symptoms following an acute MI have been reported in 60% of patients (9 and 10). Even in patients with only angiographically proven coronary artery disease, the prevalence of depression is approximately 18% (11).

The prevalence of depression after stroke has been studied in numerous countries of the world (12 ,13 and 14). These studies have found a mean prevalence of major depression of 20% among hospitalized and outpatient victims of stroke, and a prevalence of 13% has been found in community surveys (14). The mean prevalence of minor depression, defined as a subsyndromal form of major depression or the symptoms of dysthymia without the 2-year duration, has been found to be 19% in hospital and 10% in community samples (15) (Fig. 81.1).

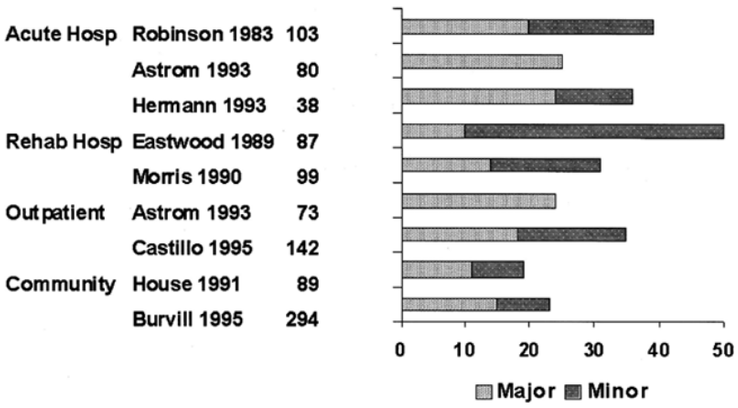

FIGURE 81.1. The percentage of patients found to be depressed after stroke based on the setting in which they were evaluated. Note that hospitalized patients and those in outpatient clinics generally show higher rates of depression than those studied in the community. This finding probably reflects the fact that the strokes of patients who seek medical service are more severe than those of patients in community surveys, in which persons with very mild or no impairment are studied. These studies represent findings from the United States, Canada, England, Sweden, Germany, and Australia.

DIAGNOSIS OF DEPRESSION IN PATIENTS WITH MYOCARDIAL INFARCTION OR STROKE

Part of "81 - Depression and the Medically Ill "

The problem of diagnosing depression in patients with medical illness has been a focus of research and a source of controversy among consultation and liaison psychiatrists for many years. Cohen-Cole and Stoudemire (16) reported that four approaches have been used to deal with this problem in the medically ill. In the “inclusive approach,” depressive diagnostic symptoms are counted whether or not they are related to physical illness. In the “etiologic approach” of Rifkin et al. (17), a symptom is counted only if the diagnostician feels it is not caused by the physical illness. Rapp and Varna (18) use the “substitutive approach” of Endicott (19), in which the psychological symptoms of depression are substituted for the vegetative symptoms, which tend to be nonspecific in a physically ill population, and the “exclusive approach” of Bukberg et al. (20), in which symptoms are removed from the diagnostic criteria if they are not found to be more frequent in depressed than in nondepressed patients.

The utility of these methods in the diagnosis of post-stroke depression was examined in a study that included 142 patients with acute stroke who were reexamined at 3, 6, 12, and 24 months after their stroke. Of the 142 patients, 60 (42%) reported a depressed mood during their acute hospitalization, and the remaining 82 patients denied a depressed mood. No significant differences in background characteristics were found between the depressed and nondepressed groups except that the depressed group was significantly younger (p =.006) and the frequency of personal

history of a psychiatric disorder was significantly higher in the depressed group (p = .04). Throughout the 2 years of follow-up, the depressed patients reported a significantly higher frequency of both vegetative and psychological symptoms of depression than did the patients who were not depressed. The vegetative symptoms that were examined included anxiety, anxious foreboding, morning depression, weight loss, delayed sleep, subjective anergia, early morning awakening, and loss of libido (21). The only vegetative symptoms that were not more frequent in the depressed than in the nondepressed group were weight loss and early morning awakening at the initial evaluation; weight loss, delayed sleep, and early morning awakening at 3 months; weight loss and early morning awakening at 6 months; weight loss, early morning awakening, anxious foreboding, and loss of libido at 1 year; and weight loss and loss of libido at 2 years. Most psychological symptoms were more frequent in the depressed patients throughout the 2-year period. The psychological symptoms assessed included worrying, brooding, loss of interest, hopelessness, suicidal plans, social withdrawal, self-deprecation, lack of self-confidence, simple ideas of reference, guilty ideas of reference, pathologic guilt, and irritability. The only psychological symptoms that were not significantly more frequent in the depressed than in the nondepressed group were suicidal plans, simple ideas of reference, and pathologic guilt at 3 months; pathologic guilt at 6 months; pathologic guilt, suicidal plans, guilty ideas of reference, and irritability at 1 year; and pathologic guilt and self-deprecation at 2 years.

The effect of using each of the proposed alternative diagnostic methods for post-stroke depression based on DSM-IV criteria was examined (22). Symptoms were assessed with the inclusive approach (i.e., a symptom was included if acknowledged, even if it was suspected that the symptom was related to the physical illness). Thus, the initial diagnoses were based on inclusive criteria during the in-hospital evaluation. When this approach was used, 26 patients (18%) met the DSM-IV diagnostic criteria for major depression. The DSM-IV diagnostic criteria were then modified by imposing a requirement for five or more specific symptoms (weight loss and early morning awakening were excluded as criteria for major depression because they were not significantly more frequent in the depressed than in the nondepressed patients). Of the 27 patients with major depression, three were excluded in comparison with the diagnosis based on inclusive criteria. The diagnoses based on unmodified symptoms had a specificity of 98% and a sensitivity of 100% in comparison with use of the “exclusive” criteria as the “gold standard.”

Next, the DSM-IV criteria were modified to examine the substitutive approach (i.e., all vegetative symptoms were eliminated and the presence of four psychological symptoms plus depressed mood was required for the diagnosis of major depression). When this approach was used, none of the original 27 patients in whom major depression had been diagnosed with the inclusive approach was excluded.

At the 3-month follow-up, use of the exclusive approach, which requires only specific symptoms (i.e., weight loss, insomnia, and suicidal ideation were eliminated), resulted in the exclusion of 1 of 12 patients (16%) with major depression. When a diagnosis based on specific symptoms was used as the gold standard, the unmodified DSM-IV criteria and inclusive approach had a sensitivity of 100% and a specificity of 97%. If the substitutive approach, which requires depression plus four psychological symptoms, had been used, none of the 12 patients would have been excluded.

At the 6-month follow-up, when the exclusive approach (i.e., weight loss and insomnia were excluded) was used, 3 of 15 patients no longer met the criteria for major depression. When specific symptoms were used as the gold standard, the unmodified inclusive DSM-IV criteria had a sensitivity of 100% and a specificity of 95%. If the substitutive approach had been used, none of the 15 patients with major depression would have been excluded. At the 1-year follow-up, when the exclusive approach (i.e., weight loss, difficulty concentrating, and suicidal ideation were excluded) was used, 3 of 7 patients no longer met the diagnostic criteria, and the unmodified inclusive DSM-IV criteria had a sensitivity of 100% and a specificity of 95%. With use of the substitutive approach, none of the 7 patients was excluded. At the 2-year follow-up, when the exclusive approach (i.e., weight loss was excluded) was used, 2 of 16 patients with major depression were excluded. With use of the unmodified inclusive DSM-IV criteria, the sensitivity was 100% and the specificity was 96% in comparison with the exclusive approach. The substitutive approach excluded none of the 16 patients.

Although Kathol et al. (23) concluded that the substitutive approach is the best one given our current knowledge, the inclusive approach previously described for patients with stroke during the first 2 years of follow-up had a sensitivity of 100% and specificity of more than 95% in comparison with the exclusive approach. Weight loss was the only symptom that was not significantly more frequent among depressed than among nondepressed patients during the entire 2-year period. Given that the unmodified DSM-IV criteria consistently showed a sensitivity of 100% and a specificity that ranged from 95% to 98% in comparison with "exclusive" criteria that counted only specific symptoms, one could reasonably conclude that the use of unmodified DSM-IV criteria and the inclusive approach is the most rational way to diagnose depression in patients with vascular disease.

DEPRESSION AS A RISK FACTOR FOR CARDIAC DISEASE

Part of "81 - Depression and the Medically Ill "

It has been suggested that depression may play a role in the development of cardiac disease (24 ,25 ,26 ,27 ,28 and 29). For example, data from a study of 2,832 U.S. adults found that persons with symptoms of depression are at 50% greater risk of fatal ischemic heart disease (relative risk, 1.5; 95% confidence interval, 1.0 to 2.3) than are persons without depression (24). A notable exception, however, is a study of more than 2,500 persons followed for 15 years in which an association between depression and increased cardiovascular mortality or ischemic heart disease was not observed (30). The relationship of depression to the development of stroke has not been studied systematically. Although a significant number of patients in whom acute stroke develops have a preexisting depressive disorder (31), a causal relationship of depression and stroke has not been established.

IMPACT OF DEPRESSION IN MYOCARDIAL INFARCTION

Part of "81 - Depression and the Medically Ill "

A higher cardiovascular mortality among patients with major depression has been reported by numerous investigators (24 ,26 ,27 ,32 ,33 ,34 ,35 ,36 ,37 ,38 ,39 ,40 ,41 ,42 and 43). Large, controlled studies have confirmed an increased cardiovascular risk in persons in whom depression develops following an ischemic event (3 ,7 ,26 ,44 ,45 and 46). Frasure-Smith and colleagues (3) studied 222 patients who had experienced an acute MI. Patients were screened with the Beck Depression Inventory and interviewed after their MI with a modified version of the National Institute of Mental Health Diagnostic Interview Schedule to determine if criteria for depression were met. Even after corrections were made for relevant variables that determine outcome, including previous MI and Killip class, major depression was a significant independent predictor of adverse outcome (adjusted hazard ratio, 4.29; 95% confidence interval, 3.14 to 5.44; $p = .013$). The same results were found for patients with modest depressive symptoms (i.e., Beck Depression Inventory > 10). During a subsequent 18-month follow-up, the risk persisted. The underlying pathophysiology and the effects of antidepressant treatment on mortality are the focus of ongoing clinical investigations.

An increased risk for mortality among patients with depression following stroke has been reported in two studies utilizing different patient populations (47 and 48). One study examined the 10-year follow-up of 91 of 103 patients evaluated following acute stroke. Among the 48 patients who had died, it was found that those with major or minor depression while in the hospital were 3.4 times more likely to have died (confidence interval, 1.4 to 8.4; $p = .007$) than were those who were not depressed while in the hospital, even when other variables (e.g., lesion volume) related to mortality were controlled (47 ,48) (Fig. 81.2).

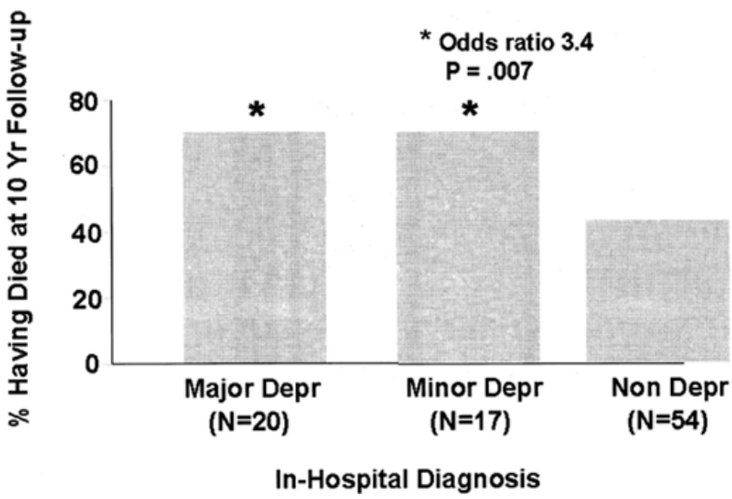

FIGURE 81.2. Survival curves during 10 years for 37 patients with major or minor depression at the time of in-hospital post-stroke evaluation and for 54 patients without in-hospital depression. By 10-year follow-up, 14 of 20 patients with major depression and 12 of 17 with minor depression had died, in comparison with only 22 of 54 nondepressed patients. (Data extracted from Morris PLP, Robinson RG, Andrezejewski P, et al. Association of depression with 10 year post-stroke mortality. *Am J Psychiatry* 1993;150:124–129, with permission.)

A 15-month follow-up of 84 Australian patients who were initially examined in a rehabilitation hospital found that 23% of the patients with major depression at initial evaluation had died, in comparison with 10% of those with minor depression and 2% of those without depression. Patients with major or minor depression were 8.1 times more likely to have died during the 15-month follow-up (confidence interval, 0.9 to 72.9; $p = .06$) than were nondepressed patients (47 ,48). However, Astrom et al. (49) found that in 21 of 80 patients who had initially been examined within the first 2 weeks following an acute stroke and had died during 3 years of follow-up, mortality was associated

with older age, disorientation during the hospitalization, greater impairment in activities of daily living, and a greater degree of cortical atrophy, but not with depression. Despite this negative finding, numerous studies have found that depression associated with stroke or MI increases the risk for death during the first 3 to 5 years after the vascular illness.

Concurrent depression also increases the risk for poor outcome among patients with MI, unstable angina, and heart failure. Unpublished data from Duke University suggest a twofold increase in mortality in depressed patients with heart failure. Besides the increase in mortality, a substantial effect on morbidity has been noted. Post-MI patients who are depressed take longer to return to work than those without depression (10 ,50 ,51). The most parsimonious explanation is that patients who are depressed following an MI are more likely to drop out of cardiac rehabilitation and exercise programs than are patients who are not depressed (52). For example, depressed smokers are 40% less likely to stop smoking than nondepressed smokers (relative risk, 0.6) (53), and depressed patients with coronary artery disease are less likely to comply with low-dose aspirin therapy than are nondepressed patients (54). These findings would suggest that all depressed patients with coronary artery disease should be treated, but data indicating the efficacy and safety of treatments for depression associated with heart disease are very limited.

Numerous studies have documented the adverse effect of depression on physical recovery from stroke (55 ,56 and 57). In a study of 25 patients with major or minor depression after stroke and some impairment in their activities of daily living versus a comparable group of 38 nondepressed patients, the degree of recovery in activities of daily living was significantly greater in the nondepressed than in the depressed patients at 2-year follow-up (p <.01), even when other factors that influence outcome (e.g., baseline deficits, early intervention, specialized stroke and rehabilitation care, nature and size of the lesion) were controlled (57). This delayed recovery was evident as early as 3 to 6 months following stroke (57 ,58) (Fig. 81.3).

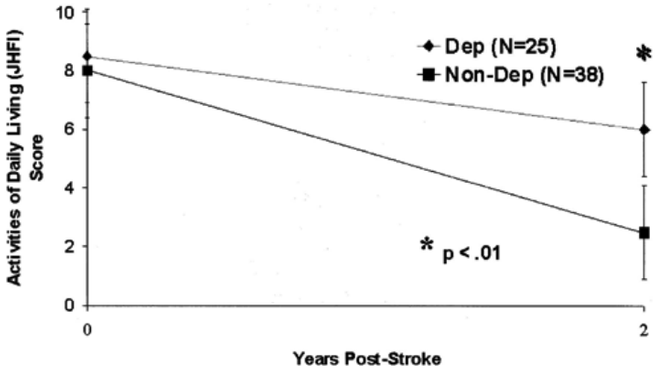

FIGURE 81.3. Changes in activities-of-daily-living scores for depressed (major or minor) patients and nondepressed patients at the time of in-hospital evaluation and 2 years later. Depressed patients show less recovery than nondepressed patients. (Reprinted from Parikh RM, Robinson RG, Lipsey JR, et al. The impact of post-stroke depression on recovery in activities of daily living over two-year follow-up. *Arch Neurol* 1990;47:785–789, with permission.)

In addition to the adverse effects of depression on activities of daily living, numerous studies have demonstrated the adverse effects of major depression after stroke on cognitive function (59 ,60 ,61 and 62). In a study of 275 patients with acute stroke, the mean Mini-Mental State Examination (MMSE) score for patients with major depression (n = 56) was 20.0 ± 6.2; for those with minor depression (n = 49), it was 22.9 ± 6.3; and for those without depression (n = 170), it was 23.3 ± 5.3 (p = .001) (63) (Fig. 81.4). To control for the possibility that the location of lesions, which has been correlated with affect during acute stroke, might have influenced these findings, patients with and without major depression were matched for size and location of stroke lesion (64). Patients with major depression had significantly lower MMSE scores than did their lesion-matched counterparts. Furthermore, on a battery of detailed neuropsychological tests, patients with major depression after stroke showed significantly greater impairment in orientation, language, visual-spatial skills, and executive motor and frontal lobe tasks than did nondepressed patients with lesions in similar locations (59). These findings indicate that major depression following stroke leads to a dementia of depression. Furthermore, this adverse effect of major depression on cognitive function lasts for the first year following stroke (63).

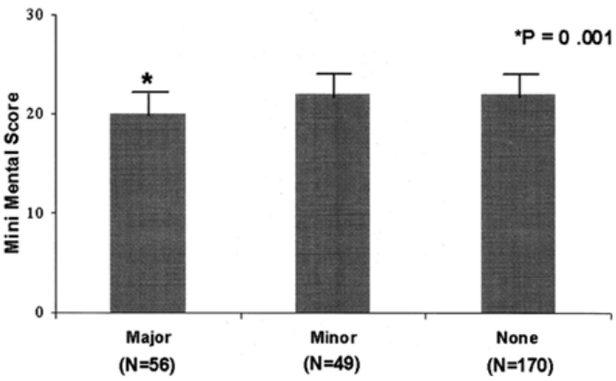

FIGURE 81.4. Mini-Mental State Examination scores in patients with major and minor depression and patients without depression.

The Enhancing Recovery in Coronary Heart Disease (ENRICHD) trial, sponsored by the National Heart, Lung, and Blood Institute, is currently under way (65). Psychosocial interventions in post-MI patients with depression or a high level of perceived social isolation are being evaluated in this multicenter mortality trial of 3,000 patients. Results should be available by the end of 2001 and should provide

answers to the question of whether psychosocial treatments should be initiated in patients with post-MI depression.

TREATMENT WITH ANTIDEPRESSANTS

Part of "81 - Depression and the Medically Ill "

The evidence for antidepressant use is also limited. Tricyclic antidepressants are known to cause adverse cardiovascular effects, including orthostatic hypotension and slowed intraventricular conduction (66 ,67); therefore, it would not be prudent to use these agents in a population at risk.

Pilot studies suggest that the selective serotonin reuptake inhibitors are safe and effective in persons with ischemic heart disease and depression (68 ,69). The only study of an antidepressant in post-MI patients is that of Shapiro et al. (70). In this study, sertraline (Zoloft) was well tolerated, and no unexpected cardiac effects were noted. Large, randomized, controlled trials are necessary to assess the effects of long-term antidepressant treatment on morbidity and mortality. A multicenter study of sertraline is under way in post-MI patients with major depression (SADHART).

Currently, at least four double-blinded, placebo-controlled studies have examined the efficacy of antidepressant medication in the treatment of post-stroke depression (71 ,72 ,73 and 74). In the first study, reported in 1984, 11 patients given nortriptyline showed a significantly greater improvement on the Hamilton Depression Scale (HAM-D), the Zung Self-Rating Depression Scale, and the profile of depressive symptoms assessed by the Present State Examination than did 14 placebo-treated controls (71). It is worth noting that three of the original 14 patients treated with nortriptyline dropped out of the study. Two patients became delirious, and one had a sudden syncopal episode of unknown cause.

In a controlled study by Reding et al. (72), seven patients with abnormal results on the dexamethasone suppression test and post-stroke depression were treated with trazodone for 5 weeks; these patients showed a significantly greater improvement in activities of daily living as measured by the Barthel Activities of Daily Living Scale than did nine patients with positive Problem Solving Therapies (PSTs) who were treated with placebo.

Andersen et al. (73) assessed the efficacy and tolerability of the selective serotonin reuptake inhibitor citalopram in a controlled study of 66 patients with stroke. HAM-D and Melancholia Scale scores were significantly better after 3 and 6 weeks of treatment in the 33 patients given citalopram (under age 65, 20-mg dose; over age 65, 10-mg dose) than in the 33 patients given placebo.

The most recent of the four studies compared nortriptyline (*n* = 16) with fluoxetine (*n* = 23) and placebo (*n* = 17) (74). About half of the patients had major depression, and the other half had minor depression based on DSM-IV diagnostic criteria elicited by the semistructured Present State Examination. The response rate (defined as a reduction of > 50% in the HAM-D score and no longer meeting criteria for depression) of patients treated with nortriptyline who completed the trial was significantly greater (77%) than the response rate of the patients treated with placebo (31%) or fluoxetine (14%). The HAM-D scores of nortriptyline-treated patients were significantly lower after 12 weeks of treatment than the scores of the patients treated with fluoxetine or placebo, which were not significantly different from each other (Fig. 81.5). The dropout rate of the patients treated with fluoxetine in doses that were increased from 10 to 40 mg during 12 weeks (10-mg increase every 3 weeks) was significantly higher (9 of 23) than those of the other two groups (3 of 16 and 4 of 17).

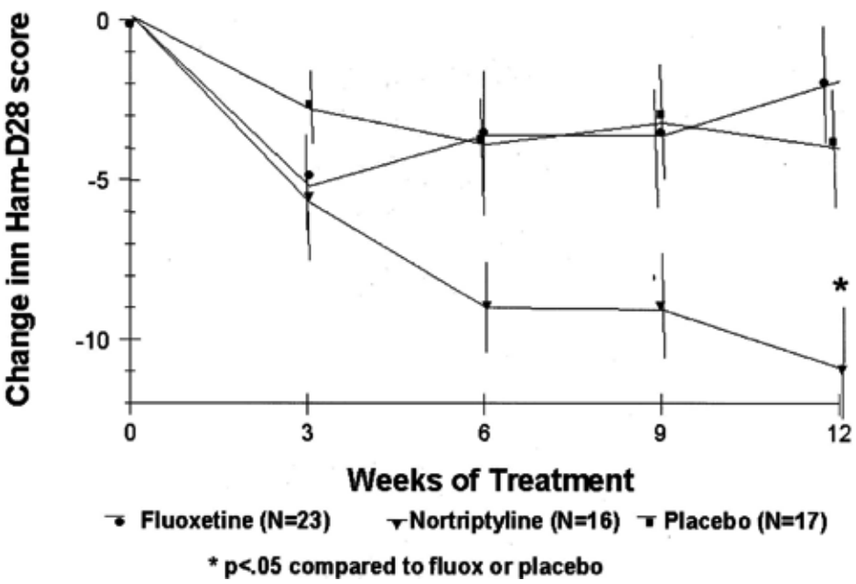

FIGURE 81.5. Change in Hamilton Depression Scale (28 items) scores during 12 weeks of treatment for all patients entered in the study (i.e., intention-to-treat analysis). *Significant group-by-time interaction (F = 3.45, df = 8, 212, p = .0035) and *post hoc* significantly greater change in patients treated with nortriptyline than in those treated with fluoxetine or placebo at 12 weeks.

CONCLUSION

Part of "81 - Depression and the Medically Ill "

Identifying depression in the medically ill population is difficult. Often, the symptoms that are used to identify depression are confused with the underlying symptoms of the medical illness. One approach is to exclude symptoms (e.g., fatigue) that may arise from the medical condition. Another approach is to replace some of the vegetative symptoms, and a third approach is to include all symptoms. The inclusive approach is favored because of its ease of use and practical applicability, and it appears to be sufficient. It is also more sensitive and relates well to functional impairment (75).

In summary, evidence is increasing that depression in patients with vascular disease can be successfully treated with pharmacologic agents. The effects of antidepressant treatment on the risk for exacerbating medical illness and on improving physical, cognitive, and quality-of-life outcomes remain to be determined. The findings of ongoing pharmacologic treatment studies will be viewed with interest.

Alzheimer and other dementias

Kenneth L. Davis

Alzheimer and other dementias - Introduction

As average life expectancies continue to rise dramatically, the aging population is at risk, now more than ever, for Alzheimer disease and other dementias characterized by impaired memory and other cognitive disabilities. In this section, age-associated alterations in cognition, brain structure, and neurochemistry of stroke, Alzheimer disease, and neuropsychiatric manifestations of HIV-1 and AIDS are addressed.

Mohs and Haroutunian summarize the issues involved in early diagnosis of Alzheimer disease. This is an area that has received intense interest, given the hope that future therapies may some day alter the course of the disease. Clearly, in such a circumstance, making a diagnosis at the earliest possible time becomes critical. Ideally, diagnosis in the premorbid state will someday be possible, a possibility further suggested in Chapter 86 by Small, who reviews positron emission tomography techniques that, when combined with the apolipoprotein E status of patients with potential Alzheimer disease, may be a very powerful tool for exceptionally early diagnosis. Yet another aspect of both these chapters, and one that is drawing increasing attention, is the question of the utility of current diagnostic criteria for Alzheimer disease and such potentially related conditions as mild cognitive impairment. Increasingly, these distinctions are becoming blurred.

Parvathy and Buxbaum provide a detailed overview of the molecular and pathologic changes in Alzheimer disease. The work they review increasingly points toward the centrality of amyloid in the pathophysiology of Alzheimer disease and makes the development of transgenic animals that overexpress ß-amyloid secondary to the insertion of various human mutations that have been linked to Alzheimer disease in humans so crucial. Chapter 85 , by Nixon, is a companion piece to Chapter 83 . Whereas Nixon focuses on cellular events, Parvathy and Buxbaum focus on genetic and molecular issues. Of particular interest in Chapter 85 is the discussion of the possible role of lysosomal enzymes in the cellular damage of Alzheimer disease. Chapter 84 , by Duff, is a concise summary of developments in transgenics, as well as the challenges the field faces in using these models, particularly from the perspective of relative contributions of tau and amyloid to the pathogenesis of Alzheimer disease. As these models continue to improve and to demonstrate their congruence with the Alzheimer phenotype, they will prove a cornerstone drug discovery in Alzheimer disease. In my chapter, Chapter 87 , I try to draw on these advances in cellular and molecular biology to discuss the exciting opportunities for the therapeutics of Alzheimer disease. In addition, I summarize the status of current treatments.

Raskind and Barnes review informative studies of psychopharmacologic management of noncognitive behavioral problems in Alzheimer disease, including depressive signs and symptoms, psychotic symptoms, and disruptive agitated behavior. It is becoming increasingly clear that such behaviors can be even more problematic than the cognitive disturbances. Regrettably, this has been a very difficulty therapeutic area, although one that is now receiving a good deal of attention. The data they review can guide the clinician in making some very difficult choices among a broad spectrum of agents that have been employed to ameliorate the host of behavioral symptoms that patients with Alzheimer disease can display.

Manca, Davies, and Burns discuss the implications of the demographic trend toward an aging population and the economic impact of neuropsychiatric disease. As is appropriate, considerable concern is raised about the magnitude of the economic implications of this disease. Given the need to justify a new therapeutic agent on its cost effectiveness,

this kind of discussion is increasingly becoming a part of drug development.

Since the publication of the *Fourth Generation of Progress*, the recognition of Lewy body dementia has increased substantially. To many clinicians, this is a diagnostic entity that was previously incorrectly diagnosed as either Alzheimer disease with some parkinsonian features or Parkinson disease with dementia. In a wonderfully lucid chapter (Chapter 91), McKeith et al. distinguish dementia with Lewy bodies from Alzheimer disease and provide a detailed account of the clinical features discovered in the 1990s.

An entire new term for a set of diseases, tauopathies, was coined in the last few years, and the group that is largely responsible for characterizing the molecular and cellular pathology of these conditions has contributed a key chapter to this section. In Chapter 94 , Higuchi, Trojanowski, and Lee address tau-positive filamentous lesions in neurodegenerative disease.

One of the most active areas of central nervous system therapeutics has been in developing drugs to decrease the cellular disease that follows stroke. Many drugs have shown promise in what seem valid animal models, but, as the chapter by Small, Morley, and Buchan points out, have not been efficacious in the clinic. Nevertheless, as this chapter details, this is a particularly rich area of experimental therapeutics and one of the best examples of the ways in which fundamental advances in neuroscience can drive rational drug development. This theme is made all the more apparent when Chapter 92 , by Graham and Hickey, is read alongside Chapter 93 , because the former so elegantly summarizes the mechanisms that exacerbate neuronal death resulting from hypoxia and hypoglycemia.

Highly active antiretroviral therapy (HAART) has revolutionized the treatment of AIDS and has had a major impact on the neuropsychiatric manifestations of HIV infection. Evans and Mason address both the neurocognitive functioning and the psychiatric manifestations of HIV-1 infection, as well as its treatment in the HAART era.

Taken together, the chapters in this section are an impressive compendium of advances in understanding and treating some of the worst diseases faced by humans. That so much has been learned in so short a time is truly remarkable, but even more remarkable is the advances that will undoubtedly occur in the future, advances whose foundations are eloquently elaborated in the following pages.

Richard C. Mohs and Vahram Haroutunian: Research Service, Mount Sinai School of Medicine, Veterans Affairs Medical Center, Bronx, New York.

INTRODUCTION TO THE NATURAL HISTORY

Part of "82 - Alzheimer Disease: From Earliest Symptoms to End Stage "

Alzheimer disease (AD) is a progressive, degenerative brain disease that is the most common cause of dementia in elderly persons. Clinically, patients with AD have impairments in memory, language, praxis, and other cognitive functions that develop very gradually but progress relentlessly. Longitudinal studies leading to autopsy have shown that the most common neuropathologic findings in elderly patients with these symptoms are neuritic plaques (NPs) and neurofibrillary tangles (NFTs). Modern diagnostic criteria for AD recognize that AD is both a clinical and pathologic entity. By definition, all patients with AD must have dementia, a progressive loss of memory, and at least one other cognitive function that is sufficiently severe to interfere with daily functioning. To differentiate AD from other acquired neuropsychiatric conditions associated with cognitive impairment, the clinical diagnosis of AD is only made when no other conditions could account for the patient's progressive cognitive impairment. Patients who meet the clinical criteria for AD are very likely to have the characteristic neuropathologic features as well. Sometimes, however, the clinical diagnosis is not confirmed at autopsy, and hence the most widely used criteria for AD reserve the term *definite AD* for those patients in whom both clinical and neuropathologic data support the diagnosis of AD.

Although progressive cognitive impairment is the core or defining characteristic of AD clinically, patients with this disease have other symptoms as well. Many patients also have other neuropsychiatric symptoms including agitation, psychosis, depressed mood, and personality change. These other symptoms are not necessary for a diagnosis of AD and tend to be quite variable both within a given patient and from one patient to another. When they are present, these symptoms can be a major problem for caregivers of AD patients, and behavioral problems have been linked to an increased need for health services including nursing home care.

The first definite symptoms of AD are often quite mild and are difficult to differentiate from the mild memory loss that is a frequent consequence of normal or usual aging. Inevitably, however, the degenerative changes of AD become sufficiently severe so the patient has difficulty with daily functioning. The functional change can be observed first in the performance of cognitively demanding tasks such as handling money, remembering appointments, following directions, and using appliances. As the disease progresses and the patient's cognitive abilities deteriorate, the patient has difficulty in more functional domains including the basic activities of daily living such as feeding, toileting, dressing, and personal hygiene. In the later stages of AD, patients are often unable to remember even very simple things, have great difficulty talking and understanding language, and may be confined to bed or to a chair. The average life expectancy of a patient with AD after the initial diagnosis is approximately 10 years, but with a great deal of variability around that mean.

In the sections that follow, we review studies of the development of the neurobiological changes responsible for AD. Later, we briefly review the epidemiology of AD and review in greater detail the development of the disease clinically. In each section, we emphasize the need to understand AD from a longitudinal perspective because both the underlying neurobiology and clinical presentation of the illness vary substantially across the course of illness. Because of intense recent interest in understanding the very early development of AD to develop preventive therapies, our presentation emphasizes recent findings on the earliest manifestations of disease.

NEUROBIOLOGICAL STUDIES ACROSS THE SEVERITY SPECTRUM

Part of "82 - Alzheimer Disease: From Earliest Symptoms to End Stage "

It has already been noted that the definitive diagnosis of AD depends on neuropathologic changes that characterize

the disease. No single neuropathologic lesion is in itself adequate for the diagnosis of AD; rather, the neuropathologic diagnosis of AD is based on the presence of multiple AD-related lesions, the density of these lesions relative to the age of the subject, and the absence of lesions characteristic of other neuropathologic diseases. The absolute weight of the brain is decreased relative to normal controls, but this decrease is generally less than 10% relative to age-matched controls, and it is neither diagnostic of nor specific to AD (1). Gross examination of the brain in AD also reveals significant apparent atrophy, widening of the sulci, and erosion of the gyri, but these changes also reflect advanced age with significant overlap between AD and normal elderly controls. However, the atrophy of the cortex is associated with significant reductions in the numbers of neurons (2 ,3). For example, Terry et al. reported 40% to 46% losses of large neurons in the frontal and temporal cortices of specimens derived from patients with AD (4). Similarly, Gomez-Isla and colleagues (5 ,6), using unbiased stereologic sampling techniques, reported approximately 50% losses in neurons of the superior temporal sulcus with even more pronounced losses in specific cortical laminae. These neuronal losses were observed not only in brain specimens from patients with severe dementia, but also in specimens derived from patients with relatively mild or questionable dementia. The magnitude of neuronal loss increases systematically with increasing dementia severity and increasing disease duration. Neuronal degeneration is not restricted to the cortex, but it is also reflected in neuronal losses in subcortical nuclei such as the nucleus basalis of Meynert (7) (the cells of origin of the cholinergic input to the cerebral cortex), the locus ceruleus, and raphe aminergic nuclei (8 ,9). Neuronal loss in these subcortical structures, especially in the nucleus basalis of Meynert (10), has also been found to correlate significantly with dementia severity and cognitive deficits.

Neuronal loss and degeneration are accompanied by significant decreases in markers of synaptic density. Although synaptic markers such as synaptophysin are reduced significantly in the cerebral cortex, especially the frontal and parietal cortices and in the hippocampus, with increasing age (11), further losses are encountered in AD, whether assessed by immunohistochemical techniques or by direct assessment of synaptic specializations and profiles (3 ,12 ,13 and 14). The loss of synaptophysin immunoreactivity in the frontal and parietal cortices, and in the hippocampus, is among the strongest correlates of dementia severity (10 ,15 ,16). These losses and correlations with cognitive function are not only evident at the immunohistochemical level, but they have also been observed with quantitative enzyme-linked immunosorbent assay techniques (10). This loss of synaptic markers is not merely a reflection of the degeneration of the cortical neurons noted earlier, but it also reflects the loss of presynaptic terminals and neuropeptide- and neurotransmitter-containing vesicles.

Various specific lesions have been found to be associated with AD. The most prominent are NPs and NFTs. However, these lesions are not exclusively associated with AD. Age-related accumulations of NPs and diffuse plaques have been noted in elderly persons who are otherwise normal. Similarly, NFTs have been found in the brains of nondemented elderly persons and in association with non–AD-like neurodegenerative diseases (17). Although NP and NFT lesions can be present in diseases other than AD, other markers and clinical phenotypes can be used to distinguish among them, and the presence of NPs and NFTs in the absence of other confounding neuropathologic lesions provides the basis for the diagnosis of AD.

NPs are extracellular deposits of varying sizes with an amyloid ß-peptide core (Aß) and neuritic inclusions. Aß is a 40 to 43 amino acid long peptide that is generated from a larger peptide (Alzheimer amyloid precursor protein or APP) by two cleavage events (18). The cleavage mechanisms that lead to the production of Aß from APP are under intense investigation. ß-Amyloid cleavage enzyme was isolated and cloned and proposed as the enzyme responsible for cleavage at the N-terminus (19 ,20 and 21). Cleavage at the C-terminus is attributed to an as yet unidentified enzyme termed γ-secretase. Some evidence suggests that presenilin 1 may be the γ-secretase (22), but this hypothesis is still under investigation. That Aß deposition plays a critical role in the pathogenesis of AD was recognized with the accumulation of evidence showing that mutations in the APP gene, as well as mutations in the gene encoding for presenilin 1 and 2, were invariably associated with AD (23 ,24). Studies in transgenic mice demonstrated that the introduction of these mutations leads to the development deposition of Aß plaques and learning and memory deficits in some mutants (25 ,26 and 27).

Despite the clear evidence implicating NP deposition in the pathogenesis of AD, few studies have addressed the relationship of NP deposition with the symptoms of AD (dementia) during the early phases of the disease. Ascertainment of the relationship between specific pathologic lesions and symptoms of AD has been difficult, because most studies have focused on the neuropathology of AD at the terminal stages of the disease, when dementia has been fully developed and neuropathologic lesions have been profuse. Studies have suggested that increases in the densities of neocortical NPs occur very early during the course of cognitive deterioration (6 ,10 ,28 ,29 ,30 ,31 and 32), and they may be among the initial pathologic events in the development of AD (31). In some of these studies, brain specimens were grouped according to the severity of dementia before death according to the Clinical Dementia Rating (CDR) scale. The density of NPs and Aß

immunoreactivity were then quantified in different brain regions. These studies showed that increases in NP density and quantitatively measured Aß immunoreactivity are evident even in those patients who die at the earliest stages of dementia, when dementia severity is very mild or even questionable. The density of NPs and Aß immunoreactivity then increase systematically as a function of increasing dementia severity. In one study (29), elevated levels of Aß-42 were detected in multiple neocortical regions before NFTs and significant immunoreactivity to abnormal tau (see later) could be demonstrated in the same cortical regions. Increases in NP density and Aß immunoreactivity were observed in cases of mild dementia before the density of neuropathologic lesions was high enough for the patients to meet the threshold criteria for the definitive diagnosis of AD.

NFTs constitute the second hallmark of AD neuropathology. Immunohistochemical and biochemical studies have shown that NFTs consist of paired helical filaments that are abnormal aggregates of abnormally folded (33 ,34) or phosphorylated (35 ,36) forms of the microtubule-associated protein tau. The progressive involvement and distribution of NFTs to different brain regions have been used to stage the neuropathologic severity of AD (37 ,38). These studies have suggested that the first signs of NFT are found within the entorhinal cortex, followed by the hippocampus, and the eventual involvement of virtually all regions of the isocortex. There is also clear evidence that the density and severity of NFTs increase as a function of increasing disease duration (5 ,6). Thus, both the density of NFTs in any given brain region and the regions of the brain affected increase with increasing disease duration. In a study identical to that described earlier, study subjects were grouped on the basis of the severity of dementia before death, and the density of NFT-bearing neurons in different brain regions was quantified as a function of dementia severity (39). The density of NFTs in all brain regions increased as a function of increasing dementia severity. However, moderate NFT involvement was documented in the entorhinal cortex of elderly patients with no clinical evidence of dementia (see also ref. 40). Neocortical NFTs were abundant only in patients with moderate to severe dementia, and NFT density increased as a function of increasing dementia severity. Although neocortical NFTs were present in patients with moderate dementia, NFT abundance was low or absent in patients with mild or questionable dementia. Similar findings have been reported in other studies (10 ,11 ,40). These studies suggest that NFTs are most abundant in the entorhinal cortex, where they can be observed in nondemented elderly subjects as well as in patients with AD. NFTs involve neocortical structures later in the course of the AD and are associated with significant dementia. As dementia severity increases, so does the density of neocortical NFTs. This correlation of NFT density with dementia severity is not restricted to the neocortex and to the hippocampus, but it also applies to the subcortical nuclei, such as the forebrain cholinergic nucleus basalis of Meynert (15). Thus, NFTs are a significant neuropathologic feature of AD and contribute to the progression of dementia.

In addition to the neuropathologic lesions associated with AD, significant deficits in neurochemical functions and indices have been observed (41). Chief among these neurochemical deficits are deficits in neocortical indices of cholinergic function and decreases in the concentrations of several neuropeptides such as somatostatin and corticotropin-releasing hormone (42). Deficits in several other neurochemicals and neurotransmitters such as norepinephrine and serotonin have also been reported, but their alterations are not as profound and do not appear to be as consistently observed (41 ,43 ,44). Deficits in the activity of cholinergic marker enzymes (choline acetyltransferase and acetylcholinesterase) were among the first to be reported in AD (45 ,46). Deficits in cortical cholinergic marker enzymes have been among the most consistently replicated neurochemical findings in AD. Some studies have reported that compensatory mechanisms interact with cholinergic enzyme deficits and lead to an up-regulation of high-affinity choline transport (47). Irrespective of compensatory mechanisms that may be engaged, the loss of cortical cholinergic enzyme activity is associated with severe degeneration of cholinergic neurons in the basal forebrain including the neocortically projecting neurons of the nucleus basalis of Meynert (7). The discovery of these profound forebrain cholinergic system deficits and the growing understanding of the role of the forebrain cholinergic system in learning and memory (48) were pivotal to the development of the current therapeutic strategies in AD (49), which focus on the restoration of these cholinergic deficits by inhibiting the activity of the acetylcholine catabolic enzyme, acetylcholinesterase.

As with neuropathologic studies of AD, most postmortem studies assessing cholinergic markers in AD were derived from patients with end-stage dementia. Those few studies in which brain biopsies were obtained and cholinergic markers were assessed ante mortem were generally restricted to patients who have a very early onset of dementia or to patients with relatively advanced dementia (50 ,51 and 52). Thus, although deficits in the activity of cholinergic marker enzymes have been shown to correlate significantly with dementia severity (43 ,53), the question whether these profound deficits in cholinergic markers found in patients with end-stage dementia extend to patients with much earlier disease remained unanswered until recently. Using the same strategy as that described for studying neuropathologic changes in early dementia, Davis and colleagues assigned patients to groups on the basis of their cognitive status at the time of death according to the CDR scale (54). After stratification of subjects to different dementia conditions, the activity of cholinergic marker enzymes was assessed in multiple neocortical regions that encompassed representative regions within the frontal, temporal, parietal, and occipital cortices. Cholinergic marker enzyme activity was profoundly diminished in patients with end-stage, severe dementia, but neither the activity of acetylcholinesterase nor the activity of choline acetyltransferase was reduced in subjects with mild and moderate dementia. Although it can be argued that adaptive changes compensate for cholinergic

deficits in mild dementia (47), the most parsimonious interpretation of these results is that cholinergic deficits are characteristic of relatively advanced dementia and contribute relatively less to the early phases of cognitive impairment in AD.

Deficits in selected neuropeptides have also been consistently reported in AD (41). The levels of somatostatin (SLI) and corticotropin-releasing factor (CRF) are the most consistently affected (55 ,56 and 57). Deficits in these neuropeptides are often found to be as profound as those observed for the cholinergic marker enzymes and are specific in that not all neuropeptides are diminished in AD cortex (58 ,59). The CRF deficits are accompanied by the up-regulation of CRF receptors (60), whereas SLI receptors density is either unchanged or down-regulated (56). Evidence of the relationship of the concentration of these neuropeptides to the severity of dementia has been sparse. Some insight into CRF concentrations in earlier stages of AD has been gained from negative correlations between CRF levels and duration of illness (61), as well as from studies of cerebrospinal fluid (62). Correlations between the severity of Alzheimer dementia and cerebrospinal fluid CRF have been found, suggesting that the CRF deficiency may be a relatively early marker of AD. This relationship has not been observed consistently (63 ,64), however. Postmortem studies of CRF and SLI concentrations in the cortices of subjects stratified to groups on the basis of their cognitive status at the time of death have suggested that although the concentrations of both neuropeptides are significantly and severely diminished in patients with severe or terminal dementia, only the levels of CRF are significantly altered in patients with mild to moderate dementia (65).

In the past few years, many epidemiologic studies have addressed the possible protective effect of antiinflammatory drug use with regard to AD (66 ,67). At a molecular level, it is apparent that an inflammatory response accompanies the neuropathologic features of AD (66 ,67 ,68 and 69). There is clear evidence of an acute-phase response with up-regulation of inflammatory cytokines such as interleukin 1 (IL-1) and IL-6 and tumor necrosis factor-α, accompanied by an increase in acute-phase proteins such as α1-antichymotrypsin and α_2-macroglobulin (66). The complement system is active in the AD brain (70 , 71), with generation of the lytic membrane attack complex and presumably with release of anaphylatoxins. Up-regulation of cyclooxygenase 2 in AD neurons (69) suggests that inflammatory lipids may also be involved in the pathogenesis of the disease. It has been hypothesized that inflammatory responses can be autotoxic to neurons and may exacerbate the fundamental pathology of AD (72). The epidemiologic studies with antiinflammatory agents and a prospective study suggesting some slowing of disease progression after indomethacin treatment support a role for inflammatory processes in AD progression (66). Although studies seeking direct evidence of the role of inflammatory processes in the progression of AD and dementia have been initiated only recently (73), one study has examined cytokine gene expression during AD progression. In this study, cytokine gene expression (IL-6 mRNA) in the hippocampus was found to increase as dementia severity progressed from moderate (CDR 2) to severe (CDR 5). Neither the epidemiologic studies nor the neurobiological studies directly address the cause and effect relationship among AD, dementia progression, and inflammatory responses within the brain. These studies do suggest, however, that even if inflammatory responses are not a critical feature of the etiology of AD, they may nevertheless play an important role in mediating the development and progression of dementia.

The results of the studies summarized earlier provide only a very general and global review of the tens of thousands of published reports relevant to the pathogenesis of AD. The results of the more recent studies, especially those that relate to the progression of the disease and dementia, have shed some new light on the pathophysiologic mechanisms involved at the onset of dementia and its progression during the disease process. These relatively recent findings have suggested that, in contrast to some earlier views, the deposition of amyloid plaques is integral to the onset and progression of dementia, and, at least in some brain regions such as the cerebral cortex, they may precede the involvement of some of the other prominent deficits and lesions (e.g., NFTs and cholinergic and neuropeptidergic deficits) characteristic of later stages of the disease. These results have also emphasized that many different lesions contribute to AD neuropathology, and each lesion (NP, NFT, neuronal loss, synaptic loss, cholinergic deficit, neuropeptide deficit, inflammatory response, and countless others) contributes significantly to the dementia symptoms of AD. Conversely, these studies have shown that AD is not characterized by random or general neural system failures, but rather that the pathologic features of AD appear to follow a course of progressive involvement of different neuronal systems, the characteristics of which are only now beginning to be elucidated.

CLINICAL AND NEUROPSYCHOLOGIC STUDIES

Part of "82 - Alzheimer Disease: From Earliest Symptoms to End Stage "

Epidemiologic Studies of Persons at Risk

Precise estimates of the proportion of dementia cases that are attributable to AD are difficult to obtain because few population-based studies obtain autopsy data that would enable a definitive diagnosis of AD. In most large-scale autopsy series, AD lesions are the primary neuropathologic finding in more than 50% of all dementia cases (74). Studies using clinical criteria also find that AD accounts for more than 50% of all dementias, with mixed AD plus vascular dementia and AD plus parkinsonism accounting for significant proportions of the remaining cases (75). Pure vascular

dementia and Lewy body dementia are also found with some regularity, but they are both far less common than AD. Because of the high prevalence of AD among dementia cases, the epidemiology of dementia in old age is largely the epidemiology of AD. Because AD is so much more common than other types of old-age dementia, some clinical guidelines have argued that AD should be treated as a diagnosis of inclusion rather than one of exclusion (76); that is, an older person with dementia should be diagnosed with AD unless there is substantial clinical evidence supporting another cause of the dementia.

The prevalence of AD rises dramatically with age, and age is the most potent risk factor for AD. Less than 1% of new cases of AD are found in persons younger than age 65 years (77), and the prevalence of AD rises steadily after that. By age 90, approximately 35% of persons remaining alive will have AD (77). Men and women are equally vulnerable to AD, but because women live longer than men on average, there are more women than men with AD. Studies looking at different ethnic and cultural groups have found that AD is common in elderly persons from all ethnic and socioeconomic backgrounds, but there may be some Asian ethnic groups who are less vulnerable to AD (78). Environmental risk factors for AD have been difficult to identify, but there is some evidence that persons with higher educational attainment are less likely to develop AD in old age (79). Neurobiological mechanisms that may account for the protective effect of education have not been elucidated, but it is possible that persons with more education have a greater reserve of brain capacity that enables those persons to remain cognitively intact for longer periods of time during the early stages of AD.

Certain genetic factors have been identified that contribute to the development of AD. Specific genetic mutations that cause AD have been identified in the gene coding for the amyloid precursor protein, in the presenilin 1 gene, and in the presenilin 2 gene (24 ,80). Persons who inherit one of these mutations develop AD when they are quite young, often as early as age 40 to 50 years. In families carrying one of these mutations, the inheritance of AD follows the classic pattern of autosomal dominant inheritance, with 50% of each generation developing the disease. Investigations of these mutations are very important because of the information they provide about possible pathophysiologic mechanisms leading to the development of plaques, tangles, cell loss, and dementia. From a population standpoint, however, these genetically determined cases of AD are of less interest because they constitute a small fraction of all cases observed clinically. Most estimates are that less than 2% of all AD cases result from specific genetic mutations (80).

Family (81) and population (82) studies have demonstrated that persons who carry the ε4 form of the apolipoprotein E (Apo E) gene *(APOE)* have a greater likelihood of developing AD than do persons who carry only the ε3 and the ε2 forms. Apo E is a cholesterol-transporting protein that is coded by a gene on chromosome 14. The gene has three allelic forms, ε3, which is by far the most common, and two rarer forms, ε2 and ε4. Persons carrying the ε4 form are at increased risk of developing AD, particularly between the ages of 65 and 75 years. The mechanism by which *APOE* genotype influences the risk of AD is currently under investigation. From a clinical standpoint, *APOE* can be useful for identifying persons at increased risk of developing AD. It is not useful in routine diagnostic evaluations, however, because many patients who develop AD do not carry the ε4 allele, and some who do carry the high-risk form of *APOE* do not develop AD (82). There is extensive research to identify other common genes that influence the likelihood of developing AD, but none have been identified that consistently associate with the risk of AD as *APOE* genotype does.

Predictive Neuropsychological Deficits

AD is a progressive disease with insidious onset in which the underlying neurodegenerative changes probably begin years before clinical symptoms are obvious. Studies of populations at risk of developing AD have been conducted to determine whether there are changes in cognitive function that can be detected with neuropsychological tests before patients meet clinical criteria for the diagnosis of AD. For these studies, persons who are cognitively normal but who are at increased risk of developing AD, usually because of old age, are followed longitudinally with a structured battery of neuropsychological tests. After a period of 1 to 5 years, the baseline performance of patients who have subsequently been diagnosed with AD is compared with the remainder of the population that has remained free of dementia. Several studies using this model have demonstrated consistently that impairment in memory is significantly worse at baseline in those persons who subsequently are diagnosed with AD (83 ,84 and 85). In most instances, the memory tests most impaired before diagnosis are those measuring delayed recall, that is, recall of newly learned information but after a delay of several minutes during which the subject must perform other cognitive tasks. A deficit in the rate of new learning for verbal material (e.g., a list of words) has also be found to predict subsequent dementia in some studies (85). Language function, particularly difficulty with naming, has also been found to differentiate those persons who subsequently develop dementia from others who remain free of dementia (83). Occasionally, other cognitive tasks such as those placing great demands on executive function and working memory show deficits before the onset of dementia, but memory impairment is uniformly the most pronounced deficit (84).

Evidence indicates that some of the predictive power of poor performance on neuropsychological tests results from the fact that memory deficits are, in part, a subclinical surrogate identifying those at increased risk because of old age or presence of an *APOE*ε4 genotype. Because studies have

clarified that *APOE* genotype may confer additional risk of AD primarily within a certain age range (86), it is likely that *APOE* genotype and neuropsychological test performance are independent predictors of dementia in most instances. Analyses of data from these data on neuropsychological antecedents of dementia have consistently shown that the memory and other deficits cannot be accounted for simply by considering age as a predictor. Rather, it appears that deficits in memory and, to a lesser extent, language and executive function are predictors of subsequent dementia across a broad range of ages and for all *APOE* genotypes.

Longitudinal Studies

Numerous longitudinal studies have documented the progression of cognitive, behavioral, and functional changes throughout the course of illness. As expected, given the studies of populations at risk for AD described earlier, studies of very mild AD have documented that memory impairment is the earliest and most prominent feature of the illness (87). As a consequence, memory measures, particularly those employing a measure of delayed recall memory, are now frequently used to identify persons thought to be in the very earliest stages of AD or who may be at high risk of developing AD. As the disease progresses, deficits in both expressive and receptive language and deficits in praxis and visuospatial ability become quite pronounced. Longitudinal studies have also documented that cognitive deterioration in AD is relentlessly progressive, with little evidence of improvement (88).

Some standard assessment tools have been developed to measure the cognitive deficits in AD in a semiquantitative fashion. Among the most commonly used assessment tools are the Mini-Mental State Examination (89), the Blessed Test of Information, Memory, and Concentration (90), and the Alzheimer's Disease Assessment Scale (91). Each of these instruments includes brief tests to assess dysfunction in cognitive domains typically impaired in AD, particularly memory, language, orientation, and praxis. The Mini-Mental State Examination and the Blessed test are quite brief and are often used as screening instruments in research and clinical practice. The Alzheimer's Disease Assessment Scale was developed as a tool for use in clinical trials and is almost always used as one of the primary efficacy measures in clinical trials of antidementia drugs (49 ,92). Longitudinal studies with each of these instruments have been performed. Those studies demonstrate that the measured rate of cognitive decline in AD is quite consistent from study to study and across different populations (88 ,93). In addition, the rate of cognitive decline in AD is curvilinear with time, such that deterioration is quite slow at the start of the illness, is faster during the middle years of illness, and is again slow when patients reach the near terminal phase of the illness. This relationship of rate of deterioration with stage of illness has important implications for clinical trials of agents that are expected to slow the rate of cognitive deterioration (88 ,94).

Factors that may be associated with differences in the rate of cognitive deterioration have been investigated extensively. Apart from the relationship of rate with stage of disease described earlier, no other factors have been found to affect the rate of deterioration consistently. Age, age of disease onset, gender, ethnicity, and *APOE* genotype have all been examined as possible predictors, and none has consistently been shown to affect the rate of decline. Once patients develop the disease, cognitive function deteriorates relentlessly and at approximately the same rate regardless of these variables (88 ,93 ,94).

Behavioral disturbances have also been investigated longitudinally, and it is clear that symptoms such as psychosis, agitation, and depressed mood can be very disturbing both to the patient and to caregivers. Because of the importance of these symptoms in patient management, new tools have been developed in an effort to provide reliable and valid assessment of their severity. Commonly used tools include the Neuropsychiatric Inventory (95), the BEHAVE-AD (96), and the noncognitive subscale of the Alzheimer's Disease Assessment Scale (91). In contrast to the cognitive deficits of AD, however, these behavioral disturbances are quite variable from one patient to another and over time in individual patients (95 ,97). These disturbances are episodic phenomena that wax and wane over the course of AD, with little evidence of progression. Most trials of potential new treatments for AD now include some assessment of these symptoms, and the overall effectiveness of treatments for AD is at least partly determined by the extent to which they improve behavioral symptoms.

By definition, all patients with AD have some impairment in their ability to perform daily activities (98). The assessment of functional ability in patients with dementia includes both an assessment of the basic activities of daily living such as feeding, toileting, dressing, and grooming and an assessment of more cognitively demanding, instrumental activities of daily living such as handling money, using the telephone, performing household chores, and using appliances (99 ,100). The definition of basic activities of daily living is quite consistent from study to study, but there is much less consensus on the kinds of activities that must be surveyed in any assessment of instrumental activities of daily living. Longitudinal data are consistent, however, in demonstrating that impairments in instrumental activities of daily living appear very early in the course of AD, whereas impairments in basic activities of daily often do not appear until patients are quite cognitively impaired (100 ,101). Thus, any comprehensive assessment of functional status in AD must include both basic and instrumental activities of daily living.

The longitudinal progression of functional impairment is relentless, and functional abilities, once lost, are rarely

regained (100 ,101). In this regard, functional impairment follows a progression similar to that of cognitive decline. Correlational studies invariably find a close relationship of functional impairment with the degree of cognitive impairment (101). There is some evidence that the severity of behavioral symptoms, including psychosis and agitation, is associated with some excess disability over that resulting from cognitive impairment, but the contribution of behavioral pathology to functional impairment is relatively small (102). Overall, the trajectory of functional impairment in AD follows the progressive downhill course determined by cognitive loss.

CONCLUDING COMMENT

Part of "82 - Alzheimer Disease: From Earliest Symptoms to End Stage "

Development of effective treatments for AD will be facilitated by a detailed understanding of the neurobiological mechanisms underlying the disease at each of its stages. Testing of treatments for AD requires an understanding of the clinical manifestations and consequences of the disease at each of its stages. Studies investigating neurobiological and clinical changes of the disease over its entire course are providing the tools necessary to develop effective interventions for the prevention and treatment of AD.

MOLECULAR PATHOLOGY OF ALZHEIMER DISEASE

Part of "83 - Molecular Genetics of Alzheimer Disease "

Pathologic Changes

Alzheimer disease (AD) is characterized histopathologically by the intraneuronal accumulation of paired helical filaments (PHFs) composed of abnormal tau proteins and extracellular deposits of an amyloid peptide (Aß) in plaques (1). AD plaques are round, spheric structures, 15 to 20 µM in diameter, consisting of a peripheral rim of abnormal neuronal processes and glial cells surrounding a core of deposited material. Several associated proteins have been identified in the plaques including heparan sulfate proteoglycans (2), apolipoprotein E (Apo E), and α-antichymotrypsin (3), as well as metal ions (4).

Alzheimer Amyloid Precursor Protein

Aß is proteolytically derived from a larger integral membrane protein, the amyloid precursor protein (APP). Because there are mutations in APP (discussed in detail later), that lead to AD, the molecular and cell biology of APP will be discussed here at some length. APP is a type I integral membrane glycoprotein containing the Aß region, which includes 28 amino acids of the ectodomain and 12 to 14 amino acids of the adjacent transmembrane domain (1 ,5). APP is a member of a family that also includes the amyloid precursor–like proteins 1 and 2 (APLP1 and APLP2). The *APP* gene is localized on chromosome 21 at 21q21.2 (6 ,7), and it is encoded by 18 exons, of which exons 16 and 17 encode the Aß peptide domain (8). Three major splice variants of APP have been identified containing the Aß sequence, that is, the APP695, APP751, and the APP770 isoform, of which APP695 is the major isoform found in neurons (6 ,7 ,9). The two longer forms (APP751 and APP770) contain a 56-amino-acids domain with homology to Kunitz family of serine protease inhibitors (KPI) (10).

APP Processing

APP can be processed by at least three secretases: α-, ß-, and γ-secretases. The site of cleavage of each of these enzymes is shown in Fig. 83.1 . In the nonamyloidogenic pathway, α-secretase cleaves the amyloid precursor protein within the Aß domain. The cleavage within the Aß domain prevents deposition of the intact amyloidogenic peptide. α-Secretase activity generates a soluble N-terminal fragment of APP known as sAPPα, and its C-terminal counterpart of approximately 10 to 11 kd remains embedded in the membrane. The site of cleavage targeted by α-secretase has been identified at the Lys16-Leu17 bond of the Aß sequence corresponding to Lys687-Leu688 peptidyl bond of APP770 (11). The 10- to 11-kd C-terminal product may undergo an additional cleavage by a protease γ-secretase activity. This process leads to the formation of p3 and its complementary product p7 (Fig. 83.1).

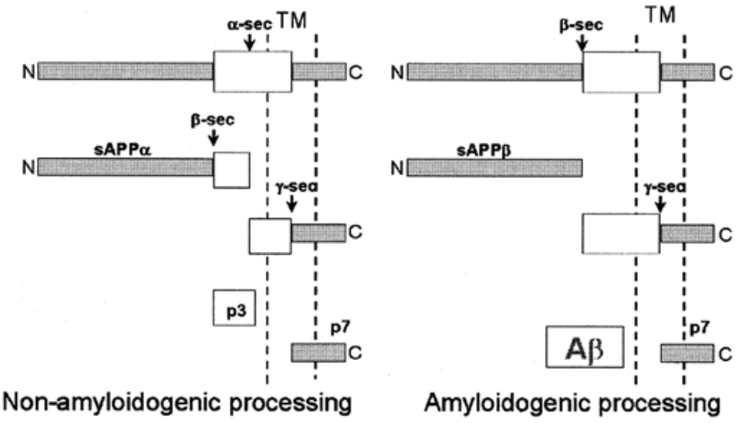

FIGURE 83.1. Processing of APP by the secretases.

The protease termed ß-secretase initiates Aß generation by cleaving APP after methionine 671 (using APP770 numbering), thus creating an approximately 12-kd membrane-retained C-terminal fragment having residue 1 (aspartate) of Aß at its N-terminus (12). This can result in the secretion of a truncated soluble APP molecule, called sAPPß, into the medium (13). The 12-kd fragment may then undergo γ-secretase cleavage within the hydrophobic transmembrane domain at either valine 710, alanine 712, or threonine 713 to release the 40, 42, or 43 residue Aß peptides (13). The varying C-terminal of Aß may be a feature of crucial importance because Aß peptides display distinct physical properties and, in particular, exhibit aggregation behavior that can vary according to their length (14).

Buxbaum et al. showed by using fibroblasts with a disrupted *TACE* (tumor necrosis factor α-converting enzyme)

gene that two classes of α-secretase exist (16), one involved in the basal secretion and the other involved in regulated secretion (16). These investigators demonstrated that TACE, a member of the ADAM family (a disintegrin and metalloprotease family) of proteases, plays a central role in regulated α-secretase cleavage of APP. The existence of two classes of α-secretases is supported by the finding that the potency of inhibition by different hydroxamic acid–based inhibitors is different between basal α-secretase activity and TACE (17). The mammalian kuzbanian orthologue mKuz (ADAM 10) has α-secretase activity and is involved in the basal release of sAPPα (18). Four groups have now identified a candidate for ß-secretase (BACE), also known as Asp-2 (19 ,20 ,21 and 22). BACE has been shown to be an aspartyl protease that is activated from the proenzyme form in cell lines. Finally, presenilin 1 (PS1) appears to facilitate a proteolytic activity that cleaves the integral membrane domain of APP by γ-secretase (23). It is possible that presenilins are γ-secretase or they facilitate γ-secretase activity through some other mechanism (discussed in detail later).

Aß Peptide

As indicated earlier, the chief peptide component of the AD plaque, Aß, has been isolated as a peptide of 40 to 43 amino acids in length (1). Brain Aß has both soluble and insoluble species with aggregation states from monomer to higher-molecular-weight oligomers. Soluble brain Aß is predominately a random coil and an α-helical folded peptide. Insoluble Aß is ß-sheeted and forms either fibrillar or amorphous deposits. These Aß fibrillar aggregates are thought to act as a nidus for subsequent deposits of other proteins, including α-antichymotrypsin, components of the complement cascade, and Apo E, and Apo J (2).

Aß production and release are normal physiologic events. Aß peptides are normally present in the media of APP-expressing cultured cells and in human and rodent cerebrospinal fluid (13 ,24 ,25 and 26). Some reports have showed evidence that there could be two distinct pools of intracellularly generated Aß: a pool that is eventually secreted and a pool that is destined to remain within the cell (27 ,28). The relative importance of intracellular versus extracellular Aß has not yet been determined.

Aß can stimulate inflammatory responses from microglia, can inhibit neuritic outgrowth, and can activate protein phosphorylation, and it is neurotoxic (29). In addition, oxidation of Aß can promote aggregation by peptide cross-linking (30), a potentially important factor in light of increasing evidence of the involvement of oxidative stress in AD. Exposure of neurons, cell lines, or endothelial cells to high concentration of aggregated Aß causes cell death, although it has been suggested that low concentrations of Aß are neurotrophic (31). Altogether, it is thought that the deleterious effect of Aß can cause the pathogenic features that lead to AD.

Functions of APP

The functions of APP and related members of the APP superfamily remain to be fully clarified (32), although APP has been shown to have a wide range of biological properties. The extracellular domain of APP is capable of binding to a range of proteoglycan molecules, and this allows it to function as a regulator of cell–cell or cell–matrix interactions, cell growth, and synaptic plasticity. APP itself may function as a cell-surface receptor. Secreted forms of APP liberated from the cells by the action of secretases may regulate Ca^{2+}, thereby having a neuroprotective effect (33). In addition, sAPPα has been shown to stimulate a protein kinase–mediated signal transduction cascade in cultured cells (34). APP also contains heparin-binding sites and metal ion-binding sites. Finally, APP isoforms containing the KPI domain can act as potent inhibitor of serine proteases (9). The physiologic consequences of the enhanced secretion of either sAPPα or Aß have not been defined.

The intracellular C-terminal domain of APP has been shown to bind to several intracellular proteins, including X11 (35), Fe65 (36), disabled protein (Dab) (37), G protein Go (38), and BP1 (39). The phosphotyrosine interaction domains of X11, Fe65, and Dab bind to the YENPTY motif found in the C-terminus of APP. These proteins can function as adapter proteins enabling APP to bind to other proteins.

Regulation of APP Processing

Several lines of evidence suggest that protein phosphorylation can modulate APP processing in various cell lines. This was shown by a series of studies that consistently reported on the effect of several agents known to activate protein kinase C (PKC) directly. Thus, cell treatment with phorbol esters such as phorbol 12-myristate 13-acetate (PMA) or phorbol 12,13-dibutyrate (PDBu) leads to significant increases in the production of sAPPα (40 ,41). Concomitant

with increased sAPPα secretion, PKC activation lowers the production of Aß (42 ,43 and 44).

The hypothesis that APP processing could be regulated by phosphorylation-dependent processes was reinforced by a study showing that okadaic acid, an inhibitor of phosphatases 1 and 2A, potentiated the PDBu-induced increase of sAPPα (42). The same studies showed that Aß formation was also under the control of phosphatase activity (42). It was demonstrated that drugs that increase cytoplasmic Ca^{2+} levels stimulated sAPPα release in the extracellular medium and increased Aß formation (45 ,46). Therefore it can be said APP processing can be regulated by PKC and by intracellular Ca^{2+} concentrations. The exact mechanism by which PKC and Ca^{2+} modulate APP processing is not clear.

The density of cholinergic receptors is affected in patients with AD, an observation that prompted some authors to examine whether the stimulation of muscarinic receptors could, through activation of the phospholipase C/PKC cascade, ultimately modulate APP processing. Release of sAPPα is found to be stimulated after treatment with various agonists of muscarinic receptors in cells overexpressing M1 and M3 receptor subtypes (47 ,48).

Several other agents have been known to activate APP processing. These include nerve growth factor, epidermal growth factor, tacrine (anticholinesterase drug), estrogen, and electrical depolarization (49). All the foregoing observations emphasize the complexity of the regulatory mechanisms of APP processing.

Localization of APP Processing

By using a mixture of protease inhibitors and by approaches such as metabolic labeling, pulse chase experiments, and cell treatments with various agents known to affect a characteristic step of the intracellular trafficking, De Strooper et al. established that α-secretase activity occurred in a late compartment of the constitutional secretory pathway (50 ,51). These data were supported by Sambamurti and co-workers (52), who demonstrated using [^{35}S] labeling and temperature block that α-secretase activity occurs in the *trans*-Golgi network or in a late *trans*-Golgi compartment just after sulfate incorporation (53).

APP can escape intracellular cleavage by α-secretase and reach the cell surface as a full-length mature product, as evidenced by labeling of APP after biotinylation (54) or radioiodination (55) of cell-surface membranes. Such an approach allows recovering secreted biotinylated or iodinated sAPPα in the cell medium (55 ,56). This finding indicates that α-secretase activity can also occur at the plasma membrane level in several cell systems (see also ref. 57).

Full-length APP that arrives to the plasma membrane can be endocytosed and recycled (58), and Aß appears to be generated both in the endocytic and the exocytic pathway. The cellular sites of Aß production have been thoroughly investigated in cell culture systems. Initial studies indicated that endosomal/lysosomal processing of APP leads to the production of fragments that contain the APP C-terminus and entire Aß region and hence are potentially amyloidogenic (56 ,59). Despite the initial excitement generated by the discovery of these Aß-containing fragments, several lines of evidence suggest that the lysosomal degradation of APP is unlikely to contribute to the production of Aß. However, agents that interfere with pH gradients (i.e., ammonium chloride and chloroquine) inhibit the production of Aß (25), a finding suggesting that Aß may be generated in acidic compartments (i.e., endosomes or late Golgi).

Furthermore, cells that express APP with various deletions in the cytoplasmic tail release lower levels of soluble Aß (60), a finding suggesting that the internalization of APP from the cell surface and subsequent recycling to the plasma membrane may be responsible for the generation of Aß. Two lines of evidence are consistent with this idea: secreted Aß can be generated from [^{125}I]surface-labeled APP (55), and the surface APP "tagged" with either monoclonal antibodies or biotin can be recycled to the plasma membrane after endocytosis (58). These studies offered a model wherein ß-secretase cleavage occurs within endocytic compartments, and γ-secretase cleavage of the residual approximately 100 amino acid membrane-bound fragment within the APP transmembrane domain occurs virtually simultaneously with the formation and release of Aß.

Although the majority of Aß appears to be generated in the endosomal recycling pathway, a few secreted Aß species are also generated in a secretory pathway (27 ,61). Aß secretion could be totally prevented by brefeldin A (24 ,62), and by monensin (24), two agents that potently block intracellular trafficking. This finding suggests that Aß may be generated during the transport of APP through the Golgi apparatus *en route* to the plasma membrane.

Taking together all the available data, it is possible to formulate a model for APP processing. APP polypeptide undergoes complex post-translational modifications, including sulfation, phosphorylation, and both N- and O-linked glycosylation (44 ,63). These modifications occur during the trafficking of the protein through the secretory pathway. Thus, APP is cotranslationally translocated into the endoplasmic reticulum by its signal peptide and then matured during passage through the Golgi by acquiring sulfate, phosphate, and sugar groups. At this stage, some of the APP may have already been processed by ß- and γ-secretases. Then, a percentage of mature molecules is transported to the plasma membrane by secretory vesicles (64). At or near the cell surface, some APP molecules undergo proteolysis by the protease designated α-secretase. Alternatively, uncleaved surface APP molecules can undergo endocytosis through clathrin-coated vesicles, apparently mediated by a YENPTY signal sequence in the distal cytoplasmic tail (65), after which the full-length precursor is trafficked to late endosomes and lysosomes for apparent

degradation (56 ,59), or it is rapidly recycled within early endosomes to the cell surface (66). The latter pathway has been shown to be principal site for the two proteolytic cleavages that generate the Aß peptide (55). It appears that, at least in cultured cells, only a few of all biosynthesized APP molecules undergo either the α-secretase or the ß-secretase fate; many full-length precursor molecules remain inserted into internal membranes, particularly in the Golgi.

Tangles

Neurofibrillary tangles are another important histologic feature of AD. They consist of PHFs in a double helix (diameter, 20 nm) found in the cytoplasm of neurons, particularly of the pyramidal cells of the cerebral cortex and hippocampus (67). PHFs are composed principally of phosphorylated tau, a low-molecular-weight microtubule-associated protein (68).

Tau is a family of six proteins derived by alternative mRNA splicing from a single gene located on chromosome 17. These molecular isoforms of tau differ in whether they contain three or four tubulin-binding domains of 31 or 32 amino acids each near the C-terminal end and no, one, or two inserts of 29 amino acids each at N-terminal end of the molecule.

Tau in AD brain, especially in PHFs, is abnormally hyperphosphorylated and glycosylated. At the later stages of tangle formation, the tau is increasingly ubiquinated. In a normal neuron, biological function depends on an intact microtubule network through which much of the axoplasmic transport is supported. The AD abnormally phosphorylated tau (AD P-tau) competes with tubulin in binding to normal tau, MAP1, and MAP2 and inhibits their microtubule assembly-promoting activities. The disruption of the microtubule network probably compromises the axonal transport and starts retrograde degeneration of the affected neurons. The neuronal cytoskeleton in AD is progressively disrupted and is replaced by bundles of PHFs, leading to the formation of neurofibrillary tangles (67).

To date, 21 phosphorylation sites in the AD abnormally phosphorylated tau have been identified (69). Among the several protein kinases that have been implicated in the phosphorylation are glycogen synthase kinase-3 (70), neuronal Cdc-like protein kinase (71), mitogen-activated protein kinase (72), Ca^{2+}/calmodulin-dependent protein kinase II (73), casein kinase I (74), and cyclic adenosine monophosphate–dependent protein kinase (75). AD P-tau can be dephosphorylated by protein phosphatases PP-2B, PP-2A, and PP-1, but not by PP-2C. Tau phosphatase activity is decreased by approximately 30% in AD brain (76); thus, the decrease in phosphatase activities may contribute to the abnormal hyperphosphorylation of tau in AD resulting from the inhibition of dephosphorylation reaction. To date, no mutations in tau have been implicated in AD; however, mutations in tau are associated with frontotemporal dementia (77).

MUTATIONS IN APP IN EARLY-ONSET AD

Part of "83 - Molecular Genetics of Alzheimer Disease "

Genes may be related to disease in two ways: through mutations that by themselves are sufficient to cause the disease (i.e., deterministic mutations), or alternatively, through gene variations (polymorphisms) that may increase disease risk without being sufficient (or necessary) by themselves to cause the disorder. This latter group is referred to as susceptibility genes. Although it is currently thought that most cases of AD occur sporadically, autosomal dominant transmission has been identified in families with early-onset AD, defined as beginning before the age of 65 years. These cases are relatively rare; worldwide, only several hundred families are currently known to carry deterministic mutations (78). Extensive research carried out since the early 1980s has isolated certain genes that, when mutated, cause AD, notably *APP* on chromosome 21 (79 ,80), the *PS1* gene on chromosome 14 (81), and the *PS2* gene on chromosome 1 (81). Mutations in these genes lead to early-onset AD and explain only a small proportion of total AD cases. Furthermore, trisomy 21 (Down syndrome or DS) increases the risk of AD, perhaps because of the tripled genetic dosage of APP. In addition, some susceptibility genes are currently being studied, of which polymorphisms of the *APOE* gene have received the most attention. The presence of the *APOE*-4 allele has been identified as a genetic risk factor for sporadic AD and familial AD (FAD) of late onset. All these genetic causes of AD are discussed in detail later.

AD in Down Syndrome

In considering the molecular pathology of DS, a matter of critical interest is that virtually all patients with DS who survive beyond 35 years of age develop neuropathologic changes that closely resemble AD (82). Thus, there is the abnormal accumulation of Aß in the brains of both patients with AD and those with DS, followed by cognitive decline. Patients with DS are thought to express high levels of APP because of an extra copy of chromosome 21. The most straightforward explanation for dementia in DS is the presence of three instead of two copies of APP in patients with DS (83). Other genes that are potentially overexpressed in DS are located within a segment of chromosome 21, termed the Down locus. Genes that are contained within the Down locus include APP, superoxide dismutase I, S100-ß (a calcium-binding protein), and BACE-2 (a homologue of BACE).

The occurrence of +1 frameshifted proteins, such as APP+1 and ubiquitin-B+1 (UBB+1) has been linked to the onset of AD in patients with DS. Frameshifts are caused by dinucleotide deletions in GAGAG motifs in mRNA and are now thought to be the result of unfaithful transcription

of normal DNA by a novel process termed *molecular misreading*. The aberrant mRNAs are translated in the +1 reading frame as "+1 proteins," that is, proteins with a wild-type N-terminus and frameshifted and often truncated C-terminus. It has been shown that expression of APP+1 protein (84 ,85) and UBB+1 protein is found in all patients with DS (85). In patients with DS and AD, the mRNA decay pathway may be impaired, and therefore +1mRNA is translated into +1 protein. Conversely, UBB+1 may have a role in directly interfering with the ubiquitin/proteasome system and may lead to an inefficient protein breakdown through the proteasomal pathway.

APP Mutations and Their Effect on Aß Formation

Several different pathogenic mutations have been found in exons 16 and 17 of the *APP* gene to date (Table 83.1). These mutations are missense mutations. The early-onset AD mutations (according to APP770 numbering), APP715, 716, 717, and APP670/671, are located outside the Aß amyloid sequence, with APP715-717 (Val715Met, Ile716Val, and Val717Ile/Gly/Phe) close to the C-terminal γ-secretase cleavage site (79) within the transmembrane domain and APP670/671 (Lys670Asn/Met671Leu) at the N-terminal ß-secretase cleavage site within the extracellular part of APP (90). In contrast, the APP692 (Ala692Gly) mutation is located inside the Aß amyloid sequence next to the α-secretase cleavage site (89). Other sequence variations in the Aß region are thought not to be pathogenic.

The localization of mutations led to the hypothesis that these mutations could influence the activity of the respective secretases, resulting in the aberrant processing of APP (95). Indeed, mutations at codons 716 and 717 lead to a selective increase in the production of Aß peptides ending at residue 42/43 (91 ,96 ,97 ,98 and 99). The Lys670Asn/Met671Leu mutation, conversely, appears to augment the production of both Aß40 and Aß42/43 (100), whereas the Ala692Gly mutation has a more complicated effect on APP processing by causing impaired α-secretase cleavage, increased heterogeneity of secreted Aß species, and increased hydrophobicity of the Aß (98). The Ala692Gly mutation also has clinical features in some cases similar to those of cerebral hemorrhage with amyloidosis of the Dutch type (HCHWA-D) (93), and in other cases more similar to AD. Recently, another mutation in APP (E693G) has been identified as the Arctic APP mutation that enhances Aß protofibril formation (94).

MUTATIONS IN THE PRESENILINS IN EARLY-ONSET AD

Part of "83 - Molecular Genetics of Alzheimer Disease "

The homologous membrane proteins presenilin 1 (PS1) and presenilin 2 (PS2) were identified in 1995 as the genes responsible for a substantial fraction of early onset, autosomal dominant AD (81 ,101). The most common causes of autosomal dominant FAD are mutations in the *PS1* gene on chromosome 14 (81). These account for 30% to 50% of all early-onset cases (102), and they are the primary cause of AD with onset before the age of 55 years. To date, more than 50 *PS1* mutations and two *PS2* mutations have been reported (Table 83.2 and Table 83.3) in FAD. All mutations in the presenilins (PS) are missense mutations, except for the mutation of a splice acceptor site resulting in the deletion of exon 9. The lack of mutations leading to loss of gene expression or frameshifts suggests that the disease phenotype results from a gain of function. The hydrophobic regions of PS1 and PS2 are almost completely identical and are highly conserved among species.

TABLE 83.3. MISSENSE MUTATIONS IN THE PRESENILIN 2 GENE

Structure, Localization, and Post-Translational Modification of Presenilins

Structure

Hydropathy analysis of PS1 and PS2, using the indices of Kyte and Doolittle, indicates the presence of a hydrophilic N-terminal followed by ten hydrophobic regions (HR) of at least 15 amino acids in length, which could potentially span the membrane (81 ,101 ,120). Most of these segments are connected by small hydrophilic loops, except one longer stretch of mostly hydrophilic residues between HR7 and HR8 called the "large loop."

Multiple studies have been aimed to determine the number of transmembrane domains as well as the orientation of the N- and C-terminus of PS. These approaches included staining with antibodies after selective permeabilization of cellular membranes, construction of chimeric proteins with protease cleavage sites, and the use of ß-galactosidase or glycosylation tags (121 ,122 ,123 ,124 ,125 ,126 and 127). All the proposed models agree that the first six hydrophobic regions represent transmembrane domains, whereas the predictions of the total number of regions varies between six and eight. In all these models except one (126), the N-terminal and the C-terminal

domains were shown to protrude into the cytoplasm. Two studies using ß-galactosidase fusion proteins support the model of eight transmembrane domains (TM) with N-terminal and C-terminal in the cytosol (124 ,125). In this model, HR7 and HR10 do not pass through but are associated with the membrane. Alternative topologies have also been suggested.

Post-Translational Modification

Presenilins are neither glycosylated nor modified by sulfation, acylation, or the addition of glycosaminoglycans (121), but both proteins are phosphorylated on serine residues (128 ,129). The most prominent post-translational modification of both PS1 and PS2 is proteolytic cleavage (130 ,131). PS1 is rapidly cleaved into a 27- to 28-kd N-terminal fragment (NTF) and an 18- to 20-kd C-terminal fragment (CTF), and PS2 is cleaved into two polypeptides of 34 and 20 kd, respectively.

Epitope mapping studies (131) and radiosequencing analysis (130) revealed that PS1 endoproteolysis occurs in the cytoplasmic loop domain, within a domain in which several of the identified FAD-linked PS1 mutations occur. The N-terminal of the CTF is heterogeneous, with the two predominant species beginning at amino acids 293 and 299 (130), encoded by exon 9. These findings are consistent with the demonstration that the FAD-linked PS1ΔE9 variant, which lacks exon 9 encoded sequences (amino acids 290 to 319), fails to be cleaved (131). Several of the PS mutations are clustered around this region.

The PS holoproteins are unstable, with half-lives about 1.5 hours (130 ,132), and their degradation is apparently mediated in part through the proteosome (133 ,134). In contrast, PS fragments produced through normal endoproteolysis of wild type and FAD-mutant presenilins are quite stable (half-life of approximately 24 hours) (130 ,132), a finding consistent with the hypothesis that the heterodimeric complexes represent the biologically active form of the protein. Presenilin molecules that are not incorporated into the complex are rapidly degraded by several proteases, including the caspases and calpain-like enzymes (134 ,135). It appears that endoproteolysis of the presenilins is not needed for activation of their putative activities but may be required to convert unstable presenilins into stable complexes (134).

Various C-terminally truncated and chimeric PS polypeptides were used to characterize the interaction between NTF and CTF. It was observed that transgene-derived human PS1 NTF expressed in mouse N2a cells neither assembled with the endogenous CTF nor inhibited the cleavage or accumulation of the endogenous mouse PS1. Furthermore, in cells coexpressing PS1 and PS2, PS1-and PS2-derived fragments did not form mixed assemblies. In contrast, cells expressing a chimeric PS1/PS2 polypeptide formed PS1 NTF.PS2 CTF assemblies. These studies provide strong evidence that intramolecular associations between PS domains precede endoproteolytic processing (136).

In addition to the regulated endoproteolytic processing cleavage by the yet hypothetical presenilinase, presenilins also undergo additional cleavage, termed *alternative cleavage*, within the hydrophilic loop domain (133). Full-length PS1, as well as PS1- or PS2 derived CTFs, can be cleaved by caspases in transfected cells and cells induced to undergo apoptosis. Several members of the caspase family of proteases, including caspases 1, 3, 6, 7, 8, and 11, are capable of cleaving PS1 and PS2 *in vitro* (138).

Localization

Endogenous presenilins have a relatively limited subcellular distribution; they are found in the early compartments of biosynthetic pathway. Presenilin proteins have been localized to the endoplasmic reticulum (ER) and the Golgi subcellular compartments (137). Confocal and electron microscopy, combined with subcellular fractionation experiments, show that presenilins in neurons reside in the smooth and rough ER, the ER Golgi intermediate compartments, and, to a limited extent, in the *cis*-Golgi, but not beyond (139). The finding of overexpressed presenilin proteins within Golgi compartments should, however, be interpreted with caution, because evidence indicates that membrane proteins with many transmembrane domains can accumulate in structures called aggresomes, structures that reflect cell stress (140). Studies provide convincing evidence that some mammalian PS1 can be found at the cell surface, where it can be biotinylated (141).

Biological Functions of Presenilins

Interaction with APP

There is strong evidence that presenilins are able to interact directly with APP. Complex formation between APP and presenilins has been demonstrated by coimmunoprecipitation of both proteins in cells either transfected or with endogenous proteins as well as with the yeast two-hybrid system (142 ,143). Thinakaran and colleagues, in contrast to these other researchers, did not observe physiologic complexes between PS1 and PS2 derivatives with APP (144).

Studies with progressive deletion of presenilin showed that the hydrophilic N-terminal of PS2 (1-87) is sufficient for the interaction with APP (127). Two different domains of APP appear to be involved in the APP-PS interaction. The last 100 C-terminal residues of APP (C100) encompassing Aß and the TM region are able to interact with PS1 and PS2 (142 ,143). However, deletion of the cytoplasmic C-terminus domain does not abrogate PS1 binding (143). In addition, two APP constructs representing physiologically secreted forms of APP (sAPPα and sAPPß) were shown to coprecipitate with PS2 in transfected COS cells (127). Taken together, these result suggest presenilin binds to the Aß/transmembrane region and at least one additional interaction domain N-terminal of Aß. Full maturation of APP does not seem to be required for the interaction, because the APP form detected in precipitated complexes is mostly immature.

Role in APP Processing

Pathogenic mutations in PS modify APP processing, thereby leading to an augmentation of Aß42 secretion. Patients with AD who carry PS1 or PS2 mutations have significant increase of plasma Aß42 levels (145) together with deposition of Aß42 in the brain (146 ,147). In fibroblasts from such patients, the APP metabolism is shifted toward an increase of Aß42 production. Similarly, the presence of mutated PS1 increases Aß42 in transfected cells (148 ,149 ,150 and 151), as well as in transgenic mice (148 ,149 and 150). How the mutant PS influences the production of Aß42 peptides remains uncertain, but these PS mutations appear to cause aberrant gain, rather than loss, of function. In neurons of PS1-knockout mice, secretion of Aß is drastically reduced, leading to the accumulation of α- and ß-cleaved C-terminus stubs of APP (23 ,152). This gives evidence that PS1 is obligatory for proteolysis of APP at the γ-secretase cleavage site.

Wolf et al. mutated the two aspartates located in analogous positions near the middle of TM6 and TM7 to alanines (153). Either mutation, when expressed in various mammalian cell types, prevented both the normal endoproteolysis of PS1 within the hydrophobic region of the TM6-TM7 loop and markedly inhibited the γ-secretase cleavage of the 99-residue C-terminal fragment of APP (C99), thereby lowering levels of Aß40 and Aß42. Conservative substitution of aspartate by glutamate still abrogated the γ-secretase cleavage of APP, a finding indicating a specific requirement for the two TM aspartates. These results are consistent with one of two mechanisms: a role for presenilin as a unique cofactor for γ-secretase that could play a role in protein trafficking or a role as a functional γ-secretase, making it an unprecedented intramembranous aspartyl protease. There is evidence for and against both possibilities.

A major concern with the hypothesis that presenilins are proteases is their subcellular localization. Presenilin proteins

have been localized to early transport compartments, whereas abundant γ-secretase activity is restricted to late transport compartments and the endosomal pathway (55 ,61). The same holds true for the release of the Notch intracellular domain (see later), which occurs after ligand binding by Notch at the cell surface (154 ,155). In contrast, the cellular localization of presenilin proteins in ER and early Golgi overlaps to some degree with the intracellular site of generation of the highly amyloidogenic Aβ42. An additional concern is that the presenilin sequences have no homology to any of the proteases identified so far. Confirmation that PS is γ-secretase will require reconstitution of the γ-secretase/presenilinase activities in artificial lipid bilayers using appropriate substrates and cellular factors. Partial characterization of detergent-solubilized γ-secretase activity shows that γ-secretase activity is catalyzed by PS1-containing macromolecular complex (156).

The alternate hypothesis holds that PS1 influences endoproteolysis of APP and Notch 1 indirectly, by altering trafficking and cocompartmentalization of each substrate and elusive protease. It was demonstrated that CTF derived from the APP homologue, APLP1, also accumulates in PS-/- neurons (152). Because APP and APLP1 transmembrane domains have very limited homology, it may be more difficult to envision that PS1 plays a role as a specific γ-secretase involved in the cleavage of APP, Notch (see later), and APLP1. Rather, a broader role for PS1 in directing membrane-bound CTFs derived from APP family members or other transmembrane proteins to appropriate cleavage or degradation compartments may be considered. It is possible that the presenilins are critical cofactors for γ-secretases, analogous to the sterol-cleavage activating protein involved in the extramembranous processing of the sterol regulatory element binding protein, (157), which is a transcription factor essential for cholesterol biosynthesis.

Notch Signaling Pathways

The Notch gene family encodes large, single transmembrane proteins in the plasma membrane. Notch function is involved in various signaling pathways, and Notch is crucial for many steps in the development of an organ and organism. A similar pathway is used in *Caenorhabditis elegans* at multiple steps in development, including singling out precursor cells involved in vulva differentiation (158). For this purpose, two cells that are initially functionally identical crosstalk through the activity of the lin-12/Notch gene product. The consequence of this interaction is that one cell will specialize in producing vulva cells, and the other will specialize in generating uterine cells. A reduction on lin-12/Notch function causes an egg-laying defect that results from failure in vulva induction.

A functional link between APP and Notch receptor was first suggested when several groups reported that disruption of PS1 not only prevented APP processing by γ-secretase, but also prevented the cleavage of the Notch C-terminus in the membrane. This result immediately suggested that either presenilins are directly involved in cleaving both Notch and APP or mediate both cleavages in a more indirect way. Processing of Notch resembles in some aspects the processing of APP. Notch is processed by a furin-mediated cleavage during its passage through the Golgi system. The resultant two fragments remain in the same protein complex and localize in the cellular membrane to form the functional receptor. The binding of the ligand to the receptor stimulates the cleavage of one of the subunits at a specific extracellular site close to the membrane. A subsequent intramembranous cleavage liberates an intracellular fragment that translocates into the nucleus. This peptide forms an active transcription complex, which activates transcription of Notch target genes. The last of these proteolytic cleavage steps of Notch resembles γ-secretase cleavage of APP.

Complex formation between Notch and PS has been observed (141). There are also data showing that presenilins are functionally implicated in the Notch signaling pathway. The phenotype observed in PS1 knockout animal models (159) consists of a severe impairment of the development of the axial skeleton. The origin of these skeleton abnormalities lies in the impairment of the segmentation of the somites. Interestingly, Notch-1 (160) knockout animals suffered from similar abnormal skeleton deformations, a finding consistent with interaction of presenilins with Notch signaling pathway. De Strooper et al. used a Semiliki forest virus system to express truncated fragments of Notch-1 in primary neuronal cultures of PS1 knockout animals to identify the steps in Notch signaling depending on PS1(161). The authors provide evidence strongly suggesting that PS1 is crucial for the final processing of Notch-1 that generates the intracellular fragments, which subsequently will translocate to the nucleus and activate the expression of Notch-1 target genes.

The genetic studies in *C. elegans* and *Drosophila* offer a powerful approach to study presenilin function. Sel-12, a nematode homologue of presenilin, was identified by screening for suppressors of lin-12 (*C. elegans* homologue of Notch) gain of function mutation (162). Sel-12 is able to facilitate the signaling of transmembrane receptors of the lin-12/Notch family, and human presenilins have been shown to complement for Sel-12 function effectively (163). The egg-laying deficiency in *C. elegans* caused by the null mutations of Sel-12, the worm's homologue of mammalian presenilin, can be rescued by wild-type, but not mutated, human presenilin (163 ,164). However, presenilin cleavage does not seem to be essential for functional activity, because the PS1 with the Δ-exon 9 mutation is still able at least partially to rescue the egg-laying defective phenotype of *C. elegans* Sel-12 mutants (164).

Proteins Interacting with PS

Presenilins have been found to interact directly with a variety of proteins. Proteins interacting with presenilins include members of the catenin family (165 ,166 and 167). Catenins have at least two different functions in the cell. First, they are components of cell–cell adhesive junctions interacting with the cytoskeletal anchors of cadherin adhesion molecules. Second, there is compelling evidence that ß-catenin is a key effector in the Wingless/Wnt signaling cascade. Wingless and its vertebrate counterpart Wnt signaling direct many crucial developmental decisions in *Drosophila* and vertebrates. ß-Catenin has been shown to become destabilized in case of PS1 mutations and PS1 deficiency (168). ß- and ð-Catenin interact with the large loop of PS1 (165 ,166). The yeast two-hybrid system was used for the identification of a neuronal calcium-binding protein termed calsenilin (15), which binds to the C-terminus of PS2. Calsenilin was shown to interact with both PS1 and PS2 in cultured cells and could link presenilin function to pathways regulating intracellular calcium levels.

Several other proteins have been identified that interact with presenilins including the cytoskeletal proteins filamin and filamin homologue (168), µ-calpain (169), Rab11, a small guanosine triphosphatase belonging to the p21 ras-related superfamily (170), G-protein Go (171), and glycogen synthase kinase-3b (172).

Apoptosis and Cell Death

There is increasing evidence of causal involvement of presenilins in apoptosis. ALG3, a 103-residue C-terminal fragment of PS2, was isolated in death trap assay as rescuing a T-cell hybridoma from T-cell receptor and Fas-induced apoptosis (173). In PC12 cells, the down-regulation of PS2 by antisense RNA protects the cells from glutamate toxicity. Similar effects of ALG3 overexpression and PS2 down-regulation suggest that this C-terminal fragment of PS2 acts as a dominant negative form of PS2. Expression of mutant PS1 (L286V) in PC12 cells enhanced apoptosis on trophic factor withdrawal or Aß toxicity (174). The alternative caspase cleavage in the C-terminal fragment of PS1 has been shown to abrogate the binding of PS1 to ß-catenin (167) and could therefore modulate the apoptotic outcome.

Finally, the FAD mutation M146V was inserted by homologous recombination in the mouse genome (knock-in) to drive the expression at normal levels of a mutated mouse PS1 protein (175). The knock-in mutation was shown to increase ER calcium mobilization and superoxide and mitochondrial reactive oxygen species production leading to caspase activation (175).

Evidence shows that mutant PS1 also renders cells less efficient to respond to stress conditions in ER. Mutations in PS1 may increase vulnerability to ER stress by altering the unfolded protein response (UPR) signaling pathway that is responsible for ensuring the proper folding of newly synthesized proteins (176 ,177).

ROLE OF APOLIPOPROTEIN E ISOFORMS IN LATE-ONSET AD

Part of "83 - Molecular Genetics of Alzheimer Disease "

In addition to the deterministic genetic mutations found in APP and presenilins, genetic factors modify the risk of developing AD. The *APOE* gene on chromosome 19 is considered as an important risk factor for the development of late-onset AD. Apo E is a 34-kd component of various lipoproteins, including chylomicrons, very-low-density lipoproteins (VLDLs), and a subset of high-density lipoproteins (HDLs) (178). These lipoproteins regulate plasma lipid transport and clearance by acting as ligand for lipoprotein receptors such as LDL-R and low-density receptor-related protein (LRP) (179 ,180). Apo E has been implicated in the transport of cholesterol and phospholipids for the repair, growth, and maintenance of membranes that occur during development or after injury (178).

Apo E is polymorphic and is encoded by three alleles (*APOE2,3,4*) that differ in two amino acid positions. The most common isoform, E3, has a Cys residue at position 112 and an Arg at position 158. The two variants contain either two Cys residues (E2) or two Arg residues (E4) at these positions. In general, it seems that E4 allele increases the risk of developing AD by approximately threefold, and that the E2 allele decreases the risk (181). The presence of one or two E4 alleles is associated with earlier onset of disease and an enhanced amyloid burden in brain, but it has little effect on the rate of progression of dementia (182). Thus, homozygous E4/E4 subjects have an earlier onset (mean age less than 70 years) than heterozygous E4 subjects (mean age of onset for E2/E3 is more than 90 years) (183).

The most obvious hypothesis is that *APOE* polymorphisms may influence the production, distribution, or clearance of Aß. This hypothesis is supported by observations that the subjects with one or more *APOE4 alleles have a higher amyloid burden than do subjects with no APOE4* alleles (184). Second, there is evidence that both Apo E and Aß may be cleared through the LRP receptor, and Apo E4 and Aß peptide may compete for clearance through the LRP receptor (179). Third, transgenic mice that overexpress APP develop a significantly lower number of Aß deposits when they are bred to an *APOE* knockout background (185). These findings strongly support a role of Apo E in the aggregation or clearance of Aß in the brain. The *APOE* genotype influences the onset of AD in patients with DS and in those with APP mutations but not in families with presenilin mutations (185 ,186 and 187).

OTHER GENETIC RISK FACTORS IN AD

Part of "83 - Molecular Genetics of Alzheimer Disease "

In addition to the *APOE* gene, which has been confirmed as a strong risk factor in various studies, polymorphisms in

several other genes have been described to increase susceptibility for AD. Most of these genetic polymorphisms are still subject to discussion because they either need to be confirmed in larger studies or show only weak influence toward the risk of developing AD.

A family-based study revealed an association between late-onset AD and the presence of an exon 2 splice acceptor deletion in the α_2-macroglobulin *(A2M)* gene on the short arm of chromosome 12 (188). Significantly, A2M binds to a variety of proteins, including proteases (189 ,190) and Aß peptide (191). In addition, A2M is also present in senile plaques and can attenuate Aß fibrillogenesis and neurotoxicity (191). Moreover, A2M may, through LRP-mediated endocytosis, allow the internalization and subsequent lysosomal degradation of Aß (192).

Other candidate AD genes that have been reported include α_1-antichymotrypsin (193), bleomycin hydrolase (194), and a gene on chromosome 3q25-26 (195). The candidacy for these genes as AD loci awaits further testing and confirmatory studies in greater numbers of AD samples.

Among the several risk factors, age is one of the most important elements that has to be considered with respect to sporadic Alzheimer-type dementia. Various cellular and molecular changes take place in the brain during normal aging, among which changes in glucose and energy metabolism are of pivotal significance (196). Reduced acetylcholine synthesis, formation of advanced glycation end products, membrane instability, and reduced energy availability are some of the other changes that occur with age. The decrease in the pool of available energy may lower or even arrest the transport of newly synthesized membrane proteins such as APP, thereby facilitating Aß synthesis intracellularly. Therefore, it can be hypothesized that these changes somehow contribute to the formation of Aß peptide and hyperphosphorylated tau. In a general context, age may be considered as a risk factor for neuronal damage and thus for age-related brain disorders such as sporadic dementia of the Alzheimer type.

AD has been reported to be in higher prevalence among old women compared with men. There is evidence suggesting that estrogen may have a protective role against AD, perhaps through its action as a trophic factor for cholinergic neurons (197), a modulator for the expression of Apo E in the brain (198 ,199), an antioxidant compound decreasing the neuronal damage caused by oxidative stress (200 ,201), or a promoter of physiologic nonamyloidogenic processing of the APP decreasing the production of Aß (202). Therefore, in older postmenopausal women, the lack of circulation of estrogen may contribute to developing AD.

CONCLUSIONS

Part of "83 - Molecular Genetics of Alzheimer Disease "

There are clearly very significant genetic contributions to AD. Practically, Apo E is the most significant genetic factor in AD because of the very high prevalence of the *APOE4* allele, even though *APOE* is only a risk factor for AD.

The mutations in *APP* and *PS* account for only a small percentage of AD cases, but when present, these are deterministic mutations leading to an aggressive early-onset form of the disease. These mutations in *APP* and *PS*, rare though they are, give crucial insight into the molecular process underlying all forms of AD. Thus, the *APP* mutations clearly underscore critical role of APP in disease initiation. The *PS* mutations implicate Aß, and particularly Aß42, in disease. A similar, crucial role for Aß in sporadic AD is supported by postmortem and tau studies. Polymorphism in *APOE* and *A2M* may also have their effects by interacting with APP and Aß. It therefore seems likely that treatments that modulate Aß formation or Aß clearance may be of benefit in AD.

If Aß changes initiate disease, it is likely that changes in tau are the actual cause of neuronal dysfunction and cognitive decline. Therefore, abrogating deleterious effects of Aß on tau phosphorylation may represent another viable therapeutic approach to AD.

Transgenic Mouse Models of Alzheimer Disease

Karen Duff

Karen Duff: Nathan Kline Institute, Orangeburg, New York.

GENERAL PRINCIPLES

Part of "84 - Transgenic Mouse Models of Alzheimer Disease "

Transgenic models of Alzheimer disease (AD) continue to gain credibility as more features of the human disease are shown to be represented in the mice. Tau pathology and extensive cell loss are still not seen, however. Despite these shortcomings, the mice are excellent models of amyloidosis, and this field of study has been highly informative in advancing our understanding of *in vivo* responses to amyloid insult and the mechanism by which genetic lesions may cause AD. Because many investigators believe that amyloid (or its precursors) is critical to initiation of the disease, the mice are now being used to test therapeutic agents that may have utility in patients with AD. In addition, new models that address the issue of tau pathogenesis have been created that may help to explain the relative contribution of tau and amyloid to the pathogenesis of AD.

AD is a progressive neurodegenerative disease. Most cases of AD occur sporadically, but familial forms of the disease have been most widely studied because of the insight they give into disease origin. Genetic causes of the disease are heterogeneous and include mutations or variants in several genes including the amyloid precursor protein *(APP)* gene, the presenilins *(PS)*, and apolipoprotein E *(APOE)* (reviewed in ref. 1). The disease phenotype is remarkably consistent and includes the accumulation of ß-amyloid (Aß) and its deposition into senile plaques, the formation of tau-containing tangles, reactive gliosis, inflammation and an immune response, neurodegeneration, cholinergic deficit, and cognitive impairment.

Report of the first transgenic mouse to develop a robust AD-related phenotype was published in 1995 by the Exemplar/Athena Neuroscience group (2). This line (known as PDAPP) overexpresses mutant *APP* at high enough levels to generate sufficient Aß for extracellular deposits (plaques) to form in relevant regions of the brain. In 1996, a second line (Tg2576), created by Karen Hsiao and colleagues, also made sufficient amyloid for deposits to form, and, in addition, this mouse showed age-related cognitive impairment (3). Subsequently, other cDNA mice (4 ,5) and mice overexpressing genomic constructs (6) have also been shown to form amyloid in old age. Several research groups have created transgenic mice that overexpress mutant presenilin (7 ,8 and 9), but these mice do not show amyloid deposition, most likely because they have insufficient levels of the Aß peptide.

Most of the current work on the mice focuses on cellular response to amyloid accumulation and its relevance to AD. Recently, the PDAPP line of mice was used to test the feasibility of modulating amyloid levels by immunization with Aß (10). The results of this experiment suggested that amyloid modulation is indeed possible and that some of the secondary effects of amyloidosis (gliosis and neuritic changes) can be prevented. This work opens up a new direction in amyloid research and may well have significant impact on the development of human therapies.

RECENT ADVANCES IN PHENOTYPE ASSESSMENT IN TRANSGENIC MODELS OF AD

Part of "84 - Transgenic Mouse Models of Alzheimer Disease "

Amyloidosis

Several studies aimed to modulate the amyloid phenotype by crossing in other transgenes such as *PS1* or *TGF-ß* (transforming growth factor-ß). The studies showed that when a *PS1* mutant mouse was crossed to an *APP* overexpressing mouse, the levels of Aß42 (43) were increased in the double transgenic mice, and this elevation had a profound influence on the age at which amyloid deposition could first be detected (6 ,11 ,12). In one cross, the age at which amyloid deposits were first identified was reduced from 9 to 12 months to 10 to 12 weeks (13) which is the earliest age at which amyloid has been reported. When *TGF-ß* cDNA mice were crossed into an *APP* overexpressing line, amyloid deposition was again accelerated, and deposition was far more prominent in the vasculature (14). Apart from showing

that these pathways interact, one outcome of the crossed-mouse studies is to enhance, and in some cases to modify, the phenotype, thus providing us with better models.

Presenilin Transgenics

In terms of the amyloid phenotype seen in AD, the most significant phenotype in the mutant *PS* transgenics continues to be the specific elevation of Aß1-42(43) (7 ,8 and 9). Mutant *PS2* transgenics have been created that also show elevation in Aß1-42(43) (15), a finding that strengthens the argument that APP and the presenilins interact, either directly, as suggested by Wolfe et al. (16), or indirectly, and *PS* mutations cause AD through APP/Aß modulation. More recently, several studies on cDNA and targeted knock-in *PS1* mice have shown that mutant *PS* mice show deficits in calcium homeostasis (17 ,18 and 19) and, in some models, impaired mitochondrial function (17).

Studies of knockout *PS1* animals have shown that PS1 plays an important role in development, because lack of the protein leads to a deficiency in somitogenesis during early embryogenesis that results in severe skeletal abnormalities and prenatal death (20 ,21). These abnormalities strongly resemble those seen in Notch knockout mice (22), and this observation, coupled with several studies *in vivo* and *in vitro*, suggests that Notch and PS1 interact in some way to affect normal cellular function that may downstream affect signaling, differentiation, and development.

PS1 has been strongly implicated in other signaling pathways because several potential components of signal transduction pathways have been identified as presenilin-interacting proteins. These include several proteins containing an armadillo repeat region, which is a 42 amino acid motif that has been identified in proteins involved in cell–cell adhesion, protein–protein interaction, and signal transduction. The best known of these is ß-catenin, and both ß- and its homologue, ð-catenin, have been shown to interact with PS1 (23). The effect of *PS1* mutations on ß-catenin stability and hence its downstream effects are controversial. In transgenic mice and human familial AD brain homogenates, for example, mutations in PS1 are linked to increased degradation of ß-catenin (24), whereas other studies have suggested no effect or increased activity for the wild-type and mutant PS1 protein (25 ,26 and 27). Quite how *PS1* mutations may lead to AD through a ß-catenin pathway is unclear, although in addition to the effect on Aß42, one action maybe on the action of GSK-ß and hence tau phosphorylation (for a review, see Alzheimer forum panel discussion at www.alzforum.org/members/forums/journals/catenin/index.html).

Neurodegeneration

Human AD brain shows extensive neurodegeneration, both in cholinergic neurons of the nucleus basalis (28) and in noncholinergic neurons throughout the cortex and hippocampus. Studies showed that fibrillar Aß peptides are toxic to neurons in culture (29), and the overproduction of human Aß in the brains of transgenic mice was therefore expected to cause extensive neurodegeneration. Several of the best characterized mouse models were examined for overt cell loss (30 ,31 and 32), but PDAPP, Tg2576, and the Tg2576/PS1 cross-mouse did not show significant cell loss, even though the amyloid burden exceeded 30%. One model was reported to show significant cell loss, but only in the hippocampus (32). Although overt cell loss is not seen in mice such as Tg2576/PS1, neurites in close proximity to amyloid deposits are severely dystrophic, and cellular disturbance is rife, as shown by extensive lysosomal activation (unpublished data). In addition, magnetic resonance imaging (MRI) revealed differences in the volume of structures such as the lateral ventricles and the corpus callosum between mice with and without amyloid, a finding that may reflect loss of neuropil, or shrinkage of cells rather than cell death *per se* (unpublished data). Advances in MRI in the study of human AD brain (33) suggest that it will soon be possible to image plaques directly *in vivo*, although contrasting agents may be required for mouse imaging because resolution is poor. Although the field is in its infancy, the application of functional and structural MRI to the analysis of models is predicted to have significant impact, especially because longitudinal analyses can be performed on the same mouse, including the effects of drug treatments.

Cholinergic Deficits

Although modulation of the cholinergic system has been a therapeutic treatment for AD dementia for many years, investigations into the response of cholinergic neurons to amyloid insult has only recently been studied in the transgenic mice. Immunohistochemical analysis has shown that cholinergic markers accumulate in swollen abnormal neurites around amyloid deposits in the cortex (4), and our own studies have shown that in the early stages of deposition, neurons in the nucleus basalis of depositing mice appear normal, but their projection areas in certain regions of the cortex show a significant reduction in synapse density and size (34). Significantly, this finding correlates with reduced cholinergic neurotransmitter activity (unpublished data). Further work to assess how cholinergic neurons in all areas of the brain respond to increasing amyloid burden and age is under way because cholinesterase inhibitors are currently considered to be valid therapeutic agents for AD.

Cognitive Impairments and Neurodegeneration

Recreating human cognitive impairment is perhaps the greatest challenge facing genetic engineers working on

transgenic models of human dementia. Mice are genetically less suitable to behavioral testing than rats because performance data on normal mice from different strains are often contradictory. Despite these reservations, most of the transgenic mice that form amyloid deposits have been tested for cognitive impairment. The PDAPP mouse (35 ,36), the Tg2576 mouse (3), and the Tg2576/PS1 cross-mouse (12) have all shown a deficit in tests of hippocampal dysfunction before amyloid deposits form, a finding that strongly suggests that overt amyloid accumulation or deposition is not responsible for this early cognitive impairment. Deficits in water maze performance that correlate with increasing age and amyloid burden and with decreasing long-term potentiation have been reported for Tg2576 mice (3 ,37).

Tau Pathology

One of the major deficits in the current AD mice is the lack of tau pathology. In humans, tau pathology takes the form of intracellular tangles of an abnormally phosphorylated form of the tau protein, which associates into paired helical filaments (PHFs). Both amyloid plaques and tau tangles are pathognomic features of human AD, and their relative contribution to the disease has long been disputed. The identification of AD-causing mutations in *APP* and the presenilin genes, however, adds weight to the amyloid-based hypothesis of pathogenesis, which assumes that tau abnormalities are a secondary lesion that form in response to amyloid accumulation. To examine this link, transgenic mice with extensive amyloid burden were examined for abnormal tau pathology by immunohistochemical analysis. This work showed that amyloid deposits in transgenic mice are ringed by dystrophic neurites that are immunoreactive for markers of phosphotau epitopes such as phosphoserine 202 (4 ,38). These epitopes are phosphorylated to some degree in normal brain, but they are hyperphosphorylated in AD brain. In the mice, it is not yet clear whether the immunoreactivity around deposits reflects local hyperphosphorylation of tau or simple elevation of tau protein levels in response to neuritic damage. In the human AD brain, subsets of neurons are also immunolabeled with antibodies to both tyrosine phosphotau and the signaling protein fyn, which is an src, nonreceptor tyrosine kinase (39). Co-IP has shown that the N-terminus of tau and the SH-3 domain of fyn interact directly, a finding suggesting that tau may be involved in signal transduction pathways (40). Interestingly, fyn binds another signaling protein, FAK (41), which is itself up-regulated by Aß (42). Ongoing work includes a study of how FAK, fyn, tau, and Aß interact in transgenic animals with and without elevated amyloid.

It is clear, however, that tau pathology does not develop further in the mutant *APP* and *PS* transgenic animals, a finding that suggests that either Aß/amyloid accumulation is not detrimental to tau or differences between mouse and human brain preclude the formation of pathogenic tau, as suggested by Geula et al. (43). This suggestion has been countered by reports that mouse tau is capable of forming PHF-like structures *in vitro* (44). We have created a line of transgenic mice that overexpress all isoforms of human tau under the control of the human tau promoter (45), in an effort to “humanize” the tau environment in amyloiddepositing mice by cross-breeding the different lines. Unfortunately, even in the presence of extensive amyloid, the mice do not form neurofibrillary pathology (unpublished data), a finding suggesting that the mice are either still deficient in another human component or that Aß accumulation does not stimulate tau pathogenesis, at least in mice.

Mutations in tau have been shown to cause frontal temporal lobe dementia (FTD-17) (46 ,47 and 48), which, in some cases, appears to result from an imbalance in tau isoform ratios (47). Transgenic mice that overexpress normal human tau isoforms and recreate this imbalance show a partly unexpected phenotype in that the mice develop hind limb weakness mainly resulting from spheroid accumulations composed of tau and neurofilament form, which are particularly prevalent in the axons of motor neurons (45 ,49 ,50). Although the tau does appear to be in an abnormal conformation, the relevance of the axopathy to human FTD-17 or the tauopathies is unclear. Mutant tau transgenic mice have been created, but their phenotype has not yet been described. It is likely that the creation of a battery of tau transgenic mice will provide long-awaited resources for the study of the normal and abnormal biology of this important cell component.

Cell and Molecular Neuropathology of Alzheimer Disease

Ralph A. Nixon

Ralph A. Nixon: Nathan Kline Institute, Orangeburg, New York.

Although forms of dementia arising late in life had been identified by Kraepelin and his colleagues in the 1800s, it was not until 1907 that Alois Alzheimer identified the presenile form of dementia with unique neuropathologic features that now bears his name. Alzheimer described a 51-year-old woman who presented with personality changes and soon developed progressively worsening memory loss, disorientation to time, and language disturbances but who had relatively normal neurologic function. Mental deterioration progressed, and she died 4½ years later. On autopsy, her brain showed clear evidence of cerebral atrophy. Under the microscope, Alzheimer discovered that many cortical neurons contained argyrophilic fibrous structures—neurofibrillary tangles (NFTs)—now known to be mainly composed of abnormal filamentous forms of the microtubule-associated protein, tau. Coexisting in the same affected brain regions were extracellular plaquelike lesions. These neuritic or “senile” plaques were later discovered to contain ß-amyloid, a fibrillar form of the Aß peptide, as their signature constituent. In 1910, Kraepelin proposed that this neuropathologic picture was pathognomic of a new presenile dementing disease and introduced the eponym *Alzheimer disease* (AD).

Nearly a century later, genetic analyses have shown AD to be the common neuropathologic outcome of different primary etiologic factors (1). Roughly one-third of patients with AD have a familial predisposition, with at least one other affected first-degree relative. In families with early-onset AD arising before the age of 65 years, a type accounting for 2% to 10% of all AD cases, the transmission pattern is consistent with an autosomal dominant disorder with age-dependent penetrance. To date, early-onset familial AD (FAD) has been linked to mutations of three different genes: the amyloid precursor protein *(APP)* gene and the presenilin 1 *(PS1)* and presenilin 2 *(PS2)* genes. Together, these mutations account for nearly half of the families with autosomal dominant early-onset AD (2). In FAD, a single gene defect, interacting with the brain aging process, causes the disease (reviewed in Chapter 83). However, in the other 90% of cases, designated *sporadic AD*, the emergence of disease is influenced by environmental factors as well as by multiple genes with either neuroprotective or disease-facilitating effects. Although all forms of AD, by definition, share common neuropathologic features, the metabolic antecedents of this pathology in sporadic forms of the disease are poorly understood. Much is known about the genetic forms of AD, yet issues as fundamental as the anatomic and cellular substrate of cognitive decline, the toxic cascades mediating cell degeneration, and the roles of Aß, ß-amyloid, and tau in the neurodegenerative process are just now being resolved. In this chapter, a discussion of Alzheimer neuropathology provides the starting point for understanding how the diagnosis of AD is made and how clinical symptoms arise and progress. Later sections address the neuroanatomic and cellular basis for dementia and the molecular events that lead to neuropathologic lesions and, ultimately, to the death of neurons. A consideration of current hypotheses on the evolution of cellular pathology identifies common features that help to reconcile the differing views of disease pathogenesis. New studies are beginning to shed light on underlying mechanisms in prevalent sporadic forms of AD, and their review complements a brief discussion of pathogenesis in the rare familial forms here and a more detailed consideration in Chapter 83 .

DIAGNOSTIC FEATURES OF ALZHEIMER DISEASE

Part of "85 - Cell and Molecular Neuropathology of Alzheimer Disease "

AD remains a diagnosis based on its histopathologic features. By the time AD can be clinically diagnosed by DSM-IV criteria, neuropathologic features are already quite extensive in some regions of the brain (3 ,4). Patients with Down

syndrome, for example, develop probable AD by neuropathologic criteria years before clinical dementia can be detected (5). According to the most widely accepted neuropathologic criteria (those of the Consortium to Establish a Registry for Alzheimer's Disease or CERAD), a diagnosis of definite AD can be made in a demented patient when neuritic plaques reach a requisite number, adjusted for age, in the most severely affected regions of the neocortex (6) (e.g., superior and middle temporal gyrus, middle frontal gyrus, inferior parietal lobule, hippocampal/entorhinal cortex, and midbrain) in the absence of other neuropathologic lesions likely to cause dementia. More stringent research criteria require semiquantitative estimates of both neuritic plaques and NFTs (7 ,8 and 9). In the most recent guidelines developed by the National Institute of Health and the Reagan Institute (9), topographic staging of NFT accumulation (7) is incorporated into the criteria and significantly increases diagnostic precision (10).

Neuritic plaques are complex spheric lesions of varying sizes, usually many times larger than a single neuron. These typically contain an extracellular core of ß-amyloid surrounded by dystrophic dendrites and axons, loosely organized fibrils of ß-amyloid, and many other proteins and protein fragments derived from degenerating cells or liberated from neurons, reactive astrocytes, and phagocytic cells (11). ß-Amyloid is a fibrillar form of the ß-amyloid peptide (Aß), a 40- to 43-amino acid peptide derived from the normal processing of a larger ubiquitous membrane glycoprotein, the ß-APP (12). As it forms fibrils, Aß assumes a ß-sheet conformation recognizable by probes such as thioflavin S. This conformation distinguishes ß-amyloid from the diffuse nonfibrillar deposits of Aß that appear several or more years before the neuritic plaques. Diffuse plaques may be widespread throughout the brains of elderly persons with no measurable cognitive impairment. By contrast, neuritic plaques are primarily confined to the neocortex, hippocampus, and amygdala (13).

Although the relationship of diffuse plaques with the development of neuritic plaques is not yet established, studies in transgenic mouse models of cerebral ß-amyloidosis have suggested that neuritic plaques originate from diffuse Aß plaques through a "maturation" process. One possibility to explain this process is based on findings that Aß peptide aggregates bind and activate the complement protein C1 and, hence, the classic complement pathway. This, in turn, sets off a local non–immune-mediated, chronic inflammatory response involving microglial activation and stimulation of the acute-phase response (14). This proposed cascade explains the presence within neuritic plaques of additional cell types (microglia, reactive astrocytes) and many proteins, including glial-derived acute-phase proteins, such as α-antichymotrypsin, apolipoprotein E (Apo E), and serum amyloid P, which may, in some cases, accelerate fibrilization of Aß. Activated microglia release potentially toxic products, including proinflammatory cytokines (e.g., interleukin-1 and interleukin-6), reactive oxygen species, and proteases, all of which contribute to the local development of dystrophic neurites (15 ,16). According to a second possibility, not incompatible with the first, primary damage to neurites initiates local Aß overproduction, neurite degenerationregeneration responses, and secondary inflammatory reactions involved in removing cellular debris (17 ,18). Indeed, ultrastructural studies show that dystrophic neurites contain increased levels of both APP and organellar machinery needed for Aß generation. Moreover, neurons injured by various toxic factors produce more Aß (19 ,20 and 21).

The NFTs first seen by Alzheimer are skeins of twisted abnormal filaments, whose presence in neurons reflects a global disorganization of the neuronal cytoskeleton (22). The abnormal filaments, which assume a paired helical structure, hence the name *paired helical filaments* (PHFs), are composed of tau protein. Although its full repertoire of functions is still unclear, tau is known to bind to microtubules and to stabilize their polymeric structure, thereby facilitating the microtubule's function in axonal transport and structural support (23). Over a half-dozen protein kinases regulate the function of tau, including its affinity for microtubules. The observation that the tau in PHFs is hyperphosphorylated has suggested that altered phosphorylation is important for the development of these lesions (24). Other modifications of tau, such as proteolysis and glycation, are also considered to be important for PHF formation and for the resistance of PHF to degradation and removal (25). The importance of tau-related pathology to AD pathogenesis is strongly suggested by the identification of tau mutations in 20% of patients with frontotemporal dementia and in nearly half the patients with frontotemporal dementia who have an affected first-degree relative. In addition, other dementing disorders previously linked to chromosome 17 and characterized by NFT formation in specific neuronal populations are now being found to involve tau mutations or polymorphisms, including progressive supranuclear palsy, corticobasal degeneration, and Pick disease (23).

PHF coexists in tangles together with fragments of various cytoskeletal proteins. Notably, abnormally phosphorylated neurofilaments may accumulate as the earliest cytoskeletal alteration associated with dystrophic neurite formation (26). Neurites (axons and dendrites) containing abnormal organized cytoskeletal elements are referred to as *neuropil threads* and are a feature of the dystrophic neurites abundant within neuritic plaques. The appearance of neuropil threads before NFTs develop reflects the slow centrifugal progression of cellular compromise from the synaptic endings toward the neuronal perikaryon over several or more years and indicates that synapse function becomes impaired well before the neuron dies.

Although they are not part of current diagnostic criteria for AD, other characteristic pathologic responses of neurons begin before the first traces of ß-amyloid are deposited. One of these responses involves endocytosis, the process by which

the cell internalizes materials that are extracellular or on the cell's surface. Endocytosis allows continuous sampling of the external environment, a process that is important for the uptake of nutrients and for cellular responses to toxic foreign agents. Constant remodeling of plasma membrane receptor topography by endocytosis also allows cells to control how they respond to external signaling molecules. Very early in AD, neuronal early endosomes, which are a major site of Aß peptide formation, display prominent morphologic and biochemical alterations reflecting increased activity of the endocytic pathway and appear to be highly specific for AD (27). Individual early endosomes in pyramidal neurons of the Alzheimer brain may enlarge as much as 32-fold compared with the normal average endosomal volume (28). These changes coincide with the initial rise in brain production of Aß peptide, which precedes ß-amyloid deposition, and they are detectable even before birth in patients with Down syndrome, a population that invariably develops in AD after the age of 40 years.

Cell stress or injury to neurons also manifests early as robust activation of the lysosomal system, a major cellular degradative pathway. This activation, which involves the proliferation of lysosomes and increased expression of a dozen or more lysosomal hydrolases (29 ,30), progressively intensifies as neurons become more compromised. Because lysosomal activity controls cell size, up-regulation of this system in AD is likely to be the molecular basis for neuronal shrinkage (31), and it is also believed to contribute to neuritic dystrophy (32 ,33) and neuronal cell death (34). At end stages of neuronal injury, gradual dysfunction of the lysosomal system is implied by the prominent accumulation within lysosomes of undigested, oxidized proteins and lipids in the form of autofluorescent lipofuscin and ceroid. Although lysosomal system activation is not entirely disease specific, its magnitude in AD is much greater than in other diseases and may reflect a specialized neurodegenerative response characteristic of AD and a subset of related disorders (34).

CELLULAR SUBSTRATES OF DEMENTIA

Part of "85 - Cell and Molecular Neuropathology of Alzheimer Disease "

That AD-related lesions may already be well developed in persons who have apparently normal cognitive function has fueled the debate about the actual neuropathologic substrate of clinical dementia. Attention is increasingly being paid to the roles of less overt pathologic features, such as rising intracellular Aß levels, synapse loss, or subtle forms of tau pathology in dendrites or axons. For example, although ß-amyloid or "plaque burden" often correlates poorly with cognitive impairment (35), levels of soluble Aß peptide may correlate better (36 ,36a), a concept supporting the possibility that accelerated formation of Aß peptide inside the neuron interferes with neuronal function or reflects dysfunction that is present before ß-amyloid fibrils form extracellularly (27). Synapse loss is not revealed by routine neuropathologic analysis but may reach 50% of synapses in affected neocortical areas by late stages of the disease (37 ,38). A high correlation with cognitive decline has suggested that the loss of synapses may be the cellular basis of dementia, although this hypothesis needs further confirmation. Neurofibrillary change in neurons (NFTs and neuropil threads) is closely associated with synaptic disease, and because it is more easily traced histologically, it is the index most frequently used to correlate structural disease progression to cognitive symptoms.

The progressive appearance of NFTs follows a consistent cytoarchitectonic pattern that parallels the severity of clinical dementia and neuronal cell loss more closely than does the evolution of senile plaques (39 ,40 and 41). The transentorhinal region, particularly layers II and IV of the entorhinal cortex, usually shows the first lesions in AD. By the time the mildest stage of cognitive impairment is detectable, the entorhinal cortex may have one-third fewer neurons than normal. Extrapolations from the rate of subsequent fallout of this cell population suggest that neuronal loss may be initiated up to 7 to 10 years before detectable cognitive symptoms.

The highly predictable development of neurofibrillary degeneration in the entorhinal cortex and its progressive extension into the hippocampus, neocortex, and later into various subcortical structures were the basis for a pathologic staging system developed by Braak and Braak (7 ,39), which uses cross-sectional data on NFT distribution to distinguish six stages of disease evolution. Inclusion of this grading system into current CERAD criteria for neuropathologic diagnosis of AD significantly increases diagnostic specificity and reduces false-negative diagnoses (10). According to this scheme, disease begins in stage 1 with the involvement of only a few transentorhinal projection cells, and it progresses in stage 2 to involve many entorhinal neurons, particularly those in layer II. In stages 3 and 4, neurofibrillary degeneration remains restricted to limbic regions, but it now begins to invade the hippocampal formation. The two principal targets of the CA1/subicular projection are the accessory nucleus of the amygdala and layer IV of the entorhinal cortex, which provide the principal output from the hippocampus to cortical and subcortical regions. The progression of changes to these targets, which gradually isolates the hippocampus from other brain structures, is associated with impaired cognitive functioning and subtle changes in personality in some persons. By stage 5, cognitive deficits have become broader, and the clinical diagnosis of Alzheimer-type dementia can usually be made (10). At this point, NFTs have increasingly appeared in projection neurons within layers II, III, and V of higher-order association cortices (42 ,43), beginning with the temporal lobe, which is more severely affected than parietal and frontal association cortices. Large cortical projection neurons in layers III and V display the most prominent cytoskeletal alterations, and

these cells may be lost to a greater extent than smaller neurons. This pattern of cell loss reflects the special vulnerability of feed-forward and feedback circuitry linking the hemispheres with each other and with the cortex of the limbic lobe and subcortical structures. The basis for the selective vulnerability is poorly understood, but it has been conjectured that it is related, in part, to unique features of the cytoskeleton in these neurons and particularly to the abundance of neurofilament proteins and their relatively low phosphorylation state (44).

Although the cerebral cortex is the primary target in AD, degeneration of subcortical structures may also contribute to memory impairment and their behavioral disturbances (45 ,46). The nucleus basalis of Meynert provides the major cholinergic input to the cortex and is important for memory, but the variability and timing of cholinergic changes suggest that they may not be the key factors in early cognitive impairment (35). The amygdala receives prominent projections from cortical areas and subcortical areas; degeneration therein is particularly relevant to disease-related impairments in motivated and emotional behavior. Extensive cell loss in the noradrenergic locus ceruleus, which richly innervates the cortex, has been associated with depressive symptoms. Changes in the serotonergic raphe nuclei and involvement of hypothalamic nuclei, including the suprachiasmatic nucleus, may explain commonly observed impairments of sleep and circadian rhythm in AD. Although dopaminergic neurons of the ventral tegmentum are severely depleted, cell loss is only moderate in the substantia nigra, as reflected by the absence of Lewy body pathology and associated extrapyramidal symptoms. The well-documented reductions in levels of various neurotransmitters and their receptors (47) are almost certainly a secondary consequence of the loss or functional deafferentation of these subcortical projection neurons.

INITIATION OF CELLULAR PATHOLOGY

Part of "85 - Cell and Molecular Neuropathology of Alzheimer Disease "

Familial Alzheimer Disease

The identification of genes that, when mutated, cause early-onset autosomal dominant FAD have provided strong clues to the cellular pathogenesis of AD (see Chapter 83).

Pathogenetic Mechanisms in Sporadic Alzheimer Disease

However, more than 90% of all cases of AD are not caused by single gene mutations, and, in these cases, the origin is less well understood. Although the factors that accelerate ß-amyloidogenesis in sporadic AD are not established, clues are emerging from studies of genes that influence the risk of developing late-onset AD. Topping the list of factors that increase AD risk is inheritance of the ε4 allele of the gene encoding Apo E, a protein that transports cholesterol and certain phospholipids into cells (48 ,49). The virtual absence of other key plasma apolipoproteins such as Apo A1, C1, and B in the brain emphasizes the critical role of Apo E in this tissue. In addition to its role in lipid transport, Apo E has antioxidant and growth-promoting properties on cells (50 ,51), and it interacts with Aß, thereby influencing its endocytosis and clearance (52), its ability to aggregate, and its neurotoxicity (53 ,54)—effects that may all be relevant to AD pathogenesis. The three isoforms of Apo E, ε2, ε3, and ε4, vary by only a single amino acid substitution, but they differ markedly in their binding affinities for low-density lipoprotein (LDL) receptors and other proteins. The most common allele, ε3, occurs in the general population with a frequency of 75%, whereas ε2 and ε4 occur with frequencies of 10% and 15%, respectively (1). Inheritance of a single ε4 allele increases the risk of AD threefold, whereas homozygosity for ε4 is associated with an eightfold increase in risk (49). The Apo E ε4 allele appears to lower the age of onset in persons in their sixties and seventies rather than influence the duration and severity of the disease. There is evidence that the ε2 allele confers some protection from the development of late-onset AD and Down syndrome (5).

Additional genes that may influence the risk of developing late-onset disease are being identified at an increasing pace (49 ,55 ,56). Among the possible positive risk factors are common population polymorphisms of the *APOE* promoter (57) and genes encoding the LDL-receptor–related protein (LRP-1) (58 ,59 ,60 and 61), α_2-macroglobulin (62), FE65 (63 ,64), very LDL (VLDL)-R receptor (65), the lysosomal protease cathepsin D (66), the lysosomal cysteine protease inhibitor cystatin C (67), bleomycin hydrolase (68), and interleukin-1 (1A and B) (69 ,70). In light of the evidence that neuronal endocytosis is altered at the very earliest stages of AD, many of these genetic modifiers of AD risk encode proteins that depend on endocytosis for their function. Apo E, its receptor on neurons (LRP), another LRP ligand (α_2-macroglobulin), and the VLDL receptor all are molecules that traffic through early endosomes as they bring cholesterol or other ligands into the cell. Inheritance of the *APOE* ε4 allele accentuates endocytic abnormalities in AD (27). Cathepsin D is a major protease of the endosomal-lysosomal pathway previously implicated by other neuropathologic and biochemical data in AD pathogenesis (34). Similarly, cystatin C mutations, which cause the Icelandic form of hemorrhagic cerebral amyloid angiopathy (71), are key regulators of proteases within the lysosomal system. The endocytic pathway is also responsible for the internalization and initial processing of APP at the cell surface. Fe65 binds to the internalization domain of APP and modulates its processing to Aß (72). Early endosomes are also a principal site of Aß generation in normal cells and mediate the cellular uptake of Aε and APPs (73 ,74).

The convergence of such a diverse group of etiologically important molecules at a known major site of Aß production

has suggested that altered early endosome function may contribute to ß-amyloidogenesis in sporadic AD (28). Supporting this hypothesis are studies showing the principal ß-secretase in cells resides largely in endosomes (75) and that cathepsin D, a protease with ß-secretase activity (76 ,77 ,78 and 79), and other “lysosomal” proteases that influence Aß formation become more abundant in neuronal early endosomes when the lysosomal system becomes activated in AD. This latter effect reflects not only the markedly increased expression of these proteases but also their enhanced targeting to early endosomes by the cation-dependent mannose-6-phosphate receptor (MPR-46), which is also more highly expressed in AD brain (28 ,80). When these conditions are recreated experimentally in cells by modestly overexpressing MPR-46, Aß generation is substantially increased (80). Thus, proteases that normally may not even be involved in Aß formation could, under pathologic conditions, become abnormally routed to cellular compartments where they promote Aß generation. This is one mechanism that explains how ß-amyloidogenesis may be accelerated in sporadic AD in the absence of a causative gene mutation.

EVOLUTION OF CELLULAR PATHOBIOLOGY

Part of "85 - Cell and Molecular Neuropathology of Alzheimer Disease "

The genetic heterogeneity of AD suggests that the disease may be initiated through distinct cellular cascades, which then converge on the final common pathways responsible for ß-amyloidogenesis, neurofibrillary pathology, and, ultimately, neuronal cell death. Secondary and tertiary responses of the brain to the presence of these neuropathologic lesions may further compromise neuronal function, making it difficult to establish what is cause or effect. Current hypotheses on the cellular pathobiology of AD emphasize different aspects of this complex multifactorial process, and, not surprisingly, these “different” views overlap considerably. To illustrate this, three perspectives on cellular pathogenesis are discussed in the following paragraphs; these emphasize metabolic decline, defective cell repair, or Aß toxicity as the driving pathophysiologic mechanism in AD.

From the *metabolic decline* perspective, cellular oxidative stress leading to neurodegeneration is a final common pathway of metabolic insults originating from different sources. According to this view, metabolic disturbances are both a cause and a consequence of ß-amyloidogenesis. The onslaught on metabolic function begins with effects of normal aging and specific genetic factors. For example, aging-related cerebral hypoperfusion leading to reduced brain glucose and oxygen utilization impairs energy production at the mitochondrial level and promotes the production of free radicals (81). The detection of regional hypometabolism in AD patients with mild cognitive impairment suggests that such hypometabolism may not be simply a result of neurodegeneration but may also precede it. Moreover, cerebral ischemia, coronary artery disease, *APP* mutations, and some inherited mitochondrial DNA mutations may increase AD risk, in part, by creating additional oxidative stress through these same pathways (82). Oxidative damage from these and other sources leads to mitochondrial membrane depolarization and increased levels of mitochondrial reactive oxygen species (82a). The resultant oxidative damage to proteins and membranes activates degradative pathways, notably the lysosomal system (31), and in doing so up-regulates cathepsins and other proteases (83), which have been implicated in mechanisms of cell death, Aß production, and cytoskeletal protein modification (34). Free radicals subsequently impair the function of glucose and glutamate transporters and damage ion-channel adenosine triphosphatases (sodium-calcium pumps), thereby reducing the ability of cells to buffer calcium (84) and rendering them more vulnerable to excitotoxins (85).

Calcium homeostasis is further altered by glutamate and other excitotoxins that stimulate receptor-mediated influx of calcium or, in FAD, by mutations of presenilin that lead to the release of intracellular calcium stores (86 ,87). Elevated cellular calcium activates major signaling cascades including stress-related protein kinases acting on tau and the cytoskeleton (24 ,88). Tau hyperphosphorylation decreases its binding to microtubules and promotes loss of microtubule stability and impaired axonal transport (89). NFT formation may compound this effect on transport by imposing physical obstructions to the movement of vital organelles to the axon and synapse. Calcium-activated neutral protease (calpain) systems, which are highly activated in AD brain (90 ,91), contribute to the truncation and breakdown of cytoskeletal proteins including tau, alter the activity of the protein kinase C cascade, cdk5, and other signaling pathways, and participate in the mechanisms underlying apoptotic and necrotic cell death (92 ,93). Ultimately, in certain cells, mitochondrial damage leads to the release of cytochrome C, which activates caspases that mediate apoptosis. FAD-linked *PS* and *APP* mutations increase the vulnerability of cultured neurons to apoptosis, presumably through one or more of the metabolic pathways discussed above (94 ,95 and 96).

Complementary to the foregoing metabolic decline perspective is a *cell repair* hypothesis, which emphasizes a putative failure by the brain to repair the cumulative neuronal damage arising from normal aging processes, ischemic and environmental insults, and genetic factors. The neurotrophic actions of APP or its mobilization during neuronal injury are most relevant here. Cells normally secrete a proteolytic derivative of APP, designated APPs, which promotes neuron growth and increases neuronal survival after certain types of injury (84). APP expression and distribution dramatically increases after neuronal injury, ischemia or oxidative stress, head injury, and exposure to toxins (97). Cerebrospinal fluid levels of APPs, however, may be reduced. Apo E also figures prominently in the processes of cell repair and regeneration by coordinating the mobilization and redistribution

of cholesterol needed for myelin and neuronal membrane synthesis (48). Functional synaptic remodeling *in vivo* is markedly compromised in mice lacking the Apo E gene (98). During regeneration, Apo E expression may increase up to 100-fold. The ε3 allele seems to be more effective as a growth-promoting or repair factor than the ε4 allele, which is linked to an increased risk of AD (99). Because Apo E is synthesized in glial cells, neurons depend heavily on receptor-mediated endocytosis to internalize Apo E–cholesterol complexes, a process that is altered at the earliest stages of AD (27). The increased levels of protease seen in neuronal early endosomes of the AD brain likely promote the degradation of internalized molecules and may prematurely abrogate their trophic or nutrient functions.

A third perspective, commonly referred to as the *Aß cascade hypothesis*, places the Aß peptide at the center of AD pathogenesis based on its neurotoxic properties in either soluble or fibrillar form. Aß deposition within senile plaques involves a balance between forces that enhance the overproduction and aggregation of Aß and countervailing forces that promote the uptake and degradation of Aß from the extracellular space. FAD-linked mutations cause varying degrees of Aß overproduction (97), but they may also favor aggregation by increasing the relative production of Aß42 or mutant Aß forms that aggregate more easily. Aß aggregation is also facilitated by additional proteins released by reactive or damaged cells (100 ,100a). In this regard, Apo E is particularly critical to Aß deposition (101 ,102 and 103). Cellular uptake and clearance of Aß involve interactions of an Apo E/Aß complex with LRP. The influence of Apo E on amyloid deposition is underscored by the observation that Apo E gene ablation abolishes amyloid deposition in transgenic mice overexpressing APP containing the London mutation (104). Microglial function also seems to be critical to Aß removal (15). In transgenic models of FAD, Aß deposition is almost completely prevented when microglia are experimentally activated by immunizing mice with Aß protein (105).

The fibrillar state of Aß is considered to be a crucial factor in Aß neurotoxicity (106 ,107); however, it is still unclear whether intraneuronal Aß accumulation or extracellular soluble Aß forms may be relevant to neurotoxicity (108 ,109). Although a sequence of events after Aß deposition has not been confirmed, it is hypothesized that Aß accumulation within diffuse plaques eventually leads to local microglial activation, cytokine release, increases in astrocyte numbers, and an inflammatory response involving the classic complement cascade, as discussed earlier (14). It has been further proposed that these glial responses and any direct neurotoxic effects of Aß initiate a cascade of biochemical and structural changes in surrounding axons, dendrites, and neuronal cell bodies in AD. Aß-initiated inflammatory and neurotoxic processes generate excessive free radicals and peroxidative injury to proteins and alterations of ionic homeostasis, particularly excessive calcium entry into neurons accompanied by the activation of calpains and kinases acting on cytoskeletal proteins (16 ,82 ,84). Aß is one of various factors that may stimulate the glycogen synthase kinase pathway, which, among other roles, is involved in both the phosphorylation of tau and still unclarified aspects of presenilin and APP processing (110). Finally, endocytic uptake of Aß 42 into cells activates and destabilizes the lysosomal system, and this further compounds the insult to this system from other sources and promotes cell death (111).

Thus, the Aß cascade hypothesis ultimately reaches the same metabolic endpoints as the metabolic decline hypothesis, but it distinguishes itself by proposing that Aß accumulation is the germinal event, rather than being a secondary, albeit important, consequence of accumulating metabolic or functional deficits within neurons. To become a comprehensive hypothesis of AD pathogenesis, the Aß cascade hypothesis still must explain the nature of the initial disturbance that causes Aß to accumulate in the 90% of AD cases that are not caused by FAD-linked mutations. Most likely, AD pathogenesis is a multifactorial process, in which Aß is necessary but not a sufficient factor.

CONCLUSIONS

Part of "85 - Cell and Molecular Neuropathology of Alzheimer Disease "

In this chapter, a discussion of Alzheimer neuropathology provides the starting point for understanding how the diagnosis of AD is made and how clinical symptoms arise and progress. Later sections address the neuroanatomic and cellular basis for dementia and the molecular events that lead to neuropathologic lesions and, ultimately, to the death of neurons. A consideration of current hypotheses on the evolution of cellular pathology identifies common features that help to reconcile the differing views of disease pathogenesis. New studies are beginning to shed light on underlying mechanisms in prevalent sporadic forms of AD, and their review complements the discussion of pathogenesis in the rare familial forms here and, in more detail, in Chapter 83 .

Structural and Functional Brain Imaging of Alzheimer Disease

Gary W. Small

Gary A. Small: Department of Psychiatry and Biobehavioral Sciences, Neuropsychiatric Institute, Alzheimer's Disease Centers, Center on Aging, University of California; Veterans Affairs Greater Los Angeles Healthcare System, Los Angeles, California.

Of the many laboratory measures and techniques available for understanding and quantifying biological aspects of *Alzheimer disease* (AD), imaging the structure and function of the brain is a particularly attractive approach in that it can provide highly relevant and diverse information using a variety of techniques. The application and interpretation of such information have considerable practical clinical relevance, but as these technologies and our understanding of the disease pathogenesis continue their rapid evolution, so do the potential utilities of these imaging methods in addressing timely neuropsychopharmacologic research issues.

Brain imaging techniques are often categorized as either structural or functional, based on the primary form of information provided. This classification method breaks down, however, when considering newer applications of these techniques. For example, magnetic resonance imaging (MRI) equipment is used to provide functional brain responses with functional MRI (fMRI). Moreover, both positron emission tomography (PET) and single photon emission computed tomography (SPECT) have the potential to provide visualizations of the pathognomonic structural lesions of AD, the amyloid neuritic plaques (NPs), and neurofibrillary tangles (NFTs).

The *in vivo* visualization of relevant structures and functions through brain imaging has several clinical and research applications for AD and other dementias. Recognition of dementia is particularly difficult in its early stages, when family members and physicians often incorrectly attribute the patient's symptoms to normal aging (1 ,2). Systematic studies indicate that the frequency of unrecognized memory impairment, beyond that associated with normal aging, or a dementia diagnosis can range from 50% to 90% of cases (3 ,4). A related application is the differential diagnosis of various dementia causes. The gradual onset and progressive cognitive decline of AD may be difficult to distinguish clinically from other chronic dementias, including dementia with Lewy bodies, vascular dementia, frontotemporal dementia, and late-life depression. Brain imaging techniques may sort out these various causes. The marginal diagnostic value (i.e., added specificity and sensitivity) that a brain imaging procedure provides also has applications to neuropharmacologic clinical trials. When brain imaging improves diagnostic homogeneity, drug efficacy and safety studies are likely to be more informative.

Another application of brain imaging is in the preclinical detection of AD. Neuropathologic, neuropsychological, and brain imaging data point to a form of gradual age-related cognitive decline that precedes AD (5). Use of imaging studies, particularly when coupled with data on genetic risk of AD, is an emerging strategy to identify candidates for pharmacologic interventions that delay cognitive decline progression and disease onset. A related application is the use of brain imaging data to predict and follow treatment response in patients with the full dementia syndrome of AD. Finally, imaging studies also may provide information that clarifies underlying disease mechanisms, which, in turn, may foster improved drug development. In this chapter, I review both available and developing brain imaging techniques and emphasize neuroimaging techniques and measures for presymptomatic AD detection and monitoring pharmacologic interventions.

STRUCTURAL NEUROIMAGING TECHNIQUES

Part of "86 - Structural and Functional Brain Imaging of Alzheimer Disease "

Computed Tomography

Computed tomography (CT) measures the attenuation of an x-ray beam through body tissues. A tissue's appearance will vary according to its attenuation. Bone has the highest attenuation and appears white, whereas gas has the lowest

and appears black. A ring of x-ray generators and detectors obtains images of multiple brain slices as the patient is advanced through the scanner (6). CT can differentiate bone, soft tissue, fluid, and gas with spatial resolution of less than 1 mm. Intravenous contrast medium enhances such pathologic features as bleeding, neoplasm, infection, and inflammation. Limitations of CT include its inability to differentiate gray and white matter and to visualize the posterior fossa clearly (6). Quantitative CT measures have demonstrated greater brain atrophy and ventricular dilatation in patients with AD compared with controls (7). The rate of clinical decline in AD is also related to the rate of ventricular volume change (8).

Magnetic Resonance Imaging

MRI measures the radiofrequency energy that hydrogen atoms of water molecules emit. In a static magnetic field, lower-energy nuclei align with the field, whereas higher-energy nuclei align against the field. When irradiated at a specific frequency, some lower-energy nuclei absorb energy and align against the field. The MRI scanner detects energy emitted when the radiation is discontinued and the nuclei return to their lower-energy state (9). Such energy level changes provide measures of brain structure representations. The rate that nuclei return to their low-energy state determines the type of image produced: T1-weighted images differentiate gray and white matter, and T2 images delineate white matter hyperintensities (9). Because MRI does not involve ionizing radiation, patients can have multiple scans. Spatial resolution is 1 to 2 mm, usually less than that of CT. Much of the work using MRI has focused on regional volumetric changes in patients with AD compared with controls, with an emphasis on atrophy of the hippocampus and nearby medial temporal structures (10).

FUNCTIONAL NEUROIMAGING TECHNIQUES

Part of "86 - Structural and Functional Brain Imaging of Alzheimer Disease "

Quantitative Electroencephalography

The development of computer-analyzed EEGs and the ability to examine regional differences in EEG activity have potential applications to the study of dementia (11). Quantitative EEG coherence measures the synchronization of neuronal activity at two different cortical sites. If different brain areas are simultaneously activated during a task, coherence between these areas will increase. In AD, reductions in resting state coherence occur between intrahemispheric parietal and prefrontal cortical areas, whereas in vascular dementia, reduction in coherence occurs between occipital and parietal areas (12). Changes in coherence in both the resting state and during task performance may become techniques for the differential diagnosis of dementia. Advantages of quantitative EEG are availability, low cost, and lack of radiation exposure. Disadvantages include the possibility of artifact and the fact that the measures are relatively distant from the brain. Moreover, the precise physiologic meaning of the measure is unclear. Resting state coherence in specific areas can be reduced in AD and in vascular dementia. In AD, the greatest reductions in coherence occur between intrahemispheric parietal and prefrontal cortical areas, whereas in vascular dementia, this reduction occurs between occipital and parietal areas (13).

Single Photon Emission Computed Tomography

SPECT involves administration of an inhaled or injected tracer or unstable isotope. Tracer decay leads to single photon emission, the scanner determines the site of the photon source, and a computer generates a three-dimensional image reflecting cerebral blood flow or receptor distribution (14). In comparison with PET, SPECT has lower spatial resolution, particularly for imaging deep structures. Moreover, determining the source of single photon emitters is less precise compared with determining the two photons traveling in opposite directions in PET scanning. Unlike PET, SPECT cannot demonstrate glucose metabolism.

Positron Emission Tomography

PET tracers are positron-emitting nuclides. When a positron encounters an electron, the positron is destroyed and releases photons traveling in opposite directions. A scanner records the simultaneous arrival of two different photons at different detectors (180 degrees apart) and determines the line along which the photons travel. PET images are then constructed from information received by the scanner (15). PET, like SPECT, delineates cerebral blood flow and receptor characteristics. Injection of high-affinity receptor ligands labeled with nuclides can measure receptor density and affinity. Studies of AD often use fluorodeoxyglucose (FDG) to measure cerebral glucose metabolism, which reflects synaptic activity. PET studies have demonstrated characteristic alterations in cerebral blood flow and metabolism in patients with AD that begin in the parietal cortex and spread to the temporal and prefrontal cortices. The degree of hypometabolism correlates with the severity of cognitive impairment (16). PET images can differentiate patients with AD from patients with other dementias and from cognitively intact people (17).

Although investigators have focused considerable attention on the cholinergic system in AD, numerous other neurotransmitter systems are affected, and PET has been used to study them. For example, striatal uptake of the dopamine reuptake ligand [11C]ß-CFT is decreased in AD, a finding indicating involvement of the brain dopaminergic system (18). In addition to serotonergic deficits (19), cholinergic

nicotinic and muscarinic receptors have been studied using PET radioligands (20).

Both PET and SPECT are noninvasive procedures that demonstrate neuronal activity or receptor characteristics. Advantages of PET include its better spatial resolution and the type of biological information it provides. Because of their radiochemical characteristics, positron emitters (PET tracers) can produce more ligands than photon emitters (SPECT tracers) for receptor studies. Lower scanner costs and greater availability of PET tracers have led to wider availability.

Magnetic Resonance Spectroscopy

Nuclei produce magnetic fields that modify the fields of neighboring atoms of the same molecule. Such “shielding” produces a small variation in the resonant frequency known as a chemical shift. The magnetic resonance spectrum display according to frequency demonstrates an element’s different chemical forms as characteristic peaks. These spectroscopy displays provide information on biologically important elements, thus reflecting tissue metabolite concentrations (21). Magnetic resonance spectroscopy (MRS) is noninvasive, lacks ionizing radiation exposure, and can provide quantitative regional measures of biochemical and physiologic processes. Schuff and associates used proton MRS (1H MRS) and tissue-segmented and volumetric MRI to determine whether hippocampal *N*-acetylaspartate (NAA, a neuronal marker) and volume used together provided greater discrimination between patients with AD and normal elderly persons than either measure alone (22). These investigators found that NAA reductions and volume losses made independent contributions to the discrimination of patients with AD from controls. Concentrations of myoinositol- and choline-containing compounds are higher in the occipital and parietal regions of adults with Down syndrome compared with controls (23).

Functional Magnetic Resonance Imaging

Developments in MRI techniques have allowed investigators to use the device to measure brain activity. The altered MRI signal intensity reflects local changes in blood volume or blood flow. The signal intensity of deoxygenated hemoglobin (highly paramagnetic) differs from that of oxygenated hemoglobin. During brain activity, increased blood flow brings more oxygenated blood into the capillary bed. The brain does not metabolize this excess oxygen, and this causes a greater concentration of oxygenated blood to cross over to the venous side leading to a decrease in the magnetic field gradient at the capillaries. The resultant greater magnetic field homogeneity yields a higher MRI signal intensity. Thus, brain regions receiving greater blood flow during brain activity produce a stronger MRI signal than do other regions. By comparing perfusion in activated and nonactivated states, areas of relative brain activity can be identified (24). Thus, fMRI provides measures of signal intensity that are associated with relative cerebral blood flow during memory or other cognitive tasks (25 ,26 ,27 ,28 ,29 and 30), and it has the advantages of high resolution in space and time and lack of radiation exposure. The MRI signal intensity associated with a particular task in comparison with the control condition reflects blood flow and consequently neural activity, but only indirectly (31 ,32). fMRI studies of patients with AD reveal lowered brain activity in parietal and hippocampal regions and relatively higher activity in primary cortices unaffected by the disease (33).

Diffusion Tensor Imaging

A critical aspect of the interpretation of normal and abnormal brain function is neuronal connectivity. One method that provides visualizations of projections of axonal fibers is diffusion tensor MRI (34). The technique offers quantitative information on the directionality (anisotropy) of water diffusion and thus information on local fiber orientation and integrity of white matter tracks. Diffusion tensor imaging (DTI) quantifies and visualizes diffusional anisotropy within each voxel, and computer algorithms relate DTI data to three-dimensional projections of axonal fibers. The degree of neuronal connectivity loss observed in AD is clearly a useful measure to monitor as the disease progresses, and combining DTI with other imaging modalities (e.g., PET, fMRI) may be a useful approach, which has been described in other neuropsychiatric disorders (35). A DTI study of diffusion anisotropy of pyramidal tract in ten older and ten younger adults subjects found that older persons had lower values in the cerebral peduncle, with no differences in the pons and medulla (36). A study of hippocampal water diffusion changes and temporal white matter using DTI in patients with AD and controls suggests that decreased fiber density occurs early in the temporal white matter, probably related to secondary degeneration from gray matter disease of the medial temporal lobe (37). Moreover, studies using DTI indicate mild myelin loss in patients with AD, even though white matter appears normal on MRI, and areas of periventricular hypertrophy show a definite loss of myelin and axons, including incomplete infarction (38).

IMAGING ANALYSIS TOPICS RELEVANT TO DEMENTIA RESEARCH

Part of "86 - Structural and Functional Brain Imaging of Alzheimer Disease "

Numerous variables influence the methodologic error introduced into imaging studies of dementia, including the stability and resolution of imaging systems, the reliability of image analysis, the effect size, undefined neuropathology, the stage of illness, and various confounding factors. The particular method of image analysis provides different levels of image detail and sources of error.

Imaging Registration

In early studies of SPECT and PET imaging, regions of interest (ROIs) were drawn directly on the PET images, matched to a standard atlas. This approach has high interrater reliability (39), but better anatomic definition is possible with computer software that provides image overlay programs merging structural and functional imaging data within the same subject for ROI analyses (40). Such algorithms also allow alignment of multiple PET images obtained from a single subject (41). Registration of PET images that have uniform three-dimensional resolution permits direct regional metabolic comparisons, whereas MRI and PET registration allows precise anatomic localization of those metabolic data in terms of the individual's structural anatomy.

Statistical Parametric Mapping

In statistical parametric mapping (SPM) analysis (42 ,43), images are coregistered and reoriented into a standardized coordinate system, spatially smoothed, and normalized to mean global activity. The set of pooled data are then assessed on a voxel-by-voxel basis, to identify the profile of voxels that significantly change between conditions (e.g., baseline versus follow-up scan). The probability of finding by chance any region containing its voxel of maximal significance is assessed after adjusting for multiple comparisons. It is not surprising that results vary according to analytic method. The ROI approach depends on *a priori* assumptions on size and shape of regions defined by structural criteria. If functionally relevant areas deviate from *a priori* assumptions, an area not functionally involved will dilute the statistical effect. By contrast, SPM analysis relies on pooled brain images spatially normalized into a common space; the extent that the original size and shapes of brains differ will inevitably introduce some error. Minoshima and colleagues applied an automated image analysis method, wherein metabolic reductions were standardized using three-dimensional stereotactic surface projections from FDG PET scans of patients with AD compared with controls (44). This approach has been useful in studies of asymptomatic subjects at risk of developing AD (45).

Atrophy Correction

Decreased functional imaging signal intensity in patients with AD may result from local atrophy causing partial volume effects. Approaches to correcting for cerebral atrophy and partial volume effects include a binary method, wherein cerebrospinal fluid (CSF) and brain tissue are segmented and the composite tissue images are convolved to the in-plane resolution of the PET image. The binary method ignores averaging between gray matter and white matter, and pathologic and imaging data suggest gray matter losses in AD greater than white matter losses (46). In trinary correction methods, CSF, gray matter, and white matter segmentation are included (47) (Fig. 86.1). Computer simulation studies (47) have shown close to 100% recovery of radiotracer concentration in neocortical gray matter and hippocampus, and they indicate that errors in gray matter segmentation and errors in registration of PET and MRI images result in less than 15% inaccuracy in the corrected image. Other work indicates that the neocortical deficits observed in AD reflect true metabolic reductions and are not just the result of atrophy (48).

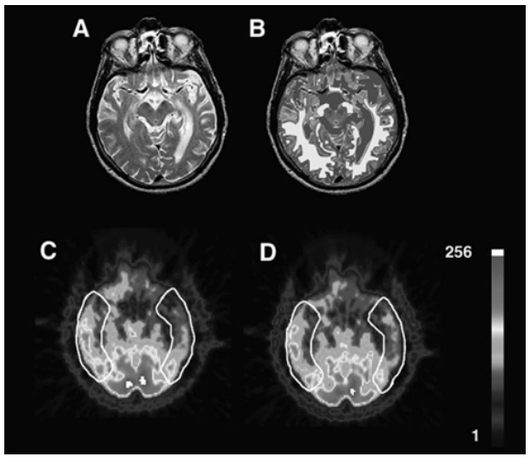

FIGURE 86.1. Partial volume correction using the trinary method. Example of the method using MRI and FDG PET images of a patient with primary progressive aphasia and left (seen on the **right** in figure image planes viewed from below the subject's head) temporal atrophy. Trinary segmentation (gray matter, white matter, CSF) was performed on the MRI image at the level of the temporal lobe. The MRI image was then registered and resliced to align with the PET image. The corrected left temporal glucose metabolic rate was higher than the uncorrected left temporal glucose metabolic rate, an expected result in light of the left temporal lobe atrophy. The corrected and uncorrected glucose metabolic raters for the right temporal lobe were nearly the same, consistent with the minimal atrophic changes in the right hemisphere. **A:** MRI scan without tissue segmentation. **B:** MRI scan with tissue segmentation (*yellow*, white matter; *gray*, gray matter; *blue*, CSF). **C:** Uncorrected PET image (*white lines* indicate temporal region of interest) showing left-to-right temporal lobe asymmetry of glucose metabolic rate. **D:** Corrected PET image showing less striking asymmetry. USE OF NEUROIMAGING FOR PRESYMPTOMATIC AD DETECTION AND PHARMACOLOGIC TREATMENT MONITORING

Part of "86 - Structural and Functional Brain Imaging of Alzheimer Disease "

During the past decade, investigators have been focusing their efforts on early detection of AD at clinical stages before

the time when a physician confirms a clinical diagnosis of probable AD (49). The aim is to begin preventive pharmacologic treatments before extensive neuronal damage develops. Brain imaging has become an important tool for the development of surrogate markers that will effectively identify people with only mild cognitive losses who are likely to progress in their cognitive loss and who will eventually develop the full dementia syndrome of AD. As novel, disease-modifying agents emerge, these surrogate brain imaging markers will be critical in determining drug efficacy and will facilitate drug development in both animal models and human studies.

Several diagnostic entities have been described in efforts to characterize age-related cognitive decline better. The mildest form of age-related memory decline is known as age-associated memory impairment (AAMI) (50), characterized by self-perception of memory loss and a standardized memory test score greater than or equal to 1 standard deviation (SD) below the aged norms. In people 65 years of age or older, its estimated prevalence is 40%, afflicting approximately 16 million people in the United States (51). Only about 1% of such patients develop dementia each year. A more severe form of memory loss is mild cognitive impairment (MCI), often defined by significant memory deficits without functional impairments. People with MCI show memory impairment that is greater than or equal to 1.5 SD below aged norms on such memory tasks as delayed paragraph recall (52). Approximately 10% of people 65 years old or older suffer from MCI, and nearly 15% develop AD each year (52 ,53). Brain imaging studies of presymptomatic AD focus on both these forms of age-related memory decline.

Evidence of Presymptomatic Disease

Neuropathologic, neuroimaging, and clinical research supports the idea that the dementing process leading to AD begins years before a clinical diagnosis of probable AD can be confirmed (49). Postmortem studies of nondemented older people indicate that tangle density in healthy aging correlates with age (54), but that some persons demonstrate widely distributed neuritic and diffuse plaques throughout neocortex and limbic structures. Other studies have found that NFT density increases in some persons (55), presumably those who will eventually develop AD, very early in adult life, perhaps even by the fourth decade. The diffuse amyloid deposits in middle-aged nondemented persons are consistent with an early or “preclinical” stage of AD and suggest that the pathologic process progresses gradually, taking 20 to 30 years to proceed to the clinical manifestation of dementia (56). Other supportive evidence includes findings that linguistic ability in early life predicts cognitive decline in late life (57). High diffuse plaque density in nondemented older persons has been observed in the entorhinal cortex and inferior temporal gyrus, in association with acetylcholinesterase fiber density (58). Evidence from animal models also supports compromised hippocampal cholinergic transmission during aging (59). Studies of glucose metabolic rates using PET (45 ,60 ,61) indicate lower regional brain metabolism in middle-aged and older persons with a genetic risk (apolipoprotein E-4 [APOE-4]), lending further support to a prolonged presymptomatic AD stage.

Structural Imaging

Computed Tomography and Magnetic Resonance Imaging

Studies of early detection logically follow from initial work demonstrating the differential diagnostic utility of a brain imaging marker. For structural imaging, particularly MRI, data have emerged on the use of regional atrophy patterns for the positive diagnosis of AD and other neurodegenerative disorders. Studies without neuropathologic confirmation report the utility of medial temporal lobe atrophy, particularly hippocampal atrophy, on CT or MRI for the clinical diagnosis of AD (62). Some, but not all, quantitative MRI studies indicate that white matter hyperintensities correlate with neuropsychological functioning in both healthy elderly persons and demented patients (63 ,64). Other studies indicate loss of cerebral gray matter (46), hippocampal and parahippocampal atrophy (65), and lower left amygdala and entorhinal cortex volumes (66) in patients with AD. In differentiating AD from older normal controls, the sensitivity of various medial temporal atrophy measures ranges from 77% to 92%, with specificities ranging from 49% to 95% (67 ,68 and 69). In older patients with MCI, hippocampal atrophy predicts subsequent conversion to AD (70). Of various analytic methods, computerized volumetric techniques are most accurate, but they are currently labor intensive and are not widely available.

A modified negative-angle axial view designed to cut parallel to the anterior-posterior plane of the hippocampus has been used to assess hippocampal volume using CT or MRI (62). Such hippocampal atrophy is a sensitive and specific predictor of future AD in patients with MCI. Baseline hippocampal ratings accurately predicted decliners with an overall accuracy of 91%. Neuropathologic studies found that the sites of maximal neuronal loss for both AD and MCI are in the CA1, subiculum, and entorhinal cortex (62). Hippocampal atrophy was also found to predict future cognitive decline in older persons without cognitive impairment who were followed-up for nearly 4 years. Visual assessments of medial temporal lobe atrophy on coronal MRI sections show significant correlations between estimated and stereologically measured volumes (71). Because the latter is much more labor intensive, visual readings may be an alternative approach with greater efficiency.

The hippocampus and the temporal horn of the lateral ventricles also may serve as antemortem AD markers in

mildly impaired patients (mean Mini-Mental State Examination [MMSE] score of 24) (72). Although hippocampal atrophy may enable one to distinguish AD from normal aging, such atrophy may be nonspecific, occurring in other dementing disorders (73). MRI hippocampal atrophy measures are not as sensitive as PET glucose metabolism measures, which begin decreasing before the onset of memory decline (74). The presence of MRI white matter hyperintensities does not improve diagnostic accuracy because they occur both in AD and in healthy normal elderly persons (75 ,76).

The entorhinal cortex, a region involved in recent memory performance, is one of the earliest areas to accumulate NFTs (55). Histologic boundaries of the entorhinal cortex from patients with autopsy-confirmed AD and controls have been used to validate a method for measurement of entorhinal cortex size relying on gyral and sulcal landmarks visible on MRI (77). Such measures may be additional early AD detection markers.

Several studies have addressed the interaction between regional atrophy and *APOE* genotype. Increasing dose of *APOE*-4 allele was associated with smaller hippocampal, entorhinal cortical, and anterior temporal lobe volumes in already demented patients (78). A study of nondemented older persons found an association between *APOE*-4 dose and a larger left than right hippocampus (79). Combining medial temporal measures with other functional neuroimaging (80) or *APOE* genotyping may improve the ability of any of these measures alone to predict cognitive decline (81).

In Vivo Imaging of Amyloid Plaques and Neurofibrillary Tangles

The evidence of NP and NFT accumulation years before clinical AD diagnosis suggests that *in vivo* methods that directly image these pathognomic lesions would be useful presymptomatic detection technologies. Current methods for measuring brain amyloid, such as histochemical stains, require tissue fixation on postmortem or biopsy material. Available *in vivo* methods for measuring NPs or NFTs are indirect (e.g., CSF measures) (82). Studies that may lead to direct *in vivo* human Aß imaging include various radiolabeled probes using small organic and organometallic molecules capable of detecting differences in amyloid fibril structure or amyloid protein sequences (83). Investigators also have used chrysamine-G, a carboxylic acid analogue of congo red, an amyloid-staining histologic dye (84), serum amyloid P component, a normal plasma glycoprotein that binds to amyloid deposit fibrils (85), or monoclonal antibodies (86). Methodologic difficulties that hinder progress with these techniques include poor blood–brain barrier crossing and limited specificity and sensitivity. In addition, most approaches do not measure both NPs and NFTs.

In a breakthrough, Barrio and colleagues (87) used a hydrophobic radiofluorinated derivative of 1,1-dicyano-2-[6-(dimethylamino)naphthalen-2-yl]propene (FDDNP) (88) with PET to measure the cerebral localization and load of NFTs and SPs in patients with AD (n = 7) and controls (n = 3). The FDDNP was injected intravenously and was found to cross the blood–brain barrier readily in proportion to blood flow, as expected from highly hydrophobic compounds with high membrane permeability. Greater accumulation and slower clearance of FDDNP were observed in brain regions with high concentrations of NPs and NFTs, particularly the hippocampus, amygdala, and entorhinal cortex. The FDDNP residence time in these regions showed significant correlations with immediate and delayed memory performance measures (89), and areas of low glucose metabolism correlated with high FDDNP activity retention. The probe showed visualization of NFTs, NPs, and diffuse amyloid in AD brain specimens using *in vitro* fluorescence microscopy, which matched results using conventional stains (e.g., thioflavin S) in the same tissue specimens. Thus, FDDNP-PET imaging is a promising noninvasive approach to longitudinal evaluation of NP and NFT deposition in preclinical AD.

Magnetic Resonance Spectroscopy

Initial studies of MRS as a preclinical AD detection technique found significantly lower NAA concentrations in persons with AD and AAMI compared with controls (90). Mean inositol concentration was significantly higher in AD than in controls, whereas persons with AAMI had intermediate values. Another study focused on patients with Down syndrome because they invariably develop AD by the time they reach their thirties or forties. Concentrations of myoinositol- and choline-containing compounds found using 1H MRS were significantly higher in the occipital and parietal regions in 19 nondemented adults with Down syndrome and in 17 age- and sex-matched healthy controls (23). Moreover, older patients with Down syndrome (42 to 62 years) had higher myoinositol levels than younger subjects (28 to 39 years), a finding suggesting that this approach may be eventually useful as a preclinical AD marker.

Functional Imaging

Positron Emission Tomography

Using FDG PET, our group reported that parietal hypometabolism predicted future AD in people with questionable dementia (91), and even people with very mild age-related memory complaints have baseline PET patterns predicting cognitive decline after 3 years (92). These initial studies using PET for early AD detection emphasized family history of AD as a risk factor for future cognitive decline. A change in focus came with the discovery of the *APOE* genetic risk for AD. The first report combining PET imaging and *APOE*

genetic risk in people with a family history of AD included 12 nondemented relatives with *APOE*-4 and 19 relatives without *APOE*-4 and compared them with seven patients with probable AD (61). "At-risk" subjects had mild memory complaints, normal cognitive performance, and at least two relatives with AD. Persons with *APOE*-4 did not differ from those without *APOE*-4 in mean age at examination (56.4 versus 55.5 years) or in neuropsychologic performance. Parietal metabolism was significantly lower and left-right parietal asymmetry was higher in at-risk subjects with *APOE*-4 compared with those without *APOE*-4. Patients with dementia had significantly lower parietal metabolism than did at-risk persons with *APOE*-4.

The following year, Reiman and associates replicated these results and extended them to other brain regions (45). These investigators found hypometabolism in temporal, prefrontal, and posterior cingulate regions in a study of 11 nondemented *APOE*-4 homozygotes (4/4 genotype) and in 22 *APOE*-3 homozygotes (3/3 genotype) of similar ages to those in our own initial study (midfifties). They also applied an automated image analysis method, wherein metabolic reductions were standardized using three-dimensional stereotactic surface projections from FDG PET scans of patients with AD compared with controls (44). The results from these two studies (45 ,61) provided independent confirmation of an association between genetic risk and regional cerebral glucose hypometabolism.

Our group confirmed these two initial reports in a study that included none of the subjects participating in our previous report on *APOE* and PET (61), in a study of 65 persons in the 50- to 84-year age range (mean ± = 67.3±9.4 years), with or without a family history of AD (93). Of the 65 study subjects, 54 were nondemented (27 were *APOE*-4 carriers and 27 were subjects without *APOE*-4), and 11 were demented and were diagnosed with probable AD (49). The nondemented study subjects were aware of a gradual onset of mild memory complaints (e.g., misplacing familiar objects, difficulty in remembering names). The nondemented subjects, however, had memory performance scores within the norms for cognitively intact persons of the same age and educational level. The *APOE*-4 carriers had a small but consistent nonsignificant reduction in cognitive performance. As predicted, baseline comparisons among the three subject groups indicated the lowest metabolic rates for the AD group, intermediate rates for the nondemented *APOE*-4 carriers, and highest rates for the nondemented group without *APOE*-4 in several cortical regions, including inferior parietal, lateral temporal, and posterior cingulate (Fig. 86.2).

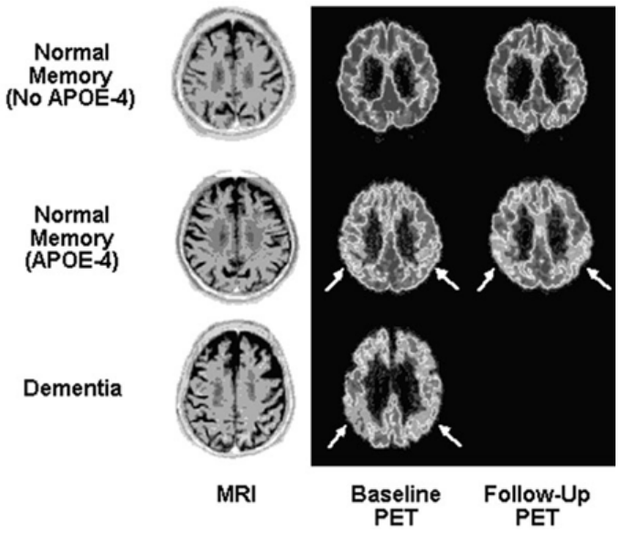

FIGURE 86.2. Examples of PET images (comparable parietal lobe levels) coregistered to each subject's baseline MRI scan for an 81-year-old nondemented woman (*APOE*-3/3 genotype; **upper images**), a 76-year-old nondemented woman (*APOE*-3/4 genotype; **middle images**), and a 79-year-old woman with AD (*APOE*-3/4 genotype; **lower images**). The last column shows 2-year follow-up scans for the nondemented women. Compared with the nondemented patient without *APOE*-4, the nondemented *APOE*-4 carrier had 18% **(right)** and 12% **(left)** lower inferior parietal cortical metabolism, whereas the demented woman's parietal cortical metabolism was 20% **(right)** and 22% **(left)** lower, as well as more widespread metabolic dysfunction resulting from disease progression. Two-year follow-up scans showed minimal parietal cortical decline for the woman without *APOE*-4, but bilateral parietal cortical decline for the nondemented woman with *APOE*-4, who also met clinical criteria for mild AD at follow-up. MRI scans were within normal limits. (From Small GW, Ercoli LM, Silverman DHS, et al. Cerebral metabolic and cognitive decline in persons at genetic risk for Alzheimer's disease. *Proc Natl Acad Sci USA* 2000;97:6037–6042, with permission.) See color version of figure.

Another FDG PET study focused on older patients with Down syndrome who were at risk of AD (94). The investigators hypothesized that an audiovisual stimulation paradigm would serve as a stress test and would reveal abnormalities in parietal and temporal cerebral glucose metabolism before dementia developed. At mental rest, younger and older patients with Down syndrome did not differ in glucose metabolic patterns. During audiovisual stimulation, however, the older patients showed significantly lower parietal and temporal metabolism. Families with familial AD linked to chromosome 14 or amyloid precursor protein (*APP*) mutations have been studied with FDG PET as well (95). In such families with early-onset AD, approximately half of relatives who live to the age at risk will develop AD. Although pedigree members with AD show typical parietal and temporal hypometabolism, asymptomatic relatives at risk of AD show a similar but less severe hypometabolic pattern.

Single Photon Emission Computed Tomography

Johnson and associates (96) used SPECT with technetium-hexamethylpropyleneamineoxime (HMPAO) to study longitudinal cerebral perfusion of patients with questionable AD (clinical dementia rating = 0.5) (97) and controls. Regional decreases in perfusion in patients whose diagnosis

converted to AD were most prominent in the hippocampal-amygdaloid complex, the anterior and posterior cingulate, and the anterior thalamus. Including *APOE* status did not influence results. A direct comparison of FDG PET and HMPAO-SPECT in their ability to differentiate AD from vascular dementia indicated higher diagnostic accuracy for PET regardless of dementia severity (98). Using ROC curves, PET diagnostic accuracy was better than SPECT for an MMSE score greater than 20 (87.2% versus 62.9%) and for an MMSE score less than or equal to 20 (100% versus 81.2%). Other studies confirmed a lower sensitivity for even high-resolution SPECT compared with PET (99). Moreover, the parietal hypoperfusion observed using SPECT in patients with AD has been observed in such other conditions as normal aging, vascular dementia, posthypoxic dementia, and sleep apnea (100).

Functional Magnetic Resonance Imaging

Two studies combined *APOE* genotyping and fMRI in persons at risk of AD. Bookheimer and associates (101) performed fMRI studies while 30 cognitively intact middle-aged and older persons (mean age, 63 years) memorized and retrieved unrelated word pairs. The 16 *APOE*-4 carriers did not differ significantly from the 14 persons without *APOE*-4 in age, prior educational achievement, or rates of AD family history. Brain activation patterns were determined during both learning and retrieval task periods and were analyzed using between-group and within-subject approaches. Memory performance was reassessed on 12 subjects after 2 years of follow-up. The *APOE*-4 carriers had significantly greater magnitude and spatial extent of MRI signal intensity during memory performance in regions affected by AD, including bilateral hippocampal and left parietal and prefrontal (Fig. 86.3). This pattern of activation was greater in the left hemisphere, consistent with the verbal nature of the task, and during the retrieval rather than the learning condition. Longitudinal data indicated that greater baseline brain activation correlated with verbal memory decline assessed 2 years later. The greater signal in persons with the *APOE*-4 genetic risk suggests that the brain may recruit additional neurons to compensate for subtle deficits. Moreover, the longitudinal data are encouraging that fMRI may be a useful approach to prediction of future cognitive decline and early AD detection.

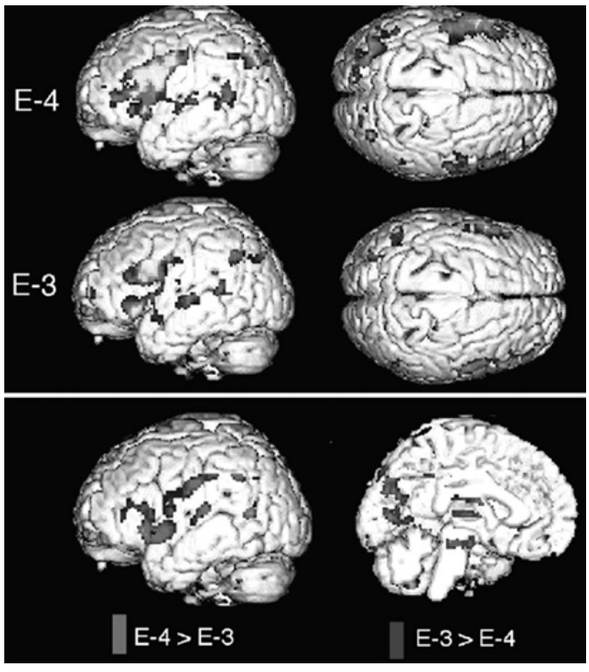

FIGURE 86.3. Statistical parametric maps of recall versus control blocks for *APOE*-4 carriers and noncarriers. Maps were standardized into a common coordinate system. Both groups showed significant MRI signal intensity increases in frontal, temporal, and parietal regions, and the *APOE*-4 group had greater extent and intensity of activation. The *APOE*-4 group showed additional activations in the left parahippocampal region, left dorsal prefrontal cortex, and other regions in the inferior and superior parietal lobes, and anterior cingulate. (From Bookheimer SY, Strojwas MH, Cohen MS, et al. Brain activation in older people at genetic risk for Alzheimer's disease. *N Engl J Med* 2000;343:450-456, with permission.) See color version of figure.

By contrast, other types of memory tasks may produce different patterns of brain activation. In another study of persons at risk for AD, visual naming and letter fluency tasks were used to activate brain areas involved in object and face recognition during fMRI scanning (102). Subjects in the high-risk group had at least one first-degree relative with AD and one *APOE*-4 allele. The low-risk group was matched for age, education, and cognitive performance. The high-risk group showed reduced activation in the middle and posterior inferotemporal regions bilaterally. Such decreased activation patterns could result from subclinical neuropathology in the inferotemporal region or in the inputs to that region.

Longitudinal Studies of Glucose Metabolism of Persons At Risk of Dementia

Both the University of California, Los Angeles (UCLA) and the University of Arizona groups have reported on longitudinal FDG PET follow-up data on nondemented persons at risk of AD. At UCLA, a total of 20 nondemented subjects (ten *APOE*-4 carriers and ten without *APOE*-4) received repeat PET and neuropsychologic testing 2 years after baseline assessment (mean±SD for follow-up was 27.9±1.7 months) (93). The ten *APOE*-4 carriers available for longitudinal study were similar to the ten noncarriers in mean±SD age (67.9±8.9 versus 69.6±8.1 years) and educational achievement (14.4±1.8 versus 16.4±2.8 years). Memory performance scores did not differ significantly

according to genetic risk either at baseline or follow-up, and the *APOE*-4 carriers and noncarriers did not differ significantly in cognitive change after 2 years.

The ROI analysis of PET scans performed after 2 years showed significant glucose metabolic decline (4%) in the left posterior cingulate region in *APOE*-4 carriers. The SPM analysis showed significant metabolic decline in the inferior parietal and lateral temporal cortices with the greatest magnitude (5%) of metabolic decline in the temporal cortex (Fig. 86.4). After correction for multiple comparisons, this decline remained significant for the *APOE*-4 group, wherein a decrease in metabolism was documented for every subject. Based on these data from only ten subjects, the estimated power of PET under the most conservative circumstances is 0.9 to detect a one-unit decline from baseline to follow-up using a one-tailed test. Such findings suggest that combining PET and AD genetic risk measures will allow investigators to use relatively small sample sizes when testing antidementia treatments in preclinical AD stages. The University of Arizona group also found that *APOE*-4 heterozygotes had significant 2-year declines in regional brain activity, the largest of which was in temporal cortex, and that these reductions were significantly greater than those in *APOE*-4 noncarriers. Their findings suggest that as few as 22 cognitively normal, middle-aged *APOE*-4 heterozygotes would be needed in each treatment arm (i.e., active drug and placebo) to test a prevention therapy over a 2-year period (103).

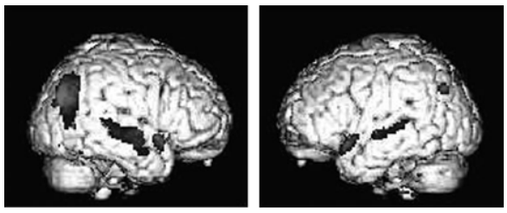

FIGURE 86.4. Regions showing the greatest metabolic decline after 2 years of longitudinal follow-up in nondemented patients with *APOE*-4 (SPM analysis) included the right lateral temporal and inferior parietal cortex (brain on the **left side** of the figure). Voxels undergoing metabolic decline ($p < .001$, before correction) are displayed in color, with peak significance ($z = 4.35$) occurring in Brodmann's area 21 of the right middle temporal gyrus. (From Small GW, Ercoli LM, Silverman DHS, et al. Cerebral metabolic and cognitive decline in persons at genetic risk for Alzheimer's disease. *Proc Natl Acad Sci USA* 2000; 343:450–456, with permission.) See color version of figure.

Clinical Trials of Presymptomatic Patients Using Neuroimaging Surrogate Markers

The longitudinal findings of significant parietal and temporal metabolic decline in asymptomatic persons at risk of AD because of age or genetic risk or both have now been confirmed at two centers in separate subject cohorts. Together, these studies indicate that combining PET imaging of glucose metabolism and genetic risk may be useful outcome markers in AD prevention trials. Functional brain imaging techniques could be used to track preclinical cognitive decline and to test candidate prevention therapies without having to perform prolonged multisite studies using incipient AD as the primary outcome measure. The consistency and extent of the metabolic decline in these well-screened populations indicate that the PET measures provide adequate power to observe such decline in relatively small subject groups. A similar but less striking metabolic decline pattern was noted in subjects without *APOE*-4 such that larger groups per treatment arm would be needed.

These observations provide an opportunity for presymptomatic treatment trials not previously available. Until now, such trials involved studies of preclinical subjects with more severe memory impairments consistent with MCI, wherein approximately 50% of subjects actually develop dementia over a 3- to 4-year period. The MCI trials have required hundreds of subjects for adequate power. These trials use a categorical variable, incipient dementia, as the primary outcome measure. The introduction of FDG PET imaging combined with *APOE*-4 genetic risk increases efficiency and reduces costs by addressing the research questions with fewer subjects. Our group is currently performing two such placebo-controlled trials, one using the cyclooxygenase-2 inhibitor celecoxib and the other using the cholinesterase inhibitor donepezil.

Cost Benefit and Cost Effectiveness

Using neuroimaging as a surrogate marker early in the disease course, even in preclinical stages, has potential cost benefits beyond the greater efficiency in preclinical trials. Because FDG PET increases diagnostic sensitivity and specificity of AD (104), the technique could improve diagnostic homogeneity in clinical trials of mild to moderate AD. Rather than treating the conventional clinical syndrome of AD, the refined phenotype would include a specific neuroimaging pattern (e.g., parietal and temporal hypometabolism). If PET can improve diagnostic accuracy, particularly in the preclinical and early disease stages, then patients would be treated earlier, with resulting improvements in their daily functioning and quality of life. When uncertain about diagnosis, clinicians generally perform costly repetitive examinations. The greater accuracy of early AD detection that neuroimaging may offer would facilitate early intervention. Offsetting the pharmacy costs would be the cost savings from avoidance of repetitive and unnecessary examinations. Following evidence from placebo-controlled studies, the assessment of economic impact would be another level of analysis driving decision makers to fund new neuroimaging technologies. Definitive diagnosis and treatment

during presymptomatic stages of AD would likely decrease both direct and indirect costs. The improved diagnostic accuracy could improve efficacy in clinical trials and could thus facilitate early optimal treatment, delay further cognitive decline, and meet patient and family expectations of the highest-quality care.

Current and Experimental Therapeutics of Alzheimer Disease

Kenneth L. Davis

Kenneth L. Davis: Department of Psychiatry, Mount Sinai School of Medicine, New York, New York.

An enhanced understanding of the neurobiology and neurochemistry of Alzheimer disease, combined with provocative epidemiologic studies, has led to a plethora of new approaches of treatment. It has been estimated that between 50 and 60 drugs are in or entering clinical trials in Alzheimer disease (1). These approaches range from symptomatic and palliative, to preventive and disease altering. Although no magic bullets have been unveiled, it is clear that since the early 1990s, the therapeutics of Alzheimer disease have inexorably proceeded along a rational course, generating an increasing number of compounds that have entered the marketplace and have shown benefit for patients and caregivers.

ACETYLCHOLINESTERASE INHIBITORS

Part of "87 - Current and Experimental Therapeutics of Alzheimer Disease "

The first drug approved in the United States and Europe with an indication to diminish the intensity of the core symptoms of Alzheimer disease, namely, problems in memory, praxis, and language, was tacrine (Cognex). A few years thereafter, approval through most of Europe and the United States was granted to donepezil (Aricept). In 1999, rivastigmine (Exelon) received approval in Europe and was approved in the United States in 2000. Most recently, galantamine (Reminyl) was approved in Sweden for the treatment of Alzheimer disease. This drug, previously available in Austria under the trade name Nivalin for a host of other indications, is now awaiting approval throughout the rest of Europe and the United States.

Although all these drugs are cholinesterase inhibitors, the mechanism of cholinesterase inhibition and other properties of the compounds make them far less than equivalent. Cholinesterase inhibition can be mediated through numerous different mechanisms, characterized as reversible, irreversible, or pseudoirreversible. Additionally, the relationship among cholinesterase, acetylcholine, and the cholinesterase inhibitor could be either competitive or noncompetitive. The specificity of cholinesterase inhibitors can also vary, with differing affinity for butyrylcholinesterase. Finally, these drugs can also differ in the degree to which they modulate the sensitivity of nicotinic receptors.

The group of cholinesterase inhibitors also differs among classical pharmacokinetic and pharmacodynamic parameters. Degree of protein binding, duration of action, and drug interactions discriminate among the drugs in this class. All these specific differences are delineated in this chapter.

Tacrine

Tacrine (Cognex) is a noncompetitive reversible inhibitor of both butyrylcholinesterase and acetylcholinesterase. In fact, its specificity for butyrylcholinesterase is greater than for acetylcholinesterase. It is of the acridine class. The bioavailability of the drug is variously estimated between 17% and 33%, its peak plasma level occurs relatively rapidly within 1 to 2 hours, and it has a serum half-life of 1½ to 2 hours. The drug has a protein binding of about 75%, and it is metabolized by numerous cytochrome pathways including 1A2 and 2D6. Four times a day dosing is required. The efficacy of tacrine was established in a series of placebo-controlled, double-blind studies (2 ,3 and 4). These studies ultimately led to United States Food and Drug Administration (FDA) approval based on tacrine's ability to improve the core symptoms of Alzheimer disease as reflected in the cognitive subscale of the Alzheimer's Disease Assessment Scale (ADAS-cog) (5) and in the assessment of global change by the clinician (6 ,7 ,8 and 9).

Tacrine has been associated with a high frequency of elevated liver transaminases. At some time in their course of drug administration, approximately 50% of patients receiving tacrine will develop elevation in liver transaminases (10). However, with discontinuation of the drug or even lowering of the dose, most such elevations return to baseline.

Indeed, it is even possible to readminister tacrine to many patients who previously had “transaminitis,” with a subsequent benign course. Given these data, it is not surprising that fatal hepatotoxicity has been extremely rare (11). Extensive experience with tacrine has led to the conclusion that rechallenge with tacrine is possible, unless patients have had jaundice, eosinophilia, or other signs of a hypersensitivity reaction. Nonetheless, frequent monitoring of liver enzymes is a necessary concomitant of administration of tacrine, as is relatively slow drug titration. The most efficacious doses of tacrine are between 120 and 160 mg per day. Patients do not often achieve this dose, and even in those patients in whom a dose of 120 mg is obtained, the minimal time to reach that level is 12 weeks. For all these reasons, tacrine is no longer actively promoted, and it is rarely used.

Donepezil

Donepezil (Aricept) is a piperidine cholinesterase inhibitor that is reversible and has both competitive and noncompetitive features. It is 100% bioavailable, and it reaches peak plasma levels between 3 and 5 hours after administration. The drug has not been shown to have any interaction with food. It is highly protein bound. The drug is metabolized by the cytochrome system, specifically 2D6 and 3A4. Donepezil has a long serum half-life, estimated to be between 70 and 80 hours. The consequence of these characteristics is that donepezil requires only a once-daily dose (12).

Large placebo-controlled, multicenter, randomized trials have established the statistically significant effects of donepezil on ADAS-cog and clinical global measures (13 ,14 ,15 ,16 and 17). The effective doses are 5 and 10 mg administered once per day. Some trials do not show a superiority of 5 mg over 10 mg, although other data would suggest greater superiority for 10 mg (17).

The major adverse events that are associated with donepezil administration are those that can be anticipated from drugs that increase cholinergic activity. These include nausea, vomiting, and diarrhea. To minimize these effects at the higher, more effective, dose of 10 mg, a titration schedule in which patients remain at the 5-mg dose for 6 weeks, before being raised to the 10-mg dose, is recommended.

Other adverse events are less common, but they are also explicable by the cholinomimetic properties of donepezil. The drug has been associated with bradycardia and syncope as well as some sleep disturbance. Increased cholinergic activity is well known to produce bradycardia, and the cholinergic system can have profound effects on sleep architecture including increasing arousal (18 ,19 ,20 ,21 and 22).

Rivastigmine

Rivastigmine (Exelon) is a carbamate that inhibits both acetylcholinesterase and butyrylcholinesterase. Its mechanism of action at cholinesterase is termed pseudoirreversible, meaning that although it binds to the cholinesterase-like irreversible inhibitors do, it is metabolized by cholinesterase, the enzyme it is inhibiting. This circumstance produces a truly “pseudoirreversible” state and accounts for rivastigmine’s half-life of 10 hours, far shorter than would be expected from an irreversible cholinesterase inhibitor. Irreversible inhibitors are active for as long as the time necessary to regenerate cholinesterase, between 2 and 4 weeks. Rivastigmine’s bioavailability is approximately 40%, and its time to peak concentration can be as rapid as half an hour or as long as 2 hours. There is some interaction with food in its absorption. Its binding to plasma proteins is approximately 40%. Its metabolism is totally nonhepatic, and it can be presumed to have minimal drug interactions. Based on its pharmacokinetic and pharmacodynamic characteristics, the drug is given twice a day, with total doses ranging from 6 to 12 mg.

Efficacy of the agent has been established (23). However, only the higher doses of rivastigmine (doses higher than 6 mg) were shown to be efficacious in two pivotal studies, in both ADAS-cog and global measures. High doses also demonstrate efficacy compared with placebo in activities of daily living, as reflected on the progressive deterioration scale. However, for some patients, it is difficult to achieve these high doses. Despite slow dose titration that took up to 12 weeks, approximately 25% of patients receiving more than 6 mg per day of rivastigmine withdrew from the study, and substantially more had some gastrointestinal complaints. The side effects predominantly occurred during dose escalation.

Galantamine

Galantamine is an alkaloid-derived, reversible, competitive acetylcholinesterase inhibitor. It occurs naturally in certain plants. It is relatively selective for acetylcholinesterase, with far less activity at butyrylcholinesterase. The drug is also an agonist at allosteric nicotinic sites, a mechanism of action that it has in common with benzodiazepines that have a similar mechanism of action at the γ-aminobutyric acid$_A$receptor. Activity at this site facilitates release of acetylcholine (24). The drug is less than 10% protein bound, it has a very high bioavailability, and it interacts with food such as to decrease its maximum concentrations (25). Twice-daily dosing is supported by approximately a 9-hour half-life (26). The drug is metabolized in the liver by 2D6 and 3A4 (27).

A series of placebo-controlled, randomized, double-blind studies established the efficacy of galantamine. A dose of 24 mg per day is recommended, although both 16 and 32 mg have been shown to also be efficacious (28 ,29 and 30). A significant difference between drug and placebo has been found on the traditional psychometric and global measures, as well as measures of activities of daily living, ADAS-ADL scale, and behavior, Neuropsychiatric Inventory (NPI).

As with other cholinomimetics, the most common adverse

events are gastrointestinal. These effects are dose related and occur predominantly when the drug's dose is increased. Gastrointestinal side effects can be minimized by dose titration of 8 mg every 4 weeks up to the 16- to 24-mg dose.

Other Cholinesterase Inhibitors

Both metrifonate and extended-release physostigmine have been studied in patients with Alzheimer disease. Indeed, attempts have been made to register these drugs for approval in the United States market, without success. Both drugs have been associated with some degree of efficacy (31 ,32 ,33 and 34). Metrifonate is an organophosphate that is a prodrug for its major metabolite, dichlorvose, which binds irreversibly to acetylcholinesterase. Physostigmine is a reversible inhibitor of both acetylcholinesterase and butyrylcholinesterase.

Development of both these drugs has been stopped, but for different reasons. Metrifonate has been associated with muscle weakness and a possible risk of respiratory muscle dysfunction leading to death. Organophosphate-related delayed neurotoxicity has been well described and has been linked to the binding of a phosphorylated metabolite of organophosphates to neurotoxic esterase (35). A likely related symptom, characterized as a myasthenic-like problem, has also been well described (35), and it seems similar to the problems that had led to the failure of metrifonate to reach the marketplace. Extended-release physostigmine has had a substantial association with nausea and vomiting, with 47% of patients reporting these symptoms during a 12-week trial (31). Unless additional work is done with these compounds to modify this adverse event profile, it is unlikely that either of these drugs will be available for routine use in the clinic.

Course-Altering Properties of Cholinesterase Inhibitors?

That cholinesterase inhibitors are efficacious in the palliative treatment of Alzheimer disease is now beyond question. A far more intriguing issue is whether these drugs alter the course of the disease. Here the data are far more tentative.

The effect of cholinomimetic activity on the processing of amyloid precursor proteins (APP) in various cell culture lines has been studied (36 ,37). Cholinergic stimulation apparently increases the production of nonamyloidogenic APP fragments. In all animals in which potentially amyloidogenic fragments of APP are increased as a consequence of lesioning in various neuronal populations, some, but not all, cholinomimetics normalize that process and diminish the production of amyloidogenic fragments (38). It has also been suggested that the toxicity of beta-amyloid peptide (Aß) itself on neurons is diminished by some cholinesterase inhibitors (39 ,40).

Nicotinic stimulation may be particularly relevant in altering the processes of neurodegeneration. Many epidemiologic studies have demonstrated that the relative risk of Parkinson disease is diminished among smokers compared with nonsmokers (41). However, prevalence studies, not incidence studies, among smokers versus nonsmokers suggest a neuroprotective effect in Alzheimer disease (42 ,43). The absence of incidence data is problematic for the imputation of any epidemiologic data to support the notion that smokers are less likely to be affected by Alzheimer disease than nonsmokers. Still, nicotinic stimulation has been found to protect neurons from ß-amyloid induced neurotoxicity (44 ,45), as well as to enhance the secretion of nonamyloidogenic forms of APP (46).

Ultimately, the question whether cholinomimetic activity, through nicotinic, muscarinic, or other unknown mechanisms, may alter the course of Alzheimer disease rests on clinical data. Such data are scanty and largely indirect. *Post hoc* analyses of patients who participated in the pivotal tacrine studies indicated that patients able to tolerate more than 80 mg per day of the drug had a substantial delay in placement in nursing homes, of the magnitude of approximately 450 days (47). Clearly, there are multiple interpretations of this observed phenomena that need not invoke the effect of tacrine on the progression of Alzheimer disease.

Acetylcholinesterase itself is present in plaques. This enzyme has been shown to enhance the aggregation of ß-amyloid into the more fibrillar form that is deposited in plaques (48 ,49 ,50 and 51). Antibodies to cholinesterase blocks Aß aggregation *in vitro* (52). Whether such effects on aggregation are produced by cholinesterase inhibitors, as occurs with antibodies directed at the cholinesterase molecule *in vitro*, has not been shown. It is possible that the aggregating effects of cholinesterase are facilitated by sites in the enzyme that are totally unaffected by cholinesterase inhibition. Alternatively, cholinesterase inhibition could alter cholinesterase in such a way as to diminish aggregating properties.

Two paradigms that could offer some insight into course-altering properties of cholinesterase inhibitors have been termed *delayed start* and *drug withdrawal*. In the delayed start paradigm, an agent that would alter the course of Alzheimer disease would be expected to have a greater effect in patients who have been started on the drug at time zero than a matched control group started 6 months later. In every study with cholinesterase inhibitors reported to date using a related but flawed delayed start procedure, placebo-treated patients who were given cholinesterase inhibitors 6 months after the group of patients on the drug did not catch up on cognitive measures to the patients who were treated with the drug from the start of the study. However, the interpretability of these data is limited because at the time of switchover from placebo to drug, the studies were no longer blinded. Furthermore, self-selection for switchover, or retention on drug, could occur and further confound these data. In the withdrawal paradigm, patients receiving the drug are randomly discontinued from the drug

on the completion of the trial and compared with the placebo group. Occasionally, this paradigm has demonstrated continued efficacy for some, but not all, cholinesterase inhibitors (52 ,53 and 54). Here too, methodologic problems limit an unequivocal interpretation of these data.

Taken together, no carefully conducted, adequately powered studies address the question of whether cholinesterase inhibitors, at any course in the illness, delay progression. Until such studies are carried out, only tantalizing pieces of the puzzle are open to interpretation. However, as interesting as this question is to clinical neuroscientists, it may be relatively moot to caregivers who struggle with patients with Alzheimer disease. To such people, the nuances of whether plaque and tangle formation may be slowed, and neurons kept alive, are less relevant than the question whether time to a particular milestone of the disease can be delayed by cholinesterase treatment. In fact, such an outcome can occur even if this class of compounds has a solely palliative effect. It can be argued that simply improving the patients' cognitive capacity increases the likelihood that a patient will be maintained at home. Additionally, the effects of some of these compounds, if not all, on such problematic noncognitive behaviors (55) can also lead to a better outcome. This seems increasingly likely given that the cholinesterase inhibitors appear to have their most robust effect in middle-stage disease, or perhaps even later (56 ,57 and 58). This result is completely compatible with postmortem findings of cholinergic parameters that find the cholinergic deficit to be most apparent in middle- or later-stage disease and to be not present in the earliest stages of illness (59).

VITAMIN E AND ANTIOXIDANTS

Part of "87 - Current and Experimental Therapeutics of Alzheimer Disease "

The production of free radical species has been considered a mediating event for many forms of neuronal death or damage. Initiating events as diverse as glutamate-induced neurotoxicity, ischemia, apoptosis, and Aß neurotoxicity all can produce oxidative stress with free radical production (60). Thus, the use of antioxidants and free radical scavengers in the prevention, or delay in the progression, of Alzheimer disease is not without a reasonable rationale. Vitamin E, in part because of its accessibility, has received greatest attention among compounds in this class. Furthermore, *in vitro* cell studies in various cell culture preparations indicate that vitamin E can have a protective effect on ß-amyloid–induced neurotoxicity (61).

A carefully conducted double-blind, placebo-controlled, multicenter investigation of the effect of vitamin E and selegiline provided some support for the efficacy of both these agents in altering the progression of Alzheimer disease (62). In this trial, patients with moderate to severe Alzheimer disease received either 2,000 IU per day of vitamin E, 10 mg per day of selegiline, or the combination of vitamin E and selegiline. An additional treatment arm exposed patients only to placebo. This was a 2-year trial in which the primary outcome measures were nursing home placements, death, or the loss of a well-defined activity of daily living. Cognitive change was also evaluated. All three antioxidant groups showed a statistically significant beneficial effect on all outcome measures except cognition. Surprisingly, a favorable effect on cognition was not found for any agent. Unfortunately, despite randomization, subjects in the treatment arms significantly differed in baseline Mini-Mental State Examination scores. Consequently, the significant results were only obtained when a covariant technique was used to adjust for the difference in baseline cognition across the treatment arms. This circumstance, combined with the negative effect on cognition, raises questions regarding the robustness of these antioxidant treatments. Nonetheless, the inclusion of 2,000 IU per day of vitamin E in the treatment regimen of patients with Alzheimer disease has become relatively commonplace.

Vitamin E ingestion is not without potential toxicity. Thrombophlebitis has been reported in adults in doses far less than the 2,000 IU recommended for patients with Alzheimer disease (63). Coagulopathy can be another vitamin E–associated adverse event (64 ,65 ,66 and 67). Interactions between vitamin E and oral anticoagulants are a real possibility and emphasize the need for monitoring prothrombin times in patients who receive this combination. In contrast to the widespread use of vitamin E, selegiline has not become a routine part of Alzheimer disease therapy because selegiline was not found to be superior to vitamin E, nor was there any benefit of combining vitamin E and selegiline to either drug alone. The adverse event profile for selegiline is far more extensive than vitamin E, and it includes hypotension with subsequent falls, as well as sleep disturbance, psychosis, agitation, and confusion. The potential for a serious interaction between selegiline and antidepressants commonly used to treat comorbid depression in patients with Alzheimer disease further limits the potential utility of selegiline.

ANTIINFLAMMATORY AGENTS

Part of "87 - Current and Experimental Therapeutics of Alzheimer Disease "

Inflammatory processes have well been characterized in the Alzheimer brain. Elevations in cytokine, acute-phase proteins, complement, and activated microglia are all present in Alzheimer disease brain (38 ,68 ,69 and 70). Of potential significance is that the complement cascade can be activated by Aß, ultimately leading to the induction of the membrane attack complex, which can be neurotoxic (71 ,72 and 73). These postmortem findings are given increased meaning by epidemiologic studies that also impute a role for inflammatory mechanisms in Alzheimer disease. The use of nonsteroidal antiinflammatory drugs (NSAIDs) well before the onset of Alzheimer disease has been associated with a decreased incidence of Alzheimer disease in late life. Studies of siblings with differential exposure to NSAIDs reveal a profound delay in the onset of Alzheimer disease in the sibling with exposure to these agents (74 ,75 ,76 and 77).

Particular interest has centered on the inhibition of cyclooxygenase in Alzheimer disease. Although the inflammatory reaction in the Alzheimer brain appears quite broad, a rationale nonetheless exists for inhibition of cyclooxygenase, especially cyclooxygenase 2 (Cox-2). Cox-2 levels are elevated in hippocampal neurons from postmortem examination of patients with Alzheimer disease (78). Additionally, Cox-2 expression is up-regulated in the frontal cortex of the patient with Alzheimer disease. The severity of Alzheimer disease neuropathology correlates with Cox-2 levels (78) and ß-amyloid increase expression of Cox-2 in neuroblastoma lines.

Given these data, it is not surprising that numerous antiinflammatory agents are being, or have been, tested in patients with Alzheimer disease. With the extensiveness of the inflammatory response in the Alzheimer disease brain, a relatively nonspecific antiinflammatory drug such as prednisone seemed a rational approach to treatment. A large, multicenter, double-blind study in which an initial dose of up to 20 mg of prednisone, followed by a maintenance dose of 10 mg for 1 year, was conducted. No evidence of efficacy in delaying the progression of Alzheimer disease was found. Indeed, patients receiving prednisone were more likely to develop behavioral worsening as well as glucocorticoidrelated medical adverse events. Although it is conceivable that a higher dose of prednisone was necessary, the administration of such a dose would seem impossible, based on the medical problems encountered with relatively modest doses of prednisone (79).

Diclofenac, another antiinflammatory agent, was investigated in a 25-week randomized, double-blind, placebo-controlled trial in patients with mild to moderate Alzheimer disease. The patient withdrawal rate from the study was exceedingly high, and it limited the interpretability of the results. Nevertheless, efficacy of this agent was not found. Conversely, indomethacin administered in a 6-month trial was reported to be efficacious, but here, too, the dropout rate was excessive, compromising both the interpretability of the results as well as the ultimate utility of this drug (80).

The most positive results obtained to date from large-scale studies derive from the clinical trials with propentofylline. This drug is an inhibitor of microglia activation. A series of studies demonstrated improvement in global functioning, cognitive measures, and activities of daily living compared with placebo (81 ,82 and 83). However, the effects were exceedingly modest, and attempts to obtain approval for an Alzheimer disease–related indication in the European community have so far been unsuccessful, because the extent of drug effect has not been deemed to be sufficient to warrant approval.

Numerous trials with selective Cox-2 inhibitors are currently ongoing. These results are eagerly awaited. However, to date, despite the relatively compelling rationale for testing antiinflammatory agents in Alzheimer disease, results have not been encouraging. The apparent contradiction between epidemiologic studies showing benefit from prior exposure to NSAIDs and treatment studies with NSAIDs could reflect the period in which NSAIDs were administrated. Conceivably, such drugs will have no effect, or even an adverse effect, once Alzheimer disease has developed, but they may still be effective in delaying onset by drug administration before patients are symptomatic. Hence, a full test of the antiinflammatory approach in Alzheimer disease will require additional studies.

ESTROGEN

Part of "87 - Current and Experimental Therapeutics of Alzheimer Disease "

As with antiinflammatory agents, the basis for estrogen therapy in Alzheimer disease, in part, derives from epidemiologic studies. One such study, the Baltimore longitudinal study of aging, followed 500 women, of whom half were estrogen users, for approximately 16 years. The relative risk of developing Alzheimer disease in the women who were taking estrogen was approximately halved (84). A similar result was obtained in an Italian longitudinal aging study (85). Other epidemiologic surveys have reached similar conclusions (86). The plausibility of these results are enhanced by the finding that estrogen replacement therapy was associated with higher cognitive test scores in healthy elderly women over the age of 65 years, compared with a cohort not receiving such treatment (87 ,88). There is, however, one large 15-year follow-up study of approximately 800 elderly women in which no relationship between estrogen replacement therapy and a host of neuropsychological test scores was found (89).

That estrogen replacement therapy may have a positive effect on the development of Alzheimer disease, or cognition in general, is supported by a series of studies investigating the actions of estrogen on neuronal tissue. For example, ovariectomized rats treated with estrogen show preservation of the integrity of hippocampal neurons and their dendritic arborization (90). Furthermore, activity of choline acetyltransferase is augmented by estrogen treatment (91 ,92). Estrogen may also have antioxidant activity, may facilitate processing of APP toward a nonamyloidogenic pathway, and may promote cell survival (92 ,93). Hence, some role for estrogen in the therapeutics of Alzheimer disease is a reasonable proposition.

Two studies examined the effect of estrogen on both the course and symptoms of Alzheimer disease. Estrogen replacement therapy for 1 year did not slow disease progression among women with mild to moderate Alzheimer disease who had previously undergone a hysterectomy (94). In another randomized, double-blind, placebo-controlled parallel group study, no effects of estrogen on cognitive symptoms was noted (95). Conversely, some benefit of a transdermal estrogen preparation was noted in an 8-week treatment trial in a very small group of women. Furthermore, positive results were found in a few, but not all,

neuropsychological tests (96). Given the effect of estrogen on cholinergic parameters, of note is a retrospective analysis of patients previously exposed to tacrine in the pivotal trials leading to the approval of that drug. Women taking estrogen replacement therapy had a significantly greater response on all outcome measures than those female patients receiving tacrine who were not receiving estrogen replacement therapy. These data raise the possibility that estrogen replacement therapy may augment the cognitive effects of cholinesterase inhibitors (97).

Selective estrogen-receptor modulators (SERMs) have been designed to have agonistic effects on some organ systems and antagonistic effects on others. Should estrogen replacement therapy have beneficial effects in preventing Alzheimer disease, delaying its progress, treating its symptoms, or augmenting other therapies, a SERM with agonist activity in the brain, but without effect on reproductive organs, would have obvious therapeutic potential, including administration to male patients. Many SERMs are currently being tested in numerous conditions. However, as yet no reports of studies on the role of these agents in any aspects of Alzheimer treatment have been published.

GINKGO BILOBA

Part of "87 - Current and Experimental Therapeutics of Alzheimer Disease "

The broad use of vitamin and herbal preparations, facilitated by their general availability without prescription, encouraged a placebo-controlled, double-blind, randomized trial of an extract of *Ginkgo biloba* for dementia (98). This extract, termed *Egb761*, was tested in a 52-week study of mild to severely demented outpatients with various forms of dementia including Alzheimer disease and multiinfarct dementia. One-third of all patients entered into the study did not provide 52-week endpoint data. A small and statistically significant effect was found on the ADAS-cog, but no effect was found on the Clinical Global Index (CGI). Thus, by a prior standard set by the FDA to establish efficacy of an agent in Alzheimer disease (statistically significant drug effect on both a psychometric and a global measure), Egb761 would not have met this standard for receiving an indication for the treatment of Alzheimer disease. Nonetheless, this compound continues to be widely used, even though it has been reported to cause spontaneous bleeding and it may interact with anticoagulant and antiplatelet aggregating agents (99).

APPROACH TO ALTERING AMYLOID DEPOSITION

Part of "87 - Current and Experimental Therapeutics of Alzheimer Disease "

Increasingly, amyloid deposition is seen as one of the earliest components, if not the earliest, of the pathologic process in Alzheimer disease, as well as an initiating event in neuronal death (100 ,101). Furthermore, the elucidation of the cellular consequences of the various mutations associated with Alzheimer disease supports the notion of the centrality of amyloid production in the pathophysiology of Alzheimer disease. Specifically, regardless of whether a mutation occurs in the amyloid precursor protein gene, presenilin 1 or presenilin 2, all mutations increase the concentrations of Aß1-42 in brain, plasma, or cell culture media. A similar outcome is associated with the apolipoprotein E-4 allele compared to E-2 or E-3 (101 ,102 and 103). The well-documented toxicity of Aß, particularly in the aggregated form, adds to the growing consensus that altering Aß production or deposition is a viable approach to the therapeutics of Alzheimer disease.

There are numerous theoretic approaches to altering the Aß concentrations in the brain of patients with Alzheimer disease. The activities of both ß- and γ-secretase are necessary to cleave APP into the Aß fragments that constitute amyloid plaques. Conceivably, inhibiting either γ- or ß-secretase could alter the production of Aß. Alternatively, enhancing the activity of α-secretase could result in the preferential cleavage of APP to nonamyloidogenic forms. Yet another approach focuses on enhancing the breakdown or clearance of Aß in the brain. This approach adopts the view that inflammatory mechanisms in the Alzheimer brain are potentially beneficial and facilitate the removal of Aß from the brain. Finally, the enhanced toxicity of aggregated Aß encourages therapeutics designed to block the aggregation of Aß. All these approaches are in various stages of clinical development.

Numerous groups have cloned and characterized ß-secretase, also termed ß-amyloid cleavage enzymes (BACE) (104 ,105 ,106 ,107 ,108 and 109). The success of this effort encourages combinatorial chemistry and screening efforts designed to identify small lipophilic compounds that could inhibit BACE activity and thereby limit Aß production. The logic of this approach is unquestioned, but the presence of relatively high levels of BACE in the pancreas leads to the question of the role that BACE may play in biological functions whose activity, if inhibited, could cause significant adverse events. Conversely, to produce meaningful changes in the course of Alzheimer disease, or simply to delay the disease onset, safe levels of brain BACE inhibition may readily exist.

Although γ-secretase has not yet been cloned, a γ-secretase inhibitor is currently in clinical trial (104). However, the intimate relationship between presenilins and γ-secretase could have implications for the ultimate safety of this approach. If, in fact, presenilins influence the critically involved Notch pathway (37), a host of potential adverse effects could arise from inhibiting the activity of presenilins. Still, elucidation of the clinical effects of the γ-secretase inhibitors will be eagerly awaited.

Transgenic mice overexpressing Aß have been used as a vehicle to determine whether inoculation with the Aß peptide could produce an immune response that would alter Aß concentrations in a mouse brain (110). Animals inoculated before the deposition of substantial amyloid deposits in the

brain subsequently displayed little amyloid deposition. Even more remarkably, animals in which amyloid deposition had already begun demonstrated an apparent diminution in amyloid plaque load following inoculation. Behavioral data now confirm that Aß peptide immunization reduces cognitive impairment and plaques in animal models of Alzheimer disease (111 ,112 and 113). Vaccination with Aß protects transgenic mice from the learning and age-related memory deficits that normally occur in the mouse model of Alzheimer disease. During testing for potential deleterious effects of the vaccine, all mice performed superbly on the radial-arm water maze test of working memory. Later, at an age when untreated transgenic mice show memory deficits, the Aß-vaccinated transgenic mice showed cognitive performance superior to that of the control transgenic mice and, ultimately, performed as well as nontransgenic mice (111).

Based on these exciting results, Aß inoculations are beginning in humans. A major question that these trials will eventually answer is whether elderly persons can generate an adequately robust immune response to Aß inoculation that will extend to the brain. Additionally, the concern that the adjunctive procedures necessary to generate an immune response to a peptide that already exists in healthy humans would also produce an autoimmune response must be considered. Still, results obtained in transgenic mice are so dramatic that it is essential that Aß inoculations proceed at least preliminarily in humans.

There are numerous theoretic possibilities to altering the aggregation of Aß fibrils into their more toxic aggregated form. Congo red, a dye that readily binds Aß, has been used as a prototypical molecule for the development of analogues that would enter the brain, bind to Aß, and inhibit aggregation (102 ,103). Other approaches have included the development of antibodies directed specifically at Aß or small molecule ligands (114) that also can block aggregation (115 ,116). Acetylcholinesterase has been found to augment Aß aggregation, and antibodies to acetylcholinesterase can, *in vitro*, decrease aggregation (50). Indeed the Alzheimer plaque contains numerous proteins, many of which may facilitate aggregation of Aß. Developing compounds that preferentially bind these plaque-containing molecules could decrease Aß aggregation.

SUMMARY

Part of "87 - Current and Experimental Therapeutics of Alzheimer Disease "

Since the early 1990s, remarkable progress has been made in the current and experimental therapeutics of Alzheimer disease. An area that was recently characterized by therapeutic nihilism can now be regarded with real optimism. It would seem highly likely that the next decade of progress should show the development of compounds that move beyond palliation and could actually either delay onset or substantially alter the course of the illness in such a manner as to bring new hope to the patient with Alzheimer disease.

Alzheimer Disease: Treatment of Noncognitive Behavioral Abnormalities

Murray A. Raskind

Robert F. Barnes

Murray A. Raskind: Veterans Administration Northwest Network Mental Illness Research Education and Clinical Center, Seattle, Washington.

Robert F. Barnes: Department of Psychiatry and Behavioral Sciences, University of Washington School of Medicine, Seattle, Washington.

The original patient described by Dr. Alois Alzheimer in 1907 (1) was remarkable for both her progressive cognitive impairment and her prominent noncognitive behavioral abnormalities. Clinical interest in the noncognitive abnormalities in Alzheimer disease (AD) has been substantial because of their high prevalence (2 ,3 and 4) and because noncognitive behavioral problems complicate patient management and often precipitate institutionalization (3 ,5 ,6 ,7 ,8 ,9 ,10 ,11 and 12). The real or apparent resemblance of delusions, hallucinations, depressed mood, agitation, hostility, and other noncognitive behavioral abnormalities of AD to the signs and symptoms expressed in such classic psychiatric disorders as depression, schizophrenia, and mania has prompted the widespread use of psychotropic drugs in the management of AD (13 ,14 ,15 and 16). However, widespread use does not imply established efficacy. In fact, data establishing the efficacy of psychotropic drugs for noncognitive behavioral problems in AD and other dementing disorders remain limited. Although reports of treatment outcome studies incorporating reliable and valid outcome measures, well-defined patient samples, and randomization to an adequate trial of active medication or placebo continue to appear, their number remains small. This chapter reviews informative studies of the psychopharmacologic management of noncognitive behavioral problems in AD. These include depression (or depressive signs and symptoms), psychotic symptoms (delusions and hallucinations), and disruptive agitated behaviors (e.g., physical and verbal aggression, motoric hyperactivity, and uncooperativeness with activities necessary for personal hygiene and safety). Placebo-controlled studies are emphasized, but results of other studies and reports are discussed when they suggest directions for future investigation or are the only studies available.

DEPRESSION IN ALZHEIMER DISEASE

Part of "88 - Alzheimer Disease: Treatment of Noncognitive Behavioral Abnormalities "

Diagnostic Challenges

The diagnosis and treatment of depression complicating the course of AD have received considerable attention. Because depression *per se* can impair cognitive function (17), it is reasonable to hypothesize that effective treatment of depression in the patient with AD may maximize potential cognitive capacity. Furthermore, the consensus is that reduction of depressive signs and symptoms improves quality of life (18). Unfortunately, the apparently straightforward goal of treating depression complicating AD becomes complex when the problems involved in the diagnosis of depression in the context of AD or other dementing illnesses are considered. A fundamental problem is the substantial overlap of signs and symptoms between depression and AD. Common to both disorders are apathy and loss of interest, impaired ability to think and concentrate, psychomotor changes (both retardation and agitation), and sleep disturbance. The ability to diagnose depression in AD is further compromised by the patient's lack of insight and poor recollection of symptoms.

Prevalence

Even if investigators agreed on uniform diagnostic criteria for syndromal depression in AD and used uniform assessment instruments and interviews, discrepant prevalence rates would likely arise from the differential characteristics of the samples of AD patients studied. Prevalence rates of AD with concurrent depression derived from clinical populations are higher than those derived from research registries that select "pure" AD subjects without a history of major

depressive disorder. For example, in an outpatient geriatric clinic, Reifler et al. (19) found that 20% of patients with AD met DSM-III criteria for major depressive episode. In contrast, Burke et al. (20) found no incident case of major depression in an AD research registry population followed longitudinally through the course of illness. The latter study included a longitudinally followed normal control group matched for age, sex, race, and social position. Signs and symptoms of depression occurred in both patients with AD and controls, but criterion-based major depression could not be diagnosed. A similarly low prevalence of major depression in a sample of subjects with AD screened to exclude those with a past history of major psychiatric disorders was reported by Kumar et al. (5). Although depressed mood was more frequent in the AD subjects than in age-matched normal controls, depressed mood in the AD subjects was unaccompanied by classic vegetative signs and symptoms of depression. These investigators, therefore, interpreted depressed mood as reflecting “demoralization” rather than major depressive disorder. Given these problems, it is not surprising that estimates of the prevalence of depression in AD are widely disparate. Perhaps the true prevalence of concurrent depression in AD lies somewhere between these disparate estimates. As early as 1955, Sir Martin Roth (21) addressed the issue of differentiating the common “affective coloring” seen in dementia patients from the relatively uncommon “sustained depressive symptom complex.” He found that the latter syndrome, which can probably be equated with DSM-IV major depressive episode, occurred in only 3% of patients with dementia.

Psychopharmacologic Approaches

It continues to be disappointing that the extensive interest in defining the prevalence of depression complicating AD has generated few interpretable studies evaluating the outcome of antidepressant treatment in such patients. The database consists primarily of anecdotal case reports and non–placebo-controlled outcome studies. These reports suggest that depression complicating AD may respond to tricyclic antidepressants (22 ,23), monoamine oxidase inhibitor (MAOI) antidepressants (24), or selective serotonin reuptake inhibitors (SSRI) (25). In an open trial of nortriptyline, given in doses sufficient to achieve therapeutic plasma concentrations, or electroconvulsive therapy in eight inpatients with AD complicated by depression, Reynolds et al. (26) reported a significant reduction in mean Hamilton Depression Scale (HAM-D) scores (27) from 17 before treatment to 9 after treatment. Although the reduction in depressive signs and symptoms was substantial in AD patients with concurrent depression, it was less robust than in a similarly treated group of elderly nondemented depressed patients. Another open trial of “naturalistic” somatic antidepressant treatment of inpatients with dementia and concurrent depression was reported by Greenwald et al. (28). This study carefully documented the presence of major depressive episode in six patients with AD and four with multiinfarct dementia (MID). Patients were treated for a mean duration of 11 weeks with a variety of conventional somatic antidepressants (doses not reported), electroconvulsive therapy, or both. HAM-D scores significantly and substantially decreased from a mean of 19 on admission to a mean of 5 at discharge. This degree of improvement did not differ significantly from that in an elderly, nondemented, depressed inpatient group treated in a similar naturalistic manner. However, the mean length of stay to achieve comparable improvement in the elderly nondemented, depressed group was substantially shorter than that in the demented, depressed group. Possible differential treatment responses between AD subjects with major depression and MID subjects with major depression were not reported. Both Reynolds et al. (26) and Greenwald et al. (28) interpreted their results as suggesting that major depression complicating dementia is responsive to somatic antidepressant treatments, but both investigators acknowledged that standardized, double-blinded, placebo-controlled studies of antidepressants in dementia patients with major depression are needed.

The SSRI antidepressants are theoretically attractive drugs for the treatment of depression in AD. Decreased numbers of serotoninergic neurons in the dorsal raphe nucleus and decreased concentrations of the serotonin metabolite 5-hydroxyindolacetic acid in forebrain and cerebrospinal fluid are consistent with a serotoninergic deficit in AD (29 ,30). Enhancing serotoninergic neurotransmission by inhibiting serotonin reuptake theoretically might alleviate depression in AD. Furthermore, the adverse effect profile of SSRIs is relatively benign compared with those of the tricyclics and MAOIs. SSRIs are not anticholinergic, nor do they produce orthostatic hypotension. These theoretic advantages likely account for the increasing use of SSRIs in elderly patients (16 ,31 ,32).

Placebo-Controlled Outcome Trials

Despite the widespread use of antidepressants in patients with AD and other dementing disorders (32), it is clear that this use is not grounded in an adequate empiric database. Only three placebo-controlled trials of an antidepressant in AD patients with depression have been published thus far, and only one of these evaluated an antidepressant from the increasingly prescribed class of SSRIs.

Reifler et al. (33) randomly assigned to either imipramine (*n* = 13) or placebo (*n* = 12) subjects who met DSM-III criteria for both primary degenerative dementia of the Alzheimer type and major depressive episode. AD outpatients (mean age, 72) had a mean Mini-Mental State Examination (MMSE) score of 17 [very comparable with the mean MMSE scores of the demented, depressed patients studied openly by Greenwald et al. (28) and Reynolds et al. (26)]

and were suffering from a similarly moderate degree of depression (mean HAM-D score, 19). Imipramine (mean dose, 83 mg/d; mean plasma level of imipramine plus desmethylimipramine, 116 ng/mL) or placebo was prescribed for 8 weeks. Substantial, highly significant, and almost identical improvements occurred in mean HAM-D scores in both the imipramine subjects (19.3 before treatment vs. 11.5 following treatment) and placebo subjects (18.6 before treatment vs. 10.8 following treatment). Imipramine was generally well tolerated in these subjects. However, its central anticholinergic effect likely accounted for subtle decrements in cognitive function in the imipramine group. The improvement in HAM-D scores was similar to that achieved in the open inpatient studies reported by Greenwald et al. (28) and Reynolds et al. (26). This outpatient study demonstrated that depressive signs and symptoms can be reduced in outpatients with AD, but the mechanism of treatment efficacy does not appear to be a specific antidepressant effect of imipramine.

Petracca et al. (34) randomly assigned 24 patients meeting criteria for AD with DSM-III-R depression to treatment with either clomipramine or placebo in a randomized, double-blinded, placebo-controlled crossover study. As in the imipramine trial reported by Reifler et al. (33), both active drug (in this case clomipramine) and placebo were associated with significant improvement in depression ratings. However, in this study, the improvement in depression in the active drug group was modestly greater than that in the placebo group. One subject in the clomipramine group dropped out of the study because of an acute confusional episode likely attributable to the central anticholinergic activity of clomipramine.

Nyth et al. (35) have reported the only placebo-controlled trial of an SSRI in patients with dementia and concomitant depression. In this study, subjects were randomized to 20 mg of citalopram per day or placebo for 6 weeks. Twenty-three patients with dementia (presumably including a substantial number of patients with AD) were “nested” in a larger controlled trial of depressed elderly persons (*n* = 149), the majority of whom were not suffering from dementia. The inclusion criterion for “depression” was an HAM-D score of at least 14. In the 23 subjects with dementia who completed the 6-month trial, modest but significant differences were noted favoring citalopram over placebo in the observer-rated fear/panic, depressed mood, and impaired recent memory items of the dementia rating scale of Gottfries et al. (36). As in the imipramine and clomipramine studies described above, a substantial antidepressant response to placebo occurred in these subjects, but citalopram was modestly superior to placebo and was well tolerated. Although the effects of citalopram on psychometric tests were not reported, observer-rated improvement in memory is supportive of other studies suggesting that SSRIs do not have an adverse effect on cognitive function (37).

These limited data from placebo-controlled studies of antidepressants in outpatients with AD and concurrent depression have several implications. First, the robust responses of the placebo group make it essential to include a placebo group in future antidepressant drug outcome trials in dementia patients if the results are to be interpretable. They also suggest that the “nonpharmacologic” aspects of trial participation contribute to a reduction of depressive signs and symptoms in patients with AD. A recent placebo-controlled trial demonstrating efficacy of behaviorally based psychotherapy for depression in AD outpatients is consistent with this interpretation (38). Second, the absence of SSRI adverse effects on cognitive function or blood pressure regulation is an advantage for this class of antidepressant in older patients (37 ,39). More placebo-controlled trials of SSRIs (and other newer antidepressants, such as venlafaxine and nefazodone) in AD patients with concomitant depression would be informative.

PSYCHOSIS AND DISRUPTIVE AGITATION

Part of "88 - Alzheimer Disease: Treatment of Noncognitive Behavioral Abnormalities "

Prevalence

The prevalence rates of psychotic symptoms (delusions and hallucinations) complicating AD cluster between 20% and 40% in carefully performed cross-sectional studies (2 ,4 ,7 ,40). Because psychotic symptoms can emerge at any time during the course of AD and probably are more prevalent in the later stages of the illness, longitudinal studies reveal even higher prevalence rates (6). Drevets and Rubin (41) longitudinally followed subjects with AD from the early through the later stages of illness and documented the occurrence of psychotic symptoms both cross-sectionally and cumulatively. This study was strengthened by the inclusion of a longitudinally followed age-matched normal control population (psychotic symptoms developed in none of them during the course of the study). Slightly more than 50% of the AD subjects manifested psychotic symptoms at some point during the course of their illness. The subjects were not considered positive for psychotic symptoms if they occurred only rarely or only in the context of a possible delirium. As in other studies of psychotic symptoms in AD (2 ,4 ,7), delusions were usually simple and persecutory, most commonly involving theft. Systematized delusions were uncommon. Hallucinations were most frequently visual, although auditory hallucinations were also common.

Disruptive agitated behaviors such as verbal and physical aggression, motor hyperactivity, uncooperativeness with essential care, persistent irritability, and repetitive vocalizations are highly prevalent in moderately to markedly demented patients with AD (8 ,11). Less severely demented patients with AD who are still able to reside in the community also manifest disruptive behaviors. Ryden (42) surveyed the caregivers of outpatients with AD and found a prevalence of aggressive behavior occurring at least once a week in 31% of subjects and daily in 16% of subjects.

Although psychotic symptoms and “nonpsychotic” disruptive agitated behaviors may not always reflect the same underlying pathophysiologic process or processes, these two classes of noncognitive behavioral problems often are expressed together. Lopez et al. (43) evaluated the presence of belligerence, uncooperativeness, and physical and verbal aggression in psychotic AD patients with delusions and hallucinations (*n* = 17) and nonpsychotic AD patients without delusions and hallucinations (*n* = 17). A greater proportion of psychotic AD patients (11 of 17) manifested these behavioral disturbances than did the nonpsychotic AD patients (1 of 17). A study addressing the relationship between psychotic symptoms and physical aggression in AD patients was reported by Deutsch et al. (40). Delusions (most commonly persecutory) and mistaken identifications (e.g., patients believing that their house is not their home or that strangers are living in the house) frequently preceded and were significantly associated with episodes of physical aggression. However, the presence of delusions could account for episodes of physical aggression in only a minority of cases. Therefore, factors other than apparent psychosis were involved in the precipitation of physically aggressive behavior.

Psychotic Symptoms and Disease Progression

A number of studies have consistently suggested that the presence of psychotic symptoms in AD is associated with more rapid deterioration of cognitive function. Stern et al. (44) were the first to report this phenomenon, and the association between psychotic symptoms and more rapid decline has since been confirmed by other groups. Lopez et al. (43) reported that AD patients with delusions and hallucinations had a more rapid decline in MMSE scores during a 1-year follow-up than did nonpsychotic AD patients, and they appeared to manifest a specific defect in receptive language. Drevets and Rubin (41) reported that the presence of psychotic symptoms predicted an increased rate of cognitive deterioration. Jeste et al. (45) compared the performance over time of delusional and nondelusional AD patients on a neuropsychological test battery. Patients with delusions had a more rapid rate of dementia progression than nondelusional AD patients. It is possible that the presence of psychotic symptoms reflects a more malignant pathobiologic process that adversely affects both behavior and neurodegeneration. The inadvertent inclusion in these studies of patients now more accurately classified as having dementia with Lewy bodies (DLB) also may have contributed to the apparent association between psychotic symptoms and more rapid cognitive deterioration. DLB is characterized by an early incidence and high prevalence of psychotic symptoms (46), and these patients appear to manifest a more rapidly deteriorating course of dementia (47).

Antipsychotic Drug Use for Psychotic and Disruptive Behaviors: Rationale

Psychotropic drugs are widely prescribed to patients with AD in long-term care facilities (16). In fact, repeated documentation of the widespread practice of prescribing antipsychotic and other psychotropic drugs in the long-term care setting, often for extended periods of time (13 ,14 ,15 and 16), has prompted the implementation of federal regulations designed to limit the use of such drugs to short-term treatment regimens with clear indications (48).

The rationale for the use of antipsychotic drugs in AD is partially attributable to the superficial phenomenologic similarities of delusions, hallucinations, and other disruptive behaviors occurring in AD to the symptoms of schizophrenia. Unfortunately, this analogy to psychotic and other behavioral signs and symptoms in schizophrenia is very imperfect. Hallucinations in AD usually are visual, whereas hallucinations in schizophrenia typically are auditory. Delusions in AD often are unelaborated persecutory beliefs, such as delusions of theft. Systematized, complex, and grandiose delusions are uncommon (9). In addition, the memory deficits of AD often appear to play a role in the development of delusional beliefs. For example, patients with AD who forget where an item has been placed and who do not understand their cognitive deficits may assume that it has been stolen. Or, a patient with AD can stubbornly insist in a delusional manner that a long-deceased person who still remains alive in available memory traces is, in fact, alive. Although such beliefs of theft, of a deceased person who continues to exist, or of a spouse who is an impostor may meet formal criteria for delusions, they are phenomenologically dissimilar to the typical delusions of schizophrenia for which the antipsychotic drugs have been demonstrated so effective. These phenomenologic differences may reflect underlying neurobiologic differences, and they may explain why the effect size of antipsychotic drugs in AD is modest (49) and much less robust than in schizophrenia.

Typical Antipsychotic Drugs: Outcome Studies before DSM-III

The interpretation of typical antipsychotic drug outcome studies in patients with dementia that were performed before the introduction of DSM-III is often hampered by the use of unclear diagnostic nomenclature. For example, the term *senile psychosis* connoted dementia with severe cognitive impairment rather than the presence of delusions and hallucinations. In addition, early studies were usually performed in state hospital populations, which included patients with a mixture of degenerative neurologic dementing disorders (at least a subgroup of whom presumably had AD) and patients with chronic schizophrenia who had grown old in the institutional setting. In such early studies targeting psychosis and disruptive agitation, chlorpromazine (50 ,51),

acetophenazine (52), and haloperidol (53) were each modestly more effective than placebo, but adverse effects such as excessive sedation, falls, unsteady gait, and pseudoparkinsonism were more common in the active drug groups.

It is not surprising that early studies of typical antipsychotic drugs in patients with dementia who did not manifest psychotic disruptive behaviors as target symptoms and signs found antipsychotic drugs no more effective than placebo (54 ,55). For example, a comparison of the effects of trifluoperazine and placebo on target symptoms of apathy, withdrawal, and cognitive and behavioral deterioration (loss of ambulation, disorientation, and incontinence) demonstrated no therapeutic effect of the active medication, and the findings were most remarkable for a high prevalence of trifluoperazine-induced sedation and extrapyramidal signs and symptoms (54). One of these studies, however, is particularly instructive concerning the substantial placebo response that can be seen in elderly patients with dementia despite the presence of cognitive impairment. In a comparison of the effects of thiothixene and placebo on cognitive deficits in a group of demented patients (55), the majority of patients in both groups were rated as globally improved (13 of 22 patients receiving thiothixene and 11 of 20 patients receiving placebo).

Typical Antipsychotic Drug Studies: Outcome Studies since DSM-III

Since the introduction of DSM-III, a small number of placebo-controlled studies have evaluated the efficacy of typical antipsychotic drugs in patients with dementia in both outpatient and institutional settings. Because of the use of operationalized diagnostic criteria for AD and MID, one can be more confident that elderly patients with chronic psychiatric disorders beginning in early life, such as schizophrenia, were excluded from these studies. In addition, the studies have clearly targeted psychotic or disruptive agitated behaviors as outcome measures.

Several studies have compared typical antipsychotics with placebo in either state hospital or community nursing home institutional settings. Petrie et al. (56) compared low-dose haloperidol and loxapine with placebo in 64 inpatients of a state psychiatric hospital (mean age, 73 years). The sample included subjects who met diagnostic criteria for either AD or MID. Both antipsychotic medications were more effective than placebo in reducing hallucinations, suspiciousness, hostility, excitement, and uncooperativeness. Global improvement ratings, however, only modestly favored the active medications. Thirty-five percent of haloperidol subjects and 32% of loxapine subjects, in comparison with 9% of placebo subjects, were rated as moderately or markedly improved. Not only were therapeutic responses to active drugs in these elderly demented patients lower than would have been predicted from outcome studies in younger subjects with schizophrenia, but adverse drug effects, including sedation and extrapyramidal signs and symptoms, were frequent. In a placebo-controlled study of antipsychotic drugs in a typical community nursing home sample of elderly demented patients, Barnes et al. (57) randomized 60 behaviorally disturbed patients with dementia (mean age, 83 years) to thioridazine, loxapine, or placebo. All subjects met diagnostic criteria for either AD or MID. Both active antipsychotic drugs were more effective than placebo for reducing excitement and uncooperativeness. Although suspiciousness and hostility tended to improve more with active drugs than with placebo, substantial improvements in these two factors also were documented in subjects receiving placebo. Like Petrie et al. (56), Barnes et al. (57) found that only approximately one-third of patients in the active medication conditions achieved global ratings of either moderate or marked improvement. Finkel et al. (58) compared the typical antipsychotic drug thiothixene with placebo in agitated nursing home patients with dementia (mean age, 85 years). Disruptive problem behaviors included physical aggression (hitting, kicking, and pushing), physical nonaggressive agitation (pacing and repetitive mannerisms), and verbal aggression (screaming and cursing). The presence and nature of psychotic delusions and hallucinations were not specified in this study. Thiothixene was more effective than placebo in this 11-week, parallel-design study, but differences between groups did not become apparent until 6 weeks of treatment had been completed. The positive effects of thiothixene appeared to persist for 3 to 6 weeks after drug discontinuation. Taken together, these three studies suggest that low-dose typical antipsychotic drugs are modestly effective for treating psychotic and nonpsychotic disruptive behaviors in patients with AD residing in long-term care facilities. However, parkinsonian rigidity and sedation occurred in some patients in each of these studies.

In a well-designed and well-executed study of the acute efficacy and adverse effects of a typical antipsychotic in AD outpatients with psychosis and disruptive behaviors, Devanand et al. (59) randomized 71 subjects to 6 weeks of standard-dose haloperidol (2 to 3 mg/d), low-dose haloperidol (0.5 to 0.75 mg/d), or placebo for 6 weeks. When an *a priori* response criterion of at least 25% improvement in one of three quantifications of target symptoms was used, response rates were significantly greater in the standard-dose (55% to 60%) than in either the low-dose (25% to 35%) or placebo (25% to 35%) groups. Although effect sizes were modest, standard-dose haloperidol clearly was effective for both psychosis and agitation. Not surprisingly, moderate to severe extrapyramidal signs developed in a subgroup of standard-dose haloperidol subjects (20%). Low-order but significant correlations were found between haloperidol blood levels and symptomatic improvement, and a stronger correlation between haloperidol blood levels and extrapyramidal signs. Haloperidol was effective for treating psychosis and agitation in AD outpatients in this study, but

the therapeutic window was narrow. A similar narrow therapeutic window in such patients may also exist for several of the newer atypical antipsychotics (see below). In a recently reported multicenter placebo-controlled comparison of haloperidol, trazodone, and behavioral management for disruptive agitation and psychosis in AD outpatients, haloperidol (mean dose, 2 mg/d) was not more effective than placebo (60). The reasons for the discrepant findings between this study and the positive study reported by Devanand et al. (59) in AD outpatients are unclear. One possibility is that the subjects in the study of Devanand et al. may have manifested more severe behavioral symptoms. In an early, placebo-controlled trial of haloperidol (53), it was in the more severely behaviorally disturbed patients that a positive effect of haloperidol was detectable.

Atypical Antipsychotic Drug Studies

A major problem in the use of traditional antipsychotic drugs to manage psychiatric and behavioral problems in AD and other dementing disorders is the frequent emergence of pseudoparkinsonian rigidity, tremor, and bradykinesia. Patients with DLB are particularly susceptible to these adverse effects (61). The atypical antipsychotic drugs such as clozapine, risperidone, olanzapine, and quetiapine offer the theoretic advantage of a reduced or minimal incidence of pseudoparkinsonism. The atypical antipsychotics may also theoretically prove more efficacious than the typical antipsychotics for psychosis and disruptive agitation in AD. The efficacy and tolerability of these drugs in AD patients with psychosis or disruptive agitation recently have been addressed in several large, well-designed, placebo-controlled outcome studies.

Katz et al. (62) reported the results of a large, double-blinded, placebo-controlled study of efficacy and safety of risperidone in institutionalized dementia patients with psychotic and disruptive behaviors (mean age, 83 years). Among the subjects, 73% met criteria for AD, 15% for vascular dementia, and 12% for mixed AD and vascular dementia. At the end of the 12-week study, BEHAVE-AD total scores, in addition to psychosis and aggressiveness subscale scores, were significantly more reduced in patients receiving either 1 or 2 mg of risperidone per day than in those receiving placebo. In contrast, a 0.5-mg low-dose group did not differ from the placebo group at 12 weeks except for a slightly greater reduction in the aggressiveness subscale of the BEHAVE-AD. Extrapyramidal adverse effects did not differ between the 0.5-mg group or the 1-mg group versus placebo. However, significantly more subjects (21%) in the group receiving 2 mg/d manifested extrapyramidal adverse effects than in the placebo group (7%). The efficacy of risperidone in this study was modest and comparable in magnitude with that reported in studies of typical antipsychotics in this type of institutionalized, very elderly sample (57 ,58). The authors concluded that 1 mg of risperidone per day is likely to be the optimal dose for the majority of dementia patients of this age and with cognitive and behavioral symptoms of this degree of severity. Another large, double-blinded, placebo-controlled trial of risperidone, haloperidol, and placebo generally supports the equivalent efficacy of these atypical and typical antipsychotics, but it also suggests an advantage of risperidone in terms of extrapyramidal adverse effects (63). Institutionalized patients with dementia (mean age, 81 years) were randomized to risperidone (mean dose, 1.1 mg/d), haloperidol (mean dose, 1.2 mg/d), or placebo for 12 weeks. Both the risperidone and haloperidol groups had significantly lower aggression cluster scores on the BEHAVE-AD at week 12 in comparison with the placebo group. The severity of extrapyramidal symptoms at endpoint did not significantly differ between the risperidone and placebo groups but was significantly greater in the haloperidol group than in the risperidone group.

The atypical antipsychotic drug olanzapine also has been studied in large, placebo-controlled trials in AD patients with psychosis and other behavioral disturbances. In an 8-week double-blinded, placebo-controlled trial that included 238 outpatients with AD and psychosis (mean age, 79 years), olanzapine (mean dose, 2.4 mg/d) was not significantly more effective than placebo in improving BEHAVE-AD scores, nor were adverse effects such as extrapyramidal signs more common in the olanzapine group (64). In a subsequent large, placebo-controlled study in AD patients residing in nursing facilities and manifesting psychosis and other behavioral disturbances (65), subjects were randomized to placebo or to 5 mg, 10 mg, or 15 mg of olanzapine per day. Clinically significant improvement, defined a reduction from baseline on the Neuropsychiatric Inventory (NPI) total score of 50% or more (66), was demonstrated in 66% of the patients receiving 5 mg/d, 57% receiving 10 mg/d, 43% receiving 15 mg/d, and 36% of the patients receiving placebo. These differences were significant for the groups receiving 5 or 10 mg/d but not for the group receiving 15 mg/d. In addition, the high-dose subjects had a significantly increased incidence of somnolence and abnormal gait. This study suggests that 5 mg per day may be an optimal dose of olanzapine for AD patients with psychosis and other disruptive agitated behaviors.

Taken together, studies of the atypical antipsychotics suggest that the efficacy of these newer agents is comparable with that of the typical antipsychotics and that, somewhat surprisingly, they may have a narrow “therapeutic window.” However, because the incidence of parkinsonism and tardive dyskinesia associated with the atypical antipsychotics is low, it is likely that they will be increasingly used to manage psychosis and disruptive agitation in patients with AD, despite their higher cost.

Maintenance Antipsychotic Drug Therapy in Dementia

When a satisfactory response to an antipsychotic drug has been achieved with an acute treatment regimen, the clinician must next decide how long to maintain the patient on the drug. This question was addressed by Risse et al. (67) in a small but informative antipsychotic drug discontinuation study in behaviorally disturbed elderly patients with dementia who appeared to have benefited from an acute course of antipsychotic medications and had then been maintained on these medications on a long-term basis. Placebo was substituted for maintenance antipsychotic medication in nine men with dementia (mean age, 65 years) who had shown a clear reduction in noncognitive behavioral problems following treatment with antipsychotic medication and who subsequently had been maintained on antipsychotic medication for at least 90 days. At the end of the 6-week placebo-substitution period, disruptive behaviors severe enough to warrant reinstitution of antipsychotic medication had developed in only one patient. Of the remaining eight patients, five actually were less agitated, two were unchanged, and only one was rated as more agitated than when he had been receiving maintenance antipsychotic medication. This small study supports the wisdom of periodic discontinuation of long-term antipsychotic medication to evaluate the need for maintenance. In a larger study performed in 36 community nursing home patients (mean age, 82 years) who met criteria for probable or possible AD, patients were randomly assigned to either continuation of antipsychotic medication or withdrawal from antipsychotic medication and substitution of placebo (68). Of the 22 patients withdrawn from antipsychotic medication, 20 (91%) were able to complete the 4-week, double-blinded withdrawal. In only two cases did the nursing home staff request that the patients be withdrawn from the study because of emergencies involving unacceptable levels of agitation. No significant difference in the incidence of emergent physically aggressive behavior was found between patients withdrawn from antipsychotic medication and those maintained on antipsychotic medication. Half of the patients withdrawn from antipsychotic medication remained off the drugs for an extended period of time after the end of the study, even after the blind had been broken. These two studies demonstrate that an attempt at withdrawal from antipsychotic medication in behaviorally stable patients with dementia is feasible.

Dementia with Lewy Bodies: Implications for Psychopharmacology

It is increasingly clear that a subgroup of patients meeting formal criteria for probable AD (69) are more accurately classified diagnostically as having DLB (46).

The defining neuropathologic feature of DLB is the presence of Lewy bodies in the forebrain. These α-synuclein-containing intracytoplasmic inclusions are the classic histopathologic lesion of Parkinson disease, but substantial numbers of Lewy bodies rarely are expressed outside the substantia nigra in this latter disorder. In DLB, numerous Lewy bodies are found in neocortex, limbic brain areas, and other parts of the forebrain. In most cases of DLB, modest numbers of the amyloid plaques and neurofibrillary tangles characteristic of classic AD are also found. In addition, the presynaptic cholinergic deficit present in AD (70 ,71) is very prominent in DLB (72). The parkinsonian features and cholinergic deficit of DLB have implications for the pharmacologic management of the noncognitive behavioral aspects of this disorder. First, the parkinsonian features of DLB make these patients extremely sensitive to dopaminergic blockade by typical antipsychotics (61). The atypical antipsychotics appear preferable for the management of psychosis in DLB (73). Also, several studies suggest that compensating for the profound cholinergic deficit of DLB with cholinesterase inhibitor therapy improves psychotic and other noncognitive behavioral problems in this disorder (26 ,74 ,75).

Other Pharmacologic Approaches to the Management of Agitated Behaviors in Alzheimer Disease

Despite their somewhat disappointing therapeutic effect size, the consensus is that antipsychotic drugs should be prescribed for clear and troublesome delusions and hallucinations. However, the rationale for prescribing antipsychotic drugs as the drug class of choice for AD patients with disruptive agitation in the absence of clear psychotic symptoms is less compelling. In such patients, attempts to demonstrate efficacy for other types of psychotropic drugs are both reasonable and important. Unfortunately, the database derived from well-designed clinical trials of psychotropic drugs other than the antipsychotics for the management of disruptive behaviors in AD is even less robust than that for the antipsychotic drugs. The following review, therefore, relies heavily on anecdotal reports and non–placebo-controlled studies when data from interpretable placebo-controlled studies are not available.

Benzodiazepines

The use of benzodiazepines in patients with AD and other dementing disorders has been reviewed (76). In a group of “emotionally disturbed” elderly patients (mean age, 81 years), Sanders (77) evaluated the efficacy of oxazepam in comparison with placebo in an 8-week treatment trial. Oxazepam was superior to placebo, particularly for reduction of agitation and anxiety. Interpretation of this study is hampered

by the vagueness of the diagnoses and the likelihood that many of the subjects were not demented. Coccaro et al. (78) compared oxazepam, haloperidol, and the sedating antihistamine diphenhydramine in elderly institutionalized patients. The mean age of these subjects was 75 years, most met criteria for AD, and target signs and symptoms included tension, excitement, aggressiveness, pacing, and increased motor activity. Ratings of target signs and symptoms improved during an 8-week period in all treatment groups. Although statistically significant differences between the groups did not emerge, a trend for greater improvement with diphenhydramine or haloperidol than with oxazepam was noted. The lack of a placebo group in this study complicates interpretation of the modest improvements in objective ratings of disruptive behaviors.

Salzman et al. (79) tapered and then discontinued benzodiazepines in 13 elderly nursing home residents and compared memory function and ratings of depression, anxiety, irritability, and sleep between the subjects who discontinued benzodiazepine and 12 nursing home residents who continued their benzodiazepine regimens. The group in which the drug was discontinued showed greater improvements in memory than did the group that continued to take benzodiazepine, and no differences between the groups were found in measures of depression, anxiety, irritability, or sleep. This study suggests that at least a subgroup of patients maintained for an extended time on short-acting benzodiazepines may benefit from a trial of drug discontinuation. In addition to adverse effects on cognitive function, benzodiazepines have been associated with falls in geriatric psychiatric inpatients (80). Taken together, these studies of benzodiazepines in behaviorally disturbed patients with dementia suggest that the use of benzodiazepines is best limited to short-term treatment of acute anxiety and agitation, and that benzodiazepines are a poor choice for long-term management of disruptive agitation in AD.

Buspirone

Buspirone is a partial 5-hydroxytryptamine subtype 1A ($5\text{-}HT_{1A}$)-receptor agonist with antianxiety activity and a relatively benign adverse effect profile. Two uncontrolled studies of buspirone in dementia patients with agitated behavior have been reported. Sakauye et al. (81) prescribed buspirone to 10 patients with AD complicated by agitated behaviors in an open-label study. A modest but statistically significant overall reduction of agitated behaviors was noted, as was a substantial variability in response, with 4 of the 10 patients demonstrating marked declines in disruptive behaviors. In a similar study, Hermann and Eryavec (82) prescribed buspirone to a group of elderly nursing home residents with heterogeneous types of dementia (AD, MID, and alcoholic dementia). All subjects had demonstrated severe behavioral disturbances, including agitation and aggression, and all had failed to improve with previous trials of other types of psychotropic medications, principally antipsychotic drugs. Six of 16 patients were rated as much or very much improved in terms of agitation and aggressive behavior. Levy (83) used buspirone to treat 20 patients with AD and behavioral disturbances rated as at least moderately troublesome on the BEHAVE-AD in a single-blinded dose-escalation study. After a 2- to 4-week psychotropic drug washout period, subjects were given placebo for 1 week and then progressively increasing weekly doses (15, 30, 45, and 60 mg) of buspirone. A dose–response improvement in anxiety rating occurred. As in the study of Barnes et al. (57) of antipsychotic drugs, placebo had a significant effect on delusions. In these studies of buspirone, adverse effects were unusual. Given the low toxicity of this drug, further placebo-controlled investigations appear warranted.

Serotoninergic Drugs

Selective Serotonin Reuptake Inhibitors

The clear serotoninergic deficit demonstrated in AD (29 ,30) and the relationship between low central nervous system serotoninergic activity and aggressive behaviors in nondemented persons (84) provide the rationale for studies addressing the behavioral efficacy of drugs that enhance central serotoninergic neurotransmission in AD patients with agitated behaviors. In a recently reported multicenter trial, AD subjects selected for the presence of psychosis or disruptive agitation were first treated openly with the cholinesterase inhibitor donepezil and then randomized to the addition of either the SSRI sertraline or placebo (85). Sertraline had a modest positive effect on agitated behaviors (but not psychosis) in comparison with placebo. Two multisite Scandinavian studies have evaluated SSRIs in demented patients with a variety of predominantly nonpsychotic behavioral disturbances. These patients were not reported to have met diagnostic criteria for depression. In demented patients with either AD or vascular dementia, the SSRI citalopram was more effective than placebo for the target symptoms of irritability, fear/panic, depressed mood, and restlessness (86). Improvement was limited to demented patients with AD. No significant effects of citalopram were noted in patients with vascular dementia. Cognitive function was unaffected by either citalopram or placebo, and citalopram was well tolerated by the elderly subjects in this study. In another study of demented patients with AD or vascular dementia (87), the SSRI fluvoxamine tended to be more effective than placebo on the target symptoms of confusion, irritability, anxiety, fear/panic, mood level, and restlessness. The differences between fluvoxamine and placebo, however, failed to reach statistical significance. Although more studies are needed to evaluate the possible roles of the SSRIs for disruptive agitation, results to date do not support their use as first-line agents for this indication.

Other Serotoninergic Drugs

Trazodone is a sedating antidepressant with serotoninergic agonist activity. Simpson and Foster (88) treated four demented

patients who manifested disruptive behaviors with trazodone after antipsychotic drug treatment had proved ineffective. In this anecdotal report, trazodone in doses of 200 to 500 mg daily was associated with decreased agitation and aggressive behavior. Pinner and Rich (89) treated seven demented patients with trazodone for symptomatic aggressive behavior. Again, all subjects had failed to improve with antipsychotic drug therapy. Three of the seven patients demonstrated an apparent marked decrease in aggressive behavior following 4 to 6 weeks of trazodone at doses ranging from 200 to 350 mg/d. In a recently reported multisite study comparing haloperidol, trazodone, behavioral management, and placebo, the results with trazodone (mean dose, 200 mg/d) did not differ from those with placebo (59). In a double-blinded, placebo-controlled crossover study, Lawlor et al. (90) treated 10 patients with AD and behavioral complications (troublesome agitation, depression, psychosis, or anxiety) with trazodone (up to 150 mg/d), buspirone (30 mg/d), or placebo. Trazodone produced a small but significant behavioral improvement in comparison with placebo, whereas buspirone had no apparent effect.

Anticonvulsant Drugs

Because the hyperactive and aggressive behaviors encountered in the manic phase of bipolar disorder at least superficially can resemble agitated behaviors in AD and other dementias, the anticonvulsant drugs effective in the treatment of mania may benefit behaviorally disturbed patients with dementia. Lithium has not been helpful for behavioral symptoms in AD (91). Marin and Greenwald (92) treated two AD patients and one MID patient with carbamazepine in an attempt to reduce combative, agitated behaviors. Within 2 weeks of carbamazepine treatment at doses ranging from 100 to 300 mg/d, behavioral improvement was noted in all subjects. In a larger open study of AD patients who had failed to respond to antipsychotic drugs (93), reduction in hostility, agitation, and uncooperativeness was noted in five of nine patients. In this study, two patients whose agitated behaviors decreased manifested ataxia and confusion, which resolved with reduction of the carbamazepine dose. The mean dose of carbamazepine in this study was 480 mg/d. In contrast to enthusiastic authors of these small reports, Chambers et al. (94) noted no overall benefit from carbamazepine in 19 elderly patients with dementia who were prescribed carbamazepine at doses of 100 to 300 mg/d. Target symptoms in this study were wandering, overactivity, and restlessness. Tariot et al. (95), in a 6-week placebo-controlled, randomized, multisite, parallel-group study, evaluated the efficacy, safety, and tolerability of the anticonvulsant drug carbamazepine in demented patients in long-term care facilities with disruptive agitated behaviors. The modal carbamazepine dose at 6 weeks was 300 mg/d, with a mean serum level of 5.3 µg/mL. Statistical superiority of carbamazepine compared with placebo was attributable primarily to a greater decrease in agitation and aggression in the carbamazepine group.

Sodium valproate is another anticonvulsant drug with demonstrated antimanic activity. Mellow et al. (96) treated four patients with AD who manifested disruptive and agitated behaviors with doses of valproate ranging from 500 mg twice daily to 500 mg three times daily; treatment lasted for 1 to 3 months. Substantial behavioral improvement was noted in two of the four patients, and adverse effects did not appear. A recently reported multisite study of the anticonvulsant valproate sodium has been less encouraging (97). Because of a high frequency of adverse effects, primarily excessive somnolence, the study was terminated prematurely. Although at the end of the study agitation was reduced more in valproate subjects than in placebo subjects, it is possible that this apparent therapeutic effect reflected the high degree of sedation experienced by the subjects in the active treatment group. Methodologically, this study was designed to address “mania-like” symptoms in persons with AD, and the higher doses of valproate typically prescribed for the treatment of mania in a younger population were achieved. Lower doses of valproate may have beneficial therapeutic effects with a more tolerable adverse effect profile.

Cholinergic Enhancement

That drugs that enhance cholinergic neurotransmission in the central nervous system decrease agitation and psychotic symptoms in persons with mild to moderate AD has been an unanticipated finding of large, multisite outcome trials demonstrating modest positive effects of these agents on cognitive function (98 ,99 and 100). The contribution of a presynaptic cholinergic deficit to memory and other cognitive impairments in AD (69 ,70) has been a cornerstone of AD drug development. Interest in a potential contribution of this cholinergic deficit to noncognitive behavioral problems in AD increased after Cummings (101) observed that the agitation and psychotic symptoms characteristic of delirium induced by anticholinergic drug toxicity resemble some noncognitive behavioral symptoms occurring spontaneously in AD (e.g., hallucinations, agitation). Cummings reasoned that enhancing brain cholinergic neurotransmission might improve such noncognitive symptoms. Empiric support for this hypothesis came from a carefully performed single-case study in which the cholinesterase inhibitor physostigmine reduced psychotic symptoms in a patient with AD (102) and from a double-blinded crossover study in which physostigmine and the typical antipsychotic haloperidol equally reduced psychotic and agitated behaviors in 13 patients with advanced AD (103). Further support has come from *post hoc* and secondary outcome analyses of large, multicenter cholinesterase inhibitor outcome trials in AD. In addition to demonstrating modest effects on cognitive function,

the cholinesterase inhibitors tacrine (104), galantamine (105), donepezil (106), metrifonate (107), and (in DLB subjects) rivastigmine (108) significantly improved such noncognitive behaviors as delusions, hallucinations, pacing, and uncooperativeness more than did placebo. However, these large, multicenter cholinesterase inhibitor studies excluded AD patients with substantial noncognitive behavioral problems. It is just such severely disturbed patients who must be studied prospectively to establish the clinical importance of cholinesterase inhibitors in the management of noncognitive behavioral problems in AD.

Perhaps the most impressive data supporting positive effects of cholinergic enhancement on noncognitive symptoms in AD come from a multicenter trial of the selective M1 muscarinic cholinergic agonist xanomeline (109). Although the effects of xanomeline on cognitive function disappointingly did not differ from those of placebo, this investigational cholinergic agonist both decreased psychotic and agitated behaviors present at study entry and reduced emergence of these symptoms during the 6-month duration of the study. Furthermore, a clear dose–response effect was observed over the three doses of xanomeline administered. That xanomeline decreases activity of A10 dopaminergic neurons in preclinical studies suggests a possible interaction between cholinergic enhancement and more traditional dopaminergic antagonist approaches to the reduction of psychotic symptoms.

ß-Adrenergic Antagonists

Despite substantial loss of noradrenergic locus ceruleus neurons in AD, studies measuring the concentrations of norepinephrine and its metabolites in either postmortem brain tissue or cerebrospinal fluid (110 ,111 and 112) suggest that noradrenergic outflow is maintained in AD, apparently through compensatory up-regulation of remaining noradrenergic neurons in the locus ceruleus. In addition, patients with AD manifest an enhanced behavioral agitation response to brain noradrenergic stimulation (113). An uncontrolled study suggested that the centrally active ß-adrenergic antagonist propranolol reduces disruptive agitated behaviors in AD (114). In a recently reported placebo-controlled pilot study of Peskind et al. (115), propranolol was superior to placebo in reducing disruptive agitated behaviors in elderly nursing home residents with AD. These patients' disruptive behaviors had been unresponsive to antipsychotic or other psychotropic medications. Propranolol was well tolerated in this small but very elderly population. These neurobiological findings and pilot clinical data warrant larger-scale placebo-controlled trials of propranolol in AD patients with disruptive agitated behaviors.

CONCLUSION

Part of "88 - Alzheimer Disease: Treatment of Noncognitive Behavioral Abnormalities "

The database supporting guidelines for the pharmacologic management of noncognitive behavioral abnormalities in AD remains limited despite the prevalence of these problems and their impact on patient management. Extrapolating from psychopharmacologic outcome studies in younger, nondemented patients with such diseases as depression and schizophrenia has not been a satisfactory approach to developing effective pharmacologic treatments for noncognitive behavioral disturbances in elderly patients with AD and other dementing disorders. The clear placebo responses noted in several carefully performed pharmacologic trials in AD patients with noncognitive behavioral problems emphasize the necessity for inclusion of a placebo condition if a study is to be interpretable. More must be learned about the neurobiological substrates of psychotic and disruptive agitated behaviors in AD. Such knowledge is essential to the rational development of more effective pharmacotherapeutics for these disturbing and costly problems.

Cost-Effectiveness of Therapeutics for Alzheimer Disease

Andrea Manca

Linda Davies

Alistair Burns

Andrea Manca: Centre for Health Economics, University of York, York, United Kingdom.

Linda Davies: School of Psychiatry and Behavioural Sciences, University of Manchester, Manchester, United Kingdom.

Alistair Burns: Department of Old Age Psychiatry, Withington Hospital, West Disbury, Manchester, United Kingdom.

Alzheimer disease (AD), the most common form of dementia, is a progressive neuropsychiatric condition, the expression of which is manifested by neuropsychological deficits (aphasia, apraxia, agnosia, and amnesia), neuropsychiatric signs and symptoms (depression, delusions, hallucinations, aggression, and wandering), and problems with self-care (activities of daily living) (1 ,2 and 3). Caring for a person with dementia places a huge strain on both formal (paid, professional) and informal careers (4).

Alzheimer disease is associated with significant and excess morbidity and mortality. Approximately 30% of elderly people with dementia are severely disabled and require intensive or specialized care and support (2). Studies also indicate that 50% of an incident cohort with dementia will be severely disabled within 3 years, and up to 70% within 7 years (5).

The average survival of people with AD has been estimated at 3 to 6 years from diagnosis, and 7 to 9 years from onset of symptoms (6). The length of survival depends on the age at diagnosis, comorbid conditions, setting of care, family situation, and gender (5 ,6). Gray and Fenn (7) estimated that AD accounts for 2.5% to 5% of all life-years lost between the ages of 60 and 95 years.

The demographic trend toward an aging population means that the burden of the condition will increase in the next 25 years. Population estimates suggest that the expected number of people with AD will rise from less than half a million in 1999 to more than 600,000 in 2020 in the United Kingdom (8). Similar increases are predicted in Canada, from 161,000 people in 1991 to 314,000 people in 2011 and 509,000 in 2031 (9), and in the United States, where the number of people with AD was 2.9 to 4.8 million in 1994 and is expected to increase to 9 million by 2040.

Data on the prevalence of dementia and AD are shown in Table 89.1 . The prevalence and incidence of AD increase with age. The prevalence of the disease broadly doubles for every 5 years of age, increasing from less than 1% of the population ages 65 to 69 years to between 10% and 40% of people ages 85 years and over. The age-specific incidence rates of AD are between 51 and 161 cases per 100,000 person-years for ages 65 to 69; they increase to between 1,000 and 2,855 cases per 100,000 person-years for ages 80 to 84 and to between 1,456 and 5,420 cases per 100,000 person-years for ages 85 and over.

AD, Alzheimer disease.

CURRENT TREATMENT OF ALZHEIMER'S DISEASE

Part of "89 - Cost-Effectiveness of Therapeutics for Alzheimer Disease "

Two theoretically distinct treatment options are available for the treatment of AD. *Symptomatic* treatments are aimed at increasing acetylcholine levels without the expectation that they will affect the underlying course of the disease. *Stabilization* treatments are directed at altering the underlying disorder (characterized by the deposition of amyloid and the presence of neurofibrillary tangles and abnormally phosphorylated tau protein); they do not necessarily produce symptomatic improvement but may delay the progression of the disorder.

Symptomatic Treatment

The most successful agents to provide *symptomatic* improvement are the acetylcholinesterase drugs. AD is associated with a number of neurologic and neurochemical abnormalities, particularly depletion of acetylcholine. Acetylcholinesterase

inhibitors (or anticholinesterases) enhance surviving cholinergic neurotransmission by inhibiting the breakdown of released acetylcholine.

Two first-generation anticholinesterases are physostigmine and tetrahydroaminoacradine (tacrine). Early trials suggested that physostigmine has short-term efficacy in improving memory. However, the results of trials vary substantially. In addition, the drug is associated with a high incidence of side effects (13). Tacrine requires a complex dosing regime and has toxic side effects (3). Systematic reviews suggest that the drug has a modest but not clinically or statistically significant effect on cognition in people with mild to moderate AD (14 ,15). Because administration of the drug has been accompanied by a high rate of adverse events (especially hepatotoxicity), rates of withdrawal from trials have been high.

Second-generation anticholinesterases include donepezil hydrochloride (Aricept, Pfizer) and rivastigmine (Exelon, Novartis).

Clinical trials of rivastigmine show a magnitude of effect similar to that of donepezil in a larger patient database with a longer duration of treatment and less restrictive entry criteria (3 ,16). Overall, patients taking the drug show an improvement in cognition, global clinical state, and carer ratings of activities of daily living.

Drugs that have a *stabilization* effect on the progress of AD are nonsteroidal antiinflammatory agents (NSAIDs), estrogen, and antioxidant agents. There is good evidence of an inflammatory component in AD, and it is well documented that NSAIDs are protective against the development of AD. The evidence of a symptomatic improvement in patients taking these drugs is inconsistent. The beneficial effects of aspirin on cardiovascular and cerebrovascular disease are well documented, but no evidence has been found that it is effective in AD. Estrogen appears to have a significant protective effect against the development of AD and may work through a number of different mechanisms. Small-scale studies have shown minor benefits in terms of improved cognitive function. A growing body of evidence indicates that free radical formation is a mediator of the excessive lipid peroxidation and cell damage seen in AD. Antioxidant vitamins (e.g., vitamins C and E) have been shown to have biological activity in acting as scavengers for free radicals. Sano et al. (17) showed that α-tocopherol in a daily dose of 2000 IU significantly delays the onset of defined milestones in the development of AD. Therefore, of the three stabilization agents currently available, only vitamin E is supported by evidence that it can delay deterioration in the disease. α-Tocopherol has the advantage that it is not toxic (even at high doses), and it is easily available and suitable for all patients. Sano et al. (17) reported no significant side effects of α—tocopherol. Estrogen has significant potential to cause gynecologic cancer and currently is suitable only for women, and antiinflammatory agents can provoke gastric inflammation and bleeding.

ECONOMIC PERSPECTIVE

Part of "89 - Cost-Effectiveness of Therapeutics for Alzheimer Disease "

Given the constraints on health and social care budgets, those responsible for the provision and financing of such

services need to ensure that resources are used efficiently. Economic evidence about the relative costs and outcomes of health and social care helps decision makers determine the best use of scarce health care resources (18 ,19). Two approaches have been used to evaluate the economic consequences of AD. These are (a) cost-of-illness or burden-of-disease studies to assess the costs and consequences of a disease to society and (b) full economic evaluations to compare the costs and consequences of alternative health or social care interventions.

Cost-of-Illness Analyses

From an economic perspective, the aim of cost-of-illness or burden-of-disease studies is to describe and value the costs and consequences of a disease to society. A cost-of-illness study should describe and value the direct costs of health and social care for people with the disease. It should also describe the mortality and morbidity consequences. These should be valued in either monetary terms (as indirect and intangible costs) or by utility-based measures such as quality-adjusted life-years (QALYs).

Cost-of-illness studies can be used to estimate the total burden of disease for a given year. In this approach, known as the *prevalence approach*, the costs and health outcomes of all people with the disease in a given year are included. An alternative approach is to estimate the lifetime costs and consequences for a cohort of people with the disease, from onset to death. This is known as the *incidence approach*.

Cost-of-illness studies do not provide information about the economic benefits of introducing or developing new health or social care programs, and they are of limited use in setting priorities or allocating resources (18 ,19).

Full Economic Evaluation

Economic evaluations compare alternative health or social care interventions and estimates of the relative or incremental costs and benefits of care. In AD, two or more drug therapies to treat the symptoms of the disease or delay progression may be compared for efficacy. The four types of economic evaluation are cost-minimization analysis, cost-effectiveness analysis, cost–utility analysis, and cost–benefit analysis. The analytic framework chosen depends on the perspective of the analysis and the economic questions posed (19).

Cost-Minimization Analysis

In a cost-minimization analysis, the direct costs of two or more health care interventions are compared. This form of analysis does not include a formal economic comparison of the outcomes of health and social care. However, the evidence that patient outcomes do not differ between interventions must be clear and reliable. If such evidence is not available, then the economic evaluation must include a cost-effectiveness, cost–utility, or cost–benefit analysis of patient outcomes.

Cost-Effectiveness Analysis

A cost-effectiveness analysis compares the direct costs of health and social care resources of two or more interventions with patient outcomes, measured in terms of clinical effectiveness. For AD, measures such as years of life with mild or moderate disability or changes in cognitive function are used.

If one intervention, such as a new drug to control symptoms or delay progression, leads to lower direct costs and improved patient outcomes, it is the dominant and preferred option. In other words, it clearly saves resources to provide care and is more beneficial to the patient. More often, a new therapy is associated with improved patient outcomes at additional cost. Incremental cost effectiveness ratios (ICER) provide a measure of the cost of gaining a unit of health improvement, such as cost per life-year gained. The ICER is calculated as follows: (Cost of A - Cost of B)/(Outcome of A - Outcome of B).

Cost-effectiveness analysis is limited by the use of effectiveness measures, which may not capture the total impact of health and social care on quality of life or overall well-being. This is particularly important in AD, in which the impact of the disease and patient care is multidimensional. In this case, an outcome measure is needed that combines several aspects, such as survival and cognitive, physical, and emotional function, into a single index.

Cost–Utility Analysis

Cost–utility analysis is similar to cost-effectiveness analysis, but utility is used as the outcome measure. Cost–utility analysis is used to estimate QALYs. As in cost-effectiveness analysis, incremental cost–utility ratios are calculated to estimate the cost of producing one additional QALY.

Cost–Benefit Analysis

A cost–benefit analysis is based on monetary valuations of the morbidity and mortality consequences of disease or interventions. These allow an estimation of the absolute and relative net social benefit of intervention. This is calculated as the monetary value of the consequences of an intervention minus the direct costs. Any health or social care intervention with a net social benefit greater than zero (i.e., the benefits are greater than the costs) is worth undertaking.

KEY COMPONENTS OF AN ECONOMIC EVALUATION

Part of "89 - Cost-Effectiveness of Therapeutics for Alzheimer Disease "

Perspective of Analysis

Economic studies should consider all costs and outcomes that are a consequence of the illness (cost of illness) or the

health or social care interventions evaluated (economic evaluation). For AD, these may include the costs of hospital care, community-based health care services, social welfare services, and care provided by voluntary agencies or family and friends. People with AD and their families may also receive social welfare or support payments. However, what constitutes a cost from one point of view may not be a cost from another.

For example, the costs of social care services or patient and family out-of-pocket expenses are a cost to society but not to those responsible for provision or funding of hospital based care. In contrast, social welfare payments are a cost to the agency that pays them, but a benefit to the patients and families who receive them. From the point of view of society, social welfare payments are both a cost and a benefit; when added together, they cancel each other out, so they should not be included.

For these reasons, an economic analysis should be clear about the viewpoint or perspective and therefore the range of costs and consequences included. Ideally, a broad perspective that reflects the costs and outcomes to society should be adopted. At a minimum, the perspective of the analysis should include the costs and outcomes to key health and social care providers or funders and to patients and their families.

Time Frame of Analysis

Economic studies should use a time frame that allows full measurement of the relevant costs and benefits. Comparative economic evaluations should monitor resource use, costs, and outcomes for the full period during which the interventions could be expected to have an effect on resource use, survival, and health-related quality of life.

Target Population and Comparators

The population considered in the analysis should be representative of the population to be treated. The interventions compared should be relevant to the health and social care choices faced by decision makers. Unless “do nothing” is a valid management strategy, comparison of a new intervention with placebo is not appropriate for an economic evaluation.

Opportunity Cost

The economic concept of cost is the value of a good or service in terms of its best alternative use, or opportunity cost. Often, the market price or value of the resources used, such as the time of a health care professional, facilities, or medicines, is a reasonable approximation of the opportunity cost or value to society of the services provided.

Measurement and Valuation of Costs

An economic study should describe and quantify the resources used to produce health and social care and support for the patients and their carers. Costs should be estimated from data on the quantity and type of resources used (e.g., number of hospital-based physician visits, number of hospital admissions, number of days per admission) multiplied by the opportunity cost or market price of those resources. If the evaluation compares two or more interventions, care must be taken to ensure that all relevant types of resource use and costs are identified. These include costs of the intervention, follow-up care and support for patients and carers, and management of side effects or adverse events.

These aspects are termed the *direct costs* to produce of health and social care. From a societal perspective, direct costs also include out-of-pocket expenses and the use of resources that do not have a market price, such as the time of family or volunteers. These should be measured and valued because they are potentially important inputs to the production of care. The time costs of volunteers and family members can be valued with average wage rates or the cost of equivalent services with a market price (e.g., private nurses).

Measurement and Valuation of Outcomes

It is crucial that an economic study include the health-related consequences of morbidity and mortality. For AD, these could be the number of years of life lost and the illness-associated reductions in health status and quality of remaining years of life for both patients and informal carers.

These consequences should also be valued to reflect the cost or loss of utility to individuals and society of reductions in the length of life or health. Two approaches have been advocated. The first is to value the consequences in monetary terms as indirect or productivity costs *and* intangible costs. The second is to combine data about length of life and morbidity to provide a single, nonmonetary measure of impact.

Monetary Valuation

Indirect costs represent the value of changes in the amount or type of work done or use of leisure time as a consequence of morbidity or mortality. They are also called *productivity* or *time costs* (18 ,19). With AD, the ability to engage in the normal daily activities of life and leisure is reduced by impaired cognitive function and, in some cases, early death. The physical and mental health of carers may also be affected. Typically, these costs are valued in the same way as the time costs of unpaid carers, by using market values of the time in full health lost, such as average wage rates. However, indirect or productivity costs do not include the costs of patient or carer time used to provide health and social care.

Intangible costs represent the monetary value to individuals and society of health and life *per se*. In practical terms, a determination of intangible costs requires an assessment of the amount of money that individuals would accept as compensation for reductions in health or life expectancy, or the amount they would be prepared to pay for improvements in health or life expectancy.

Nonmonetary Valuation

An alternative approach is to estimate individual and social preferences for life, health, or disability states. This approach combines measures of life-years lost because of early mortality with a value for the morbidity or ill health associated with the remaining years of life. Examples are qualityadjusted life-years (QALYs) and disability-adjusted life-years (DALYs). These are calculated as the number of years of remaining life weighted by the quality or utility of that life. The utility weight is the relative value of society for states less than full health.

Discounting

The costs and consequences of a disease and health and social interventions can occur at different times. For analyses that include a time frame of more than 1 year, it is conventional to discount the costs and outcomes to present values, so that the relative importance of events occurring in the future, rather than the present, is reduced. Discounting is based on the assumption that individuals and society prefer to receive benefits sooner rather than later and to delay costs. There is some debate about whether outcomes and costs should be discounted at the same rate. The rule of thumb is to use a discount rate of 5% for both and repeat the analysis with alternative rates for the costs and outcomes.

HOW SHOULD ECONOMIC DATA BE COLLECTED AND ANALYZED?

Part of "89 - Cost-Effectiveness of Therapeutics for Alzheimer Disease "

To be useful to those concerned with choices in the allocation of health and social care resources, the design of economic evaluations should ensure that the results are timely, relevant, credible, and accurate (20). The economic study can use modeling techniques to synthesize secondary and primary data from several sources, or it can analyze data collected prospectively with a controlled study design. Which of these techniques is used depends on the type of question addressed.

The first type of question assesses the available evidence about the relative costs and outcomes of current and new forms of health and social care. The existing literature and data should be reviewed to determine the following: natural history of the disease; incidence and prevalence of the disease; possible indications and target populations for the new intervention; current treatment patterns; relevant comparators; and the costs and benefits of current treatment or health care. The initial assessment should be based on a synthesis of available data and expert opinion, which requires the development of internally and externally valid and logical models that are consistent and robust. If the quality or completeness of existing data is doubtful, sensitivity analysis should be used to generate minimum and maximum values for key clinical and economic parameters. Best and worst case scenarios should be incorporated to ensure that interactions between key parameters are explored.

If the modeling study indicates that clinical or economic evidence is highly uncertain, the prospective collection of data is required. The objective is to establish whether differences in clinical and economic endpoints are directly attributable to the interventions compared. To this end, well-controlled evaluations with a high level of internal validity are required, such as an integrated economic and clinical controlled trial. Whether randomized, controlled trial methodology or alternative study designs are used depends on the feasibility and relative efficiency of conducting a large pragmatic trial, which is typical of routine practice on a representative sample of patients. If the correlation between resource use and the interventions studied is high, even tightly defined explanatory clinical trials may be appropriate to address the question of efficiency. Alternatively, if the correlation is low and other factors, such as patient characteristics, comorbidities, and organization of health care services, are equally important determinants of service use, then the most pragmatic trial may fail to provide usable economic information.

The costs of the interventions studied should be estimated from activity data, which quantify resources used, and price or unit cost data. All health and social care activity data are potentially important and should be collected, particularly if variability in the intensity of resource use between diseases, patients, or centers is likely to be large.

Costs of Alzheimer's Disease

A number of studies have evaluated the burden of AD in different countries. These have focused primarily on the direct costs of illness and so are partial analyses. The costs have been updated to 1997 figures, with the use of health and social care inflation indices, to provide a common price year for comparison. The costs were then converted to U.S. dollars by means of purchasing power parities (PPPs). The PPP is the rate of currency conversion that ensures that the price level in each country, when expressed in dollars, is the same as that in every other country. The advantage of PPPs over conventional exchange rates is that they reflect the price levels and purchasing power of the currencies converted (21).

Table 89.2 presents data on the direct costs of health and social care for cohorts of people with AD. The variations

in costs within each of the countries and also between them are large. The average cost per person ranges between $14,107 and $50,461 in Canada, $4,747 and $156,794 in the United Kingdom, and $14,216 and $70,939 in the United States. These variations reflect differences in the methods used to collect and analyze the epidemiologic and cost data (31), the range of costs included, timing of the study, and disease severity and setting of care of the sample of people with AD included in the study.

TABLE 89.2. CARE SETTING, INFORMAL CARE, AND COST PER PERSON (U.S. DOLLARS, 1997)

Sources of Data

Data for the cost estimates shown in Table 89.2 and Table 89.3 were derived from a number of sources. One study used

secondary analysis of administrative databases in the United Kingdom (7 ,33). These gave aggregate measures of the use of hospital inpatient care, residential and nursing home admissions, and general practitioner consultations for people with mental disorders in 1984 and 1985. They were supplemented by surveys and expert opinion to generate measures of the use of day care, home-based care, and payments to informal carers. Cost data from other sources were used to estimate total expenditure for people with AD (7 ,33). The primary disadvantages of this approach are that the data for resource use may not be detailed enough to allow a complete measurement of the range of resources used. In addition, coding errors and highly summarized diagnostic categories and comorbidities make it difficult to allocate resource use to specific diseases. These problems may account for the substantially lower community-based costs found in this study.

TABLE 89.3. ESTIMATED INCREMENTAL COSTS OF ALZHEIMER DISEASE (U.S. DOLLARS, 1997)

Four of the costs studies were based on detailed data from large-scale national surveys (22 ,23 ,26 ,27). The U.K. studies both used two surveys of people with disabilities living in private households (*n* = 5,699) and communal establishments (*n* = 3,037) that had been conducted in the middle to late 1980s (22 ,23). The Canadian studies both used the Canadian Study of Health and Ageing, which surveyed a total of 10,263 randomly selected Canadians over the age of 65 (26 ,27). Resource use information was collected by interviewing people with disability and their carers.

The remaining studies in Table 89.2 and Table 89.3 used surveys of selected samples of people. The samples of respondents varied in size from 64 to 679 people. Similar methods were used to identify resource use. Two of the studies collected data prospectively from respondents during 6-month (30) and 2-year periods (28). Most studies included validated measures to determine the presence and severity of cognitive disability.

Estimating resource use from individual patient or carer data is associated with several advantages and disadvantages. First, the use of screening instruments allows a clear identification of people with cognitive disability or AD. However, the use of a variety of instruments may lead to differences in the categorization of people with cognitive problems, so that the comparability of results is reduced. For example, the surveys in the United Kingdom used a broad classification of cognitive disability that resulted in a higher prevalence estimate than that obtained in other epidemiologic research (22).

Secondly, the use of individual patient or carer data allows the health and social care services actually used by the people in the study to be identified. It also allows the use of informal care time and personal expenditures to be measured. However, the use of interviews and questionnaires to determine resource use may be subject to problems with accurate recall or recording the type and quantity of services actually used. This problem is illustrated by the greater range of costs found for people living at home, where a greater range of services may be used, than for people in long-stay care. The highest cost estimates for people living at home were 6 to 7 times greater than the lowest, whereas they were 1.7 to 1.9 times higher for people in long-stay care.

Thirdly, if the study is based on large samples, the impact of random variation in the use of health and social care services is reduced. If a small sample by chance overrepresents people with an extremely high or low use of services, substantial underestimation or overestimation of the costs

can result. For example, the range of costs found in the large U.K. and Canadian studies was relatively small, with the highest estimate between 1.3 and 1.9 times greater than the lowest estimate. However, the range was far greater for the smaller studies. In particular, for people living at home, the highest costs were 5.6 to 6.9 times greater than the lowest costs.

Measurement and Valuation of Informal Care

A key difference between the studies was the use of unpaid care and the method utilized to cost this care. One study did not include the costs of unpaid informal care time (23). When included, informal care costs ranged from 48% to 81% of home-based care for people with mild to moderately severe disease and from 27% to 79% of home-based care for people with severe disease. For people in long-stay care, the proportion of informal care costs ranged from zero to 12%. Excluding the costs of unpaid care does not reduce the variability in the total costs of care. This suggests that in some cases, unpaid care may be a substitute for rather than an addition to formal health and social care services.

Kavanagh et al. (22) used U.K. social security allowances for carers of people with disabilities as a proxy for the costs of informal care. This gave the lowest proportion of informal care costs for people living at home (27%). Three studies used the replacement cost method to estimate the opportunity cost of unpaid carer time (26 ,28 ,29). The time spent by informal carers was estimated and then multiplied by the average wage of professional (paid) caregivers. The informal care costs ranged between $7,900 (50% of costs) (26) and $48,948 (81% of costs) (28).

The other studies used the national average wage (24) or minimum wage (27) to value unpaid carer time. The informal care costs ranged from $14,496 (80% of costs) (27) to $106,620 (69% of costs) (24). These data illustrate the impact of different methods of valuing informal care time on estimates of cost.

Organization and Availability of Care

Rice et al. (28) estimated the expected cost per person with AD. This was based on data for a sample of people living in both community and residential care in northern California. The estimated annual costs per person were higher than the estimates from the other studies reported in Table 89.2 and Table 89.3 . However, the authors stressed that the organization and level of provision of services in California were such that the results should not be generalized to other geographic settings in the United States.

The organization and availability of health and social care vary with time as well as between settings. In many countries, the trend has been toward the provision of mental health and social care services in the community rather than in institutions, with an emphasis on support from family and informal carers (34). This means that earlier studies may overestimate the current costs of institutional care and the potential benefits of reducing the need for such care. At the same time, the costs of community or home-based care and informal carers will be underestimated. This is particularly important if the opportunity costs of informal care are not included or are underestimated in the direct costs of providing health and social care.

Severity of Disease and Setting of Care

The costs of health and social care for people with AD are also affected by two interrelated factors: the severity of disability caused by the disease and the setting of care.

Severity of Disease

The cost data in Table 89.2 indicate a trend toward higher costs of care as the severity of the disease increases. This applies in both community/private home settings and long-stay care settings. Three studies used statistical analysis to compare costs by disease severity. All of them found some degree of statistically significant correlation between some of the costs and disease severity (23 ,27 ,29). Holmes et al (25) used regression analysis to estimate average cost by age and years since diagnosis. In their analysis, total costs were positively related to years since diagnosis. Each additional year since diagnosis was predicted to increase costs by roughly $1,100 per person. However, cost was negatively related to age. Each additional year of age predicted a decrease in costs of about $850. The authors suggested that this finding may have reflected more intensive hospital-based care for younger people with AD.

It has also been suggested that as the cognitive and functional ability of people declines, they can no longer live alone supported by formal health and social care services. They may move to live with family or friends, who provide informal care. In this case, informal care may be a substitute for previous formal care services. If informal care is not adequately costed, then the financial cost decreases, but not the opportunity cost of providing care (35). In contrast, in a secondary analysis of a large-scale disability survey in the United Kingdom, disabled elderly people with more severe cognitive disability received more intensive care and were referred more often to health care services (23).

In an analysis of Canadian data (27) in which a bivariate regression model was used to assess the relationship between severity of disease and costs, each 1-point decrease in Mini-Mental State Examination (MMSE) scores was associated with an average increase in costs of $1,343 (Canadian dollars, 1996 prices). Even when informal care time was valued by using industrial aggregate wage levels rather than minimum wage levels, the relationship between severity and costs remained statistically significant. The relationship between

costs of care and severity of disease is complex. Increases in the costs of care as disease becomes more severe represent in part a greater use of institution-based care as people become more cognitively and functionally disabled by their disease. They may also reflect aging and the effect of comorbidities (23). In addition, informal carers age and may be affected by declining health and less ability to provide care.

Setting of Care

An important determinant of the costs of health and social care is the distribution of people with AD by setting of care. For most of the studies reported in Table 89.2 , the costs of long-stay care are 1.5 to 2.5 times higher than those of home-based care. The exceptions to this are the study by Gray and Fenn (7), in which the costs of long-stay care were 10 times higher than those of community care. The study by Rice et al. (28) indicated roughly equal costs for long-stay and home-based care.

Determinants of the setting of care include the severity of cognitive and functional disability, the presence of other health problems, the ability of informal carers to support the person at home, and the structure of health and social care service provisions. The data in Table 89.2 indicate that the proportion of people cared for in long-stay care settings is between 6% and 53% for people with mild to moderate disease and 33% to 86% for people with severe disease.

Kavanagh and Knapp (23) found cost variations between long-stay care locations in their sample, and they also found the prevalence of severe cognitive disability to be higher in the more expensive settings. In the regression analysis by Holmes et al. (25), the use of institutional care increased with the number of years since diagnosis and the age of the carer. For each additional year of age of the carer, the costs of institutional care were predicted to increase by roughly $264 per year.

Incremental Costs of Alzheimer Disease

Table 89.3 presents estimates of the additional or incremental costs of care associated with AD only, rather than with other illnesses or age. With the exception of those in the study by Souêtre et al. (24), the incremental costs tend to be lower than the full costs reported in Table 89.2 . In the study by Kavanagh and Knapp (23), the costs of people with disabilities, but no cognitive disability, were approximately $25,299. The additional costs of people with cognitive disability in this group can be estimated at $10,042 to $17,587. The studies by Souêtre et al. (24) and Østbye and Crosse (26) estimated the costs of care for people in a similar age group with no disabilities. The study by Ernst and Hay (32) estimated the net costs of care from aggregate data sets and surveys.

Evidence of Cost-Effectiveness

It is clear that the costs of health and social care and informal care for people with AD is high, and evidence suggest that the costs increase with the severity of cognitive disability and need for long-stay care or institutional care. It has been argued that it might be rational to support the introduction of drug treatments to slow down the progression of the disease and delay the onset of institutionalization. This would lead to a saving of costs to offset the acquisition costs of the drugs. However, this proposal has been criticized on the grounds that it would shift the burden of the disease from the public sector budget to private citizens, without a real beneficial effect for society as a whole. A full evaluation from the societal viewpoint of the new drugs used to manage AD is clearly needed (36). A number of economic studies have been published to assess the relative value for money of tacrine, donepezil, and rivastigmine. Table 89.4 gives details of the methods used and comparators of the studies.

TABLE 89.4. ECONOMIC MODELS OF DRUGS FOR ALZHEIMER DISEASE

Study	Country	Drug	Method	Perspective	Costs Included	Discount Rate	Comparators	Time Horizon
Stewart et al., 1998 (37)	United Kingdom	Donepezil	Cost-effectiveness analysis	Societal	Direct costs and costs of informal care	6%	5-mg and 10-mg dose/d vs. placebo	5 y (6-mo cycles)
O'Brien et al., 1999 (38)	Canada	Donepezil	Cost-effectiveness analysis	Societal and government payer	NHC, CCS, CG, drug costs	5%	5-mg dose/d vs. no treatment	5 y (6-mo cycles)
Jönsson et al., 1999 (40)	Sweden	Donepezil	Cost-effectiveness analysis	Not clearly stated	Residential costs, home help, and drug cost	3%	5-mg and 10-mg dose/d vs. no treatment	5 y (6-mo cycles)
Neumann et al., 1999 (39)	United States	Donepezil	Cost-effectiveness analysis	Societal	Direct medical and nonmedical costs; costs of informal care	3%	pooled 5-mg and 10-mg doses/d	1 y (6-mo cycles)
Stein 1997 (41)	United Kingdom	Donopezil	Drug evaluation, NHS report		Acute/geriatric hospital in- and out-patient care, mental hospital care, GP consultations, drug costs	6%	5-mg and 10-mg doses/d and placebo	2, 5, 8, and 10 y
Fenn and Gray, 1999 (33)	United Kingdom	Rivastigmine	Cost-saving analysis	Health and social care system	Long-term care institutions costs, drug costs, costs occurring when living at home	Not stated	1 to 4-mg and 6 to 12-mg doses/d vs. placebo	26 wk, 1 yr, and 2 y
Stein, 1998 (42)	United Kingdom	Rivastigmine	Drug evaluation, NHS report		Acute/geriatric hospital in- and out-patient care, mental hospital care, GP consultations, drug costs	6%	1 to 4-mg and 6 to 12-mg doses/d and placebo	1, 2, and 5 y
Small et al., 1998 (43)	United States	Donepezil	Longitudinal survey	Not clearly stated	Direct medical costs and drug costs	n. a.	drug vs. no drug treatment	6 mo
Henke and Burchmore 1997 (44)	United States	Tacrine	Cost-minimization analysis	Public and private payers	All paid medical and societal services	5%	tacrine 80 mg/d vs. no drug treatment	Lifetime cost for patients newly diagnosed with AD
Lubeck et al., 1994 (45)	United States	Tacrine	Cost-minimization analysis	Not clearly stated	Community and nursing home care, drug costs, treatment-related costs, informal care costs (?)	5%	tacrine 160 mg vs. tacrine (various doses)	Lifetime costs
Wimo et al., 1997 (46)	Sweden	Tacrine	Cost-saving analysis	Public payer	Residential costs, drug costs, laboratory and GP visits costs, costs of diagnostic procedures, cost of informal care	3%	tacrine 160 mg vs. no tacrine treatment (i.e., standard treatment)	Lifetime costs
Wimo et al., 1998 (47)	Sweden	Propentofylline	Cost-saving analysis	Public payer	Direct medical costs	5%	propentofylline vs. usual care without propentofylline	Lifetime costs
Hauber et al., 2000 (48)	United States	Rivastigmine	Cost-saving analysis	Not stated	Not stated	3%	Rivastigmine vs. no treatment	6 mo, 1 yr, and 2 y

AD, Alzheimer disease; CCS, community care services; CG, caregiver's time; GP, general practitioner; n.a., not applicable; NHC, nursing home care; NHS, national health service.

Most of these analyses are modeling exercises that extrapolate the results of randomized, controlled trials to a longer time period and broader population. Only four meet the criteria for full economic evaluations, and these are shown in Table 89.5 , which reports the estimates of the expected net benefits and costs likely to occur from the introduction of these drugs. The four studies analyzed the same drug treatment (donepezil) in four different countries/settings: United Kingdom (37), Canada (38), United States (39), and Sweden (40). Stewart et al. (37) evaluated the cost-effectiveness of donepezil in the United Kingdom for individual patients ages 75 years and over with a diagnosis of either mild or moderate AD. O'Brien et al. (38) considered a hypothetical cohort of people with nonsevere AD (MMSE ≥ 10) in Canada. Finally, Neumann et al. (39) focused on patients in the United States with mild or moderate AD.

TABLE 89.5. FULL ECONOMIC EVALUATIONS OF DRUGS FOR ALZHEIMER DISEASE

Study	Outcome Measure	Year of Costing	Original Currency	Incremental Cost (Health PPP$, 1996)	Health Gain
Stewart et al., 1998 (37)	Expected life-years in condition less than severe (ELY<S)	1997	British pounds	1,333	0.120 ELY<S
O'Brien et al., 1999 (38)	Expected life-years in condition less than severe (ELY<S)	1997	Canadian dollars	−1,292	0.200 ELY<S
Jönsson et al., 1999 (40)	Expected life-years in condition less than severe (ELY<S)	1998	Swedish kronor	−1,962	0.522 ELY<S
Neumann et al., 1999 (39)	Quality-adjusted life-years (QALY)	1997	U.S. dollars	483	0.015 QALYs

PPP, purchasing power parity.

Despite differences in the provision of health care between the United Kingdom, the United States, and Canada, these studies found donepezil to be approximately cost-neutral under several alternative scenarios. Three studies found that the distribution of severity states of patients is the most important variable affecting the cost-effectiveness of drugs. However, it is important to note that these results are preliminary and uncertain and that a number of issues must be considered when the results are interpreted.

Costs

First of all, no prospective measurement of resource use associated with the drug or usual care was made. Costs were estimated from retrospective analysis of available data sets (40) or analysis of published literature (37), sometimes integrated with expert opinion (38 ,39). The range of cost items and the costing methodologies employed in each study were heterogeneous. Some authors included both direct costs and

informal carers' time (37 ,38 and 39), whereas others considered only direct medical costs (40).

Three analyses (37 ,38 ,49) directly or indirectly associated the dynamic of treatment costs with the progression of disease severity, measured with the MMSE. The MMSE score was shown to be strongly correlated with costs of dementia care, but it is unclear to what extent the use of this instrument is robust in modeling studies. It has been suggested (49) that other factors may be strongly correlated with costs, such as indices of activities of daily living and instruments that measure behavioral disturbances.

Outcome Measures

One study used QALYs to measure the benefits derived from introducing the drug (39). In the other studies, benefits were measured in terms of "time spent in condition less than severe." The QALYs were estimated with the Health Utility Index Mark II in a sample of patients and carers. However, this instrument has not been validated in patients with AD, and its ability to detect small improvements in potentially important clinical aspects is doubtful. The QALY data were collected alongside a cross-sectional study, which means that no information was obtained on how the effectiveness of the drugs and utilities varied over the course of the disease. In addition, the sample of patients used to elicit utility values may have been unrepresentative of the population of people with AD (39). There were also potential problems with the use of proxy respondents. However, given the cognitive and behavioral degenerative process associated with AD, the use of alternative respondents may be unavoidable. Additionally, measuring outcomes as "time spent in less than severe state" does not inform health and social care decision makers about the value of quality of life for people with AD and their family and carers.

Effectiveness

Effectiveness data about the new drugs were derived from a limited number of trials that were short in duration and explanatory rather than pragmatic in design. Some of these trials have been criticized elsewhere (50) for having enrolled a carefully selected subgroup of patients with mild-to-moderate AD and excluded those with coexisting illness or concurrent treatment. In real practice, the eligible population may be considerably different. Consequently, only a limited proportion of people may be adequately and safely treated.

Furthermore, the lack of data meant that the duration of the treatment effect of the drug was based on experts' opinions (38 ,39) or was disregarded by assuming that the treatment effect ceased after 6 months (37). The cost-effectiveness of cholinesterase inhibitors depends on the distribution of patients across different severity states (38). In this context, the correct assessment of the duration of the treatment effect of anticholinesterase drugs assumes a central role because it affects the number of people having mild-to-moderate AD at any one time.

Modeling

Some authors have recently challenged the use of Markov models in the evaluation of antidementia drugs (33 ,48). The use of alternative modeling tools, such as statistical models, to extrapolate the results of a short trial to a longer time horizon needs to be explored. Given the considerable uncertainty surrounding the available data, deterministic models in which simplistic sensitivity analysis techniques are used may not be adequate to assess the robustness of the results. The application of stochastic models allows the uncertainty associated with relevant parameters of a model to be incorporated and quantified.

CONCLUSION

Part of "89 - Cost-Effectiveness of Therapeutics for Alzheimer Disease "

As a direct consequence of changes in the age structure of the population, elderly generations are expected to become the largest consumer group of health care resources. Because no cure for AD is yet available, the management of the

disorder focuses on assisting patients in their daily activities and supporting carers. The progressive nature of AD and the aging of the population mean that many people with this condition will require intensive support and long-term residential or nursing home care. A number of factors may trigger the need for long-term institutional care, including the age of family carers, the behavioral problems of patients, and the loss of self-care ability for those who live alone in a private household. Institutionalization has been identified as one of the main cost drivers in the care of people affected by AD (2 ,51).

Some clinical evidence indicates that anticholinesterase drugs may slow the progression of AD or relieve some of the symptoms. If the drugs are effective in controlling symptoms or slowing progression of the illness, they may delay the need for intensive support or institutionalization of patients. The high acquisition cost of the drugs, however, has raised considerable concern about the potential value for money associated with their use, which has prompted a significant number of studies addressing the issue of costs and patient benefits.

To date, a conclusive analysis has not clarified the most appropriate management strategy for the disorder. In the near future, new drugs for the treatment of AD are expected to be licensed, and it would be extremely valuable to be able to compare them in a clear and well-defined framework. In addition, if economic evaluation is to inform health and social care providers and policy makers about the potential impact of new interventions in practice, an estimation of the value for money of these new interventions requires consideration of (a) the perceived and objective risks and benefits of care; (b) the attitudes of people with dementia, carers, and health and social care providers to risk; (c) the utility to these groups of health care interventions; and (d) quantification of the uncertainty surrounding estimates of risk, utility, and costs.

Although the first attempts to analyze currently available antidementia drugs provided limited conclusive results, the contribution of simulation models may help to shed light on several aspects that have not yet been explored. In a context largely characterized by uncertainty surrounding the value of the key variables, modeling techniques can be used to assess the value for money of new management strategies for the treatment of AD and compare them with the alternative policy options. Further primary and secondary research is required to provide robust estimates of the formal and informal care costs associated with the new drugs and the value of health improvements to patients and carers.

Neuropsychiatric Manifestations of Hiv-1 Infection and Aids

Dwight L. Evans

Karen I. Mason

Dwight L. Evans: Department of Psychiatry, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania.

Karen I. Mason: Department of Psychiatry and Biobehavioral Sciences, University of California at Los Angeles, Los Angeles, California.

By 1999, the United Nations estimated that more than 33 million people worldwide had been infected by HIV-1 and more than 16 million had died of AIDS. Approximately 90% of these infections occurred in developing countries, particularly in sub-Saharan Africa, which accounts for 65% of HIV cases (1). In the United States and Canada, more than 920,000 adults and children were living with HIV/AIDS by the end of 1999, and more than 400,000 had died. Initially, HIV-1 infection primarily affected men, but today, women comprise more than 16% of all AIDS cases in the United States. Among U.S. women with AIDS, the proportion of African-Americans and other minorities has been rising faster than the proportion of women in other segments of the population. By the end of 1997, African-American women accounted for 56% of AIDS cases among women in the United States. Another change in the demographics of the epidemic is seen in the mode of transmission. In the United States, homosexual transmission has stabilized or declined while infection via heterosexual transmission (5% to 18%) and injection drug use (15% to 23%) has increased significantly.

Neuropsychiatric and neurologic signs and symptoms have been described since the earliest reports on AIDS. The neuropsychiatric manifestations described in these early reports included progressive dementia, depression with pronounced apathy and psychomotor slowing, manic symptoms, and atypical psychosis. Initially, these mental disturbances were attributed to psychological reactions to a systemic illness, the effects of psychosocial stressors associated with the disease, or the consequences of opportunistic infections or neoplasms within the central nervous system (CNS). It is now recognized that the neuropsychiatric manifestations of HIV infection can result from the direct effects of HIV on the brain and CNS or from indirect effects, such as opportunistic infections or tumors associated with immunosuppression, cerebrovascular disease, systemic toxicity, and complications of antiretroviral therapy. As understanding of the broad range of neuropsychiatric manifestations of HIV infection has grown, new classification and diagnostic criteria have replaced the earlier, more inexact terms, such as HIV encephalopathy and AIDS dementia complex, terms that combined diverse cognitive, motor, and affective–behavioral complications. The following sections review neurocognitive functioning in HIV-1 infection and the neuropsychiatric manifestations of such infection and their management.

NEUROPSYCHOLOGICAL MANIFESTATIONS OF HIV-1 INFECTION

Part of "90 - Neuropsychiatric Manifestations of Hiv-1 Infection and Aids "

Neurocognitive Functioning in HIV Infection

HIV-related neurocognitive deficits are manifestations of the direct and indirect effects of HIV on the CNS and can range from subtle changes in attention and psychomotor processing to full-blown dementia (2). Postmortem neuropathologic examination of HIV-seropositive patients has implicated both cortical and subcortical structures, specifically the frontal lobes, subcortical white matter, and basal ganglia (3 ,4 and 5). The caudate nucleus and basal ganglia are primary areas of HIV pathogenesis (6 ,7).

Neuropsychological assessment has played a crucial role in the identification of patterned impairment in HIVinfected persons. It has proved useful in the diagnosis of HIV-related cognitive disturbances and is used widely to quantify changes in cognitive processes associated with treatment. A battery of neuropsychological tests designed to cover the cognitive and behavioral domains affected by

HIV-1 infection has been widely used to assess neurocognitive functioning in HIV-infected persons (8).

Although it is generally agreed that patients in the symptomatic stages of HIV infection and those in whom AIDS has developed exhibit deficits in a variety of cognitive domains (9 ,10 ,11 ,12 and 13), the question of whether significant neurocognitive deficits occur in the asymptomatic stages of infection or in those who are mildly symptomatic remains controversial. Some investigators have found neuropsychological deficits in asymptomatic HIV-seropositive persons (14 ,15 ,16 ,17 ,18 ,19 ,20 and 21 ,22). However, a large number of studies have found subtle or no differences in neuropsychological functioning between asymptomatic HIV-seropositive and HIV-seronegative subjects (23 ,24 ,25 ,26 ,27 ,28 ,29 ,30 ,31 ,32 and 33).

It has been argued that a subgroup of asymptomatic HIV-seropositive patients may show cognitive deficits (12 ,16 ,20 ,34 ,35). In other words, HIV may have a deleterious effect on brain function in certain asymptomatic HIVinfected persons. Evaluating group differences in overall impairment ratings may be the most sensitive and accurate method of assessing neurocognitive impairment in asymptomatic persons (9). In a review of 57 studies that examined neuropsychological functioning in asymptomatic persons, the median percentage of impaired test performances in asymptomatic persons was 35%, and in seronegative persons it was 12% (36). In another review of 36 cross-sectional studies and nine longitudinal studies, about half the reviewed studies indicated no significant difference in neuropsychological test performance between symptomatic and nonsymptomatic participants (37). In the majority of longitudinal studies (66.6%), no cognitive impairment in HIV-positive persons was found at baseline or at subsequent follow-up visits (37). Methodologic differences in study design and analysis probably account for discrepancies between studies.

Asymptomatic persons at risk for neurocognitive impairment have been found to display one of two patterns of deficits: (a) depression, psychomotor slowing, and diminished verbal memory or (b) lowered verbal and nonverbal cognitive functioning in the absence of a mood disturbance (38). Current research indicates that cognitive impairment is uncommon in asymptomatic HIV-seropositive persons (22 ,37), is not associated with deficits in social or occupational functioning (9 ,11), and, when present, is subtle and limited to a few cognitive domains.

It has been estimated that 55% to 86% of persons in the AIDS stages of HIV infection demonstrate significant neurocognitive deficits (9 ,16). Objective impairments in HIV disease include psychomotor slowing, forgetfulness, and difficulties with attention and concentration. In the later stages of HIV infection (symptomatic HIV and AIDS), executive skills and motor speed may also become impaired.

Attention/Concentration

HIV infection has been associated with deficits in attention (9 ,39 ,40 and 41). Specifically, HIV-infected persons show deficits in dual-task or divided-attention paradigms (41 ,42). It has been argued that cognitive slowing may be at the root of the attentional deficits seen in many symptomatic persons (41). Additional work is needed to examine whether other components of attention (e.g., switching, engagement/disengagement, spatial attention) are also disrupted.

Working Memory

One critical cognitive function is “working memory,” the ability to hold information “on line” in the service of performing an impending task (43 ,44). Evidence suggests that persons with HIV infection demonstrate deficits in working memory because of the affinity of HIV-1 for frontal-subcortical circuits (45). Given the anatomic evidence for involvement of frontal and related subcortical structures in executive functioning and HIV infection, it is not surprising that executive processes are affected by HIV infection. In fact, recent studies have found evidence for the *selective* impairment of verbal and spatial working memory processes in HIV-seropositive persons (13 ,45 ,46 ,47 ,48 and 49). Deficits of working memory tend to be observed in the later stages of HIV infection (i.e., after AIDS has been diagnosed) (45).

Learning and Memory

Patients with subcortical disorders (e.g., Parkinson disease, Huntington disease, basal ganglia disease) typically demonstrate deficits of recall in the context of relatively spared recognition memory but show fewer false-positive errors than are typically seen in patients with cortical dysfunction (50 ,51). This pattern, which supposedly reflects a problem with the retrieval of information rather than difficulties with encoding, is also seen in patients with HIV infection (5 ,7 ,12 ,51).

Motor/Psychomotor Speed

Psychomotor slowing appears to be the most common HIV-related neurocognitive deficit and may underlie deficits in higher-order cognitive processes (52). Slowed complex cognitive processing may occur independently of peripheral nerve compromise, basic motor impairment, or psychiatric status (10). Psychomotor and motor impairment in HIV-infected persons has been well documented (5 ,53) and may be evident even in the earliest stages of HIV infection (31 ,39). Reaction time tasks have been particularly helpful in detecting HIV-related cognitive slowing because they allow for a more precise analysis of the effects of HIV on psychomotor processing (42).

Progression of Neurocognitive Deficits

The progression of HIV disease is associated with neurologic deficits (54) and deteriorating neurocognitive performance (9 ,14 ,36 ,55). Neurocognitive impairment is a proximal predictor of AIDS and mortality in HIV-infected persons (56 ,57 and 58). Slowed information processing and memory deficits before the development of AIDS have been associated with mortality independently of Centers for Disease Control and Prevention (CDC) clinical stage, $CD4^+$ T-lymphocyte count, hemoglobin level, antiretroviral treatment, or sociodemographic variables such as age, education, and socioeconomic status (58). Patients with advanced HIV disease who are neurocognitively impaired are at higher risk for death than those at the same stage of infection without cognitive disturbance (56). In addition, prominent psychomotor slowing has been associated with more rapid neurologic progression in persons with HIV-associated dementia (59).

HIV-1-Associated Dementia Complex

In 1986, Navia et al. (60) described a triad of clinical symptoms that were later categorized as AIDS dementia complex (ADC). These symptoms included cognitive impairment, motor dysfunction, and behavioral changes in the context of a diagnosis of AIDS. In this landmark study of 70 patients with AIDS subjected to autopsy, 46 were characterized as demented. The majority of the patients with ADC (63%) had a preexisting diagnosis of AIDS. However, in 37% of the cases, ADC had developed before clinical evidence of AIDS. This finding led to problems with the ADC label because it was evident from the Navia study that a subgroup of patients who did not meet diagnostic criteria for AIDS displayed cognitive symptoms associated with HIV infection. In addition, certain patients displayed some, but not all, of the symptoms necessary to be classified as having ADC.

In 1990, the World Health Organization (WHO) recommended a new diagnostic term, *HIV-1-associated dementia* (HAD), to replace ADC (61). The American Academy of Neurology also adopted this new term for research purposes (62) (Table 90.1). Today, the two terms are often used interchangeably. However, because the progression of HIV infection to AIDS can now be delayed with aggressive antiretroviral therapy, a focus on HIV rather than on AIDS may be a more appropriate way to classify neurocognitive impairment.

I. Sufficient for diagnosis of AIDS
- A. HIV-1-associated dementia complex
  - *Probable* (must have *each* of the following):
    1. Acquired abnormality in at least *two* of the following cognitive abilities (present for at least 1 month): attention/concentration, speed or processing of information, abstraction/reasoning visuospatial skills, memory/learning, and speech/language
       The decline should be verified by reliable history and mental status examination. In all cases, when possible, history should be obtained from an informant, and examination should be supplemented by neuropsychological testing.
    2. At least *one* of the following:
       a. Acquired abnormality in motor function or performance verified by clinical examination (e.g., slowed rapid movements, abnormal gait, limb incoordination, hyperreflexia, hypertonia, or weakness), neuropsychological tests (e.g., fine motor speed, manual dexterity, perceptual motor skills) or both.
       b. Decline in motivation or emotional control or change in social behavior. This may be characterized by any of the following: change in personality with apathy, inertia, irritability, emotional lability, or new onset of impaired judgment characterized by socially inappropriate behavior or disinhibition.
    3. Absence of clouding of consciousness during a period long enough to establish the presence of #1.
    4. Evidence of another etiology, including active central nervous system opportunistic infection or malignancy, psychiatric disorders (e.g., depressive disorder), active alcohol or substance use, or acute or chronic substance withdrawal; must be sought from history, physical and psychiatric examination, and appropriate laboratory and radiologic investigation (e.g., lumbar puncture, neuroimaging). If another potential etiology (e.g., major depression) is present, it is *not* the cause of the above cognitive, motor, or behavioral symptoms and signs.
  - *Possible* (must have *one* of the following):
    1. Other potential etiology present (must have *each* of the following):
       a. As above (see *Probable* #1, 2, and 3).
       b. Other potential etiology is present but the cause of #1 above is uncertain.
    2. Incomplete clinical evaluation (must have *each* of the following):
       a. As above (see *Probable* #1, 2, and 3).
       b. Etiology cannot be determined (appropriate laboratory or radiologic investigations not performed).

[a]From the Working Group of the American Academy of Neurology Task Force, 1991.

TABLE 90.1. CRITERIA FOR A CLINICAL DIAGNOSIS OF HIV-1-ASSOCIATED DEMENTIA[a]

HIV-associated dementia complex is the most common neurologic disorder in HIV infection, affecting 6% to 30% of all infected persons (11 ,63 ,64 and 65). It has an insidious onset, although persons with HAD may experience an acceleration of symptomatology. Before the introduction of highly active antiretroviral therapy (HAART), the median survival time for patients with late-stage HAD was 6 months (60 ,65). HAD affects cognitive, motor, and behavioral functioning, and patients often exhibit apathy, cognitive and motor slowing, and impaired memory, abstract reasoning, and judgment. HAD represents the more severe end of a continuum of HIV-related cognitive deficits; the milder end is represented by the presence of a single cognitive impairment,

such as psychomotor slowing. The deficits observed in this disorder result in impaired social and occupational functioning.
A diagnosis of HAD requires laboratory evidence of HIV-1 infection and the exclusion of other CNS conditions (e.g., toxoplasmosis, CNS lymphoma, cytomegalovirus ventriculitis, cryptococcal meningitis, meningitis associated with syphilis, progressive multifocal leukoencephalopathy). Other causes, such as depression and delirium, which can manifest as cognitive impairment, must also be ruled out.
The American Psychiatric Association has defined dementia due to HIV disease as a dementia that is judged to be the direct pathophysiologic consequence of HIV disease and has outlined its own diagnostic criteria (Table 90.2).

A. The development of multiple cognitive deficits manifested by both
   1. memory impairment (impaired ability to learn new information or to recall previously learned information) and
   2. one (or more) of the following cognitive disturbances:
      a. aphasia (language disturbance)
      b. apraxia (impaired ability to carry out motor activities despite intact motor function)
      c. agnosia (failure to recognize to identify objects despite intact sensory function)
      d. disturbance in executive functioning (i.e., planning, organizing, sequencing, abstracting)
B. The cognitive deficits in criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning.
C. Evidence from the history and physical examination or laboratory findings indicate that the disturbance is the direct physiologic consequence of HIV infection affecting the central nervous system.
D. Deficits do not occur exclusively during the course of a delirium.

TABLE 90.2. DIAGNOSTIC CRITERIA FOR DEMENTIA DUE TO HIV DISEASE

HIV-Associated Dementia and HIV Disease Progression

Price and Brew (66) argued that it is not enough simply to characterize HIV-infected persons as demented or not. Diagnosis should also involve staging of the severity of dementia and a description of specific impairments. Therefore, ADC was divided into different stages to differentiate levels of neurocognitive and neuropsychiatric functioning in HIV-infected persons (Table 90.3).

ADC Stage	Characteristics
Stage 0 (normal)	Normal mental and motor function.
Stage 0.5 (equivocal/ subclinical)	Either minimal or equivocal *symptoms* of cognitive or motor dysfunction characteristic of ADC, or mild signs (snout response, slowed extremity movements), but *without impairment of work or capacity to perform ADL;* gait and strength are normal.
Stage 1 (mild)	Unequivocal evidence (symptoms, signs, neuropsychological test performance) of functional intellectual or motor impairment characteristic of ADC, but able to perform *all but the more demanding aspects of work or ADL;* can walk without assistance.
Stage 2 (moderate)	Cannot work or maintain the more demanding aspects of daily life, but able to perform *basic activities of self-care;* ambulatory, but may require a single prop.
Stage 3 (severe)	Major *intellectual incapacity* (cannot follow news or personal events, cannot sustain complex conversation, considerable slowing of all output) or *motor disability* (cannot walk unassisted, requiring walker or personal support, usually also with slowing and clumsiness of arms).
Stage 4 (end stage)	*Nearly vegetative;* intellectual and social comprehension and responses are at a rudimentary level; nearly or absolutely mute; paraparetic or paraplegic with double incontinence.

ADC, AIDS dementia complex; ADL, activities of daily living.

TABLE 90.3. AIDS DEMENTIA COMPLEX STAGING SCHEME

The course of HAD is highly variable. HAD begins with subtle deficits in cognitive processes (e.g., difficulties with concentration, forgetfulness, mental slowing). In some patients, HAD progresses rapidly after the diagnosis has been made (within weeks to months), whereas other patients show cognitive stability for months or years or very slow neurologic and neurocognitive progression (5 ,50 ,60). Persons in the early stages of HAD often complain of poor concentration, psychomotor retardation, and forgetfulness (60). They typically present with significantly less impairment in functions of daily living, cognition, and social and occupational functioning than is seen in the later stages of HAD. Hallmark symptoms of early-stage dementia are apathy, lethargy, poor concentration, and social withdrawal. Psychotic symptoms are not typically observed at this stage.

The later stage of HAD corresponds to ADC as originally defined, and survival expectancy at this stage may be 6 months or less. Features includes global cognitive dysfunction, significant functional impairment, and psychotic symptoms. Late-stage symptoms also may include aphasia, confusion, disorientation, delusions, hallucinations, seizures,

and muscular weakness and paralysis (particularly in the lower limbs). Advanced dementia may result in disinhibition, mutism, catatonia, and incontinence (5 ,60). Neuropsychiatric complications of late-stage HAD include depression, mania, and psychosis.

The introduction of HAART has altered the course of HIV infection and AIDS and has diminished the CNS manifestations of HIV, even though protease inhibitors exhibit relatively poor penetration of the blood–brain barrier.

Prevalence of HIV-Associated Dementia

An early prospective study of HIV infection in the United States revealed that HAD develops in approximately 15% of patients with AIDS (65). The WHO cross-cultural study examining the neuropsychiatric consequences of HIV infection represents the best study of the prevalence of HAD based on a diverse clinical sample. This study examined persons at five sites around the world (Bangkok, Thailand; Kinshasa, Zaire; Munich, Germany; Nairobi, Kenya; and Sao Paulo, Brazil). The prevalence rates for dementia in patients with AIDS ranged from 4.4% to 6.9% and did not differ between four of the five recruitment centers (in Bangkok, no cases of HAD were recorded). In addition, no patients met the criteria for HAD while in the asymptomatic stage (11). In 1997, the CDC reported that 5% of adults with an AIDS-defining opportunistic illness had HIV encephalopathy (dementia) (67).

Early HIV-1-Associated Cognitive Motor Impairment

To classify appropriately HIV-1-seropositive persons who do not meet the criteria for dementia, the American Academy of Neurology AIDS Task Force introduced the term *HIV-1-associated minor cognitive/motor disorder* (MCMD) (62) (Table 90.4), a correlate of the WHO diagnosis of HIV-1-associated minor cognitive/motor disorder (61). In comparison with HAD, MCMD involves subtler neurocognitive difficulties that may not necessarily affect a patient's activities of daily living or occupational functioning.

II. Not sufficient for diagnosis of AIDS
- A. HIV-1-associated minor cognitive/motor disorder
  - *Probable* (must have *each* of the following):
    1. Cognitive/motor behavioral abnormalities (must have *each* of the following):
       - a. At least *two* of the following acquired cognitive, motor, or behavioral symptoms (present for at least 1 month) verified by reliable history, when possible, from an informant):
         - (1) Impaired attention or concentration
         - (2) Mental slowing
         - (3) Impaired memory
         - (4) Slowed movements
         - (5) Incoordination
         - (6) Personality change, or irritability or emotional lability
       - b. Acquired cognitive/motor abnormality verified by clinical neurologic examination or neuropsychological testing (e.g., fine motor speed, manual dexterity, perceptual motor skills, attention/concentration, speed of processing of information, abstraction/ reasoning, visuospatial skills, memory/learning, or speech/ language)
    2. Disturbance from cognitive/motor/behavioral abnormalities (see #1) causes mild impairment of work or activities of daily living (objectively verifiable or by report of a key informant).
    3. Does not meet criteria for HIV-1-associated dementia complex or HIV-1-associated myelopathy.
    4. *No* evidence of another etiology, including active central nervous system opportunistic infection or malignancy, or severe systemic illness determined by appropriate history, physical examination, and laboratory and radiologic investigation (e.g., lumbar puncture, neuroimaging). The above features should not be attributable solely to the effects of active alcohol or substance use, acute or chronic substance withdrawal, adjustment disorder, or other psychiatric disorders.
    5. Criteria for minor cognitive motor disorder include at least two of the following acquired cognitive, motor, or behavioral symptoms, generally assessed with neuropsychological evaluation:
       - a. Impaired attention or concentration
       - b. Mental slowing
       - c. Impaired memory
       - d. Slowed movements
       - e. Incoordination
       - f. Personality change, irritability, or emotional lability

[a]From the Working Group of the American Academy of Neurology Task Force, 1991.

TABLE 90.4. CRITERIA FOR A CLINICAL DIAGNOSIS OF HIV-1-ASSOCIATED COGNITIVE/MOTOR COMPLEX3

The American Academy of Neurology AIDS Task Force specified that persons with HIV could be given this diagnosis regardless of their medical status. In other words, patients who are otherwise asymptomatic according to the CDC definitions may meet the criteria for MCMD. MCMD and HAD may represent areas along a common continuum of cognitive impairment, but they may also exist as distinct elements (62). However, the pattern of deficits observed in both disorders is characteristic of patients with dysfunction of frontal-subcortical neuronal circuitry (68), which means that persons with HAD or MCMD demonstrate differential deficits in the retrieval of information relative to the encoding or storage of information (51). HIV seropositivity with MCMD has been associated with a poorer prognosis relative to HIV seropositivity without MCMD (56), which suggests that MCMD may be a precursor of HAD.

Confounding Variables

To diagnose HIV-related cognitive deficits in patients (i.e., to conceptualize cognitive impairment in these patients as

specifically related to the HIV virus), other potential causes of neurocognitive impairment must be ruled out. Depression, anxiety, and substance abuse are conditions seen in HIV disease that may contribute to neurocognitive impairment (69 ,70).

Depression and Apathy

Significant depressive symptomatology has been reported in patients with HIV-1 infection (71 ,72 ,73 and 74). Clinical assessments of persons with HIV infection can be confounded by the overlap of symptoms of HIV infection and somatic symptoms of depression (e.g., lack of motivation, low levels of energy, fatigue, weight loss, poor sleep patterns) (75), so that the severity of depression in HIV-seropositive persons is potentially overestimated (76 ,77). Therefore, cognitive and affective symptoms may be more accurate indicators of an underlying mood disorder in persons with HIV/AIDS because somatic symptoms may reflect advanced stages of disease and be unrelated to depression.

Although symptoms of depression and neuropsychological impairment may occur together in many HIV-infected persons, most studies have demonstrated that neuropsychological abnormalities observed in HIV infection are distinct and cannot be attributed to depression *per se* (18 ,35 ,73 ,77 ,78 ,79 ,80 ,81 ,82 ,83 and 84). It has been shown that depressed patients with HIV-1 infection may exhibit deficits in learning and memory (79 ,81 ,85), but the contributions of depression to the development and degree of these impairments appear to be minimal.

Apathy and reduced motivation are frequently observed in HIV-seropositive patients (45 ,60). Apathy, but not depression, also has been associated with deficits of working memory in HIV-seropositive patients, which suggests that both are manifestations of dysfunction in frontal–subcortical circuitry (45).

Substance Abuse

It is well known that HIV infection can be contracted through the intravenous administration of drugs with shared needles. The persistent use of drugs through other routes (e.g., inhaling crack/cocaine) may also increase the risk for HIV infection; drug abusers may practice prostitution to support their habit or engage in risky sexual behavior while under the influence of drugs or alcohol. The use of drugs such as crack/cocaine has been significantly associated with earlier progression to AIDS in HIV-seropositive persons (86). Injection drug use has also been associated with more rapid progression of HAD (59), and recreational drug use has been found to diminish overall neuropsychological performance and reduce visuomotor processing, executive functioning, motor speed and strength, and sensorimotor perception in persons in the early stages of HIV infection (87).

Many investigators have postulated that drug use may increase the risk of HIV-seropositive persons for cognitive impairment (19); possibly, drug use induces CNS impairment independent of that caused by HIV infection. For example, it is known that chronic cocaine use can result in seizures, cerebrovascular accidents, and movement disorders. Deficits in attention, learning and memory (88 ,89 and 90), word production, visuomotor integration (90), and executive function (91) are specifically affected by cocaine use. These deficits have been related to dysfunction in prefrontal brain regions, the orbitofrontal cortex, and the anterior cingulate gyrus (91) and to cerebral hypoperfusion in the frontal, periventricular, and temporal–parietal areas (90). Although this is a plausible hypothesis, most studies have found that substance abuse does not independently contribute to neuropsychological dysfunction after HIV seropositivity is taken into account (92). The interaction of HIV infection and drug use does not appear to produce additional cognitive deficits (26 ,27 ,80 ,93 ,94 ,95 and 96).

Other Cofactors

Other factors may potentially confound the neuropsychological functioning of HIV-infected persons, including gender, ethnicity, level of education, and medication regimen.

Gender and Ethnicity

Racial and ethnic minorities have been disproportionately affected by HIV/AIDS, and women constitute one of the most rapidly increasing groups at risk for AIDS in the United States (96 ,97). Although neuropsychological assessment has been helpful in elucidating patterns of impairment in persons with HIV/AIDS, most of the study participants have been well-educated, Caucasian, homosexual men. It remains unclear whether neuropsychological instruments are equally valid in assessing HIV-related neurocognitive functioning in populations who differ in terms of ethnicity/culture, language, educational background, and socioeconomic status. Neuropsychological tests and batteries, in addition to being sensitive to the presence of cerebral pathology, are also sensitive to demographic factors, including gender, ethnicity, socioeconomic status, education, and age.

Neuropsychological tests may overdiagnose organic impairment in neurologically intact African-Americans (98); thus, clinicians must be cautious about reporting increased neurocognitive impairment among HIV-infected members of minorities. Ideally, separate norms for specific ethnic subgroups (e.g., African-Americans) should be established. Studies that examined the effect of ethnicity on neuropsychological performance in the context of HIV infection have found that after correction for education, ethnicity accounts for additional variance (99). One possible explanation for these findings is that matching for grade level does not always resolve the effects of disparate educational experiences of test subjects. Also, within the African-American population, the incidence of poverty and homelessness is higher, situations that can have a pervasive influence on the

interactions of persons with their environment and thus their performance on neuropsychological tests. Also, many tests ignore the fact that African-Americans display ideals, values, beliefs, and cultural traditions that contribute to unique psychological processes not often tapped by mainstream neuropsychological instruments (100).

African-Americans who were HIV-seropositive and matched for age, education, gender, and HIV disease stage obtained lower scores than their Caucasian counterparts on neurocognitive measures (101). However, acculturation level accounts for the vast majority of these differences in performance. Acculturation level refers to the degree to which a person's beliefs, values, and behaviors are consistent with European-American culture, the dominant cultural basis for most standardized neuropsychological measures. Therefore, it is important to examine acculturation level to improve the accuracy with which HIV-related neurocognitive deficits are diagnosed in ethnic minorities. Manly et al. (101) suggest that measures that assess attention, psychomotor speed, and retention may be of greater utility in assessing HIV-associated cognitive deficits across cultural groups.

African-Americans show a pattern of performance deficits in neuropsychological functioning that are similar to those reported in majority populations. For example, studies have found deficits in verbal and nonverbal memory in symptomatic men (77) and women (102). As in ethnic minority populations, the incidence of HIV-1 infection in women has continued to rise. However, few studies have explored the neuropsychological sequelae of HIV infection in women. It has been reported that HIV-infected women report more psychological symptoms than HIV-infected men (103 ,104) and that the early signs of HIV infection in women are often overlooked and underrecognized in comparison with the symptoms of men (105). HIV disease progression does not appear to differ according to sex (86). Gender does not appear to be related to rates of $CD4^+$ cell decline, first $CD4^+$ count below 200/mm^3, clinical progression to clinical AIDS, or mortality (86).

However, neurocognitive functioning does appear to differ between HIV-seropositive men and women. Whereas HIV-infected men and women show similar vulnerability to cognitive dysfunction, AIDS in women is associated with a poorer neuropsychological test performance (52). Also, the degree of impairment in symptomatic HIV-seropositive women has been found to be greater than that in either HIV-seropositive homosexual men or HIV-seropositive intravenous drug users (106). These differences do not appear to be secondary to differences in age, education, or mood, which suggests that neuropsychological impairment may become apparent earlier in HIV-seropositive women than in HIV-seropositive men.

Few studies have examined neurocognitive functioning solely in HIV-seropositive women. The studies that have been conducted seem to demonstrate a similar pattern of deficits in both women and men. In a longitudinal study, HIV-seropositive women demonstrated slower reaction times and motor speed and less improvement in verbal memory than did seronegative women at 6-month follow-up (107). Cross-sectional analyses have found no differences between asymptomatic women and seronegative controls (30 ,102). However, with progression to AIDS, deficits in attention and memory became evident (102). In a preliminary investigation, Costa et al. (108) found no differences between asymptomatic HIV-seropositive and HIV-seronegative women in quantitative EEG activity during various conditions, nor between the two groups on any of the neurocognitive or neuropsychiatric measures administered.

Psychosocial Variables

Fewer years of education, lower estimated premorbid intelligence, lower occupational attainment, and lower socioeconomic status may put patients at particular risk for HIV-related neurocognitive impairment (38 ,109 ,110). Satz (109) found the rate of impairment in asymptomatic HIV-seropositive participants to be comparable with that of seronegative controls among participants with more than 12 years of education. The rate of impairment in asymptomatic HIV-seropositive participants with 12 or fewer years of education was more than twice that of seronegative controls (38% vs. 17%). Stern et al. (110) found that HIV-seropositive participants with a low cognitive reserve (based on measures of education level, occupational attainment, and vocabulary) performed worse on neuropsychological measures than did HIV-seronegative and HIV-seropositive participants with a high cognitive reserve. According to the cognitive reserve theory, the threshold for neuropsychological symptoms of persons with a greater cognitive or brain reserve may be higher after acquired brain injury (109). These studies suggest that a low cognitive reserve increases one's risk for cognitive dysfunction and underscore the need to consider demographic variables in any evaluation of neuropsychological function in HIV infection.

Clinical Significance of Early Cognitive/Motor Disturbance and Its Relationship to Future Disease

The identification of HIV-related neurocognitive and neuropsychiatric disturbances has potential medical and vocational implications for patients. In particular, cognitive disturbances can affect the ability to adhere to antiretroviral medication regimens and can affect occupational functioning.

Adherence to Medication Regimen

The administration of protease inhibitors in combination with nucleoside analogues has successfully suppressed HIV replication in many persons with HIV-1 infection. However, the long-term effectiveness of medication regimens that include protease inhibitors depends on strict adherence

to the prescribed drug regimen. Poor adherence can lead to changes in plasma levels of HIV RNA and the development of treatment-resistant viral mutations (111). In other words, resistance to a particular drug and cross-resistance to drugs within a particular class can develop in persons who comply poorly with their medication regimen. Understanding the various factors that contribute to medication adherence is critical to optimizing the treatment of persons with HIV/AIDS.

Factors affecting adherence may include relationships with health care providers, complexity of antiretroviral regimens, depression, substance abuse, cultural beliefs, and neurocognitive functioning. Factors affecting medication adherence may vary across HIV disease stage. For example, it is well established that persons in the later stages of HIV infection exhibit neuropsychological deficits associated with frontal–subcortical brain dysfunction. Therefore, in more advanced HIV infection, poor compliance may be related to neurocognitive compromise. Poor adherence to antiviral medication has been associated with poor performance on measures of divided attention, learning and memory, executive function, and psychomotor ability (42 ,112 ,113). Hinkin et al. (42) examined the relationship between neurocognitive and neuropsychiatric symptoms, substance abuse, medication complexity and side effects, and a variety of psychosocial factors in predicting adherence to antiretroviral medication. Medication adherence was assessed by computerized monitoring (medication event monitor system, or MEMS), in which a computer chip embedded in the cap of a pill bottle records the date and time when the bottle is opened. Preliminary data from this group revealed that medication adherence is associated with executive function and prospective memory. Apathy, but not depression, was also found to predict poor adherence.

Employment

It has been proposed that neurocognitive impairment is clinically significant when it affects everyday functioning (114). For some HIV-infected persons, cognitive difficulties result in occupational problems even in the early stages of infection, when cognitive impairment is mild (114 ,115 and 116). When employed persons rated their job performance relative to that before their HIV diagnosis, self-perceived decreases in work abilities were five times more prevalent in those with neurocognitive impairment (114). Impaired persons also performed worse on standardized work samples and displayed more discrepancies between expected levels of functioning (based on work history) and observed levels (based on work samples), which suggested an acquired decrease in vocational abilities (117). Furthermore, HIV-seropositive persons who demonstrated neurocognitive impairment were two to three times more likely to be unemployed than were those without cognitive impairment, even after control for medical status (114 ,115). A poorer performance on tasks of learning and executive functioning seems to be a good predictor of loss of employment status (115).

Pharmacologic Treatment of HIV Infection

Highly active antiretroviral therapy has changed the epidemiology of HIV disease progression. In 1996, the annual AIDS incidence decreased for the first time in the United States. In 1997, this pattern continued as the number of new AIDS diagnoses decreased (97). However, AIDS prevalence increased from 1996 to 1997, probably because of longer survival times after diagnosis. This decline in the incidence of AIDS and AIDS deaths and the observed delay in progression to AIDS are in part a consequence of HAART. In a HAART regimen, three or more antiretroviral drugs, such as a nucleoside analogue reverse transcriptase inhibitor, a protease inhibitor, and a non-nucleoside reverse transcriptase inhibitor, are usually combined.

Before the advent of HAART, monotherapy with zidovudine (AZT) was reported to improve neurocognitive functioning, slow progression to dementia (118 ,119 and 120), decrease neuropathologic features of AIDS (4), and prevent mild cognitive impairment associated with HIV (121).

In a patient population largely comprising persons on monotherapy (81%), treated patients showed superior information processing on a reaction time task (a sensitive measure of HIV-related cognitive slowing) in comparison with untreated participants (48). High doses of AZT are reportedly more effective in improving neurocognitive functioning (120), and long-term use of AZT has been associated with improved cognitive performance in subjects with early symptomatic HIV infection and AIDS (122).

The introduction of protease inhibitors has resulted in new approaches to the treatment of HIV infection. Patients on an HAART regimen perform better than do those treated with less intensive antiretroviral therapy (e.g., regimens that do not include a protease inhibitor) (116). However, persons on combined antiretroviral therapy, regardless of whether a protease inhibitor is included, have shown improved psychomotor speed in comparison with antiretroviral-naïve patients and patients treated with monotherapy (123). Improvement in neurocognitive functioning has been associated with a reduction in viral load (116). HAART has resulted in undetectable levels of HIV in the blood. Even though the CNS penetration of protease inhibitors is poor, multiple drug regimens lower serum viral load, slow disease progression, and in some cases improve HIV-associated cognitive motor complex, reverse HIV encephalopathy, and improve cognitive impairment (124 ,125). Future research will focus on the mechanisms of HAART-associated improvement in neuropsychological functioning and the possibility that the CNS may act as a reservoir for HIV.

PSYCHIATRIC MANIFESTATIONS OF HIV-1 INFECTION

Part of "90 - Neuropsychiatric Manifestations of Hiv-1 Infection and Aids "

Psychiatric Symptoms in HIV-1 Infection

Major depression is the most common psychiatric disease among HIV-1-infected persons (74) Earlier controlled studies showed that the prevalence of major depression and other mood disorders is higher in asymptomatic HIV-1-infected homosexual men than in the general population (126 ,127) but is similar to the prevalence in HIV-1-seronegative homosexual men (71 ,128 ,129). In several early studies, from 4% to 9% of *both* HIV-1-infected and uninfected homosexual men reported a major depression in the month before study evaluation, and in the study of Perkins and colleagues (73), a major depression developed in 6% of both HIV-1-infected and uninfected subjects during a 6-month follow-up period. Evidence also indicates that similar proportions (from zero to 5%) of HIV-1-infected and uninfected persons meet DSM-III-R criteria for current anxiety disorders (73). Thus, after more than 15 years of research, the available data suggest that the prevalence of major depression is high in asymptomatic HIV-1-infected gay men in comparison with the prevalence in men of similar age in the population at large, but no higher than that in seronegative gay men of similar age and somewhat lower than that in patients with serious medical illnesses, such as cancer and heart disease (130 ,131 ,132 and 133). These findings underscore the issue that mood disorders should not be considered a "normal" phenomenon in HIV-1-infected persons. Rather, they should be assessed carefully and treated appropriately.

Diagnosing major depression in HIV-1-infected patients can be complicated because several symptoms of major depression (i.e., fatigue, sleep disturbance, and weight loss) are also common symptoms of progression of HIV-1 disease (134 ,135). However, although complaints of fatigue and insomnia in asymptomatic HIV-1-infected homosexual men are significantly associated with depressed mood and other symptoms of major depression, they are not associated with low $CD4^+$ counts or decreased neuropsychological functioning (136 ,137). Thus, complaints of fatigue and insomnia in otherwise asymptomatic HIV-1-infected patients are highly suggestive of an underlying mood disorder, and patients with such complaints should be assessed routinely for major depression.

Factors that influence the development of major depression in HIV-1-infected persons have not been well studied. However, several studies suggest that the prevalence of a past history of major depression is relatively high in HIV-infected persons and may be a risk factor for the development of major depression (74). The first of these was the study of Perkins and colleagues (73), who found a relationship between major depression in asymptomatic HIV-1-infected homosexual men and a prior history of major depression. Coping with the threat of AIDS also may be related to the overall level of depressed and dysphoric mood. Leserman and colleagues (138) reported that a depressed and anxious mood was less frequent in asymptomatic HIV-1-infected men using active coping strategies to deal with the threat of AIDS (e.g., fighting spirit, reframing stress to maximize personal growth, planning a course of action, seeking social support) than in those using passive coping strategies (denial or feeling helpless). Like the studies of persons with other potentially life-threatening diseases, early studies of HIV-1-seropositive persons found that they usually are able to adjust successfully to their infection and that most are able to maintain hope over time. More recently, the availability of HAART has led to a still greater sense of hope. Therefore, coping strategies in HIV-infected persons may influence the development of depression or anxiety.

Studies of psychiatric and psychosocial factors in HIV-infected women are emerging as the demographics of the HIV epidemic change. Early studies are difficult to interpret because study methodology and populations differed considerably (74). A high rate of major depression was found in women using intravenous drugs, but this rate did not differ from that of men using intravenous drugs (139 ,140); high rates of major depression were found in both seropositive and seronegative men and women using intravenous drugs. However, a gender difference was found; the prevalence of depressive and anxiety symptoms, but not syndromes, was higher in women than in men. This finding held for both seropositive and seronegative subjects. In a related study of Boland et al. (141), HIV status was not related to depressive symptoms at baseline in a large, multicenter, prospective sample of U.S. women. Both seronegative and seropositive women had a high prevalence of depressive symptoms on the Center for Epidemiological Studies Depression Scale (CES-D); however, diagnoses of depressive disorder were not obtained. In the study of Morrison et al. (142), who examined the prevalence of depressive and anxiety disorders in a large cohort of rural U.S. women, the prevalence of major depressive disorder and anxiety symptoms was significantly higher in seropositive women without active substance abuse than in seronegative controls (142).

As reviewed earlier, the effects of HIV-1 on the CNS may result in a variety of neurocognitive and related psychiatric symptoms in the later stages of illness. In addition, persons infected with HIV-1 may be at further risk for the development of psychiatric symptoms because of diseases secondary to AIDS that also have CNS effects and because of medications used to treat HIV-1 infection. Although psychiatric symptoms in HIV-1-infected persons in the later stages of illness may represent new-onset psychiatric disorders, it is more likely that these symptoms reflect the direct CNS effects of HIV-1, HIV-1-related CNS disturbances, and CNS effects of medications used in the treatment of AIDS. Thus, although Leserman and colleagues (138) found an increase in depressive symptoms approximately 1.5 years before the

onset of AIDS, in the study of Rabkin et al. (140), the onset of syndromal depression and anxiety did not increase despite worsening HIV infection during a 4-year period.

Evidence from earlier stages of the epidemic suggests that HIV-1 may cause organic mood disturbance. In a 17-month retrospective chart review of patients with AIDS, Lyketsos and colleagues examined associated historical and clinical features in an attempt to separate organic and functional symptoms (145). They used a family history of mood disorder as a "marker" for functional mood disorders. They further assumed that coexisting dementia and a low $CD4^+$ count are "markers" of HIV-1-related mood disorders. None of the patients with a personal or family history of mood disorder had coexistent dementia, and all but one of the patients without a personal or family history of mood disorder had coexistent dementia. In addition, among the 8% of patients who experienced manic episodes, the $CD4^+$ count was significantly higher in those without a personal history of mood disorder. Although these findings suggest that mania may be a consequence of the direct or indirect effects of HIV-1 on the brain, controlled studies have yet to find this relationship (74). Vitamin B_{12} deficiency may also place HIV-1-infected patients at risk for organic mood disturbance. Between 20% and 30% of patients with AIDS and 7% of asymptomatic HIV-1-infected patients have been reported to have a vitamin B_{12} deficiency. Furthermore, vitamin B_{12} deficiency has previously been shown to be associated with depression and can occur in the absence of hematologic or neurologic signs (146). Although the relationship between vitamin B_{12} level and depressive symptomatology in HIV-1-infected patients is not clear (147), it is prudent that the medical evaluation of depressive symptoms in HIV-1-infected patients include an assessment of serum B_{12} levels.

Although relatively uncommon, psychosis may result from HIV-1 involvement of the CNS. Earlier case studies of symptomatic HIV-1-infected persons have reported psychotic symptoms, including delusions, bizarre behavior, and hallucinations. Mood disturbances, including euphoria, irritability, and labile or flat affect, have often accompanied psychotic symptoms in these patients. Similarly, anxiety and agitation were reported in almost half of the reported cases. In addition, some evidence indicates that psychosis may be a symptom of the terminal stages of AIDS; half of the patients described had a progressively worsening course, with dementia or death occurring within a few months after the onset of psychotic symptoms. Psychosis may be more frequently found in patients with significant AIDS-related neurocognitive impairment than in patients in earlier stages of the disease. In one retrospective chart review of 46 patients identified with HIV-1-associated dementia, Navia and Price (148) found that psychotic symptoms had developed in 15%. Relatedly, data from the San Diego HIV Neurobehavioral Research Center (149) suggest that HIV-1-infected patients with psychosis trend toward greater neurocognitive impairment than do nonpsychotic HIVinfected controls. Thus, new-onset psychosis may be secondary to HIV-related encephalopathy. Accordingly, a complete organic workup should be considered for HIV-1-infected patients with significant disturbance of mood or psychosis.

Treatment of Psychiatric Disorders in HIV-1 Infection

Available evidence suggests that mood symptoms and syndromes in the asymptomatic stage of HIV-1 infection are not secondary to the effects of HIV-1 on the brain and should be evaluated and treated as in the general population. Although confirmatory data are lacking, this probably also holds true in the symptomatic stages of the disease.

Controlled Studies with Antidepressant Drugs

Only a small proportion of the published studies of the treatment of mood disorders in patients with HIV-1 infection have been double-blinded, randomized, placebo-controlled studies. In the study of Rabkin et al. (150), imipramine was effective in 97 HIV-infected patients. At 6 weeks, they found a response rate of 74% in the imipramine group versus 26% in the placebo group. No changes in $CD4^+$ helper/inducer cell counts were found in the imipramine-treated subjects. However, adverse anticholinergic side effects led to discontinuation of imipramine within 6 months in more than one-third of the responders. Elliott and co-workers (151) blindly and randomly assigned 75 HIV-seropositive patients to treatment with imipramine, paroxetine, or placebo. Of the 75 enrolled subjects, 75% completed 6 weeks of treatment; only 45% completed the full 12-week trial. The two antidepressants were found to be equally efficacious at 6, 8, and 12 weeks, and both were significantly more efficacious than placebo. Side effects of the tricyclic antidepressants markedly influenced attrition. The dropout rate in the imipramine group was 48%, 20% in the paroxetine group, and 24% in the placebo group. Zisook and colleagues (152) reported that fluoxetine was more effective than group therapy in a randomized, double-blinded, placebo-controlled study of 47 HIV-seropositive men with major depression. Rabkin and colleagues (153) recently completed a double-blinded, placebo-controlled, 8-week trial with fluoxetine in 120 HIV-seropositive subjects. Among the subjects who completed the 8-week trial, 74% of the fluoxetine group responded to treatment, in comparison with 47% of the placebo group. When intention-to-treat analysis was used, the differences between the treatment groups were less remarkable (57% of the fluoxetine-treated subjects responded compared with 41% of the placebo group). Drug treatment did not alter levels of $CD4^+$ cell counts. Thus, the available data suggest that the selective serotonin re-uptake inhibitors (SSRIs) are effective and well

tolerated in the treatment of HIV-associated major depression.

Open Trials with Antidepressant Drugs

In a study related to the one described above, Rabkin and colleagues (154) enrolled HIV-infected subjects with depression who had failed imipramine treatment (i.e., they had relapsed, could not tolerate the side effects, or did not respond to the drug) in a 12-week open-label trial of fluoxetine. Although depression at baseline as measured on the Hamilton Depression Scale (HAM-D) was more severe in this sample (12.5) than in the imipramine study sample (15.8), 83% of subjects treated with fluoxetine (at doses of 15 to 60 mg/d) responded and exhibited significant reductions in their HAM-D scores. Fluoxetine treatment did not alter $CD4^+$ counts. Fluoxetine was tolerated better than imipramine. In an open-label trial of 28 depressed HIV-infected subjects, Rabkin et al. (155) found a 70% response rate among subjects who had 8 weeks of treatment with sertraline. Side effects resulted in a loss of 18% of the total sample. Sertraline did not alter the counts of either $CD4^+$ cells or natural killer cells.

Ferrando and colleagues (156) conducted a 6-week open-label, parallel-group trial of the SSRIs paroxetine, fluoxetine, and sertraline in 33 symptomatic HIV-infected patients with depression. Seventy-three percent of subjects completed the trial, and of these, 83% responded to their assigned treatment. Most of the subjects who dropped out did so because of complaints of agitation, anxiety, and insomnia during weeks 1 through 3. Both depression and somatic symptoms perceived to be related to HIV infection improved with SSRI treatment. Differences in efficacy between the three SSRIs could not be ascertained reliably because of the study design and small sample size. More recently, these authors performed a small open trial comparing fluoxetine (n = 21) and sertraline (n = 9) in HIV-infected women (157). Sixty percent of the women completed the trial, and of these, 78% were responders (e.g., HAM-D score decreased 50% or more). Grassi et al. (158) performed a 6-week open trial of the efficacy of paroxetine in 10 HIV-seropositive patients with major depression. Significant improvement in HAM-D scores was noted between weeks 2 through 6 of the study. Recently, a 73% response rate was demonstrated with nefazodone in a small open trial of 15 outpatients. Few adverse side effects were noted (159). As discussed in the next section, clinicians must be aware of the potential for drug interactions between antidepressants that potentially inhibit the CPY450 3A4 isoenzyme system and protease inhibitors and for adverse effects of herbal therapy. Although the outcomes of the open-label studies have generally been consistent with those of the available double-blinded, randomized, placebo-controlled trials, these findings must nonetheless be interpreted cautiously.

Effects of Psychostimulants and Novel Agents

Fernandez et al. (160) compared desipramine with methylphenidate in a treatment trial of 15 subjects. With either agent, subjects showed a response rate of approximately 50%; however, subjects treated with desipramine experienced more adverse events, including dry mouth, anxiety, and insomnia. In the open trial of Wagner et al. (161) of 24 patients with AIDS, debilitation, low levels of energy, and a DSM-III-R diagnosis of depressive disorder, the response rate to dextroamphetamine treatment was 75%. Improvements in mood and energy coincided, and analysis revealed significant reductions in HAM-D scores after as little as 2 weeks of treatment. Although systematic follow-up evaluations were not conducted, anecdotal evidence suggested that the treatment effect (improved mood and energy) was maintained for up to 2 years in some subjects. In a small treatment series of Rabkin et al. (154), all seven patients treated with a combination of fluoxetine and dextroamphetamine (5 to 25 mg/d) responded during the 12-week course of treatment, another preliminary observation that warrants further study. Placebo-controlled trials are necessary to confirm these promising observations.

HIV-associated reductions in testosterone levels have been found to correlate with changes in mood, appetite, and energy and with sexual dysfunction. In a double-blinded, placebo-controlled trial (6-week trial followed by 12-week open-label maintenance), testosterone injections were effective in improving both mood and libido, energy, and body muscle mass in 70 HIV-seropositive men with hypogonadal symptoms who completed the trial (162). The authors also found that exercise may augment improvement in psychological and nutritional status in HIV-seropositive patients receiving testosterone therapy (163). In an 8-week open-label pilot study of 45 HIV-positive subjects, the adrenal steroid dihydroepiandrosterone (DHEA) appeared promising for improving mood in addition to anabolic and androgenic parameters (153).

Treatment Considerations for Mood Disorder and Other Psychiatric Conditions

Antidepressant therapy is effective and can improve the quality of life of HIV-infected persons. SSRIs and newer agents may be particularly well suited for use in depressed HIV-seropositive patients because these agents do not produce the significant side effects (e.g., anticholinergic, α-adrenergic, histaminergic, and cardiac effects) caused by the tricyclic agents and other older classes of antidepressants (164). Further study is required.

Pain is frequently undertreated in patients with HIV infection (165), although it is well established that antidepressants are effective agents for the treatment of chronic pain, particularly antidepressants with noradrenergic properties (132). However, patients with AIDS experience adverse effects

more frequently with tricyclic antidepressants than do patients with AIDS-related complex and asymptomatic HIV-seropositive patients (166). Better-tolerated antidepressants with effects on serotoninergic and noradrenergic neurotransmitter systems include venlafaxine, mirtazepine, and paroxetine; these may prove useful and are awaiting controlled studies. Finally, placebo-controlled clinical trials have not demonstrated that stimulants are effective in treating primary depression (167), but they may be useful adjunctive agents in depressed patients with HIV infection, as noted above.

Treatment of Psychotic Symptoms

The treatment of psychotic disorders in HIV-infected patients has been less well studied than the treatment of mood disorders. Several reports have noted that HIV-seropositive patients may be more sensitive to the extrapyramidal side effects associated with dopamine-receptor antagonists (149 ,168). This is thought to be related to the subcortical motor slowing associated with HIV infection. In a case series of 21 patients with psychotic symptoms (12 had mania with psychotic features), risperidone was found to be efficacious and caused fewer side effects than did conventional antipsychotic drugs (169), although some anecdotal data suggest that the sensitivity of AIDS patients to both older and newer antipsychotic agents may be increased (170). Controlled studies are needed in this area.

In general, the same strategies used to treat the general population with psychotropic drugs are appropriate in HIV-infected patients with psychotic symptoms or mood disorders. Pharmacologic knowledge can be used to therapeutic advantage and to avoid potential untoward effects. Factors such as drug interactions related to psychotropic drug metabolism and protein binding, half-life, and effects on appetite require careful consideration, particularly in more debilitated HIV-infected patients. Potential interactions between psychotropic drugs and the antiretroviral agents used in HIV therapy with multiple drugs warrant consideration by the clinician because a potential for drug interactions exists. Psychotropic drugs, non-nucleoside reverse transcriptase inhibitors, and protease inhibitors may serve as substrates for various cytochrome P-450 enzymes in the liver. Each of these classes of compounds may possess enzyme-inducing or enzyme-inhibiting properties, and drugs such as the protease inhibitor ritonavir may simultaneously modify a number of isoenzymes (171).

The nontraditional herbal psychotropic agents used to treat psychiatric syndromes must also be monitored closely in HIV-positive patients. An open-label study recently revealed that the efficacy of the protease inhibitor indinavir (which is a metabolized by the 3A4 isoenzyme system) is markedly reduced by the concomitant administration of St. John’s wort (a potent inducer of the 3A4 system) (172). The reduction in indinavir levels was estimated to be sufficient to cause drug resistance and treatment failure. Finally, given that psychotropic drugs such as antidepressants can improve the quality of life of HIV-positive persons, further research is needed to determine whether effective treatment can improve medical outcomes in selected subsets of HIV-infected patients.

Psychoneuroimmunology of HIV-1 Infection

The multifactorial nature of HIV infection has led researchers to examine the influence of stress, depression, and other psychosocial factors on the course of this disease. A growing literature points to the potentially harmful effects of stress and depression on cellular immunity (173 ,174 ,175 and 176), and to the potentially negative impact of these psychosocial factors on the course of several types of cancer (177 ,178 ,179 and 180). Among patients with breast cancer, severe life stress has been associated with a greater probability of relapse (179), and psychosocial interventions to improve coping skills have resulted in increased numbers and function of natural killer cells and longer survival in patients with breast cancer or melanoma (177 ,178 ,181). These studies await replication.

Early findings on the significance of depression in predicting a decline in immune status and disease progression were inconsistent. Investigators found no relationship between psychosocial and psychiatric factors such as depressive disorders, distress, and stressors, on the one hand, and measures of HIV-1 disease progression, including $CD4^+$ and $CD8^+$ cell counts, on the other. However, a relationship was noted between the number and severity of HIV-related symptoms and levels of depressive disorders, distress, and stressors (182 ,183 and 184). In a 1996 metaanalysis, Zorilla et al. (185) found that depressive symptoms were longitudinally related to self-reported symptoms of HIV infection, but not to changes in $CD4^+$ T-lymphocyte counts or other commonly accepted markers of HIV disease progression. The mixed findings of this metaanalysis may have resulted from the inclusion of studies in which cross-sectional designs and relatively brief follow-up periods were used.

Prospective studies conducted for longer time intervals have found that depression may significantly predict HIV disease progression. In the San Francisco Men’s Health Study, a 9-year longitudinal study of 395 seropositive gay men, researchers found that subjects classified as depressed at study entry on the CES-D (186) progressed more rapidly to AIDS (187). The median time to first AIDS diagnosis was 6.2 years for subjects who were depressed at study entry and 7.6 years for nondepressed subjects. This finding held after control for baseline demographic variables, $CD4^+$ T-lymphocyte count, HIV-related medical symptoms, and health habits. At 5 years, this cohort showed no significant association of baseline depression with AIDS diagnosis; however baseline depression was associated with a decline in $CD4^+$ T lymphocytes (188). After 7 years of follow-up,

subjects with elevated depressive symptoms at every visit had a 1.7 times greater risk of mortality than did those who had never had an elevated depression score (189).

Initial analysis of 1,809 HIV-seropositive gay men in the Multicenter AIDS Cohort (MAC) study found no relationship between baseline depression, measured by the CES-D, and progression of HIV infection during 8 years of follow-up (190). Disease progression was defined as time to AIDS, death, or decline in $CD4^+$ T lymphocytes. In a subsequent report on years 2 through 6, a robust increase of 30% to 104% above baseline levels (depending on CES-D depression cut point) was noted in self-reported depressive symptoms beginning 1.5 years before a clinical diagnosis of AIDS and continuing beyond the diagnosis of AIDS (191). The authors interpreted these findings as an indication that depression may increase toward the later stages of HIV infection and thus be a manifestation of the HIV disease process. However, a subsequent survival analysis of these data, in which the level of depressive symptoms during the 6 months before AIDS diagnosis was used, showed no relationship between depression and time to death (144). A limitation of both these prospective cohort studies is the method of ascertainment of depression. The CES-D is not a clinical diagnostic tool; its sensitivity for DSM-III major depression is 80% to 90%, and its specificity is 70% to 80% (192).

The Coping in Health and Illness Project (CHIP) is a prospective study of initially asymptomatic HIV-infected gay men who are followed every 6 months; extensive clinical interviews are used to define depression and stressful life events. An analysis of this cohort at study entry showed a significant effect of stress on parameters of cellular immunity (143); furthermore, depressive symptoms, especially in the presence of severe stress, were related to declines in several lymphocyte subsets (e.g., CD16 and CD56 natural killer cells and CD8 cytotoxic suppressor cells) during a 2-year period (193). At 5.5 years, an increased risk for AIDS was associated with a higher cumulative level of depressive symptoms, measured by a modified Hamilton Depression Rating Scale (HDRS) excluding somatic symptoms that could be related to HIV disease. For every increase of one severe depressive symptom (3-point increment on the HDRS), the risk for AIDS doubled (194). This result, however, lost statistical significance after control for stressful life events and social support, which overlapped with depressive symptoms. The small number of subjects with elevated scores may partially account for this outcome.

The CHIP investigators are also directly investigating the effect of stressful life events on clinical outcome. Evans et al. (195) found that for each severe stressful event per 6-month study interval, the risk for early HIV disease progression doubled in men studied for up to 3.5 years. At 5.5 years (194) and 7.5 years (196) of follow-up of the CHIP cohort, Leserman et al. reported that more cumulative stressful events were associated with faster progression to AIDS. At both time points in follow-up, every increase in cumulative average stress equivalent to one severe stressor or two moderate stressors doubled the risk for AIDS. At 7.5 years, 47% of those above the median for stressful life events had progressed to AIDS, versus 27% of those below the median. Higher levels of serum cortisol were also associated with faster progression to AIDS, but variations in cortisol did not account for the stress findings (196).

Other studies also lend support to the hypothesis that stressful events may hasten the progression of HIV infection. In the study of Kemeny and Dean (197), the stress of bereavement before study entry was associated with a more rapid decline in $CD4^+$ count during 3 to 4 years of follow-up in 85 gay men. Bereavement did not predict progression to AIDS or mortality rate. Ironson et al. (198) found that in men with whose distress was greater at the time of HIV serostatus notification, the likelihood for the development of HIV-related clinical symptoms at 2-year follow-up was greater. In a recent study of 67 asymptomatic HIV-infected African-American women, trauma (e.g., death of child, assault, rape), particularly among those with posttraumatic stress disorder, was associated with a greater decrease in the $CD4^+/CD8^+$ ratio during 1 year of follow-up (199).

It is noteworthy that studies in which relatively short follow-up periods and questionnaire methods are used to assess life stress have generally not shown an association of stress with reduction in $CD4^+$ T-lymphocyte counts. Studies that examine actual stressors (e.g., bereavement) or interview-based contextual ratings of cumulative stressful events are more likely to show such results than studies based on questionnaire assessments of stress.

Other psychosocial variables (social support and coping) have been linked to HIV disease progression. Recently, Leserman and colleagues reported faster progression to AIDS during 5.5 and 7.5 years of follow-up in men with less cumulative average social support satisfaction and more cumulative average denial (194 ,196). These findings echo those of some earlier research showing potentially harmful effects of denial and potentially beneficial effects of social support (200 ,201 and 202). In the study of Antoni and colleagues (203), HIV-infected gay men scoring above, rather than below, the median on passive coping strategies (e.g., denial, behavioral and mental disengagement) had lower $CD4^+/CD8^+$ ratios and lymphocyte proliferative responses to phytohemagglutinin at 3 weeks and 1 year after serostatus notification. An increase in denial from before to after serostatus notification was also associated with a greater probability of development of symptoms and AIDS during a 2-year follow-up study of gay men (198). In the study of Solano and colleagues (201) of 100 male and female HIV-infected subjects, those who became symptomatic after 1 year had shown more denial and less “fighting spirit” at baseline.

The findings of other studies regarding the effects of social support have been less consistent. Larger social networks

and greater emotional support predicted longer survival during 5 years in men who were symptomatic or had AIDS; however, larger social networks were associated with faster progression to AIDS in those who were asymptomatic at entry (202). Loneliness was associated with a more rapid decline in $CD4^+$ levels but was unrelated to AIDS or mortality during 3 years of follow-up in 205 symptomatic HIV-infected men (204). Other prospective studies have reported no significant associations of social support with HIV disease progression or decline in $CD4^+$ T lymphocytes (205).

In summary, the evidence is substantial that psychosocial factors such as depression and stressful life events may adversely affect disease progression in persons infected with HIV. It must be noted that most of the cited studies of psychosocial moderators of HIV infection have been conducted in men, primarily before the advent of protease inhibitors. Therefore, we need additional studies of women and patients currently on HAART.

CONCLUSION

Part of "90 - Neuropsychiatric Manifestations of Hiv-1 Infection and Aids "

Considerable preclinical and clinical research has been conducted in an effort to describe the neuropsychiatric manifestations of HIV-1 disease and increase our understanding of its underlying neuropathologic mechanisms. The virus enters the CNS early in the course of disease and causes both direct and indirect CNS effects. Subtle abnormalities can be detected on pathologic, neuroimaging, and neuropsychological studies before the onset of AIDS-defining illnesses, although the clinical significance of these findings continues to be unclear. In symptomatic AIDS, neuropsychiatric and neurologic complications are prevalent, and these can often be among the first manifestations of AIDS.

Since the earliest years of the HIV epidemic, most persons infected with HIV-1 have coped well. Major depression continues to be the most prevalent common psychiatric diagnosis in HIV-1-seropositive men; the prevalence is high compared with epidemiologic estimates in the general population, but it is similar to that in seronegative gay men and no higher than that in patients with other serious medical illnesses. The interrelationships between the CNS, endocrine system, and immune system are being actively investigated. Moreover, recent studies suggest that stress and depression may adversely affect immune function and accelerate the progression of HIV-1 disease. However, these studies require confirmation by comprehensive, longitudinal investigations in which similar methodologies are used. Future study is also necessary to increase our understanding of the neuropsychiatric manifestations of HIV-1 infection in women and its special effects on neurologic development in infants and children.

Recent controlled trials of psychopharmacologic treatment have yielded positive results for the alleviation of depression, and preliminary evidence also indicates a reduction in neurocognitive impairment. Future neuropsychopharmacologic approaches will likely focus on both direct and indirect effects of HIV-1 in the brain in an effort to develop novel interventions that may alter the course of disease and symptomatic treatments to improve clinical outcome and quality of life. The long-term impact of HAART on HIV-related CNS disease and associated neuropsychiatric manifestations will also be extensively studied.

The concept of dementia with Lewy bodies (DLB) has been slowly gaining momentum since 1961, when Okazaki et al. (1) published case reports about two male patients, ages 69 and 70 years, who presented with dementia and died shortly thereafter with severe extrapyramidal rigidity. Autopsy showed Lewy body pathology in the cerebral cortex. During the next 20 years, a total of 34 such cases was reported, all by Japanese workers, who adopted the term *diffuse Lewy body disease* to describe the typical distribution of Lewy bodies in subcortical and cortical regions (2).

During the following decade, cortical Lewy body pathology was found in up to 20% of all cases of elderly demented patients reaching autopsy (3 ,4 and 5), and in 1990, Hansen et al. (6) reported that 36% of patients given a clinical diagnosis of Alzheimer disease (AD) had Lewy bodies at autopsy—the Lewy body variant of AD (6). The significance of these reports was unclear—whether this was a new type of dementing disorder that had not previously existed, or whether the Lewy bodies had previously been overlooked. Reexamination of original material from a cohort of autopsy material collected during the 1960s in Newcastle upon Tyne revealed that 17% of the cases had cortical Lewy bodies, a prevalence similar to that found today. It appears, then, that DLB is not a new disorder but is one that has only recently been recognized, even though it is the second most common form of degenerative dementia in old age, only AD being more common.

Lewy bodies are spherical, intracytoplasmic, eosinophilic, neuronal inclusions; they have a dense hyaline core and a halo of radiating filaments composed of abnormally truncated and phosphorylated intermediate neurofilament proteins that include ubiquitin and associated enzymes. They were first described by the German neuropathologist Friederich Lewy when he was working in Alzheimer's laboratory in Munich between 1910 and 1912. Subcortical Lewy bodies are easily seen with conventional hematoxylin and eosin staining. The presence of Lewy bodies in pigmented brainstem nuclei (the substantia nigra in particular), coupled with neuronal loss and gliosis, comprise the characteristic pathologic findings in the prototypal Lewy body disease, which is Parkinson disease (PD).

Cortical Lewy bodies lack the characteristic core and halo appearance of their brainstem counterparts and were therefore difficult to detect until the late 1980s, when the development of anti-ubiquitin immunocytochemical staining methods allowed their true prevalence to be appreciated (4). More recently, α-synuclein antibodies have been shown to label purified Lewy bodies, and the α-synuclein antibodies PER1 and PER2 strongly stain Lewy bodies and Lewy neurites (7 ,8) (Fig. 91.1). Axon pathology in DLB involves not only α-synuclein but also ß- and γ-synucleins (9). α-Synuclein antibodies reveal presynaptic axon pathology in various regions of the hippocampus, and γ-synuclein antibodies detect axonal spheroid-like inclusions in the dentate molecular layer.

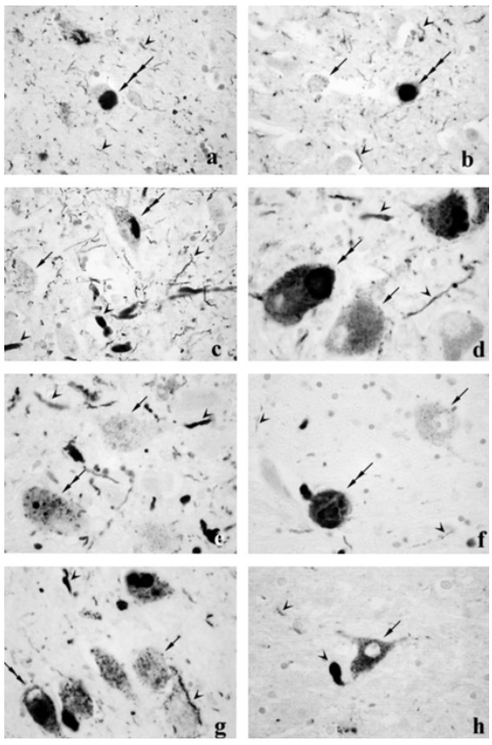

FIGURE 91.1. Examples of α-synuclein pathology from cases with Parkinson disease or dementia with Lewy bodies. Immunohistochemistry was performed with α-synuclein monoclonal antibodies from Novocastra Laboratories on formalin-fixed, paraffin-embedded sections pretreated with formic acid, Vectastain Elite ABC peroxidase kit, diaminobenzidine tetrahydrochloride (DAB), and hematoxylin counterstain. *Single arrow*, granular neuronal inclusions. *Double arrow*, combined granular and solid irregular neuronal inclusions. *Triple arrow*, Lewy body-like neuronal inclusions. *Arrowhead*, thin and thick neurites. See color version of figure.

Current opinions on the classification of Lewy body disorders is that a spectrum of disease exists, with the clinical presentation varying according to the site of Lewy body formation and neuronal loss (10) (Table 91.1). Although “pure” presentations are seen in clinical practice, heterogenous combinations of parkinsonism, dementia, and signs of autonomic failure are most frequent. Recommendations have recently been made as to which brain regions should be examined for Lewy bodies, and a simple, semiquantitative scoring system has been devised in which a score of 1 is assigned if any Lewy bodies are seen in a given area and a score of 2 if more than five are seen per field (11). These

scores are then added to generate three possible pathologic categories—brainstem-predominant, limbic (or transitional), and neocortical DLB. It has not yet been established to what extent these three patterns of pathologic distribution correlate with different clinical profiles. Extensive neocortical pathology is not necessary for the development of dementia or other psychiatric symptoms, all of which may occur in the presence of limbic disease alone.

Region Primarily Affected	Clinical Syndrome	Classification
Substantia nigra	Extrapyramidal movement disorder	Parkinson disease
Limbic cerebral cortex	Cognitive decline and neuropsychiatric symptoms	Dementia with Lewy bodies
Sympathetic neurons in spinal cord	Autonomic failure	Primary autonomic failure
Dorsal vagal nuclei	Dysphagia	Lewy body dysphagia
Pedunculopontine nucleus[a]	Sleep disturbance	REM sleep behavior disorder

REM, rapid eye movement.
[a]Precise clinicopathologic correlate for this is yet to be established, although involvement of the pedunculopontine nucleus is highly probable from current data.

TABLE 91.1. PRIMARY LEWY BODY DISORDERS

A heated debate has surrounded the interpretation of the Alzheimer-type changes that are also seen in most patients with DLB. Numerous senile plaques are found in most, although these are morphologically indistinguishable from those of pure AD (12). Two reports have appeared of a relative sparsity of ß-amyloid proteins 1 through 40 in DLB in comparison with AD (13 ,14). However, the plaques are seldom tau-immunoreactive, and indeed in 80% to 90% of cases of DLB, no evidence of significant neocortical tau pathology, paired helical filaments, or neurofibrillary tangles can be found (15). Whether or not DLB is considered to be a variant of AD depends on the pathologic definition of AD used (16). Thus, 77% of cases with Lewy body pathology and dementia had “plaque-only” AD, a concept derived from definitions of AD that depend heavily on plaque density. By contrast, 80% to 90% of DLB cases failed to fulfill definitions of AD that require numbers of neocortical neurofibrillary tangles above a certain threshold (17). The new NIA/Reagan Foundation criteria for AD appear to be responsible for a significant shift in this direction, with a proposed requirement for frequent neurofibrillary tangles equivalent to Braak stages 5 and 6 (18). DLB and pure AD are, according to such criteria, pathologically distinct in the majority of cases. Gomez-Isla et al. (19) recently concluded that the lack of a relationship between the extent of Alzheimer-type changes and Lewy body formation in DLB suggests that DLB is a distinct disease rather than a variant of AD.

In summary, at least three anchor points appear to be recognizable along a spectrum of neurodegenerative disorders. PD is a disorder of predominantly subcortical Lewy body neurofilament inclusions, which are the most visible markers of an extensive neuritic degeneration involving α-synuclein and ubiquitin. A more extensive distribution of Lewy bodies typifies DLB, in which significant ß-amyloidosis and senile plaque formation that fall short of what is seen in AD are also usually present. AD, in contrast, is characterized by a combination of ß-amyloidosis and neocortical neurofibrillary tangles—the latter representing dysregulation of microtubule assembly proteins—tau-related cytoskeletal abnormalities that are not found in most cases of DLB.

Alzheimer disease and DLB do share the features of ß-amyloidosis, senile plaque formation, and severe depletion of acetylcholine, which is even greater in DLB than in AD. Interestingly, they both also share an increased frequency of apolipoprotein e4 allele (20), which is not seen in nondemented cases of PD. Additional vascular changes are seen in up to 30% of cases of AD and DLB.

CLINICAL FEATURES

Part of "91 - Dementia with Lewy Bodies "

Most cases of DLB coming to autopsy are men (21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 and 29). Although the mean age at onset and survival are similar to those in AD, survival times in DLB are sometimes skewed by rapidly progressive illness. The reduction in survival is probably partly attributable to neuroleptic sensitivity reactions (23). More recently, no differences in age at onset or survival were reported by Heyman et al. (30) and Walker et al. (31) between 24 and 32 patients with DLB and 74 and 43 patients with AD, respectively, although cognitive decline appeared to be faster in DLB (32).

Dementia is usually, but not always, the presenting feature of DLB; a minority of patients present with psychosis in the absence of dementia, some with mood disorders or psychosis, and others with orthostatic hypotension and falls. Fluctuation occurs in half to three-fourths of patients, but the range reported is wide, probably because this is such a difficult symptom to define. Fluctuation, irrespective of definition, is not commonly seen in AD. Visual hallucinations are present in one-third to one-half of DLB patients, although in some series the prevalence is 80%. Auditory hallucinations may occur in 20% of DLB subjects but seldom in AD. Depressive symptoms are common in both disorders, but a 38% prevalence in DLB is significantly greater than that in AD and similar to the rates reported in PD. Shimomura et al. (33) reported disproportionately more severe visuoperceptual, visuoconstructive, and visuospatial dysfunction and disproportionately milder impairment of memory. Ballard et al. (34) reported that although recent memory function is better preserved, visuospatial praxis is more impaired, a finding that potentially provides a psychological tool for differentiating DLB from AD.

A history of bursts of vigorous movements of the arms and legs with vocalization during sleep and associated with dream recall is highly suggestive of rapid-eye-movement (REM) sleep behavior disorder. Although REM sleep disorder may occur in, or indeed precede, a range of neurodegenerative disorders, including PD and multiple-system atrophy, in the context of degenerative dementia it suggests DLB (35).

The reported frequency of extrapyramidal signs in DLB varies greatly. Furthermore, the presence of extrapyramidal signs in DLB and their value in discriminating DLB from AD is unresolved. A number of issues must be considered in this context. First, the “background” population prevalence of parkinsonism is very common in the age range in which both DLB and AD occur. In one recent community-based study of 467 residents, parkinsonism (defined as the presence of at least two of the following: bradykinesia, gait disturbance, rigidity and tremor) was found to affect nearly

15% of people 65 to 74 years of age, 30% of those 75 to 84, and 52% of those 85 and older (36). Second, a wide range of frequencies (5% to 90%) of extrapyramidal signs has been reported in patients with AD (37). Although this may be related in part to differences in disease severity and study duration, it also likely reflects imprecision in the clinical definition of so-called extrapyramidal signs. Thus, predominantly cortically determined signs, such as ideomotor apraxia, paratonic rigidity (Gegenhalten), and frontal gait disorder, may be mistaken for bradykinesia, parkinsonian rigidity, and parkinsonian gait, respectively. Such motor disturbances produce “pseudoparkinsonism,” which is fundamentally different from the true parkinsonism determined by basal ganglia pathology (38). Finally, the reported rates for parkinsonism in DLB undoubtedly partly reflect case ascertainment biases. Patients collected through neurologic departments, which primarily receive referrals for movement disorders, are more likely to exhibit extrapyramidal signs than are DLB cases identified through memory clinics and psychogeriatric services.

Overall, probably fewer than half of DLB cases have extrapyramidal signs at presentation, and a fourth continue to have no evidence of them throughout their illness. Clinicians must therefore be prepared to diagnose DLB in the absence of parkinsonism—if they do not, their case detection rates will be unacceptably low.

When extrapyramidal signs do occur in DLB, a number of studies have contrasted them with the signs in PD in an attempt to characterize parkinsonian syndrome and identify potential diagnostic markers for DLB (39 ,40). In comparison with PD, less resting tremor and myoclonus, greater disease symmetry (especially at presentation), and a poor response to levodopa have all been reported for DLB, albeit inconsistently. It should be emphasized that any differences reported reflect group differences. The positive predictive value of any particular sign, or combination of signs, in differentiating DLB from PD in an individual patient has not been established. In common with PD, rigidity and bradykinesia, hypophonic speech, masked facies, stooped posture, and festinant gait have all been reported for DLB.

Finally, recurrent falls affect up to a third of DLB cases, a proportion significantly greater than in AD, as does neuroleptic sensitivity, detected in 61% of all DLB patients who receive neuroleptics but in only 15% of AD patients. Two studies have examined interrater reliability and found agreement rates and κ values to be acceptable for some symptoms of DLB, such as delusions, hallucinations, parkinsonism, and falls, but unacceptably low for others, particularly fluctuation (41 ,42).

The recent consensus criteria for the clinical diagnosis of DLB are shown in Table 91.2 (11). Emphasis is placed on the particular characteristics of the dementia syndrome—attentional deficits and prominent frontal–subcortical and visuospatial dysfunction. Fluctuation is no longer essential for the diagnosis, although it is frequently present. It seems probable that the fluctuating attentional deficit is linked to dysregulation of central cholinergic mechanisms controlling the level of consciousness (see section below on neurochemical clinical–pathologic relationships). The important hallucinatory symptoms are specified as visual, recurrent, and detailed, usually occurring most days of the week; they are typically colorful, three-dimensional images of animals and children. Insight into the unreal nature of these hallucinations is usually absent while they occur but is gained after the event. Ballard et al. (43) reported that more than 90% of patients with DLB experience such hallucinations and that in comparison with those of AD, the hallucinations are more persistent and the images are more likely to be accompanied by vocalization. Spontaneous parkinsonism not attributable to medication is a key symptom in most patients with DLB. If two of these three symptoms (fluctuations, visual hallucinations, and parkinsonism)

are present, a diagnosis of probable DLB is made; if only one is present, a diagnosis of possible DLB is allowed.

TABLE 91.2. CONSENSUS CRITERIA FOR THE CLINICAL DIAGNOSIS OF PROBABLE AND POSSIBLE DEMENTIA WITH LEWY BODIES

Consensus criteria for the clinical diagnosis of *probable* and *possible* dementia with Lewy bodies (DLB)

1. The central feature required for a diagnosis of DLB is progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function. Prominent or presistent memory impairment may not necessarily occur in the early stages but is usually evident with progression. Deficits on tests of attention and of frontal–subcortical skills and visuospatial ability may be especially prominent.
2. Two of the following core features are essential for a diagnosis of *probable* DLB; one is essential for *possible* DLB.
   a. Fluctuating cognition with pronounced variations in attention and alterness
   b. Recurrent visual hallucinations that are typically well formed and detailed
   c. Spontaneous motor features of parkinsonism
3. Features supportive of the diagnosis are the following:
   a. Repeated falls
   b. Syncope
   c. Transient loss of consciousness
   d. Neuroleptic sensitivity
   e. Systematized delusions
   f. Hallucinations in other modalities
   (Depression and REM sleep behavior disorder have been suggested as additional supportive features.)
4. A diagnosis of DLB is less likely in the presence of
   a. Stroke disease, evident as focal neurologic signs or on brain imaging
   b. Evidence on physical examination and investigation of any physical illness, or other brain disorder, sufficient to account for the clinical picture

DLB, dementia with Lewy bodies; REM, rapid eye movement.
Adapted from McKeith IG, Galasko D, Kosaka K et al., Consensus guidelines for the clinical and pathologic diagnosis of dementia with Lewy bodies (DLB): report of the consortium on DLB international workshop. *Neurology* 1996;47:1113–1124.

The sensitivity and specificity of the consensus clinical criteria against autopsy findings have been examined in several studies (Table 91.3). All find the diagnostic specificity to be relatively high, comparable with that of existing clinical criteria for AD and PD. This high specificity suggests that the DLB clinical criteria are appropriate for confirmation of the diagnosis (few false-positives). Sensitivity of case detection is reported as more variable and generally lower. The tendency to clinical underdiagnosis was noted during the second international workshop on DLB (44). However, two studies prospectively applying consensus criteria (as opposed to retrospective inspection of previous case records) did detect more than 80% of autopsy-confirmed DLB cases (45 ,46). A prospective validation study in Newcastle reported on a sample of 50 hospital-referred demented cases followed to autopsy (46). The sensitivity and specificity for a clinical diagnosis of probable DLB were 0.83 and 0.95, respectively.

DIFFERENTIAL DIAGNOSIS

Part of "91 - Dementia with Lewy Bodies "

Four main categories of disorders should be considered in the differential diagnosis of DLB. These are the following:

1. Other dementia syndromes. Sixty-five percent of autopsy-confirmed DLB cases meet the NINCDS/ADRDA clinical criteria for probable or possible AD (47), which is the most frequent clinical misdiagnosis applied to patients with DLB presenting with a primary dementia syndrome. For this reason, DLB should routinely be excluded when a diagnosis of AD is made. Up to a third of DLB cases are additionally misclassified as vascular dementia on the Hachinski ischemic index by virtue of the fluctuating nature and course of the illness. However, pyramidal and focal neurologic signs are usually absent. The development of myoclonus in patients with a rapidly progressive form of DLB may lead the clinician to suspect sporadic Creutzfeldt–Jakob disease (11).
2. Other causes of delirium. In patients with intermittent delirium, appropriate examination and laboratory tests should be performed during the acute phase to maximize the chances of detecting infective, metabolic, inflammatory, or other etiologic factors. Pharmacologic causes are particularly common in elderly patients. Although the presence of any of these features makes a diagnosis of DLB less likely, comorbidity is not unusual in elderly patients, and the diagnosis should not be excluded simply on this basis.
3. Other neurologic syndromes. In patients with a prior diagnosis of PD, the onset of visual hallucinations and fluctuating cognitive impairment may be attributed to side effects of antiparkinsonian medications, and this possibility must be tested by dose reduction or withdrawal. Other neurodegenerative akinetic-rigid syndromes associated with a poor response to levodopa, cognitive impairment, and postural instability include progressive supranuclear palsy, corticobasal degeneration, and progressive subcortical gliosis. Normal-pressure hydrocephalus must be considered in a patient with so-called lower-body parkinsonism, cognitive impairment, and urinary incontinence. Syncopal episodes in DLB are often incorrectly attributed to transient ischemic attacks despite an absence of focal neurologic signs. Recurrent disturbances in consciousness accompanied by complex visual hallucinations may suggest complex partial seizures (temporal lobe epilepsy), and vivid dreaming with violent movements during sleep may meet the criteria for REM sleep behavior disorder. Both these conditions have been reported as uncommon presenting symptoms of autopsy-confirmed DLB. Patients with REM sleep behavior disorder differ clinically from those without, performing worse on attentional tasks (48).
4. Other psychiatric disorders. If parkinsonian features or cognitive decline develops spontaneously in a patient, or if a patient shows excessive sensitivity to neuroleptic medication in the course of late-onset delusional disorder, depressive psychosis, or mania, the diagnosis of DLB should be considered.

NEUROTRANSMITTER ABNORMALITIES

Part of "91 - Dementia with Lewy Bodies "

Neurochemical activities have been widely investigated in AD and PD, including in some instances PD with dementia, but fewer reports are available on DLB. These are summarized in Table 91.4 as they relate to neurotransmitter systems.

[b]Denotes more extensive in PD + dementia.
[c]Striatal activities.

Reductions in presynaptic cholinergic activities, particularly in the cerebral neocortex, are more marked in DLB than in AD and are similar to those in PD with dementia (49). As in PD, the cortical cholinergic deficit appears to reflect neuronal loss in the basal nucleus of Meynert (50).

The cortical cholinergic pathology is independent of the extent of Alzheimer pathology, being equally great in DLB cases with and without this type of pathology (51). Cholinergic deficits in DLB extend beyond the cortex to the striatum and certain nuclei of the thalamus (52). Also, in contrast to AD and similar to PD with dementia, DLB is associated with elevation of the muscarinic receptor subtype M1 (53), a finding that has recently been confirmed by immunoabsorption studies (54). However, muscarinic M1 receptors are not uncoupled to the same extent as in AD (52; Perry et al., *in preparation*). Changes in nicotinic receptors in the cortex include a loss of the high-affinity agonist binding site (likely to reflect the α_4 subunit), but no change in the α_7 subunit or α-bungarotoxin binding (54a). In contrast, little change in nicotine binding occurs in the thalamus, but highly significant reductions in α-bungarotoxin binding are seen in the reticular nucleus (55). Similar nicotinic receptor abnormalities occur in AD and (as far as has been investigated) in PD, although the loss of nicotine binding in the striatum is greater in PD, in keeping with the more extensive reduction in basal ganglia dopaminergic projections (56). Although the loss of high-affinity nicotinic receptor binding in AD has been related to synapse loss, measured by synaptophysin levels (57), synaptophysin loss occurs in DLB only when the pathology includes the Alzheimer type (58).

The involvement of the dopaminergic system is the other consistent neurochemical feature of DLB (Table 91.4); however, as might be expected from the variations in extrapyramidal features (absent/mild to severe, as in classic PD), the extent of dopamine or dopamine transporter loss in the striatum varies widely. Earlier reports that dopamine loss was in some cases severe despite the absence of neurologic symptoms (49), a finding that was interpreted to indicate compensatory striatal pathology, need to be replicated in prospectively assessed cases because symptoms may have been overlooked in psychogeriatric clinics; furthermore, neuroleptic medication reduces striatal dopamine. Although in PD striatal dopamine deficits are more marked in caudal regions, particularly putamen, in DLB the loss of dopamine transporter is similar at different rostral caudal levels (59). Whereas in PD dopamine D2 receptors are up-regulated, at least in earlier stages of the disease, receptors are not increased in DLB and in particular are not up-regulated as a result of neuroleptic medication (60). In addition to striatal dopamine deficits, dopamine losses in cortical areas also occur (Table 91.4).

The significance of the serotoninergic, noradrenergic, and neuropeptide (e.g., somatostatin and corticotropinreleasing factor) abnormalities that occur in DLB, as in AD and PD, has not generally been evaluated in pathologic or clinical terms. The clinical significance of some of the cholinergic abnormalities that have so far been examined in prospectively assessed cases is discussed in the section on clinical–pathologic relationships .

GENETICS

Familial cases of DLB have been reported, although the majority of cases appear to be sporadic. Following the discovery of two separate missense mutations in the α-synuclein gene on chromosome 4 in a small number of families with pathologically confirmed early-onset PD, mutation screening was undertaken in this gene in both familial and sporadic cases of DLB (61). These studies failed to reveal any nucleotide changes within the exons screened.

Although, like cases of PD, most cases of DLB appear to be sporadic, this does not exclude a potentially significant genetic influence in the etiology of either condition. Such an influence may be via so-called susceptibility genes. Because DLB shares pathologic overlap with PD and AD, susceptibility genes of interest for both conditions have been considered in candidate gene approaches. For PD and DLB, allelic frequencies of the cytochrome P-450 gene *CYP2D6* (debrisoquine-4-hydroxylase) have been examined. The results of these studies have been conflicting. An increased frequency of the *CYP2D6*B* allele has been reported in DLB (62), whereas another study found no association (63). Others found no difference between the frequency of this allele in AD and DLB despite an increased frequency in PD (64). The current balance of evidence suggests that the *CYP2D6*B* allele is not a major genetic determinant of DLB.

The ε4 type of apolipoprotein E is significantly elevated in both DLB and AD, with a concomitant reduction in the Eε3 type of apolipoprotein. Interestingly, although the ε4 allele was associated with an increased risk for the development of DLB, it did not appear to affect the burden of pathology, measured by senile plaque and neurofibrillary tangle density in the neocortex (65). In AD, the ε4 allele is associated with neuronal loss in the substantia nigra (66). In PD, the ε4 allele increases the risk for drug-induced hallucinations (67).

Most recently, a significant difference has been reported for the allelic distribution of a pentanucleotide repeat within the promoter region of the nitric oxide synthase gene *(NOS2A)* in a comparison of autopsy-proven DLB cases with controls (68). Nitric oxide functions normally in the brain as a physiologic neuronal mediator, but excessive production of nitric oxide (e.g., after ischemic brain injury) can cause cell death through the generation of potent oxidants. Furthermore, with use of a murine MPTP model of parkinsonism, it has been shown that inhibitors of nitric oxide synthase may provide protective benefit in the treatment of PD (69).

Associations between polymorphisms within the α_2-macroglobulin, α_1-antichymotrypsin, and presenilin 1 genes and DLB have not been demonstrated (after accounting for apolipoprotein E ε4 allele frequency) (70 ,71 and 72).

Accumulating evidence suggests that patients with DLB are more responsive to cholinergic therapy than those with AD at a similar stage of dementia. The polymorphism causing the K allele in the gene for butyrylcholinesterase has been reported to be associated with AD, although this finding has not been replicated by others. In DLB, an increased number of butyrylcholinesterase K homozygotes have been found. It has been suggested that this genotype may partly explain the enhanced responsiveness to cholinesterase inhibitors in DLB (73). Although abnormalities in butyrylcholinesterase are evident in AD, including elevated enzymatic activity associated with both amyloid plaques and neurofibrillary tangles, the enzyme has not been examined in DLB.

CLINICAL–PATHOLOGIC RELATIONSHIPS

Part of "91 - Dementia with Lewy Bodies "

Cognitive and Neuropsychiatric

In DLB, a consistent gradient of LB density has been noted, as follows: substantia nigra > entorhinal cortex > cingulate gyrus > insula > frontal cortex > hippocampus > occipital cortex. Paralimbic and neocortical LB densities are highly correlated with each other but not with nigral pathology, which suggests that DLB should not be considered merely a severe form of PD (74). One study of pathologic burden versus clinical severity examined correlations between two simple measures of cognitive ability and a range of lesion counts and neurochemical measures in the midfrontal cortex of DLB cases (75). Severity of dementia was significantly correlated with LB density, plaque density, and severity of cholinergic deficit, but not with neurofibrillary tangle density or synaptophysin levels. In contrast, in AD cases, tangle density and synaptophysin levels were most highly correlated with clinical severity. This suggests that the dementias of DLB and AD may have different pathologic but similar neurochemical substrates. Other studies have failed to find robust correlations between LB density and clinical features (74 ,76).

Neurologic

Cell loss in the ventrolateral tier of the substantia nigra is the dominant pathologic correlate for parkinsonism in both DLB and PD. This is associated with gliosis and Lewy body formation. Dopaminergic neurons in this area of the substantia nigra project predominantly to the putamen, which, in turn, is an integral component of the so-called basal ganglia “motor loop” (77). The net effect of loss of the modulating effects of dopamine within the putamen is increased neuronal activity in the globus pallidus (internal segment). Because output from the globus pallidus (internal segment) is inhibitory to the ventrolateral thalamic nucleus, this leads to excessive inhibition of thalamic activity and thus reduced feedback to the motor cortex. The perturbation in this loop, resulting from dopamine deficiency, is believed to be the basis of the neural substrate for bradykinesia.

Although systematic studies have not yet been performed,

some evidence suggests that responsiveness to levodopa in DLB may be less than that in PD. Because the presynaptic lesion is similar in the two disorders, the answer may therefore lie postsynaptically. Evidence to support this notion comes from postmortem neurochemical studies comparing dopaminergic activities in DLB with those in PD and AD (59). In these studies, dopamine D2 receptor binding was reduced in the caudal putamen and was significantly lower than in PD at all levels.

Although the increased falls reported in DLB may be multifactorial, it is likely that more widespread involvement of brainstem nondopaminergic nuclei is a contributing factor. Degeneration of the predominantly cholinergic pedunculopontine nucleus is a likely explanation because neuronal loss in this structure has been associated with postural instability (78). In addition, degeneration of the pedunculopontine nucleus has been implicated as the pathophysiologic basis for REM sleep behavioral disorder, which is also reported in DLB (79).

Neurochemical

As yet, only a few clinical–neurochemical relationships have been identified in DLB. In earlier reports of the loss of cholinergic activity from the cortex, correlations were identified, as in AD, with the severity of cognitive impairments (17 ,75).

In regard to noncognitive or neuropsychiatric symptoms, patients with visual hallucinations have significantly lower levels of choline acetyltransferase than do nonhallucinators (80); recently, they have also been found to have lower levels of nicotinic α-bungarotoxin receptor binding in visual association cortex (Ballard et al., *in preparation*). Muscarinic M1 binding in temporal cortex is increased in patients experiencing persistent delusions (81). Delusional misidentification has also been associated with lower levels of α-bungarotoxin binding in this region (Ballard et al., submitted). Disturbances in consciousness are associated with a tendency for choline acetyltransferase to be lower in the thalamic reticular nucleus (53) and with a relative preservation of the high-affinity nicotinic receptor in the cortex (Ballard et al., submitted). Although reductions in this receptor correlate with attentional deficits, it appears that the ability to return periodically to normal levels of consciousness (fluctuations) depends on a degree of integrity of the nicotinic receptor. It has been suggested that greater EEG slowing is related to the greater cholinergic deficit in DLB than in AD (82). A hypothesis relating the function of cerebral acetylcholine in the integrative processes that generate conscious awareness has recently been proposed (83).

In regard to noncholinergic transmitter abnormalities, sensitivity to neuroleptic medication has been related to a lack of dopamine D2 receptor up-regulation, and depression to relatively preserved serotonin transporter levels (Ballard et al., submitted).

CLINICAL INVESTIGATIONS

Part of "91 - Dementia with Lewy Bodies "

As with any patient presenting with cognitive impairment, obtaining a full history and performing a mental and physical examination are essential steps toward making a firm clinical diagnosis. As with suspected cases of AD, the level and extent of laboratory investigations vary according to the clinical picture, associated comorbidity, and physical examination findings. However, because of the particular associations of DLB with fluctuations in attention and cognition and visual hallucinations, both very commonly associated with a variety of other organic disorders, the investigation of a suspected case of DLB requires a very careful laboratory evaluation. This usually includes routine hematology and biochemistry, determinations of erythrocyte sedimentation rate and creatine phosphate, thyroid function tests, measurements of B_{12} and folate levels, syphilis serology, and urinalysis. A chest roentgenogram may also be considered routine in view of the high incidence of lung carcinomas in the elderly, especially smokers. As in the diagnosis of AD, neuroimaging investigations are often helpful, both in excluding other intracranial disorders (including cerebrovascular disease) that may be responsible for the cognitive impairment and in providing supportive features for the diagnosis.

The EEG findings may be abnormal in up to 90% of DLB patients; loss of alpha rhythm and transient slow-wave activity in the temporal lobe areas are the most common changes (82). Patients with AD are less likely to have transient slow waves, and slowing of the dominant rhythm is less marked. However, the positive predictive value of the EEG in suspected cases of DLB has not been assessed in a prospective clinicopathologic study. Increasingly, some form of structural imaging is becoming essential to apply diagnostic criteria rigorously, such as the NINCDS/ADRDA criteria for AD, the NINCS/ADRDA criteria for vascular dementia, and the consensus criteria for DLB.

Structural Imaging Changes

Few studies have investigated computed tomographic (CT) or magnetic resonance imaging (MRI) changes in DLB. In a longitudinal study of AD subjects who came to postmortem examination, Förstl et al. (24) reported more pronounced frontal lobe atrophy on CT in eight subjects with LB pathology in a comparison with pure AD cases. However, using MRI, Harvey et al. (84) found no differences in frontal lobe volumes between AD and DLB subjects, a finding replicated in a different and larger cohort by Barber et al. (85). Although further studies are awaited, frontal lobe atrophy does not seem to be a particular feature of DLB. Similarly, DLB does not seem to differ from AD in terms of degree of ventricular enlargement or presence of white matter changes on MRI (86).

The strong association between AD and atrophy of the

medial temporal lobe, whether assessed by a linear measurement of medial temporal lobe width on CT (87) or visual or volumetric ratings of hippocampal atrophy on MRI (88 ,89), led to an investigation of whether similar changes are associated with DLB. Jobst et al. (87) found medial temporal lobe atrophy of similar magnitude to that in AD in two of their four cases of DLB. However, with the use of MRI, both case reports and controlled studies have shown DLB to be associated with relative preservation of temporal lobe structures in comparison with AD (84 ,85 ,90 ,91). Volumetric analysis of subregions within the temporal lobe indicates that the differences lie in medial temporal lobe structures (i.e., hippocampus and parahippocampal gyrus) rather that in the lateral temporal lobe, which does not show any differences between AD and DLB. Volumetric analysis, although essential for research studies and investigating clinical correlates, is currently too time-consuming to be adopted into routine clinical practice. Using visual ratings, which can be performed quickly (1 minute per scan) and simply, Barber et al. (85) found that 38% of DLB subjects but no AD subjects had a normal rating of temporal lobe atrophy, which suggests that at least in some cases relative preservation of the hippocampus and medial temporal lobe may support a diagnosis of DLB. Sample medial temporal lobe images are shown in Fig. 91.2 . The reason for this variability in temporal lobe atrophy in DLB is unknown, although based on a very limited autopsy examination of four cases, Harvey et al. (84) suggested that temporal lobe atrophy on MRI may be a marker of concurrent AD pathology in DLB. However, although cross-sectional imaging may be helpful in some cases, it clearly is not diagnostic. It is yet to be determined whether accurate longitudinal assessment of regional volume change on MRI increases the accuracy of diagnosis, as may be the case for AD (92).

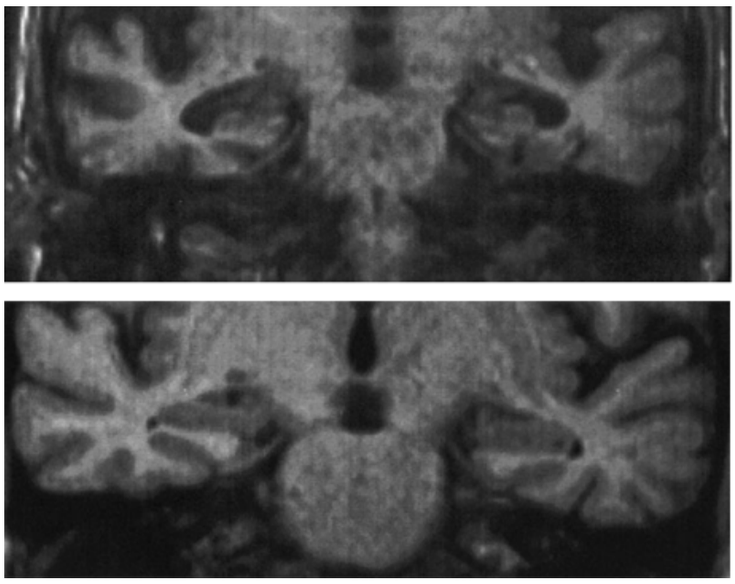

FIGURE 91.2. Coronal magnetic resonance imaging slices of patients with Alzheimer disease (AD) and dementia with Lewy bodies (DLB). Note severe atrophy of hippocampus and medial temporal lobe structures bilaterally in subject with AD. In contrast, the appearance of the medial temporal lobe in the subject with DLB is normal for age.

In summary, the limited evidence available suggests that structural imaging in DLB reveals generalized atrophic changes similar to those of AD in most cases, although approximately 40% of DLB subjects show preservation of medial temporal lobe structures.

Functional Imaging Changes

Single-photon emission tomography (SPET) with the use of blood flow markers such as Tc-HMPAO (hexamethylpropylene amine oxime) has been extensively investigated in dementia. In AD, the classic appearance is one of posterior bilateral symmetric temporoparietal hypoperfusion (87 ,93), which contrasts with the frontal hypoperfusion characteristically seen in frontal lobe dementia (94). Vascular dementia is associated with a mottled, uneven, patchy appearance, reflecting the variable anatomic localization of vascular disease (95). In PD, the blood flow in basal ganglia is decreased, and when PD is associated with dementia, bilateral parietal changes similar to those seen in AD are reported (96 ,97). In the few SPET studies of DLB, patterns of blood flow changes similar to those of AD have been found, although Donnemiller et al. (98) found a subtle difference in perfusion patterns, with a greater degree of occipital hypoperfusion in DLB than in AD, and Defebvre et al. (99) found decreased frontal perfusion in DLB. Perfusion of the medial temporal lobe may be less impaired in DLB than in AD (100), consistent with the structural imaging findings described above of preservation of the same structures in DLB. Higuchi et al. (101) have suggested that glucose hypometabolism in occipital cortex is a diagnostic aid in distinguishing DLB from AD, and Imamura et al. (102) found that hypometabolism in this region in conjunction with relatively mild hypometabolism in temporal and parietal cortex is associated with visual hallucinations in DLB.

The more powerful, although still research-based, use of SPET involves the use of specific ligands for different neurochemical systems. Ligands have been developed for presynaptic and postsynaptic dopaminergic and cholinergic systems. Donnemiller et al. (98), using positron emission tomography (PET), found significant differences between DLB and AD in ß-carbomethoxy-iodophenyl-tropane (CIT) binding (a ligand for the dopamine transporter), a difference that would be predicted from the known neurochemical differences between AD and DLB. However, one disadvantage of CIT is that imaging has to be delayed for 24 hours after injection. A single case report has suggested that a ligand with faster imaging kinetics, FP (fluoropropyl)-CIT, can distinguish DLB from AD (103). A reduced density of dopamine D2 receptors in basal ganglia, demonstrated with [^{123}I]iodobenzamide, has been reported in DLB (104). With use of a marker of the vesicular acetylcholine

transporter, significant differences between AD subjects and controls and between PD subjects with and without dementia have been found (105). In summary, current evidence suggests that SPET studies of blood flow show similar appearances in DLB and AD, although SPET may still be useful in distinguishing DLB, like AD, from frontal lobe dementia or vascular dementia. New chemical imaging techniques, although not yet clinically available, show great promise in differentiating DLB from other disorders and are an exciting area of current research.

TREATMENT

Part of "91 - Dementia with Lewy Bodies "

Neuropsychiatric Symptoms

Some of the key clinical features of DLB are similar to those induced in normal subjects by anticholinergic, specifically antimuscarinic, agents. Clouding of consciousness, confusion, and visual hallucinations are recognized effects of anticholinergic drug toxicity, and cumulative effects of subcortical and cortical cholinergic dysfunction probably play a major role in the spontaneous generation of similar fluctuating symptoms in DLB. As discussed in the earlier section on neurochemical clinical-pathologic relationships , reductions in choline acetyltransferase are correlated with cognitive impairment (75), and hallucinations may be related to hypocholinergic and (relatively) hypermonoaminergic neocortical neurotransmitter function (80).

Several reports have indicated that patients who respond well to cholinesterase inhibitor treatments are more likely to have DLB than AD at autopsy (106 ,107). This finding is consistent with the neurochemical profile of DLB and the fact that postsynaptic cortical muscarinic receptors are functionally intact. Case reports suggest that cholinesterase inhibitors can reduce psychotic symptoms in DLB (108), and a recently completed placebo-controlled study of rivastigmine in patients meeting consensus criteria for probable DLB found significant improvements in both neuropsychiatric features and cognition (109).

It is possible that cholinergic drugs may emerge as the antipsychotic treatment of choice in dementing diseases of the elderly, such as DLB. Not only are typical neuroleptics inappropriate (23); according to more recent reports, so are atypical drugs such as olanzapine (110 ,111).

Neurologic Symptoms

Because of the combination of parkinsonism with neuropsychiatric symptoms, the management of extrapyramidal signs in DLB is rather like walking a tightrope. The best outcome will invariably be a compromise between a relatively mobile but psychotic patient and a nonpsychotic but immobile patient.

Many currently available antiparkinsonian drug treatments, including monoamine oxidase B inhibitors, anticholinergic agents, and dopamine agonists, have an unacceptably high risk of precipitating or exacerbating hallucinations and confusion. In addition, most of these agents can cause or worsen orthostatic hypotension and lead to an increased incidence of falls. Although it has never been formally assessed, avoidance of these drugs in DLB patients would seem prudent. Indeed, for a DLB patient presenting with parkinsonism, in whom dementia and neuropsychiatric symptoms then develop, the first therapeutic decision should be to review the antiparkinsonian medication and undertake a gradual withdrawal if necessary.

At a practical level, the antiparkinsonian drug with the best risk-to-benefit ratio currently available for the treatment of extrapyramidal signs in DLB is levodopa. However, although the efficacy of levodopa for the treatment of PD is beyond question, how effective is this drug in the management of DLB? The evidence regarding the responsiveness of DLB patients to levodopa is conflicting. Some reports suggest that up to 100% of patients with DLB may improve, but the numbers of patients have usually been small in these series, and the degree of functional change and duration of the response have not been specified (39 ,40). Furthermore, the effects of levodopa therapy on neuropsychiatric symptoms are poorly documented in this group. Given the postsynaptic changes in dopamine D2 receptors noted in postmortem studies, it might be postulated that levodopa responsiveness is diminished in DLB. Clearly, a number of issues regarding the efficacy of dopaminergic treatment in DLB have not been resolved, and further trials are in progress to address these issues.

The most important point in the management of patients with DLB is to exercise caution in (or preferably avoid) prescribing neuroleptic medications, which are the mainstay of antipsychotic treatment in other groups of patients. Severe neuroleptic sensitivity reactions can precipitate irreversible parkinsonism, further impair the level of consciousness, and induce autonomic disturbances reminiscent of neuroleptic malignant syndrome (22 ,23). They occur in 40% to 50% of DLB patients treated with neuroleptics and are associated with a twofold to threefold increase in mortality. Acute blockade of D2 receptors is thought to mediate these effects, and despite some promising initial reports, atypical and novel antipsychotics such as risperidone and olanzapine seem to be just as likely to cause neuroleptic sensitivity reactions as the older drugs.

Until safe and effective medications become available, the mainstay of clinical management is undoubtedly to educate patients and carers about the nature of their symptoms and suggest strategies to cope with them. The clinician must ascertain which symptoms are most troublesome for the patient and explain the risks and benefits associated with changes in medication (112).

SUMMARY AND CONCLUSION

Part of "91 - Dementia with Lewy Bodies "

Dementia with Lewy bodies appears to be distinct both clinically and neuropathologically from AD and is the second most common form of degenerative dementia, accounting for up to 20% of cases in the elderly. It is characterized by fluctuating cognitive impairment, spontaneous parkinsonism, and recurrent visual hallucinations. Consensus clinical and neuropathologic criteria were published in 1996, and the clinical criteria have been shown to be highly specific, although they may still lack sensitivity. As in PD, the defining neuropathologic feature is the presence of Lewy bodies and neurites (positive for α-synuclein and ubiquitin) in a range of subcortical nuclei and in cortical regions, particularly cingulate and entorhinal. Alzheimer-type pathology is variable, ranging from none in the neocortex to, most commonly, extensive ß-amyloidosis and, rarely, additional neurofibrillary tangle formation. The main neurotransmitter abnormalities include the following: extensive reduction in presynaptic cholinergic activities in the cortex, related to psychotic features such as hallucinations; elevations of muscarinic receptors; abnormalities in nicotinic receptors, related to disturbances in consciousness; and both presynaptic and postsynaptic dopamine abnormalities, related to extrapyramidal dysfunction, including sensitivity to neuroleptic medication. The recognition of DLB is clinically important in view of the high incidence (60%) of adverse and life-threatening reaction to antipsychotic medications, the difference in prognosis, and the differential treatment response to cholinergic therapy. Neuroimaging changes have not been described in DLB to any extent, but some show promise as potential markers to differentiate DLB from AD. These include relative preservation of temporal lobe structures on MRI and loss of presynaptic and postsynaptic dopaminergic markers on SPET. Patients with DLB respond positively to cholinesterase inhibitors with reductions in neuropsychiatric symptoms such as hallucinations, delusions, and agitation.

This chapter has summarized the major advances that have taken place within the last decade in understanding the mechanisms underlying DLB, in diagnosing the disease, and in treating some of the clinical features. In relation to neuropsychopharmacology, the disease provides a unique opportunity to understand mechanisms underlying symptoms such as hallucinations and disturbances in consciousness because such symptoms can occur in the absence of significant Alzheimer pathology and be correlated with quantifiable neurotransmitter abnormalities.

In terms of understanding the core pathologic mechanisms, however, as in AD and PD, the objective of disease prevention still appears to be a long way off. Transgenic mice expressing wild-type α-synuclein have synuclein-positive inclusions in cortex and substantia nigra and decreased dopamine levels in basal ganglia (113). It is interesting that this model, relevant to PD and DLB, expresses the phenotype in relation to transmitter abnormality (at least in regard to dopamine), whereas the equivalent model considered relevant to AD—overexpression of mutated amyloid precursor protein (APP)—does not. However, one report of numerous and widespread α-synuclein-negative Lewy bodies in an asymptomatic patient raises the question of just how pathogenic abnormalities of this synaptic protein really are (114).

With improved methods of diagnosing DLB now available, epidemiologic studies are needed. It would be interesting to determine whether tobacco use is associated with a decreased risk for the development of DLB, as it is for PD. The potential for neuroprotection based on stimulation of nicotinic receptors is increasingly being recognized (115).

Better genotype–phenotype correlation is also needed for DLB. For example, do functional polymorphisms within the dopamine D2-receptor gene influence levodopa responsiveness? In addition, does butyrylcholinesterase K homozygote status predict therapeutic response to cholinesterase inhibitors? Improved knowledge in this area could conceivably rationalize the use of drug treatments for DLB.

The involvement of brainstem nuclei in DLB other than the substantia nigra needs to be explored further. The quality of future clinicopathologic correlations will be enhanced by the prospective acquisition of clinical data in longitudinal studies with the use of standardized and validated instruments.

The role of levodopa in the treatment of the extrapyramidal syndrome associated with DLB needs to be defined better. For example, levodopa-induced “on/off” responses and dyskinesias have not been reported in DLB, as they have in PD. This may be because parkinsonism is generally less severe and may take longer to develop than DLB or because distinct striatal pathology (e.g., loss of cholinergic activity) is present. Novel therapies aimed at relieving parkinsonism that do not exacerbate neuropsychiatric features are needed. Drugs acting via nondopaminergic neurotransmitter systems may be applicable in this area (e.g., adenosine A_{2A} antagonists).

Molecular Pathophysiology of Stroke

Steven H. Graham

Robert W. Hickey

Steven H. Graham: Department of Neurology, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania.

Robert W. Hickey: Department of Pediatrics, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania.

Cerebral ischemia occurs when the amount of oxygen and other nutrients supplied by blood flow is insufficient to meet the metabolic demands of brain tissue. In ischemic stroke, the blood supply to the brain is disrupted by cerebrovascular disease. For decades, extensive research and clinical approaches to combat stroke have focused on the vascular aspects of cerebral ischemia. Therapeutic advances, including carotid endarterectomy, thrombolytic therapy, anticoagulation for cardiogenic stroke, antiplatelet agents, and the treatment of risk factors such as hypertension and hyperlipemia, have had significant effects on the morbidity and mortality of stroke.

The final event in cerebral ischemia is the death of neurons, resulting in irreversible loss of neurologic function. The advent of animal and tissue culture models of ischemia has led to many new insights into the mechanisms by which ischemic neurons die. If ischemia is complete and prolonged, neuronal death is inevitable. However, it has become increasingly clear that many secondary biochemical changes that exacerbate injury occur in response to the initial insult. In models of cerebral ischemia in rodents, as much as 50% or more of ischemic brain may be spared from infarction by preventing these secondary biochemical events. Understanding of the mechanisms by which neuronal cell death takes place has resulted in a number of therapeutic strategies that aim to prevent secondary biochemical changes and thus decrease the damage that results from cerebral ischemia. These basic mechanisms may also have relevance to other neurodegenerative diseases associated with excessive neuronal death.

This chapter summarizes many of the mechanisms that have been demonstrated to exacerbate the neuronal death caused by hypoxia and hypoglycemia. Ischemic neuronal death may involve the activation of enzymes and receptors that are constitutively expressed in brain. These existing receptors and enzymes do not require energy or the synthesis of new protein to exacerbate *necrotic* cell death. New evidence suggests that ischemic injury may also be exacerbated by the inducible proteins that mediate *programmed* cell death. These mechanisms are appealing targets for therapeutic intervention because they may occur hours or days after the initiation of ischemia.

CELL DEATH: NECROSIS VERSUS PROGRAMMED CELL DEATH

Part of "92 - Molecular Pathophysiology of Stroke "

It has been observed that an orderly expression of new gene products is required to produce programmed cell death during development of the roundworm *Caenorhabditis elegans* (1). This observation has led to intense interest in the hypothesis that the expression of similar death-promoter genes could be important in the pathogenesis of human disease (2). Support for this hypothesis is derived from the existence of oncogenes, death-regulating genes that are either deleted or overexpressed in cancer. Genetic mechanisms that control cell death are clearly relevant to mitotic cells in development, cancer, and the maintenance and turnover of regenerating adult tissues. Neurons may also die by these mechanisms. A classic example is the withdrawal of nerve growth factor from dorsal root sympathetic neurons that results in delayed death, which requires the transcription of new messenger RNA (mRNA) and the synthesis of new proteins (3). Before their death, these neurons undergo morphologic changes associated with *apoptosis* (4), a term originally used to describe the morphologic characteristics associated with programmed cell death.

Programmed cell death is a mechanism by which the organism can remove unnecessary or redundant cells during development or in mature tissues where cell turnover is required. Programmed cell death has several key characteristics: (a) The death process is active, and the expression of new proteins is often involved. (b) Cellular energy stores

are normal until the final stages of cellular death; therefore, energy failure is a late, secondary event in programmed cell death. (c) The activation of endonucleases results in numerous double-stranded DNA breaks at the boundaries between histosomes. The result is DNA fragments in multiples of 400 base pair size that produce characteristic “laddering” on DNA gels. (d) Morphologic changes characteristic of apoptosis, including cytoplasmic and nuclear budding (“apoptotic bodies”), are present. (e) In contrast to necrosis, programmed cell death results in neuronal death with little or no accompanying inflammation. Thus, “collateral damage” to neighboring cells is avoided.

In contrast to programmed cell death, necrotic cell death is characterized by energy failure, which results in inhibition of protein synthesis. Therefore, new gene products may not be expressed. Histologic characteristics of necrotic cell death are cytoplasmic and nuclear swelling, loss of integrity of cell organelles, rupture of the cell membrane, and dissolution of all cell structures. *In vivo*, necrotic cell death is often accompanied by intense inflammation with recruitment of inflammatory cells. This inflammatory response can injure adjacent normal cells. The characteristics of programmed cell death and necrosis are summarized in Table 92.1 .

	Necrosis	Programmed Cell Death
Process	Passive	Active
Energy failure	Primary	Secondary
Protein translation	Blocked	Exacerbates cell death
Morphology	Coagulative necrosis	Apoptosis
DNA fragmentation	None or random, resulting in either no migration or a smear on DNA gels	Occurs at histosome boundaries, resulting in multiples of 400 base fragments producing laddering on DNA gels
Inflammation	Prominent	Little or none

TABLE 92.1. CHARACTERISTICS OF NECROSIS AND PROGRAMMED CELL DEATH

NATURE OF NEURONAL DEATH IN CEREBRAL ISCHEMIA

Part of "92 - Molecular Pathophysiology of Stroke "

In ischemia, a mismatch between energy supply and demand may result in energy failure. Without adequate energy, protein synthesis cannot occur, and the genes that execute programmed cell death may not be expressed. The predominant histologic feature of stroke is infarction. Infarction is synonymous with necrosis (i.e., cytoplasmic swelling, dissolution of organelles and plasma membranes, and inflammation are present). In the permanent middle cerebral artery occlusion model in the rat, loss of glucose utilization is rapid and complete within a few hours (5), with little time or energy available for the synthesis of new gene products. Thus, one would surmise that necrosis is the primary mode of cell death in this model.

Under other circumstances, however, cerebral ischemia may produce neuronal death with many of the characteristics of programmed cell death. In models of transient ischemia, for example, energy failure is transient, and neuronal death develops more slowly than in permanent focal ischemia, with many features of apoptotic cell death. Under these circumstances, cleavage of genomic DNA into fragments of various sizes on DNA gels, characteristic of programmed cell death, occurs (6 ,7). However, the most convincing evidence that the production of new gene products may be important in the pathogenesis of neuronal death after transient ischemia is that protein synthesis inhibitors block delayed death of neurons (8 ,9 and 10). Thus, depending on the duration and severity of ischemia, stroke may produce cell death with features of necrosis or apoptosis.

MECHANISMS OF NECROTIC CELL DEATH

Part of "92 - Molecular Pathophysiology of Stroke "

The primary pathologic mechanism in stroke is the depletion of energy stores; however, considerable evidence indicates that excitatory amino acids (EAAs) exacerbate ischemic injury. EAAs such as glutamate are released by approximately 40% of all synapses in the central nervous system (11). Under physiologic conditions, EAAs participate in many neurologic functions, including memory, movement, sensation, cognition, and synaptic plasticity (12 ,13). However, EAAs can also have a pathologic effect. EAA-mediated toxicity was first demonstrated by Olney and co-workers (14) by peripheral administration of an EAA agonist that selectively killed neurons in the arcuate nucleus of the hypothalamus. These neurons contain high concentrations of glutamate receptors. Choi (15) demonstrated that micromolar extracellular glutamate and other EAAs produce rapid increases in intraneuronal cytosolic Ca^{2+} concentrations.

This increase in intracellular calcium concentration is rapidly lethal to primary neuronal cultures. The importance of calcium entry and excitotoxicity is supported by data demonstrating a direct correlation between extracellular calcium stimulation and neuronal death following exposure to glutamate (16).

The increase in intraneuronal Ca^{2+} in response to extracellular EAAs *in vitro* is mediated by the opening of a receptor-gated ion channel, the *N*-methyl-D-aspartate (NMDA) channel (17). The NMDA channel, named after its highest-affinity ligand, primarily gates calcium entry into the neuron. Treatment with antagonists that compete with glutamate and other EAAs for the receptor (competitive NMDA antagonists) or antagonists that bind to the ion channel itself (noncompetitive antagonists) can block calcium entry into neurons and prevent cell death induced by glutamate (18 ,19). Glycine is a co-agonist that is required in addition to glutamate to open the NMDA Ca^{2+} channel (20). Antagonists that bind to the glycine site on the NMDA receptor also block excitotoxicity *in vitro* (21). In addition to rescuing cells from EAA toxicity by blockade of the EAA receptors, it is possible to rescue neurons in culture by removal of extracellular calcium and sodium from the culture media following glutamate exposure (18). Conversely, inhibition of the sodium–calcium exchanger that normally facilitates extrusion of calcium results in an increase in neuronal death (18 ,22). Similarly, dantrolene, which attenuates decompartmentalization of intracellular stores of calcium, can reduce glutamate neurotoxicity in cortical neurons (23). Finally, neurons containing high concentrations of calcium-binding proteins, such as calbindin or parvalbumin, are relatively resistant to excitotoxic injury (24 ,25). These data provide compelling evidence that EAA-induced increases in intracellular Ca^{2+} are toxic to neurons in culture.

Compelling evidence is also available to indicate that excitotoxicity mediated by the NMDA receptor contributes to injury from cerebral ischemia *in vivo*. A rapid and large increase in the concentration of extracellular amino acids can be monitored by microdialysis after cerebral ischemia (26). Although NMDA antagonists are not effective in global ischemia models in which temperature is carefully controlled (27), a large number of studies have found that they decrease infarction volume in both permanent and temporary middle cerebral artery occlusion models in rodents (28). Blocking the translation of a gene that encodes a subunit of the NMDA receptor with intraventricular injection of antisense oligonucleotides also decreases infarction volume after middle cerebral artery occlusion in the rat (29). These data and many other studies support the hypothesis that excitotoxicity contributes to ischemic injury *in vivo*.

Several calcium-dependent or calcium-induced enzymes mediate the toxic effects of increased intracellular calcium (Fig. 92.1). These include nitric oxide synthase, cyclooxygenase, phospholipase A_2, and calpain 1. Calpain 1 is a calcium-activated protease that has been specifically linked to glutamate receptors in the rat hippocampus (30). Calpain 1 participates in the conversion of xanthine dehydrogenase to xanthine oxidase, which metabolizes xanthine to its reactive oxygen species, superoxide (31). Similarly, phospholipase A_2 is activated by calcium and facilitates the release of arachidonic acid from injured cell membranes (32). Arachidonic

acid is then metabolized by the enzyme cyclooxygenase into a prostaglandin, PGH_2. The cyclooxygenase enzyme may produce a superoxide ion as a by-product of arachidonic acid metabolism (33). In addition, intracellular calcium can activate calcium-dependent isoforms of nitric oxide synthase to produce nitric oxide (34). The nitric oxide then combines with the superoxide produced as the by-product of cyclooxygenase, xanthine oxidase, or other sources to form the highly reactive species peroxynitrite, which exacerbates tissue damage (35). Therefore, EAA-mediated elevation of intracellular calcium concentrations activates both cyclooxygenase and nitric oxide synthase, which then synergistically contribute to ischemic brain injury (36).

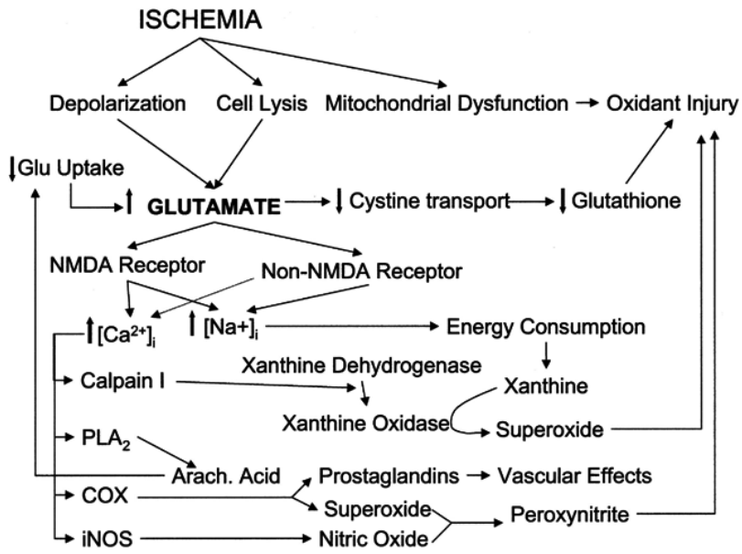

FIGURE 92.1. Schematic diagram illustrating the mechanisms by which ischemia and excitotoxicity injure neurons.

Extracellular EAAs may activate other receptors besides the NMDA channel. EAA receptors can be categorized as ionotropic or metabotropic receptors. Ionotropic receptors are coupled directly to membrane ion channels, whereas metabotropic receptors are coupled to G proteins and modulate intracellular second messengers such as inositol triphosphate, calcium, and cyclic nucleotides. More than 20 genes have been identified that encode subunits of these receptors. The subunits combine in a variety of confirmations to yield receptors with specific pharmacologic and electrophysiologic characteristics (37). Ionotropic receptors can be categorized based on their sensitivity to the selective agonists NMDA, AMPA (α-amino-3-hydroxy-5-methyl-4-isoxasole-proprionic acid), and kainate. The ionotropic receptors depolarize membranes by facilitating an influx of positively charged ions. The NMDA receptor facilitates an influx of both sodium and calcium, whereas the non-NMDA receptors (AMPA and kainate receptors) primarily facilitate an influx of sodium. However, some of the kainate and AMPA receptors are comprised of subunits that allow calcium permeability (38). This may be relevant to ischemic injury because in neurons after cerebral ischemia, glutamate receptor 2 (GR_2), a subunit necessary for non-NMDA receptors to exclude Ca^{2+}, is relatively depleted (39). Accordingly, these non-NMDA subunits may become calcium-permeable after ischemia. The metabotropic receptors may also increase intracellular calcium by mobilizing calcium from stores in the endoplasmic reticulum. Studies with antagonists of the metabotropic receptor show that, depending on their subunit specificity, some, but not all, drugs of this class are neuroprotective in models of focal ischemia (40 ,41).

In addition to the direct downstream effects of enzymes that are activated by elevation of intracellular calcium, a number of complex interactions and positive feedback loops augment the contribution of EAAs to ischemic brain injury. For example, free arachidonic acid can potentiate NMDA-evoked currents in neurons (42) and inhibit reuptake of glutamate by astrocytes (43). In addition, platelet-activating factor, a phospholipase A_2 metabolite, can stimulate the release of glutamate (44). Acidotic conditions favor the release of free iron, which can then participate in the metabolism of peroxide into the hydroxyl radical (Fenton reaction) (45). In addition, glutamate can interfere with the function of the cystine transporter. Inhibition of the cystine transporter results in decreased intracellular concentrations of glutathione and diminished intracellular endogenous antioxidant stores (46).

In vivo, excitotoxicity may be ameliorated by additional strategies besides inhibition of the NMDA receptor (Fig. 92.2). Glutamate release into synaptic cleft, where it interacts with EAA receptors, is primarily mediated by the release of glutamate from the synaptic pool. Thus, a large component of excessive neuronal excitation may be the result of synaptic release of EAAs. Neuronal depolarization of presynaptic neurons in turn depends on activation of non-NMDA receptor-gated channels and other depolarizing neurotransmitter receptors. The excitatory action of depolarizing neurotransmitter receptors is countered by hyperpolarizing receptor-gated ion channels, such as the GABA (γ-aminobutyric

acid) receptor. Propagation of the action potential induced by depolarization of the neuronal cell body requires voltage-dependent sodium channels. Finally, the release of glutamate itself depends on P- and Q-type voltage-dependent calcium channels. Glutamate release into the synaptic cleft can bind to the NMDA receptor and open the calcium channel. As a result, calcium enters the cell driven by its concentration gradient. However, intraneuronal calcium may increase by other mechanisms. Postsynaptic voltage-dependent calcium channels may allow calcium entry into the neuron when cells are depolarized, and glutamate released into the extracellular cleft may activate non-NMDA receptor-gated channels and depolarize the neuron. Also, Na^+ may enter the cell via the NMDA receptor-gated channel and depolarize the neuron. Thus, excitotoxicity may be ameliorated at a number of sites *in vivo*.

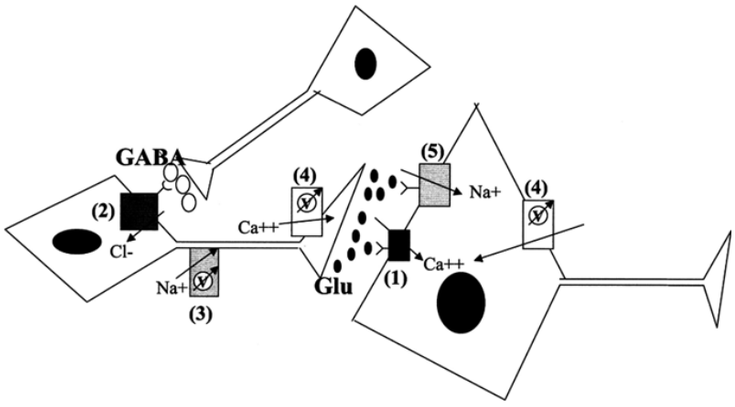

FIGURE 92.2. A simplified neuronal circuit diagram illustrating the ion channels that determine the synaptic release of glutamate and intraneuronal Ca^{2+} concentrations in response to ischemia. 1, *N*-methyl-D-aspartate (NMDA) receptor-gated ion channel; 2, α-aminobutyric acid (GABA) receptor-gated Cl^- channel; 3, voltage-dependent Na^+ channel; 4, voltage-dependent Ca^{2+} channel; 5, non-NMDA receptor-gated ion channel. See color version of figure.

Many drugs that can inhibit excitotoxicity at each of these steps have been developed. GABA agonists such as clomethazole have been shown to be neuroprotective *in vivo* and are currently undergoing clinical trials (47 ,48). In rodent models of stroke, BW1003,619 and phosphenytoin prevent prolonged opening of the voltage-dependent sodium channel, ameliorate increases in extracellular glutamate, and decrease infarction volume (49 ,50 and 51). Drugs that prevent prolonged opening of P- and Q-type calcium channel antagonists are also neuroprotective in animal models of stroke (52). In contrast to their very limited effects in primary neuronal tissue culture models, non-NMDA antagonists are very effective in both global and focal ischemia models in rodents. Indeed, such agents have a longer time window of efficacy than do NMDA antagonists when administered after the onset of ischemia (53 ,54). Likewise, voltage-dependent calcium channel antagonists are not effective *in vitro*; however, the voltage-dependent calcium channel antagonist nimodipine is effective in reducing infarction volume in temporary focal ischemia in rats (55).

Blockade of excitotoxicity via all these pharmacologic strategies has proved effective in temporary focal ischemia models in rodents, the model that most closely resembles human stroke. Unfortunately, results with these agents in human trials have to date been very disappointing, for several possible reasons. First, drugs that affect neurotransmission in the brain have many undesirable side effects, which in turn have led to reductions to doses that may have been ineffective. Side effects include effects on respiration and cardiac rhythm. In addition, agents that directly antagonize the NMDA receptor may injure a circumspect population of neurons in the cingulate and retrosplenial cortex in rodents (56), and may induce hallucinations and psychosis in humans (57). Another obvious reason for the lack of efficacy in these drugs in clinical trials is the time interval between the onset of ischemia and the administration of drug. When given before the onset of ischemia, these treatments can spare 50% or more of ischemic rat brain tissue from eventual infarction. When given after the onset of ischemia, they are progressively less effective; however, such agents are effective up to 2 hours after the onset of middle cerebral artery occlusion in the rat. In the clinical trials, most patients were enrolled 6 to 12 hours after the onset of ischemia, long after the time that these drugs were effectively administered in animal studies.

Whatever the reason for the failure of these anti-excitotoxic drugs in human trials, it has become clear that it may be more practical to select treatment approaches that target mechanisms that are active at longer intervals after ischemia. Accordingly, efforts to understand the delayed mechanisms of neuronal injury have been increased, in particular the role of programmed cell death in ischemic neurons.

MECHANISMS OF PROGRAMMED CELL DEATH

Part of "92 - Molecular Pathophysiology of Stroke "

Many of the key molecular events in programmed cell death have now been determined (Fig. 92.3). Just as calcium entry into the neuron is a key step in excitotoxicity, the release of cytochrome *c* from the mitochondria is a key event in initiating apoptosis in many cell types. Cytosolic cytochrome

c complexes with APAF-1 and procaspase 9 (58). As a result, procaspase 9 is cleaved into its active form, caspase 9. Caspase 9 then cleaves and activates other caspases, including caspase 3.

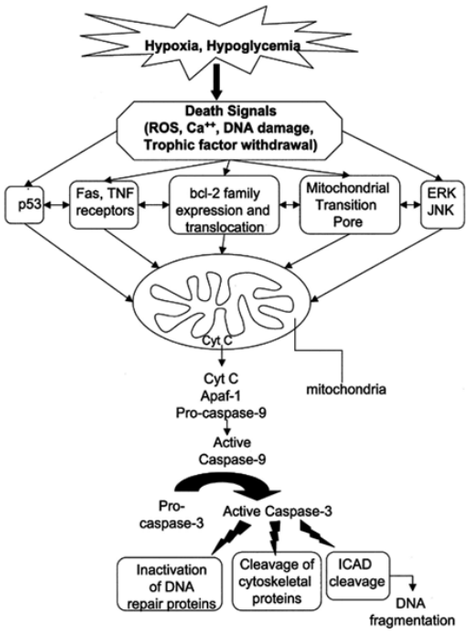

FIGURE 92.3. A schematic diagram illustrating the molecular mechanisms that control programmed cell death.

Caspases are a family of proteases that play a key role in executing programmed cell death. They were first identified by their homology with *CED3*, the key gene that irreversibly commits neurons in *C. elegans* to programmed cell death. A dozen mammalian caspases have been identified that have a variety of roles in executing programmed cell death and other cellular functions. Among the caspases, caspase 3 has the closest homology with *CED3* and appears to play a key role as the final committed step in programmed cell death. Caspase 3 executes programmed cell death via cleavage of many other proteins. These proteolytic targets of caspase 3 include cytoskeletal protein(s), DNA repair proteins such as PARP, and other proteins (59). Caspase 3 also cleaves ICAD, an inhibitor of CAD, an endonuclease that cleaves DNA between histosomes. The result is cleavage of DNA between histosomes, a hallmark of programmed cell death (60).

The egress of cytochrome ^{c} from the mitochondria into the cytosol is controlled by several mechanisms. Genes of the bcl-2 family play an important role in controlling cytochrome *c* egress. Anti-apoptotic bcl-2 family members, such as bcl-2 itself and bcl-x-long, inhibit the egress of cytochrome ^{c} (61 ,62). Pro-apoptotic members of the bcl-2 family, such as bcl-x-short and bax, can form dimers with themselves or with anti-apoptotic bcl-2 family members. The balance between the pro-apoptotic and anti-apoptotic bcl-2 family proteins in the mitochondrial membrane determines whether permeability of the membrane will increase to allow egress of cytochrome *c* into the cytoplasm. Under some circumstances, cytochrome *c* exits the mitochondria via the mitochondrial permeability transition pore. This pore can open in response to prolonged depolarization, produced by such stimuli as an increase in intracellular calcium (63). Furthermore, pro-apoptotic bcl-2 family members such as bax may also interact with this pore (64). However, bcl-2 family members themselves may form pores in membranes (65), and some evidence indicates that bax induces egress of cytochrome *c* from the mitochondria independently of the mitochondrial permeability transition pore (66). Initiation of the mitochondrial apoptosis is also controlled by expression and translocation of other numerous bcl-2 family members. For example, translocation of bax from the cytosol to the mitochondria initiates programmed cell death (67). Bad is phosphorylated before being translocated to the mitochondria (68). More than 20 additional proteins are found in the bcl-2 family, including many that are also involved in mitochondrial homeostasis. Thus, a key event in apoptosis, egress of cytochrome *c* from the mitochondria, is controlled by bcl-2 family proteins.

The molecular mechanisms by which programmed cell death is initiated are numerous and complex. Programmed cell death may be activated via cell surface receptors, including the Fas receptor and tumor necrosis factor-α (TNF-α) (69 ,70). Activation of these receptors triggers activation of caspase 8, which in turn cleaves the bcl-2 family protein bid (71). The cleaved bid then translocates from the cytoplasm to the mitochondria, where it initiates cytochrome *c* egress (72). Other mechanisms by which the initiation of programmed cell death is controlled include the ERK (externally regulated kinase) and JNK protein kinase cascades (73). Finally, DNA base oxidation and other DNA damage may initiate programmed cell death via expression of the p53 transcription factor. These and other mechanisms may be involved in the initiation of programmed cell death in ischemic neurons.

PROGRAMMED CELL DEATH AFTER CEREBRAL ISCHEMIA

Part of "92 - Molecular Pathophysiology of Stroke "

Evidence indicates that many of the mechanisms that initiate programmed cell death are activated in ischemic neurons under certain conditions. The mRNA of the Fas ligand is induced by forebrain ischemia (74). Expression of the Fas ligand and associated proteins and infarction volumes was smaller in LPR mice that expressed a dysfunctional Fas ligand than in wild-type controls (75). The Fas receptor is also up-regulated after cerebral ischemia in rat brain (76). TNF-α mRNA transcription is induced as an early response after cerebral ischemia (77). Expression of the TNF receptor is also increased after cerebral ischemia (78). TNF-binding protein, a protein that binds and inhibits TNF-α, reduced infarction volume after middle cerebral artery occlusion in rats (79). However, ischemic injury was exacerbated in TNF-α-receptor null mice, which suggests that TNF signaling pathways may instead have beneficial effects in ischemic injury under some circumstances (80). Caspase 8, which is activated by both the Fas and TNF receptors, is expressed and activated after cerebral ischemia (81). Changes in expression and activity of both the ERK and JNK kinase pathways occur following cerebral ischemia. The M-terminal kinases of c-Jun are activated after ischemia and phosphorylate c-Jun (82). The increased expression of ERK after focal ischemia and inhibitor of NEK-1, another kinase in the ERK pathway, protect the brain against focal cerebral ischemia (83 ,84). Single-stranded DNA damage is an early event in cerebral ischemia reperfusion injury and may trigger expression of p53 (85 ,86). Expression of p53 is induced after cerebral ischemia (87).

A number of studies in cerebral ischemia support a role for bcl-2 family genes in controlling ischemic neuronal death. In rodent models of ischemia, anti-apoptotic members of the bcl-2 family, including bcl-2 and bcl-x long, are expressed in neurons that are ischemic yet survive. Expression of pro-apoptotic members of the family, such as bax, is increased in neurons that are ischemic and die, such as

CA1 hippocampal neurons in models of global ischemia (88 ,89). Overexpressing anti-apoptotic members of the bcl-2 family protects neurons against ischemia. Transgenic mice that overexpress bcl-2 in neurons have a smaller infarction volume after temporary focal ischemia than do wild-type controls (90). Similarly, overexpression of bcl-2 by means of herpes simplex viral vectors protects neurons against ischemia *in vivo* (91 ,92). These studies show that overexpression of bcl-2 protein before ischemia is neuroprotective. To address whether bcl-2 that is endogenously expressed after ischemia has a protective role, antisense oligonucleotides were used to prevent translation of bcl-2 induced after ischemia. Rats treated with bcl-2 antisense oligonucleotides had a larger infarction volume than did rats treated with sense oligonucleotides or vehicle after temporary focal ischemia. These results suggest that expression of endogenous bcl-2 increases survival of ischemic neurons (93).

Abundant *in vivo* evidence also suggests that caspase activity exacerbates ischemic injury. Transgenic mice that express a dominant negative mutation of caspase 1 had smaller infarctions than did their wild-type litter mates (94). Furthermore, intraventricular infusion of peptide inhibitors of caspases decreased infarction volume in rats subjected to temporary middle cerebral artery occlusion. These peptide inhibitors of caspases also blocked damage in response to injection of excitotoxins (95). Caspase 3 mRNA and protein expression is induced in CA1 neurons after global ischemia. Caspase 3 is activated, and treatment with a specific peptide inhibitor of caspase 3 ameliorated neuronal death in the global ischemia model (96). These and other studies support a role for caspases in ischemic neuronal injury.

CONCLUSION

Part of "92 - Molecular Pathophysiology of Stroke "

If ischemia is of long duration or severe, death is rapid and necrotic. However, if ischemia is transient or incomplete, the genes that execute programmed cell death may be activated. Which process occurs depends on the duration and severity of the ischemic insult (97 ,98). In rodent models of ischemia, the duration and severity of ischemia are controlled, so one can produce ischemic neuronal death with either characteristic. Indeed, a spectrum of biochemical and morphologic changes occurs with characteristics of both death processes. In the human disease, the duration and severity of ischemia depend on the exact location of the arterial occlusion and whether or not reperfusion occurs. Reperfusion can occur spontaneously or as the result of thrombolytic therapy. Just as in the animal models, arterial occlusions produce regions where blood flow is nearly completely absent, and also surrounding zones with incomplete ischemia. Therefore, transient and incomplete ischemia occurs in the human disease and so provides the conditions necessary for programmed cell death.

Our knowledge of the mechanisms by which ischemic neurons die has increased considerably. It is now clear that the toxic effects of EAAs exacerbate injury resulting from ischemia. Antagonizing excitotoxicity via a variety of approaches can ameliorate injury in animal models of ischemia; however, these treatments appear to be too toxic and are effective for too short an interval after the onset of ischemia to be practical treatments in humans. When ischemia is transient or less severe, programmed cell death is activated. These events occur hours or days after the onset of ischemia and thus may be more practical targets for treatment. Further work is needed to determine the most effective and practical therapeutic strategies to prevent neuronal death after ischemia.

Stroke is the third leading cause of death in the United States; approximately 730,000 Americans have a new or recurrent stroke each year. That's one every minute and it costs the health care system $30 billion annually. The incidence of stroke is expected to rise dramatically as the population ages because stroke risk increases with age. The risk of stroke doubles for each decade after age 55. Stroke is a major factor in the late-life dementia that affects more than 40% of Americans over the age of 80. One in four men will have had a disabling stroke by the age of 80 and one in five women by the age of 85.

Currently Alteplase (recombinant tissue plasminogen activator [rtPA]) is the only treatment for acute stroke approved in the United States. Alteplase is a thrombolytic agent that restores cerebral blood flow by removing the vascular occlusion. Alteplase is only an appropriate therapy for a small proportion of stroke patients (˜2%) because it must be given early to achieve efficacy and functional recovery following delayed reperfusion. Less than 15% of patients, however, are admitted to the hospital within the 3-hour safety window (1). Several other new treatments are being tested in the clinic and even more are in preclinical development. Antiplatelet therapy and thrombolytics are aimed at improving cerebral blood flow but there are other therapeutic strategies such as neuroprotectants, antiinflammatory agents, free radical scavengers, and neurotrophic agents. In this chapter we survey the current status of clinical trials for stroke and review these therapeutic strategies.

PATHOPHYSIOLOGY AND PRECLINICAL MODELS OF STROKE

Part of "93 - Current and Experimental Treatment of Stroke "

Stroke in the clinic is represented predominantly by ischemic stroke (80%), in which there is a loss of cerebral blood flow owing to vascular occlusion. The remaining 20% of strokes result from cerebral hemorrhage. Experimentally, there are two main types of *in vivo* stroke models, global and focal ischemia. In global models, the entire forebrain is made ischemic for a brief period (5 to 20 minutes) and then reperfused. After a significant delay (>3 days), selective neuronal death evolves in layers III, V, and VI of the cortex, the CA1 region of the hippocampus, and the striatum (2 ,3 and 4). These models are representative of cardiac arrest and coronary artery bypass surgery rather than clinical stroke. In focal models, the middle cerebral artery is occluded for a more prolonged period (60 to 120 minutes in temporary models and permanently in permanent occlusion models). Focal models are representative of clinical stroke and produce histologic damage similar to ischemic stroke in humans. The focal model produces a pannecrotic core surrounded by a narrow penumbral border. The penumbra is at risk of becoming necrotic but is potentially salvageable given the appropriate therapeutic intervention (3 ,4). The evolution of delayed neuronal death in global and focal ischemia occurs by a cascade of events that unfold temporally and spatially (5). Blocking biochemical processes in the excitotoxic cascade is the rationale behind the various therapeutic strategies for treating stroke and will be the framework for this chapter as we describe therapeutics that have been tested, or are currently being tested, in the clinic.

THERAPEUTIC STRATEGIES FOR TREATING STROKE

Part of "93 - Current and Experimental Treatment of Stroke "

Neuronal damage and death do not occur immediately after ischemia, which suggests temporal thresholds for reperfusion as with tPA and possibly therapeutic thresholds for neuroprotection. Thrombolytic therapy attempts to reestablish blood flow in ischemic regions with the aim of preventing or minimizing cell damage (6 ,7). Various agents have been used in clinical trials to restore cerebral blood flow

(Table 93.1). All of the agents designed to restore blood flow are inappropriate for treating hemorrhagic stroke because of the danger of exacerbation of cerebral bleeding (8). In fact, most of the drugs that restore blood flow are associated with an increased risk of hemorrhage particularly when administered late (>6 hours). The drugs used to restore blood flow can generally be grouped into antithrombotics, antiplatelet agents, fibrinogen depleting agents, or thrombolytics (Table 93.1).

Drugs to improve blood flow
- Antithrombotic
  - Heparin
  - Nadroparin (low molecular weight heparin)
  - Tinzaparin (low molecular weight heparin)
  - Danaparoid (low molecular weight heparinoid, Org 10172)
- Anti-platelet
  - Aspirin
  - Abciximab
- Fibrinogen depleting
  - Ancrod
- Improve capillary flow
  - Pentoxifylline
- Thrombolytics
  - Pro-urokinase
  - Tissue plasminogen activator
  - Streptokinase
  - Urokinase

Drugs to protect brain tissue (neuroprotective agents)
- Calcium channel blockers
  - Nimodipine
  - Flunarizine
- Free radical scavengers—antioxidants
  - Ebselen
  - Tirilazad
  - NPY-059
- GABA agonists
  - Clomethiazole
- Glutamate antagonists
  - AMPA antagonists
    - GYKI 52466
    - NBQX
    - YM90K
    - YM872
    - ZK-200775 (MPQX)
  - Kainate antagonist
    - SYM 2081
  - NMDA antagonists
    - Competitive NMDA antagonists
      - CGS 19755 (Selfotel)
    - NMDA channel blockers
      - Aptiganel (Cerestat)
      - Dextrorphan
      - Dextromethorphan
      - Magnesium
        - Memantine
        - MK-801
        - NPS 1506
        - Remacemide
        - AR-R15896AR
        - HU-211
      - Glycine site antagonists
        - ACEA 1021
        - GV150526
      - Polyamine site antagonists
        - Eliprodil
        - Ifenprodil
- Growth factors
  - Fibroblast Growth factor (bFGF)
- Leukocyte adhesion inhibitor
  - Anti-ICAM antibody (Enlimomab)
  - Hu23F2G
- Nitric oxide inhibitor
  - Lubeluzole
- Opioid antagonists
  - Naloxone
  - Nalmefene
- Phosphatidylcholine precursor
  - Citicoline (CDP-choline)
- Serotonin agonists
  - Bay × 3072
- Sodium channel blockers
  - Fosphenytoin
  - Lubeluzole
  - 619C89
- Potassium channel opener
  - BMS-204352

[a]From: *http://www.neuro.wustl.edu/stroke/stroke-drug-categories.htm#ACUTE STROKE THERAPY.*

TABLE 93.1. CLINICAL TRIALS FOR ACUTE STROKE TREATMENT[a]

Antithrombotics such as heparin and warfarin have been tested in numerous trials. There is no evidence to date to support the use of warfarin in the treatment of acute stroke (9). Heparin, followed by coumadin, is an extremely important modality to prevent secondary strokes, particularly cardioembolic stroke, in certain circumstances arterial occlusion following dissection, and nearly always following venous infarction. In a large-scale randomized trial comparing heparin with the antiplatelet aspirin, heparin was associated with only three fewer deaths per 1,000 at 14 days and no difference at 6 months (10). Although there were fewer recurrent strokes within 14 days, more of them were hemorrhagic. Moreover, 12,500 IU heparin was associated with significantly more transfused or fatal extracranial bleeds, hemorrhagic strokes, and deaths than 5,000 IU (10). Low molecular weight heparinoids have been developed that have greater bioavailability and less effect on platelet function than heparin, thus reducing complications such as hemorrhage and thrombocytopenia (11). Results from the trials of two of the low molecular weight heparinoids have been reported. ORG 10172 (Danaparoid) was tested in the Trial of ORG 10172 in Acute Stroke (TOAST) (12). Despite an apparent positive response at 7 days, there was no significant improvement in favorable outcome at 3 months (12). In contrast, Nadroparin (Fraxiparine) was effective in improving outcomes at 6 months when treatment was initiated within 48 hours of symptom onset for a period of 10 days (13). Unfortunately, this study has not been replicated. The results of a 1,500-patient phase III trial (Tinzaparin in Acute Ischemic Stroke Trial [TAIST]) for a third low molecular weight heparinoid, tinzaparin (Innohep), are completed and are currently being analyzed (14).

Antiplatelet agents such as aspirin have also been tested in numerous trials (Table 93.2). Two large-scale phase III trials (Chinese Acute Stroke Trial [CAST] and International Stroke Trial [IST]), in which there were 20,000 patients in each, found that there was a small but worthwhile improvement in the main outcome measures (absolute risk reduction of <1% [need to treat 111 to benefit one]) at 6 months and that aspirin should be started as soon as possible after the onset of symptoms (10 ,15). In the IST trial, there were fewer deaths and recurrent ischemic strokes with no significant excess of hemorrhagic strokes among the aspirin-allocated patients (10). Recently, the Abciximab in Ischemic Stroke Investigators (16) reported that Abciximab (ReoPro), a potent parenterally administered platelet glycoprotein IIb/IIIa

antagonist, when administered up to 24 hours after stroke onset, resulted in an improved functional outcome. At 3 months, there was a trend toward a higher rate of minimal residual disability (Barthel Index ≥95 or modified Rankin scale ≤1) among Abciximab patients compared with those who received placebo. Antiplatelets may prove a viable therapy for both prevention and intervention.

[a]From: *http://www.neuro.wustl.edu/stroke/therapy/Therapy_1Page5.html*

TABLE 93.2. CLINICAL TRIALS INVOLVING ASPIRIN AS A THERAPEUTIC FOR STROKE[a]

Ancrod (Viprinex/Arvin) is a fibrinogenolytic agent that comes from the venom of the Malaysian pit viper (17). Ancrod has recently completed a North American phase III trial (Stroke Treatment with Ancrod Trial [STAT]). Treatment was a 5-day paradigm initiated within 3 hours of onset (18). There was an increase in symptomatic intracranial hemorrhage (5.2% versus 2% for placebo), and there was no difference in mortality at 3 months (18). There is a European trial (ESTAT) for Ancrod that has yet to be completed but BASF, who was jointly conducting the phase III trials, has decided not to continue the trials after an independent group looked at the interim results and failed to see any evidence of efficacy (19).

Thrombolysis has been performed with a variety of compounds administered by various routes. From numerous trials, one thing is clear of all agents in this category: They must be given early or serious hemorrhagic complications are likely (7). Urokinase (uPA) is an endogenous proteolytic enzyme, secreted as a proenzyme, which converts circulating plasminogen to plasmin, producing a systemic lytic state. Intraarterial administration of pro-urokinase (the single chain precursor of urokinase) was evaluated in the Prolyse in Acute Cerebral Thromboembolism Trial (PROACT) with high- or low-dose heparin (20) and in the PROACT II trial with low-dose heparin (21). Although prourokinase and intravenous high-dose heparin resulted in an increased rate of hemorrhage, intraarterial pro-urokinase with low-dose heparin significantly improved the proportion of good outcomes from 25% to 40% and hemorrhage was seen in 10% of patients, consistent with other thrombolytic trials.

Streptokinase is derived from B-hemolytic streptococci and it converts plasminogen to plasmin following the formation of a complex with plasminogen. Metaanalysis of the three major trials of streptokinase, Multicentre Acute Stroke Trial–Europe (MAST-E), the Australian Streptokinase (ASK) trial and the Multicentre Acute Stroke Trial–Italy (MAST-I), showed an increased risk of hemorrhage and death (22 ,23). The trials were all terminated prematurely.

Intravenous administration of tissue plasminogen activator (tPA) within 3 hours of symptom onset has been approved for the treatment of acute ischemic stroke in the United States for 4 years and it remains the only approved treatment for acute ischemic stroke. There have been four large trials of Alteplase, the European Cooperative Acute Stroke Studies (ECASS I and II), the National Institutes of Neurologic Disorders and Stroke (NINDS) trial, and the Alteplase Thrombolysis for Acute Noninterventional Therapy in Ischaemic Stroke (ATLANTIS). The metaanalysis of these trials shows a significant reduction in death and disability (160/1,000 or a number needed to treat of 6 versus 9/1,000 with a number needed to treat of 111 for aspirin). More trials are needed to gain a better understanding of the timing, safety, and efficacy of Alteplase in different patient populations. However, a recent study has demonstrated the efficacy of tPA for acute stroke in a community setting (24). It remains unclear whether intravenous (IV) or intraarterial (IA) tPA delivery is superior in acute ischemic stroke treatment (7 ,25 ,26 ,27 ,28 ,29 and 30). IV therapy is faster and more convenient, whereas IA therapy allows for mechanical disruption and higher drug concentration at the clot site (7). A protocol was recently tested in which severe stroke patients with little or no CT changes were given IA tPA following IV tPA if there was no clinical improvement and a persistent occlusion was identified on transcranial Doppler (30). Combined therapy was performed on nine patients and no intracerebral hemorrhages or significant systemic bleeding complications occurred. Marked clinical improvement was noted in four patients, suggesting that combined IA and IV tPA therapy is feasible and safe and that future studies should consider combining rather than comparing these two delivery strategies (30). There is an NIH-approved trial (Interventional Management Study, IMS trial) comparing IV versus combined IV and IA tPA therapy that will be underway by the time this is published.

NEUROPROTECTIVE AGENTS

Part of "93 - Current and Experimental Treatment of Stroke "

Once the excitotoxic cascade has begun, the first therapeutic strategy, and the one that has raised the most hope in the last decade, utilizes neuroprotective agents targeting mediators in the excitotoxic cascade (Fig. 93.1). The cascade can be separated spatially and temporally. The cascade begins with an increase in presynaptic calcium influx, followed by glutamate release, postsynaptic glutamate receptor activation resulting in sodium and calcium influx, which results in postsynaptic depolarization and further calcium influx.

Voltage-gated sodium and potassium channels are targets that affect depolarization, whereas calcium channels mediate calcium influx and affect depolarization. Most of the neuroprotective agents tested in the clinic have targeted either voltage-gated calcium channels or glutamate receptors, particularly the NMDA receptor subtype. In addition, GABA receptor agonists attenuate excitotoxicity (31) and free radical scavengers are neuroprotectants aimed at the later stages of the excitotoxic cascade (32). After the excitotoxic cascade has progressed, an inflammatory response occurs in which there is infiltration of leukocytes and monocytes (33). Microglia and astrocytic glial cells are activated and macrophages begin responding to chemoattractants. Still other therapeutic strategies have targeted leukocyte adhesion (34 ,35) and nitric oxide production (36 ,37). Once much of the damage has occurred and neuroprotection is no longer a viable strategy, neural regeneration and trophism becomes an option. This approach has been mounted with infusion of growth factors but trials to date have been unsuccessful (38). We now look at trials of compounds targeted to these various processes in the excitotoxic cascade.

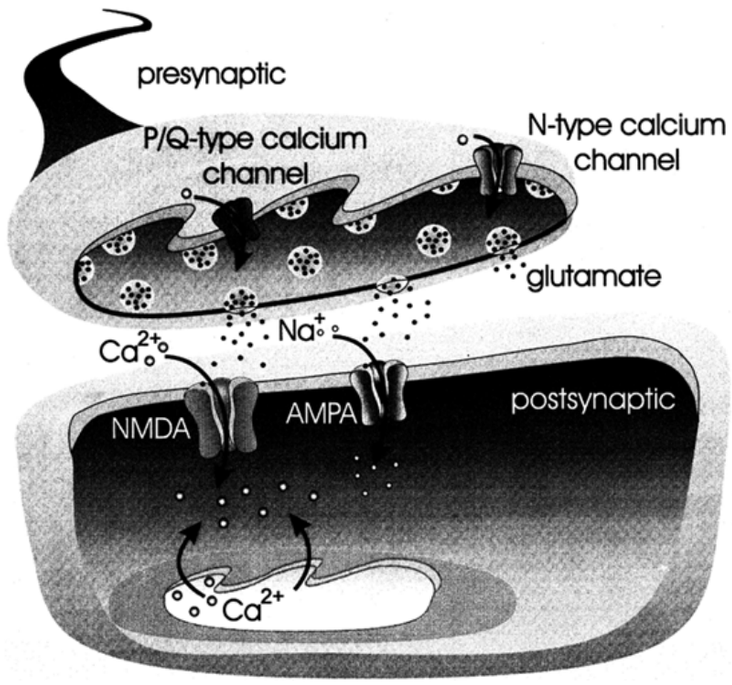

FIGURE 93.1. Thereapy utilizing neuroprotective agents targeting mediators in the excitotoxic cascade. See color version of figure.

CALCIUM CHANNEL ANTAGONISTS

Part of "93 - Current and Experimental Treatment of Stroke "

Clinically, L-type calcium channel antagonists have been used extensively for the treatment of cardiovascular disorders such as hypertension; however, very few have been tested in the arena of stroke therapy. Although the metaanalysis of oral nimodipine (Nimotop) trials demonstrated no significant effects on neurologic or functional outcome, the drug was administered within a very large therapeutic window (i.e., 24 to 48 hours) following symptom onset (39). More recently, a more aggressive trial (Very Early Nimodipine Use in Stroke, VENUS) designed to treat with nimodipine within 6 hours of symptom onset was terminated before completion because the results indicated that there was no beneficial role of early administration of oral nimodipine at 3 months (40). Although nimodipine failed to demonstrate efficacy in treating acute stroke, it was approved for the treatment of subarachnoid hemorrhage more than a decade ago. The results of a phase III trial of flunarizine (Sibelium) for acute stroke suggested that it also did not improve neurologic or functional outcome at 3 months when administered early (<6 hours) (41).

The N-type calcium channel antagonist, SNX-111 (Ziconotide), preferentially blocks presynaptic calcium channels and inhibits neurotransmitter release. In both focal and global animal models of cerebral ischemia SNX-111 is highly neuroprotective, even when administered after a delay of 24 hours following reperfusion (42). SNX-111 has also been tested in clinical trials for acute stroke. Although the stroke trials of SNX-111 were discontinued because of severe hypotension that exacerbated the ischemic damage (43), SNX-111 has progressed to phase III trials for head trauma (44 ,45) and has just been approved by the FDA for the treatment of pain (46). Spider toxin antagonists of the P/Q-type neuronal calcium channels are neuroprotective *in vitro* but their *in vivo* toxicity in animals, primarily respiratory depression causing death, has limited their clinical development. However, efforts to generate small peptide analogues of these spider toxins, which exhibit efficacy *in vitro*, are ongoing.

GLUTAMATE RECEPTOR ANTAGONISTS

Part of "93 - Current and Experimental Treatment of Stroke "

Numerous clinical trials have been carried out for NMDA receptor antagonists based on preclinical testing in animal models of cerebral ischemia (47). All the phase III trials to date have failed. Optimism for the use of NMDA receptor antagonists in the treatment of acute ischemia has waned and has even prompted some pharmaceutical companies to abandon efforts to develop therapeutics for acute stroke. The experience with NMDA receptor antagonists in the clinic has been that most NMDA receptor antagonists result in psychosis as a common adverse effect (48). NMDA receptor antagonists with greater specificity for various binding sites on the receptor, or selectivity for a given receptor subunit, are being developed which demonstrate greater safety and fewer adverse effects (49 ,50 ,51 and 52).

NMDA receptors are heteromeric pentamers composed of at least one NR1 subunit and one or more of the four different NR2 subunits, NR2A, NR2B, NR2C, or NR2D. There are a number of sites on the NMDA receptor at

which antagonists can bind (Fig. 93.2). Competitive antagonists bind to the same site as NMDA or glutamate. Glycine and polyamines each bind as activators of the NMDA receptor and there are antagonists of these two sites, respectively. There are also noncompetitive antagonists that bind to the inside of the pore of the channel and sterically inhibit the influx of ions (53 ,54 and 55). These compounds are called use-dependent. Competitive NMDA receptor antagonists block channel activity best when glutamate levels are low. These antagonists would be expected to be less efficacious during ischemia compared to a normally functioning brain because glutamate levels rise during ischemia (56); therefore, the therapeutic index of these agents would be expected to be low.

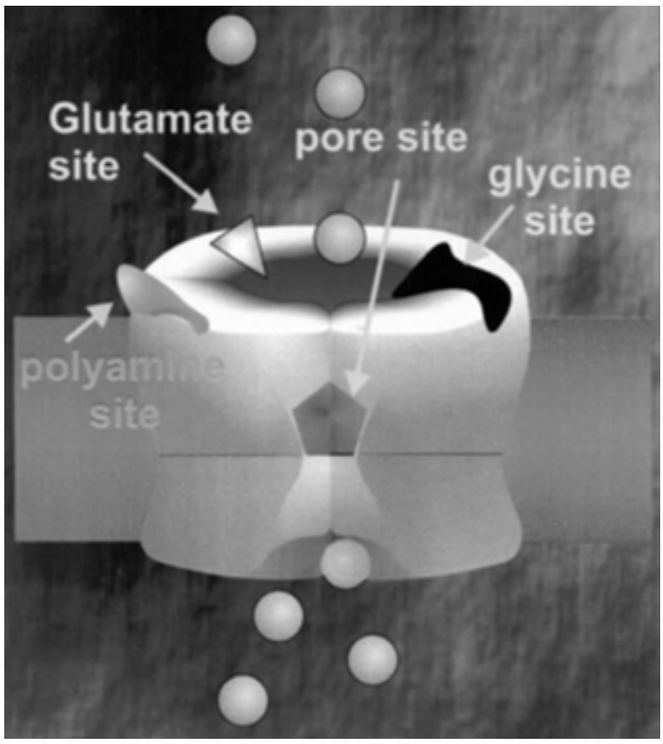

FIGURE 93.2. Sites on the NMDA receptor at which antagonists can bind. See color version of figure.

Not surprisingly, two phase III trials (Acute Stroke Trials Involving Selfotel Treatment [ASSIST] and a head injury trial) of the competitive NMDA receptor antagonist CGS 19755 (Selfotel) were suspended given that they were not effective and caused neurotoxic side effects (57 ,58 and 59). The principal side effects were agitation, hallucinations, and psychotomimetic effects similar to those seen with phencyclidine (PCP) (60 ,61). Furthermore, among the patients with severe stroke, there was a trend toward a significant difference in the number of deaths between those treated with Selfotel (33%) and those in the placebo group (22%) (58).

Two years later, phase III trials for the noncompetitive NMDA receptor antagonist Aptiganel (Cerestat/CNS-1102) were discontinued (62). In a subsequent analysis of the phase III trial, some potential therapeutic benefit was identified in a subset of the stroke population. Cambridge Neuroscience plans to further investigate these beneficial effects in partnership with Boehringer Ingelheim (63). The most common side effects with this high-affinity channel blocker were motor retardation, elevated blood pressure, perceptual disturbances, and hallucinations, similar to those seen with Selfotel (60). The rest of the noncompetitive NMDA receptor antagonists exhibit much lower affinity for the ion channel pore than Cerestat. Although memantine has been shown to be neuroprotective in both *in vitro* and *in vivo* models (64) and memantine is progressing for the treatment of dementia (65), it is not currently being developed for the treatment of acute stroke to our knowledge. Remacemide and its active desglycinyl metabolite are well-tolerated at relatively high doses in humans, have demonstrated significant neuroprotective efficacy in animal models of cerebral ischemia, and were doing well in phase II trials for acute stroke (66); however, there is some question as to whether optimal neuroprotective doses would be achieved within the early hours of treatment in humans (51). Thus, the low-affinity compound ARR-15896 was developed as a backup to remacemide and is currently in early Phase II trials (66). Hu-211 (dexanabinol, Cypros) is a nonpsychogenic cannabinoid with both low affinity use dependent block of NMDA receptors, as well as inhibition of tumor necrosis factor-α and antioxidant properties. It exhibits widespread neuroprotective actions in several animal models of stroke and head trauma (67) and has just recently completed a small phase II trial for head trauma clearing the way for a large multinational clinical trial of several hundred severe head trauma patients to commence later this year (68). Magnesium, also a low-affinity noncompetitive NMDA receptor antagonist, is currently in phase III clinical trials for the treatment of acute stroke (Intravenous Magnesium Efficacy in Stroke [IMAGES]). Patients are randomized to receive placebo or intravenous magnesium (16 mmol over 15 minutes followed by 65 mmol over 24 hours) within 12 hours of symptom onset (69). Recruitment of the 2,700 patients is ongoing and should be completed by 2002. Magnesium infusions are well tolerated in humans and have been demonstrated to be neuroprotective in animal models of cerebral ischemia (49 ,69 ,70). In a smaller trial, magnesium-treated patients improved neurologically and the need for institutional care 6 months after the stroke was reduced (49 ,71).

NPS-1506 is another open channel blocker being developed for the treatment of acute stroke. NPS-1506 acts at a novel site within the pore and is an orally active small molecule developed by drawing on the knowledge of spider toxins with pore-blocking abilities (72). NPS-1506 is currently in phase Ib and to date is devoid of the side effects normally attributed to noncompetitive antagonists. In animal models of cerebral ischemia, significant protection is achieved even when NPS-1506 is administered up to 2 hours after onset of stroke. At neuroprotective doses there were no PCP-like behavioral effects, no learning or memory impairment, no neuronal vacuolization, and no significant sedation or cardiovascular side effects (72 ,73).

Polyamine site NMDA receptor antagonists like eliprodil (SL 82-0715) and ifenprodil have also not done well in

clinical trials (54). Their failure has been attributed to the cardiovascular side effects they possess by virtue of their affinity for sodium and calcium channels in addition to NMDA receptors (74 ,75). Eliprodil had electrocardiographic effects that limited dosing such that efficacy was not obtained and phase III trials were abandoned in 1997 (74). Another feature of the polyamine site antagonists is that they are relatively specific for NR2B receptor subunits (76). The affinity of eliprodil for NR2B subunits is more than 100-fold greater than that for NR2A or NR2C receptor subunits. A number of other NR2B subunit selective antagonists are currently under development for the treatment of stroke (Table 93.3). Ro 25-6981 and CP-101,606 are both high-affinity NR2B-selective antagonists with very slow kinetics (76 ,77 and 78). CP-101,606 is neuroprotective in animal models of cerebral ischemia but the slow kinetics may limit the rate at which neuroprotective doses may be achieved in human stroke. The fact that there were no psychotomimetic effects of CP-101,606 in phase II trials for moderate head injury and hemorrhagic stroke and that the drug was well tolerated suggest that CP-101,606 might be well tolerated in occlusive stroke (79). Compounds such as Co 101244/PD 174494 are being developed with high-affinity antagonists such as CP-101,606 but more rapid kinetics like isoxsuprine in anticipation of the slower kinetics of CP-101, 606 presenting problems in efficacy in treating stroke (80). Something else which may increase the chances of success of Co-101244/PD174494 is that it also had much less affinity for α1-adrenergic receptors and displayed a reduction in inhibition of potassium channels, something that most other high-affinity compounds possess (80).

Subunit Compound	NR2A	NR2B	NR2C	Cortical Neurons (Mostly NR2B)	Rank Order Kinetics

[a]All numbers are IC50s in μM and are from Whittemore et al., 1996 unless indicated by[a], in which case they are from Trube et al., 1996. The more potent, the slower the kinetics but also the more protective. From Whittemore ER, Ilyin VT, Woodward RM, Subtype-selective antagonism of NIMDA receptors by Nylidrin. *Soc Neurosci Abat* 1996;22:506–507 and Trube G, Elrhard P, Huber G. The selectivity of RO 25-6981 for NMDA receptor subtypes expressed in Xenopus oocytes. *Soc Neurosci Abat* 1996;22:691–693.
[b]Glutamate dependence: lower affinity with lower glutamate, than with higher glutamate concentrations. All IC50s are done with high glutamate.

TABLE 93.3. NR2B SUB UNIT-SPECIFIC NMDA RECEPTOR ANTAGONISTS

Glycine site antagonists exhibit better safety profiles than NMDA receptor antagonists that bind to other sites (48). Most of the clinical attention on glycine site antagonists has been focused on two therapeutic candidates, ACEA 1021 (Licostinel) and GV150526. ACEA 1021 (5-nitro-6,7-dichloro-2,3-quinoxalinedione) is a member of a family of compounds called kappagems. ACEA-1021 has demonstrated neuroprotective efficacy in animal models of focal and global ischemia (81) and it exhibits minimal adverse CNS or cardiovascular side effects (50 ,82). The compound, originated by ACEA, was being developed by CoCensys for Novartis, but Novartis stopped participating in its development after crystals of ACEA-1021 were found in the urine of some participants in a phase I study (83). CoCensys retains the rights to the drug and is continuing to evaluate it in phase II trials. One approach to dealing with the problems of ACEA-1021 excretion has been to treat in combination with probenecid, which nonselectively inhibits secretion of anionic compounds (84). The combination of ACEA-1021 and probenecid resulted in significantly larger infarct reductions in animal models of cerebral ischemia suggesting that the limiting factor in ACEA-1021 efficacy is related to the steady-state levels that can be elevated by combination therapy with probenecid (84).

GV150526 is significantly neuroprotective in animal models of cerebral ischemia and like ACEA-1021, has shown good tolerability with minimal CNS side effects in the Glycine Antagonist in Neuroprotection (GAIN) phase I and II trials (The GAIN Investigators) (52). Minor abnormalities in liver function were noted with higher maintenance doses, but these changes were asymptomatic and resolved

within 10 days (52). The results of the dose-escalation phase II clinical trial for GV150526 (85) were reported last year and were followed with the GAIN Americas and the GAIN International phase III trials. Approximately 1,600 patients were recruited into randomized double-blinded placebo controlled trials. Two substudies in each trial were planned, to measure lesion volume by MRI-DWI (Magnetic Resonance Imaging-Diffusion Weighted Imaging) and to measure health-related quality of life outcomes. The results of the GAIN International were presented at the 25th International American Heart Association meeting and were less than anticipated and completely neutral. Unlike most trials with NMDA receptor antagonists, the problem with GV150526 was not safety but rather efficacy (85). The results from the GAIN American study are not yet available.

In contrast to NMDA receptor antagonists, there is little experience using AMPA and KA receptor antagonists to treat acute stroke. Fewer binding sites have been characterized on the AMPA receptor compared to the NMDA receptor. Competitive quinoxalinedione antagonists bind to the AMPA binding site and there are also noncompetitive GYKI [GYKI 52466,1-(4-aminophenyl)-4-methyl-7,8-methylenedioxy-5H-2,3-benzodiazepine HCl] site-binding antagonists, benzodiazepine binding-site antagonists, and pore-blocking antagonists (86). The pore-blocking antagonists are mostly from spider toxins and are not appropriate for clinical development. There is one noncompetitive AMPA/KA receptor antagonist, EGIS-9637, which demonstrates neuroprotective efficacy in both focal and global animal ischemia models, but the clinical development has not begun and little is known of the tolerability (87). One of the more common CNS effects of AMPA receptor antagonists is sedation. All of the AMPA receptor antagonists in clinical trials for the treatment of acute stroke are competitive antagonists based on the quinoxalinediones such as NBQX. NBQX and other quinoxalinediones are neuroprotective in animal models of ischemia, even when administered up to 12 hours following reperfusion (88). The main problem with quinoxalinediones has been nephrotoxicity owing to the poor solubility of these compounds (89). One AMPA receptor antagonist, ZK-200775, progressed to phase IIa but these trials were discontinued in 1998 owing to excessive sedation (90). Yamanouchi Pharmaceuticals have developed a series of competitive AMPA receptor antagonists that are neuroprotective in animal models and exhibit improved solubility (91 ,92 and 93). In phase I trials YM90K was well tolerated and in spite of a high rate of urinary excretion there were only mild changes in kidney function markers with a single intravenous dose of 36 mg and repeated doses of 24 mg over 3 hours (94). These phase I trials were followed by phase II trials using the AMPA receptor antagonist, YM872, which has a solubility 800-fold greater than NBQX or YM90K at pH 7 (95). Phase IIa trials are ongoing. The only adverse effect reported in the YM872 phase I study was euphoria in some patients at the higher dose levels (96). The challenge with YM872 will be overcoming the short half-life of the drug to maintain the elevated plasma levels necessary to effect neuroprotection.

GABA RECEPTOR AGONISTS

Part of "93 - Current and Experimental Treatment of Stroke "

Clomethiazole (Zendra), a GABA receptor agonist, has just completed large-scale phase III clinical trials for the treatment of acute stroke, Clomethiazole Acute Stroke Study (CLASS and CLASS-I, H and T) (97). Clomethiazole was well tolerated and appeared safe. Sedation was the most common adverse event that led to treatment withdrawal in almost 16% of treated, compared to only 4% in the placebo group. In the main efficacy analysis 56.1% of patients taking clomethiazole and 54.8% of placebo patients reached relative functional independence (97). The difference was not significantly different but in a subgroup analysis of 545 patients who had total anterior circulation syndrome (TACS), the percentage of those reaching relative functional independence was 40.8% on clomethiazole and 29.8% in the placebo group (98). This subgroup efficacy has prompted the testing of clomethiazole in large ischemic cerebral infarctions (CLASS-I), ischemic infarctions in those who receive tPA (CLASS-T), and intracerebral hemorrhage (CLASS-H). Previous failed clinical trials for stroke may have shown efficacy had there been subgroup targeting like that being carried out in the CLASS-I study. However, it is difficult to categorize subgroups of strokes while operating under the extreme time constraints stroke treatment requires. A recent protocol for grading strokes has been developed (ASPECTS, which addresses the need for rapid diagnosis and assessment of infarct (99).

OTHER THERAPEUTIC TARGETS

Part of "93 - Current and Experimental Treatment of Stroke "

Voltage-Gated Channels

Potassium channel openers may rescue injured penumbral neurons, thus reducing the size of the infarct and improving neurologic outcome. The novel potassium channel opener, BMS-204352, is being assessed in the Potassium-channel Opening Stroke Trials (POST) in which medication is administered within 6 hours of onset of symptoms. The primary endpoint is change in lesion volume at 12 weeks determined by diffusion/perfusion MRI.

Opioid Receptor Antagonists

The competitive κ-selective opioid receptor antagonist Cervene (Nalmefene) is neuroprotective in animal models of

ischemia and clinically safe (100). In a phase II trial in patients with acute ischemic stroke treated with 6, 20, or 60 mg Cervene there was no significant functional improvement compared to placebo after 3 months (100). A secondary analysis showed an improved 3-month outcome in patients less than 70 years of age.

Free Radicals, Nitric Oxide, and Inflammation

During reperfusion, oxygen-free radicals contribute to damage neurons when antioxidant defense mechanisms are not optimal. Superoxide, hydrogen peroxide, and hydroxyl radicals are responsible for damaging membranes and degrading DNA. In experimental models, agents such as vitamin E, glutathione, superoxide dismutase, iron chelators, lazaroids, NPY-059, and catalase have been tested as free radical scavengers. One of the most tested agents, Triliazad mesylate (Freedox), an inhibitor of lipid peroxidation, is neuroprotective in stroke models (37). In a phase II study of over 400 patients treated with 6 mg/kg per day tirilazad for 3 days within 6 hours of onset, no significant outcome relative to placebo control was observed (101). The Randomized Trial of High Dose Tirilazad in Acute Stroke (RANTTAS II) phase III trials of a higher dose was stopped because of a lack of efficacy (102). Similarly, the antioxidant Ebselen, which has glutathione peroxidase-like activity, showed no efficacy (103). NPY-059 is currently in early phase II trials by Centaur.

Lubeluzole (Prosynap) is a benzothiazole that blocks glutamate-induced nitric oxide-mediated neurotoxicity in rats. In a phase II trial patients presenting within 6 hours were randomized to a placebo group or to receive iv Lubeluzole at 7.5 or 15 mg over 1 hour as a loading dose, followed by a continuous infusion of 10 or 20 mg per day for 5 days, respectively. This trial was terminated early owing to high mortality in the high-dose group (36). Clinical development was subsequently stopped after a large phase III trial (Lub-Int-13) failed to show efficacy.

Citicoline provides cytidine and choline as precursors in the synthesis of the integral membrane component phosphatidylcholine. During ischemia phosphatidylcholine is broken down into free fatty acids, which in turn generate free radicals. Citicoline has been studied as a neuroprotectant as well as a promoter of neural plasticity and repair after stroke through its actions to promote membrane synthesis, to decrease the levels of free fatty acids and to promote the regrowth of axons and nerve terminals. In a phase II study, oral citicoline (CerAxon; 500, 1,000, and 2,000 mg per day) was administered within 24 hours for a 6-week period (104). A dramatic improvement in functional independence outcome (61% versus 39% in the placebo group) was seen in the 500 mg and 2,000 mg (but not the 1,000 mg) dose groups. A second study of 500 mg per day citicoline versus placebo failed to demonstrate significant differences in outcome or mortality. The results from the 899 patient phase III trial comparing 2,000 mg citicoline to placebo (105) failed to meet the primary endpoint, an improvement in neurologic function. However, citicoline was shown to be safe and there was a higher percentage of citicoline-treated patients with reduced infarct volumes compared to the placebo group.

Treatment with a monoclonal anti-ICAM-1 antibody inhibits leukocyte adhesion by blocking leukocyte attachment and migration through cerebral endothelial cells and reduces neurologic deficits in rodent ischemia models (34). The Enlimomab Acute Stroke Trial (EAST) completed in 1996 showed that the anti-ICAM-1 antibody treated patients had a worse outcome than placebo-treated patients (35). LeukArrest (Hu23F2G) is another human antibody that inhibits neutrophil movement from the blood into the brain by specifically targeting CD11/CD18 molecules on the surface of neutrophils. A recently completed phase II trial showed LeukArrest to be safe and suggested an improved neurologic outcome. The Hu23F2G Phase III Stroke Trial (HALT) with 310 patients was begun in early 1999.

CONCLUSION AND FUTURE DIRECTIONS: THE ARSENAL OF A UTOPIAN STROKE CARE CENTER

Part of "93 - Current and Experimental Treatment of Stroke "

Given the worldwide efforts focusing on cloning the human genome and the parallel efforts to identify disease specific genes and proteins through genomics and proteomics, we have no way of knowing how many stroke specific genes and proteins will be identified. Estimates of the total number of disease genes are between 10,000 and 30,000. Because there are currently only 450 clinical targets of therapeutic intervention worldwide, there are at least 9,000 new genes for which we have no idea of function and no pharmacologic tools with which to study them. One thing is certain; we will be faced with an explosion of information in 2001, the expected completion date of the human genome project.

In terms of the strategies described in the preceding, efforts to increase blood flow may include angiogenesis using a recombinant adenovirus expressing vascular endothelial growth factor (VEGF) or perhaps other gene therapy delivered vascularly. Still more effort is being focused on NMDA receptors, but in developing safer compounds such as ARL 15896 and GV150526 with a better therapeutic ratio than agents that previously failed in trials. Trials are well underway for some AMPA receptor antagonists like YM872 and the results of these will reveal whether this strategy is a viable one worthy of further attention.

Growth factor therapies are targeted to improve neuronal survival, repair, and plasticity following acute ischemic stroke. A phase III trial of fibroblast growth factor (Biblast, bFGF, Trafermin) was discontinued because of no efficacy

relative to the placebo group. The glial derived growth factor, GFG2, is being developed by Cambridge NeuroScience (CNSI) for treating neurodegenerative disorders and may perhaps treat stroke (106). Another avenue of therapy is to promote the growth of new vessels through angiogenesis, but this too has yet to be realized in trials for stroke. Neurogenesis is an area that is generating attention in animal models but the growth of new neurons occurs very late and experimentally only in the dentate; therefore, the relevance to the clinical situation is somewhat obscure (107). A viable alternative to promoting the growth of the brain's own cells is to treat with stem cells that have the potential of generating new neurons. Recently this was successfully attempted *in vivo* (108).

Although the recent Heart Outcomes Prevention Evaluation (HOPE) trial, which looked at ramipril versus vitamin E, failed to demonstrate effects of vitamin E on any of the cardiovascular outcome measures, including myocardial infarction, unstable angina, congestive heart failure, stroke, and death from cardiovascular causes (109), two new trials, Vitamin Intervention for Stroke Prevention or VISP (110) and Vitamins to Prevent Stroke or VITATOPS (111) have recently begun to determine whether daily B_{12}, B_6, and folate, which reduce homocysteine levels, are better than the best medical practice and surgical management alone to reduce the recurrence of vascular events in stroke patients.

The Women's Estrogen for Stroke Trial (WEST) will assess whether postmenopausal estrogen therapy (1 mg estradiol per day) in women with recent transient ischemic attacks or nondisabling stroke can reduce the risk of death or recurrent stroke (112).

Inasmuch as we have laid out spatially distinct strategies, there is an overlapping temporal association of these strategies. This temporal aspect can be exploited in the form of co-therapies. Because ischemic death occurs via a cascade involving several processes, it is likely that targeting one single process will prove inadequate and instead, targeting several of the processes with a cocktail of therapeutic agents given in a specific temporal sequence will prove efficacious. The development of safe therapeutics for the intervention of stroke should provide a brighter future for stroke survivors with the increase in stroke awareness and the number of centers with dedicated stroke care units.

TAU-POSITIVE FILAMENTOUS LESIONS IN NEURODEGENERATIVE DISEASES

Part of "94 - Tau Protein and Tauopathy "

Neurofibrillary Lesions of Alzheimer's Disease Brains

Although the mechanisms underlying the onset and progression of Alzheimer's disease (AD) have not been fully elucidated, the two diagnostic neuropathologies in the AD brain (i.e., amyloid plaques and neurofibrillary lesions) (1 ,2) have been implicated mechanistically in the degeneration of the AD brain, and they are considered to be plausible targets for the discovery of potential therapeutic agents to treat this common dementing disorder. AD is a genotypically and phenotypically heterogeneous disease. In spite of this genetic heterogeneity, abundant amyloid plaques and neurofibrillary lesions, including neurofibrillary tangles (NFTs), neuropil threads, and plaque neurites are observed consistently in all forms of AD, and both plaques and tangles are required to establish a definite diagnosis of AD in a patient with dementia.

Amyloid plaques are extracellular deposits of fibrils formed by ß-amyloid (Aß) peptides cleaved from APP, but Aß also forms diffuse plaques that contain primarily nonfibrillar deposits of Aß peptides. The neuritic type of amyloid or senile plaque (SP) binds amyloid dyes such as thioflavin-S and Congo red because of the presence of Aß fibrils with a ß-pleated sheet structure. The neurofibrillary AD lesions also contain aggregated filaments, but they are formed by abnormally phosphorylated tau proteins that accumulate as NFTs in neuronal perikarya and as neuropil threads or dystrophic neurites in dendrites and axons. However, NFTs may be released into the extracellular space of the AD brain, following the degeneration of tangle-bearing neurons, and they are referred to as "ghost tangles." Finally, dystrophic neurites are frequently associated with amyloid plaques to form neuritic plaques.

Both amyloid plaques and neurofibrillary lesions are considered to play independent and/or interrelated roles in the mechanisms that underlie the onset and relentless progression of brain degeneration in AD. Indeed, serveral studies have shown that NFTs correlate with the severity of dementia in AD, as do losses of synapses and neurons (10 ,11 ,12 and 13). Although there is a poor correlation between these parameters and the concentration or distribution of amyloid deposits (11 ,13), this could reflect the turnover of these lesions. Furthermore, it has been reported that a small population of AD patients show abundant NFTs but very few amyloid plaques (14), which may signify that there is a causal relationship between the accumulation of NFTs and the clinical manifestations of AD.

Despite heterogeneity in the AD phenotype, the progressive accumulation of NFTs follows a stereotypical pattern as described by Braak and Braak (15), who defined six neuropathologic stages of AD progression determined by the distribution and severity of NFTs. Stage I shows NFTs and neuropil threads confined to pre-α neurons of the transentorhinal cortex, and stage II shows a more remarkable involvement of this area and a mild involvement of the pre-α neurons in the entorhinal cortex. AD brains in stage III show severe neurofibrillary lesions in the above-mentioned regions as well as the emergence of extracellular tangles, and extensive neurofibrillary lesions are found in the deeper layers of entorhinal and transentorhinal cortex in stage IV. Stages III and IV are also characterized by neurofibrillary pathology in layer I of Ammon's horn in the hippocampus and in subcortical nuclei. Finally, increasingly abundant neurofibrillary lesions in isocortical association cortex define stages V and VI.

Neurofibrillary lesions such as NFTs, neuropil threads, and plaque neurites are argyrophilic structures, but they are visualized most effectively using immunohistochemistry and antibodies to phosphorylated tau proteins. In addition to neurofibrillary tau lesions, some neurons show diffuse perikaryal tau immunoreactivity, and this so-called "pretangle"

tau pathology is not stained by amyloid dyes such as thioflavin-S and Congo red, unlike NFTs and other neurofibrillary lesions. Thus, “pretangle” tau pathology may be an early stage in the formation of NFTs prior to the accumulation of abnormal tau filaments.

Tauopathies Other than AD

Neurofibrillary lesions that are positive for thioflavin-S, silver stains, and anti-tau antibodies are also observed as the predominant brain pathology in a group of neurodegenerative disorders other than AD, which are now categorized as tauopathies (Table 94.1). Some of these diseases also show the abundant coexistence of amyloid plaques. For example, neurofibrillary lesions coexist with Aß deposits in AD as well as in Down syndrome (16 ,17), dementia pugilistica (18), and inclusion-body myositis (19 ,20 and 21). Further, in some cases of Gerstmann-Sträussler-Scheinker disease (GSS) (22 ,23), Creutzfeldt-Jakob disease (24), and prion protein cerebral amyloid angiopathy (25), neurofibrillary lesions coexist with prion protein amyloid deposits. On the other hand, amyotrophic lateral sclerosis/parkinsonism-dementia complex (ALS/PDC) found in the Chamorro inhabitants of Guam and Rota in the Mariana Islands shows abundant NFTs but very few amyloid plaques (26 ,27 ,28 and 29). Moreover, neurofibrillary lesions without amyloid plaques are observed in argyrophilic grain dementia (30 ,31), Pick disease (32 ,33 and 34), corticobasal degeneration (CBD) (35 ,36 ,37 and 38), progressive supranuclear palsy (PSP) (39 ,40 and 41), multiple system atrophy (MSA) (42), Niemann-Pick disease type C (43 ,44 and 45), diffuse neurofibrillary tangles with calcification (46), Hallervorden-Spatz disease (47), subacute sclerosing panencephalitis (48), and frontotemporal dementia and parkinsonism linked to chromosome 17 (FTDP-17) (49 ,50). However, some of these disorders, such as MSA, various subtypes of AD, Hallervorden-Spatz disease, and so on also have prominent synuclein brain lesions.

Diseases showing coexistence of tau and amyloid pathologies
Alzheimer's disease
Creutzfeldt-Jakob disease
Dementia pugilistica
Down's syndrome
Gerstmann-Sträussler-Scheinker disease
Inclusion-body myositis
Prion protein cerebral amyloid angiopathy
Diseases without distinct amyloid pathology
Amyotrophic lateral sclerosis/parkinsonism–dementia complex
Argyrophilic grain dementia
Corticobasal degeneration
Diffuse neurofibrillary tangles with calcification
Frontotemporal dementia with parkinsonism linked to chromosome 17
Hallevorden–Spatz disease[a]
Multiple system atrophy[a]
Niemann–Pick disease, type C
Pick's disease
Progressive subcortical gliosis
Progressive supranuclear palsy
Subacute sclerosing panencephalitis
Tangle-predominant Alzheimer's disease

[a]Diseases in which synuclein-positive lesions are the most prominent neuropathologic feature.

TABLE 94.1. DISEASES WITH TAU-POSITIVE NEUROFIBRILLARY LESIONS

The tau pathology of AD is almost limited to neurons, whereas some other tauopathies exhibit both neuronal and glial tau inclusions. Brains of MSA, CBD, PSP, and FTDP-17 contain abundant tau deposits in astrocytes as well as oligodendrocytes (50 ,51 ,52 ,53 ,54 ,55 ,56 ,57 ,58 ,59 ,60 and 61). On the other hand, in familial multiple system tauopathy with presenile dementia (MSTD), affected glial cells are primarily oligodendrocytes (62 ,63 and 64).

Neurofibrillary Lesions with Aging

Abundant amyloid plaques indistinguishable from those in AD brains have been demonstrated in the brains of elderly individuals who are not cognitively impaired (12 ,65 ,66); this indicates that accumulation of amyloid plaques alone is not sufficient to cause dementia. Moreover, nondemented elderly individuals also show sparse neurofibrillary lesions with increasing age, but this occurs in limited brain regions (67). Although extensive analysis by Braak and Braak has suggested that neurofibrillary changes of Braak and Braak stage I/II in elderly people may represent early stages of AD pathology (68), this has yet to be proven in studies of subjects who have been subjected to longitudinal cognitive testing up until the time of death.

Significances of Tau Pathology in Neurodegenerative Disorders

Aggregation of tau into neurofibrillary lesions is a neuropathologic hallmark of many neurodegenerative diseases, and these tauopathies can be subclassified with regard to coexisting amyloid or other brain pathology, the affected cell types and the affected CNS areas. Coexistence of tau and amyloid pathologies in some diseases suggests an interaction between tau and amyloid in mechanisms of brain degeneration. The presence of tau lesions in the brain without amyloid plaques in other tauopathies indicates that these neurofibrillary lesions are not mere consequences of neurotoxicity owing to amyloid deposits, but are direct causes of neurodegeneration. Although it is likely that the diversity of affected cell types and/or CNS regions in tauopathies will be explained more fully based on mechanistic relationships between genetic and biochemical differences among these cells, brain regions, and diseases, the clinicopathologic, biochemical, and genetic aspects of these disorders so far remain unsettled.

Ultrastructure of Filamentous Tau Lesions

According to transmission electron microscopic (EM) and immuno-EM analyses of tau filaments in various neurofibrillary lesions, the filamentous lesions consist of three types of morphologies. Approximately 95% of the neurofibrillary components in AD NFTs are paired helical filaments (PHFs), and the rest consists of straight filaments (SFs) (69 ,70). PHFs have a helical structure consisting of two ribbon-like strands that are paired together in filaments that have a diameter of 8 to 20 nm and a stereotypical periodicity of 80 nm (70 ,71). In Down syndrome, ALS/PDC, prion diseases with tangles, dementia with tangles only, Nieman-Pick disease type C, and the Seattle family A FTDP-17 kindred with the V337M tau gene mutation, the filamentous tau pathology is composed of fibrils that are ultrastructurally indistinguishable from the PHFs in AD tangles (29 ,43 ,44 and 45 ,70 ,72 ,73). Moreover, PSP and Pick disease show tangles composed of numerous SFs and smaller numbers of twisted tau filaments similar to PHFs (63 ,74). Twisted ribbon-like tau filaments that are morphologically different from AD PHFs and SFs are found in the tangles of the familial MSTD FTDP-17 syndrome caused by a G to A mutation in the intron following exon 10 of the tau gene (64), Dutch family 1 FTDP-17 syndrome owing to the P301L mutation in exon 10 of the tau gene (75), and CBD (76). Unlike AD PHFs, these filaments have an irregular periodicity of 90 to 130 nm (64).

Nonetheless, immuno-EM studies have demonstrated that all the filamentous structures in the tangles of all of these tauopathies are composed of aberrantly hyperphosphorylated tau proteins, and possess the same tau epitopes (77 ,78 ,79 ,80 ,81 and 82), although the relative abundance of different pathologic tau isoforms may vary in these tauopathies, as discussed in the following. Currently, there seems to be no association between ultrastructural diversity and biochemical or genetic property in tauopathies. Observation of hybrid filaments suggests a transition from PHF to SF.

BIOCHEMICAL FEATURES OF TAU PROTEINS IN NORMAL AND PATHOLOGIC CONDITIONS

Part of "94 - Tau Protein and Tauopathy "

Localization and Function of Tau Protein

Tau is a low molecular weight component of cytoskeletal structures and is known as one of the microtubule-associated proteins (MAPs). Neuronal MAPs consisting of tau and MAP2 regulate the assembly of microtubules (MTs). Although tau and MAP2 are thought to have similar functions, intracellular localization of tau largely differs from that of MAP2. The mRNAs encoding tau proteins are expressed predominantly in neurons, where these tau proteins are localized mostly to axons of the CNS and PNS under normal physiologic conditions (83 ,84), whereas the neurofibrillary lesions in AD accumulate in the neuronal perikarya, axons, and dendrites. In contrast to the axon-specific distribution of tau in normal states, MAP2 has somatodendritic localization (85 ,86). Although it is likely that the compartment specificity of normal tau and MAP2 in neurons may subserve functional differences such as organization of neuronal polarity and spacing of intermicrotubule distances, or other aspects of axonal and somatodendritic MT distribution and architecture (87 ,88 ,89 ,90 and 91), there is no direct evidence for these different roles for tau and MAP2. Lower expression of tau mRNA and less abundant tau protein have been observed in astrocytes as well as in oligodendrocytes (92 ,93), and this suggests that the formation of glial tau inclusions in several neurodegenerative tauopathies results from the aggregation of tau proteins produced in glial cells themselves.

It has been shown in a number of studies from many laboratories that tau proteins play a major role in regulating neuronal MT assembly and stability (94 ,95 and 96). For example, tau proteins promote the polymerization of tubulin into MTs (97), and tau bound to MTs help stabilize these structures in the polymerized state (98). Moreover, developing neurons treated with antisense oligonucleotides to tau mRNA to block expression of tau fail to extend axon-like processes, suggesting that tau protein also functions in, or is required for, the establishment of neuronal polarity during development (99 ,100). However, mice lacking tau protein present no major phenotypic changes initially, and the only abnormal findings in these mice are decreased MT density and stability in some small-caliber axons (101), but they show motor impairments with age (102). Tau is likely to play an essential role in the development of neurons and even glial cells, but it is also probable that other proteins such as MAP1A can be upregulated to partially compensate for the loss of tau at least early in life, as indicated in the preceding tau-knockout mouse study (101 ,102).

Expression of Multiple Tau Isoforms

As a consequence of alternative mRNA splicing, the single tau gene on the long arm of chromosome 17 gives rise to six brain tau proteins that are normally expressed in the adult human CNS (77 ,103 ,104 and 105) (Fig. 94.1). The differences among these six brain tau isoforms result from the presence of three (3R tau) or four (4R tau) imperfect MT binding repeats of 31 or 32 amino acids in the carboxy-terminal half of each of two sets of these proteins, as well as from the presence of inserts of 29 or 58 amino acids or no insert at all in the amino-terminal region (77 ,103). The tandem repeats in the carboxy-terminal half are encoded by exons 9, 10, 11, and 12, and the alternative splicing of exon 10 (E10) results in the generation of E10+ 4R tau and E10- 3R tau mRNAs and their corresponding 4R and 3R tau isoforms, respectively. This consecutive repeat region

constitutes the MT-binding domain of each tau protein (106 ,107). In each domain, binding affinity to MTs is provided by a binding element that consists of 18 amino acids (107), but the remainder of this motif, known as the interrepeat sequence, also may contribute to the binding of tau to MTs. Indeed, the interrepeat sequence between MT-binding repeats 1 and 2, which is included only in 4R tau isoforms, has a binding affinity for MTs that is more than twofold higher than any MT-binding repeat (108). This may suggests that 4R tau plays a much greater role in regulating the MT-binding than 3R tau, and it is possible that 3R and 4R tau have different MT-binding sites on MTs. The function of the amino-terminal region remains unsettled, but this region is supposed to affect inter-MT distances by forming a bridge between two adjacent MTs. In the PNS, a high molecular weight tau isoform (110 kDa) with one additional exon (exon 4A) is expressed (known as “big tau”) (84 ,110).

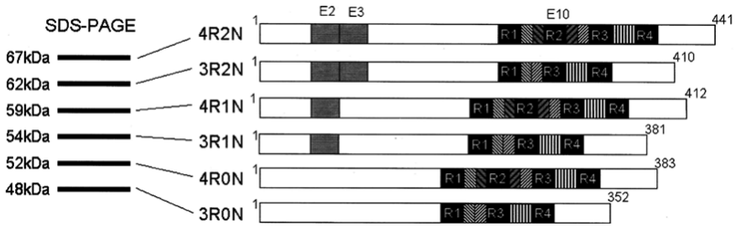

FIGURE 94.1. Six human CNS tau isoforms produced by alternative splicing of the tau gene. The differences among the six isoforms are the number of MT-binding repeat domains *(black boxes)* and the number of amino-terminal inserts. The alternatively spliced exons, exons 2 (E2), 3 (E3), and 10 (E10) are indicated with gray boxes, and hatched boxes indicate the inter-repeat sequences. The recombinant tau proteins run as six bands on SDS-PAGE *(left)*.

The alternative splicing of the six brain tau isoforms is developementally regulated, and only the shortest tau isoform with three repeats and no amino-terminal inserts (i.e. “fetal tau” or 3R0N tau) is present in fetal human brains (102). By analyzing fresh biopsy-derived nomal fragments of human adult brain, it has been demonstrated that the adult CNS contains the following tau isoforms: tau with one amino-terminal insert (1N tau, 50%), tau with no amino-terminal insert (0N tau, 40%) and tau with two amino-terminal inserts (2N tau, 10%) in order of abundance. In the same analysis, the ratio between 4R and 3R tau isoforms has been found to be approximately 1 (111). However, it also is known that the isoform composition of tau protein differs among species. For example, only the three 4R tau isoforms are known to be expressed in the adult rodent brain, while a 3R0N or fetal tau isoform is expressed in the developing CNS of rodents (112). Although the reasons for this difference between the adult rodent and human brains are not known nor is the functional consequence thereof evident at this time, it is possible that the lack of a stem-loop structure in the intron following E10 in rodents versus humans may account for the failure to express 3R tau isoforms in the adult rodent brain.

Phosphorylation of Tau in Normal and AD Brains

Tau is a phosphoprotein, and tau isolated from the developing and adult brain is phosphorylated at multiple sites. PHF-tau extracted from the AD brain shows three major bands (approximately 60, 64, and 68 kDa) and one minor band (approximately 72 kDa) in SDS-PAGE. Enzymatic dephosphorylation of PHF-tau *in vitro* using alkaline phosphatase changes the electrophoretic mobility of these three bands to generate six bands that are identical to the six tau isoforms extracted from normal human brain after dephosphorylation and the six recombinant human tau proteins. This suggests that PHF-tau in AD is composed of all six tau isoforms that are abnormally phosphorylated. Indeed, these PHF-tau bands are detected using antibodies specific for phosphorylated tau epitopes as well as by other phosphorylation-independent anti-tau antibodies.

Approximately 20 serine and threonine residues in tau, some of which are followed by a proline, currently are known to be sites of normal phosphorylation (113 ,114) (Fig. 94.2). Although many of these sites initially were thought to be unique to PHF-tau in AD (114), subsequent studies summarized in the following did not confirm this. Most of these phosphorylation sites are clustered in regions flanking the MT-binding domains, and thus it is presumed that the phosphorylation of these sites influences the binding of tau to MTs. In fact, the conformation of tau is changed by phosphorylation (115), and this reduces binding of tau to MTs (98 ,116 ,117 ,118 and 119), lowers the ability of tau to promote MT assembly (120) and decreases the stability of MTs (121 ,122). It has also been shown that PHF-tau cannot bind to MTs (117 ,118), and that the binding ability is restored after enzymatic dephosphorylation of PHF-tau *in vitro* by phosphatase (118 ,123 ,124). If phosphorylation of a certain site is unique to PHF-tau in AD, elucidation of the mechanism for phosphorylation of such a site could provide much information on the pathogenesis of AD. However, the phosphorylation at multiple sites on tau is considered to be requisite for eliminating the MT-binding ability of PHF-tau (125). In addition, normal human fetal tau is more phosphorylated than tau proteins extracted from

postmortem normal adult brain, but almost all of the phosphorylated sites in normal fetal tau are identical to those in PHF-tau (114 ,117 ,126), and it is known that fetal tau also is less capable of binding to MTs than normal adult tau (117). Furthermore, normal adult human tau isolated from biopsy-derived brain sample is phosphorylated at most of the known phosphorylation sites in PHF-tau, albeit to a much lesser extent (127 ,128). Nevertheless, there still remains a possibility that the difference between PHF-tau and normal tau is not only the extent of phosphorylation, but also the aberrant phosphorylation of some sites that are unique to PHF-tau. In fact, serine212 and serine214, the two phosphorylated residues contained in the epitope that are required for recognition by the anti-phospho-tau antibody AT100/AT10 (129 ,130), are at least two abnormally phosphorylated sites that are known to be unique to PHF-tau (128). This antibody fails to recognize tau isolated from fetal and biopsy-derived normal adult human brain (128), and thus phosphorylation of Ser212/Ser214 appears to be highly specific to PHF-tau in AD, but these sites also may be phosphorylated in the abnormal tau proteins in other tauopathies. Therefore, PHF-tau is likely to be “hyperphosphorylated” (i.e., phosphorylated to a greater extent) as well as “aberrantly phosphorylated” (i.e., phosphorylated at unique sites).

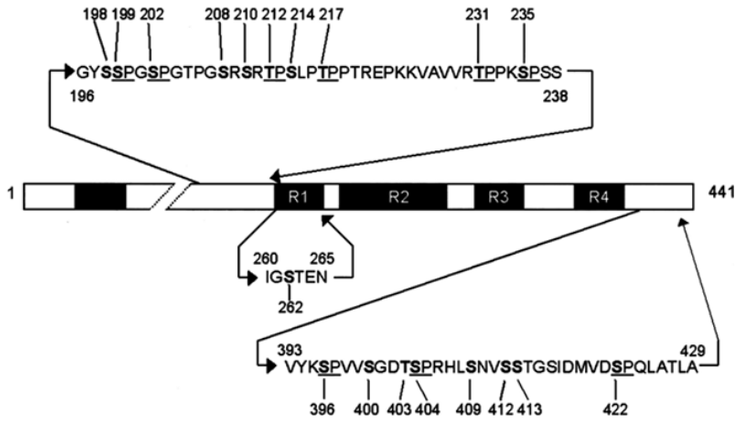

FIGURE 94.2. Phosphorylation sites identified in human PHF-tau. The numbers are based on those in the longest isoform with 441 amino acid residues. The proline-oriented sites are indicated with underlines.

The extent of tau phosphorylation is regulated by the activities of phosphatases and kinases. Therefore, increased activities of kinases and/or decreased activities of phosphatases could presumably lead to the hyperphosphorylation of tau, thereby resulting in the formation of PHF-tau. Although several different kinases have been demonstrated to be capable of phosphorylating tau *in vitro*, the specific kinases that are responsible for the phosphorylation of tau in the living human CNS remain to be identified. Only two kinases, glycogen synthase kinase-3ß (GSK-3ß) and cyclin-dependent kinase 5 (Cdk5), have been copurified with MTs (131 ,132). GSK-3 is known to phosphorylate endogenous tau expressed in neurons (133), and it is abundant in the brain (134). Cdk5 is normally activated by a regulatory protein p35 (135). Cdk5 is supposed to be active in neurons because p35 is expressed primarily in neurons (135 ,136). However, a recent study has shown that a truncated form of p35 (known as p25) accumulates in neurons of the AD brain, and that p25 binds to Cdk5, leading to a deregulation of this kinase (137). Accordingly, hyperactivated Cdk5 may be caused by accumulation of p25, and this may be part of the mechanism that causes the hyperphosphorylation of tau in AD.

Among many phosphatases, protein phosphatase 2A (PP2A) and 2B (PP2B or calcineurin) have been shown to be enzymatically active in biopsy-derived human brain tissue, and *in vitro* studies have shown that these enzymes dephosphorylate several phospho-serine and phospho-threonine residues in tau (70 ,124 ,128 ,129 ,139 ,140). Thus, these phosphatases may be involved in the generation of PHF-tau, but there has been no evidence for decreased phosphatase activity in the AD brain, and thus roles played by these enzymes in formation of PHF-tau are still to be elucidated. Nonetheless, a recent study has demonstrated reduced PP2A subunit mRNAs in the AD hippocampus when NFTs are abundant, so it is plausible that this might contribute to mechanisms underlying PHF-tau formation in AD (140a).

Other Tauopathies

Immunoblot analyses of brains from patients with tauopathies other than AD have demonstrated that insoluble tau fractions are detectable using many different phosphorylation-dependent antibodies to epitopes spanning the tau molecule, suggesting that the filamentous inclusions in these diseases are composed of hyperphosphorylated tau similar

to PHF-tau in AD. Three types of abnormal tau isoform profiles have been found in tauopathies other than AD (Fig. 94.3). For example, similar to AD, three predominant PHF-tau–like bands of 60, 64, and 68 kDa and one minor band of 72 kDa are observed in Down syndrome, GSS disease, ALS/PDC of Guam, Niemann-Pick disease type C, and some FTDP-17 kindreds caused by certain tau mutations (17 ,23 ,29 ,43 ,72). These bands have been shown to contain all six tau isoforms in several studies. On the other hand, biochemical analyses of Pick disease have shown a characteristic pattern of tau isoform composition consisting of two major tau bands of 60 and 64 kDa and one minor tau band of 68 kDa (34 ,141). In some studies, these bands are not positive for anti-phospho-tau antibody 12E8, which recognizes an epitope in E10, but our study demonstrated weak but specific recognition (34). Further, several studies have indicated that these bands include only 3R tau isoforms (142 ,143). The third type of abnormal tau isoform profile is found in CBD (40 ,76), PSP (41), and some FTDP-17 kindreds with specific tau gene mutations (64 ,144), and this profile is characterized by two major tau bands of 64 and 68 kDa as well as one minor tau band of 72 kDa. Notably, several studies have indicated that these tau bands predominantly consist of 4R tau isoforms (64 ,110 ,144 ,145).

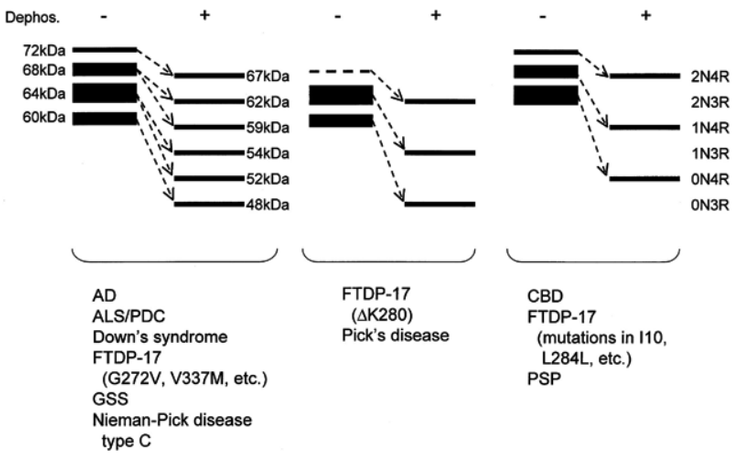

FIGURE 94.3. Schematic representation of sarkosyl-insoluble tau bands from different tauopathies before (-) and after (+) dephosphorylation. The insoluble tau composed of all six isoforms shows three major bands (60, 64, and 68 kDa) and one minor band (72 kDa) before dephosphorylation. In some tauopathies, 3R tau isoforms are major components of the insoluble fraction, running as two major bands (60 and 64 kDa) and one minor band (68 kDa). Tauopathies with insoluble tau consisting of 4R tau isoforms shows two major bands (64 and 68 kDa) and one minor band (72 kDa).

FRONTOTEMPORAL DEMENTIA WITH PARKINSONISM LINKED TO CHROMOSOME 17: CAUSED BY MULTIPLE EXONIC AND INTRONIC TAU GENE MUTATIONS

Part of "94 - Tau Protein and Tauopathy "

FTDP-17 is a group of familial neurodegenerative tauopathies characterized by diverse but overlapping clinical and neuropathologic features (50 ,60 ,146). According to several reports on clinical and neuropathologic features of FTDP-17, three major clinical syndromes have been delineated, and albeit preliminary, they include: disinhibition-dementia-parkinsonism-amyotrophy complex (DDPAC) (55 ,147), pallido-ponto-nigral degeneration (PPND) (148), and MSTD (64). However, it is important to note that more than 20 kindreds caused by diverse tau gene muations and variably characterized phenotypes have been reported so far (50). Clinical characteristics of these FTDP-17 tauopathies variably include memory and language impairments, behavioral and psychiatric abnormalities, extrapyramidal signs, and motor deficits (50), each of which presumably reflects differential degeneration of specific brain regions. However, all FTDP-17 brains from affected patients share a common neuropathology characterized by abundant neuronal and to a lesser extent glial fibrillary lesions composed of hyperphosphorylated tau proteins associated with a remarkable loss of neurons in affected regions (144 ,149 ,150 and 151).

Autosomal dominant inheritance of these FTDP-17 syndromes suggested that one or more genetic mutations might be pathogenic for these disorders, and linkage analyses showed cosegregation of disease with a genetic locus on chromosome 17q21-22 (49 ,50 ,60 ,146 ,152 ,153). Because the pathologic hallmarks of these disorders are tau lesions and the tau gene resides within the disease locus of chromosome 17, the tau gene was an obvious candidate for pathogenic mutations in FTDP-17 kindreds. Thus, as expected, several research groups discovered multiple tau gene mutations in 1998, and these mutations were found to segregate with FTDP-17 patients, but they were not seen in normal individuals (151 ,154 ,155). Further studies have identified at least 20 distinct pathogenic mutations in exons and introns of the tau gene in many FTDP-17 kindreds, many of which were identified for the first time with the identification of a tau gene mutation. Approximately 10 missense mutations were found in exons of the tau gene, and they include K257T, I260V (Hutton M, personal communication),

and G272V (154) in exon 9; N279K (142), P301L (142 ,152 ,155), P301S (156 ,157), and S305N (158 ,159) in E10; V337M (155) in exon 12; and G389R (160) and R406W (154) in exon 13 (numbered according to the longest CNS tau isoform consisting of 441 amino acids). Moreover, two silent mutations have been reported, including L284L (159) and S305S (161) in E10 and a mutation resulting in the deletion of single amino acid ΔK280 (159 ,167) in E10. On the other hand, intronic tau gene mutations in FTDP-17 kindreds are clustered around the 5′ splice site in the intron following E10. They contain E10+3 (151), E10+12 (163), E10+13 (164), E10+14 (145 ,164), E10+16 (164 ,165), and E10+33 (162). The currently known tau gene mutations in FTDP-17 kindreds are listed in Table 94.2 and are depicted schematically in Fig. 94.4 . The increasing number of tau gene mutations that continue to be identified suggests that FTDP-17 is likely to be more frequent than previously recognized.

Mutation	Location (Domain)	Effects on Exon 10 Splicing	Predominant Tau Isoforms	Effects on MT Binding	Disease/Syndrome	Tau-Positive Neuropathology	References
K257T	E9 (R1)	N/A	N/A	N/A	N/A	Tau as well as Pick body-like inclusions	[a]
I260V	E9 (R1)	N/A	N/A	N/A	N/A	N/A	[a]
G272V	E9 (R1)	None	All isoforms	Reduced	HFTD2; "familial Pick's disease"	Inclusions in cortical and subcortical areas	154
N279K	E10 (IR1–2)	Increased	Mainly 4R	None	PPND	Neuronal and glial fibrillary tangles	142

TABLE 94.2. MUTATIONS ON THE TAU GENE FOUND IN FTDP-17

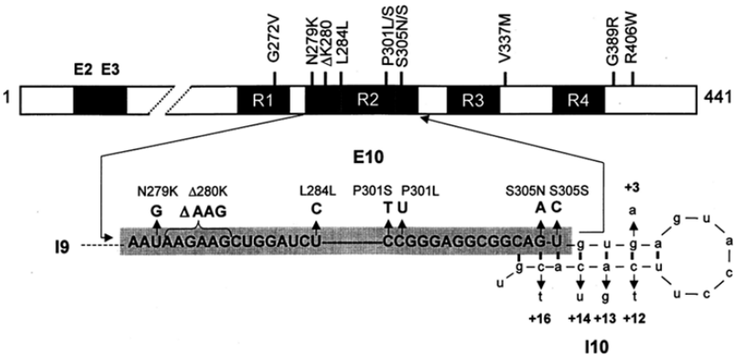

FIGURE 94.4. Mutations identified on tau gene in FTDP-17. The mutation sites are depicted on the longest tau isoform. The alternatively spliced inserts are indicated as gray boxes and MT-binding repeats are shown as black boxes. Sequences in intron 10, which form a stem-loop structure, are presented in lower case.

In FTDP-17, pathogenic mutations in the tau gene may be pathogenic by one or more abnormalities in tau proteins, and at present, two mechanisms have been proposed to mediate the effects of these mutations based on recent molecular and biochemical analyses (111 ,154 ,159 ,166). The first mechanism involves perturbations of the alternative splicing of E10 by mutations in E10 or around the 5′ splice site in the intron following E10, thereby resulting in an altered ratio of 4R tau to 3R tau proteins. The second pathogenic mechanism directly impairs the ability of tau to bind to MTs and to promote the polymerization and stability of MTs.

The ratio of 4R tau to 3R tau isoforms is approximately 1 in the normal adult human brain, but an increase in the 4R/3R ratio of brain tau isoforms has been demonstrated in brains of FTDP-17 patients with mutations clustered around the 5′ splice site in the intron following E10 and with E10 tau gene mutations including: N279K, L284L, S305N, and S305S (111 ,154 ,159). The altered splicing of E10 caused by these mutations results in increased levels of E10+ tau mRNA in FTDP-17 brains presumably owing to greater E10 usage of the E10 5′ splice site as demonstrated by exon-trapping experiments (154 ,159). Biochemical analyses of tau extracted from autopsied brain samples of patients with PPND (N279K), DDPAC (E10+14) and MSTD (E10+3) have shown a predominance of 4R tau isoforms (111 ,145 ,151). It has been suggested that these mutations affect multiple cis-acting elements that enhance or suppress the usage of 5′ splice site of E10 (151 ,154 ,159). A stem-loop structure consisting of sequences around the 5′ splice site in the intron following E10 is thought to inhibit the splicing of E10 presumably by blocking the association of snRNA with the splice site (151 ,154). Accordingly, it is postulated that these intronic mutations and the exonic mutations S305N and S305S may cause a disruption of this stem-loop structure (154). The S305N mutation has also been suggested to increase the strength of the 5′ splice site (167). However, the S305S mutation, which increases the 4R/3R ratio like the S305N mutation, has been demonstrated to weaken the 5′ splice site (161). Another potential regulatory element might be an exon-splicing enhancer (ESE) or exon-splicing silencer (ESS) element within E10 adjucent to the following intron (159). The N279K mutation is thought to augment the ESE and consequently cause an increase in the 4R/3R ratio of tau isoforms because of the fact that it raises the purine content of this purine-rich domain (i.e., by changing TAAGAA to GAAGAA) (168 ,169 ,170 and 171). This mechanistic hypothesis is supported by the observation that the ΔK280 mutation, which produces a deletion of the three adjacent purines (AAG), abolishes the splicing of E10 into tau mRNAs (159). The silent mutation L284L is likely to disturb the ESS (159), but it also is possible that this mutation augments the effects of the ESE.

The binding sites on MTs for 4R tau and 3R tau isoforms have been suggested to be different (109), and increases in the 4R/3R tau isoform ratio is likely to produce an excess

amount of 4R tau isoforms that are not bound to MTs. This abnormal increase of free tau may result in the formation of insoluble tau aggregates and consequently neurodegeneration.

The second hypothetical pathogenic mechanism to account for brain degeneration in FTDP-17 owing to other tau gene mutations suggests that these mutations directly cause deficits in the abilities of tau to bind to MTs and promote assembly and stability of MTs. This disease mechanism has been linked to several tau gene missense mutations including: G272V, ΔK280, P301L, P301S, V337M G389R, and R406W by *in vitro* studies (111 ,159 ,166). On the other hand, the mutations that increase E10 splicing do not have similar effects on the functions of tau (111 ,159). Nonetheless, a loss of the binding ability of tau to MTs may produce an increase in the levels of free tau proteins in the neuronal cytoplasm, and this could promote their fibrillogenesis. Mutant tau proteins are also likely to accelerate the accumulation of insoluble tau filaments within neurons. This notion has been supported by several studies of the *in vitro* assembly of tau filaments, which also demonstrated that tau filament formation is enhanced by heparin using recombinant G272, P301L, V337M, and R406W tau mutant proteins compared to wild-type tau protein (172 ,173). Moreover, mutations in exons other than those in E10 (i.e., V337M and R406W) promote tau aggregation composed of all six isoforms, whereas other E10 mutations (i.e., P301L) increase 4R tau in insoluble FTDP-17 brain fractions (111 ,145). Although there are preliminary data to account for the differential effects of these mutations, additional studies are needed to fully elucidate how they cause diverse FTDP-17 syndromes.

DEVELOPMENT OF EXPERIMENTAL ANIMAL MODELS OF FILAMENTOUS TAU PATHOLOGY

Part of "94 - Tau Protein and Tauopathy "

The discovery of tau gene mutations pathogenic for FTDP-17 indicates that genetic abnormalities directly influence the levels or functions of tau proteins, thereby resulting in the aggregation of insoluble tau and neurodegeneration. However, it is difficult to specify the precise underlying mechanisms whereby these mutations cause distinct biochemical, neuropathologic, and phenotypic abnormalities in FTDP-17 syndromes that vary from patient to patient by analyzing human cases because of the following reasons: (a) limited sample size of kindreds with each mutation; (b) the difficulty of conducting biochemical and pathologic studies in early stages of the disease; and (c) the possibility that several additional but as yet unknown environmental and/or genetic factors might modify the biochemical and clinicopathologic phenotype of FTDP-17. Accordingly, animal models that reproduce tauopathies are required for better understanding of the central roles played by tau abnormalities in neurodegenerative disorders. Such models are also expected to be useful for assessing methods of early diagnosis and the effectiveness of therapeutic agents for the treatment of neurodegenerative tauopathies.

The strategies for making animal models that recapitulate tauopathies are summarized in the following and include:

1. Selection of DNA constructs to be expressed in the CNS of the model, and the use of cDNA or genomic DNA tau constructs is a straightforward strategy to induce accumulations of tau in the CNS of experimental animals. Indeed, tau cDNAs or minigenes have been used to overexpress specific tau isoform(s), and cause an imbalance of the tau isoform profile similar to that seen in human tauopathies. Further, animal models engineered to express human genomic tau DNA using bacterial artificial chromosome (BAC) or a P1-derived artificial chromosome (PAC) containing the entire tau gene may be informative for elucidating the biochemistry (including E10 splicing) and neuropathology (including emergence of tau deposits) in animals with and without a tau gene mutation. Other possible strategies to generate animal models of tauopathies are to express proteins that regulate the phosphorylation of tau proteins, or to express APP, PS-1, and PS-2 in tau transgenic (Tg) animals to investigate the interaction of these molecules with tau to model tauopathies that show coexistence of tau and amyloid pathologies.
2. Overexpression of tau without mutation to assess the effects of excess tau proteins in the cytoplasm of neurons and glia on the formation of tau aggregates. Because animal models expressing a mutant human tau gene may reproduce the biochemical and pathologic abnormalities in FTDP-17, it is necessary to do this by expressing mutations such as ΔK280, P301L, V337M, and R406W, because they impair the ability of tau to bind to MTs and promote assembly and stability of MTs. Further, the generation of tau DNA with mutations that alter the splicing of E10 to produce animal models would be informative using the entire gene or minigene of human tau. However, the phenotypes of these mutant tau animals should be assessed in comparison with animals showing a similar expression level of wild-type human tau.
3. Use of neuron-specific promoters including the Thy-1, 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoA) and prion protein (PrP) promoters to generate tau pathology in neurons, whereas animals showing glial tau pathology can be developed by using glia-specific promoters including glial fibrillary acid protein (GFAP) promoter for astrocytes and 2′,3′-cyclin-nucleotide phosphodiesterase (CNP) and myelin basic protein (MBP) promoters for oligodendrocytes. Tg animals with genomic DNA are generally driven by endogenous promoters.

The generation of a tau Tg mouse using a cDNA for the longest tau isoform (T40, 4R2N tau) combined with Thy-1 promoter was reported in 1995 (174), followed by a study of tau Tg mice expressing the shortest tau isoform (T44 or fetal tau, 3R0N tau) driven by the HMG-CoA reductase promoter (175). In these studies, somatodendritic overexpression of human tau was observed using anti-phospho-tau antibodies. However, these Tg mice did not show tau aggregates in any of the CNS regions nor other tauopathy-like phenotypic changes, probably owing to the low expression level of the transgene product. Filamentous tau aggregates have been observed in the spinal cord and brainstem of tau Tg mice generated by using a transgene consisting of fetal tau and the PrP promoter (176) (Fig. 94.5). This Tg mouse showed approximately ninefold more tau protein than the wild-type control, and thus the successful development of tau inclusions is presumably owing to the high expression levels of human tau. The tau aggregates in this Tg mouse are spheroidal inclusions in proximal axons, and they showed an increase in number with aging, consistent with an age-dependent increase in the extent of tau phosphorylation and an age-dependent decrease in the solubility of overexpressed human tau. In addition, this tau Tg mouse showed axonal degeneration and reduced axonal transport as well as motor weakness. Hence, this Tg mouse is thought to be a good model for age-related neurodegeneration in tauopathies, and it is useful for studying the time course of CNS degeneration in a human tauopathy. The spheroidal tau inclusions in these tau Tg mice have also been shown to contain neurofilaments (NFs) and tubulin. This colocalization of tau and NFs is found in the inclusions of ALS/PDC spinal cord. Further studies using these tau Tg mice crossed with NF-knockout mice could be informative by determining whether or not NFs promote the formation of tau aggregates, and whether or not tau can form aggregates in the absence of NFs.

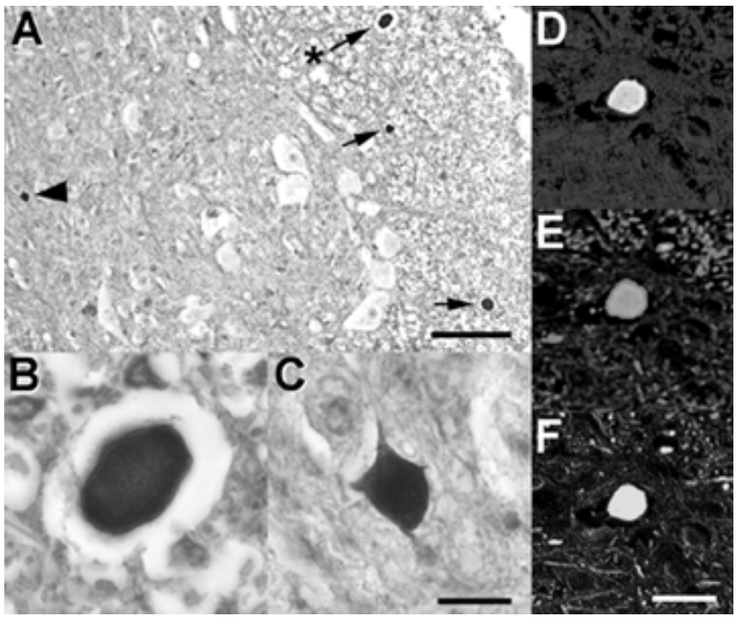

FIGURE 94.5. Spheroidal tau deposits in the spinal cord of tau Tg mice over-expressing the shortest human tau isoform. **A:** Low power field of the spinal cord section of a 6-month-old Tg mouse stained with anti-tau antibody T14. Spheroidal deposits *(arrows)* are observed in axons, and somatodendritic tau stain *(arrowhead)* is found in the neuron. **B:** Higher magnification of the spheroidal tau deposit indicated with asterisk in *(A)*. **C:** Higher magnification of the somatodendritic tau stain shown in *(A)*. **D,E,F:** Triple-labeled indirect immunofluorescence of the spinal cord deposit from a 6-month-old Tg mouse. Blue, anti-tau antibody T14 and AMCA *(D)*; red, anti-low-molecular-mass-neurofilament (NFL) antibody and Text Red *(E)*; and green, anti-high-molecular-mass-neurofilament (NFH) antibody and FITC *(F)*. Note that tau is colocalized with neurofilaments in the spheroid deposits. Scale bar, 50 µm *(A)*; 10 µm *(B,C)*; and 10 µm *(D,E,F)*.

Tau Tg mice with the T40 transgene combined with the Thy-1 promoter have been developed recently (177 ,178). These mice exhibit spheroidal tau inclusions in axons of the spinal cord and brainstem as well as cerebral cortex, and the colocalization of tau and NFs has also observed in these inclusions. Axonal degeneration and corresponding phenotypic changes were found in these Tg mice, and thus they may be regarded as models of neurodegenerative tauopathies with increased 4R tau. In addition, these 4R tau Tg mice showed somatodendritic tau expression to a greater extent than 3R tau Tg mice. This suggests that the difference in affected brain areas between 4R tau and 3R tau Tg mice as well as the effect of predominant tau isoforms on the distribution of pathology should be analyzed by using tau Tg mice with the same promoter and a similar expression level of human tau.

To date, only a few genomic tau Tg mice using PAC and BAC have been generated, and they have shown a somatodendritic pattern of phosphorylated tau expression (179). Although all of the mentioned tau Tg mice have shown a somatodendritic tau expression that resembles the “pretangles” in AD, none of them have developed NFTs containing a ß-pleated sheet structure that can be recognized by thioflavin-S and Congo red. In fact, overexpressed tau in the cytoplasm and processes of neurons is rather diffuse and does not show a filamentous structure by EM (179). One possible method to generate NFTs in tau Tg mice would be to use a mutant tau gene construct to decrease the ability of tau to regulate MTs. Another method would be to follow tau Tg mice showing an age-related increase of tau pathology to vary advanced ages.

One of the major goals in developing animal models is to generate a model for AD, which is the most common neurodegenerative tauopathy. It seems feasible to develop mice with human APP, PS-1, PS-2, and ApoE transgenes to elucidate the mechanism of biochemical and clinicopathologic changes caused by genetic abnormalities in AD. Tg mice overexpressing APP with FAD mutations have shown diffuse and neuritic Aß plaques in the brain, but they have lacked tau-positive NFTs and neuron loss (180 ,181 and 182). Moreover, Tg mice with a PS-1 transgene linked to FAD

with and without a mutant APP transgene have developed no tau pathology (183). Taking together, these studies suggest that the generation of Aß plaques in mice is not sufficient to model AD pathology and to elucidate interactions between tau and Aß pathologies in the pathogenesis of AD. Thus, the generation of double Tg mouse overexpressing tau and mutant APP, and "humanized" genomic tau Tg mouse with tau-knockout mice to over-express only the six human tau isoforms may be better strategies to develop Tg mouse models recapitulating AD pathology.

CONCLUSION

Part of "94 - Tau Protein and Tauopathy "

Genetic, biochemical, and pathologic analyses have indicated that tau proteins play a central role in the pathogenesis of various neurodegenerative tauopathies, including AD. Transgenic experiments have also shown that overexpression of tau can cause neurodegenerative tauopathies in experimental animals. However, genetic abnormalities that influence tau phosphorylation and/or functions of tau in AD remain unsettled. The mutations on APP, PS-1, and PS-2, polymorphism of ApoE and other yet-to-be-identified genetic susceptibilities as well as environmental factors may promote the dysfunction of tau in AD. Among other tauopathies, genetic abnormalities have been confirmed only in FTDP-17 kindreds. The onset of PSP has been associated with an intronic polymorphism in the tau gene (184), but the major genetic factors that cause tau aggregation and neurodegeneration in many tauopathies are still to be elucidated.

Substance Use Disorders - Introduction

Although the prevailing view for many decades was that drug dependent patients simply suffered from character weakness, the persuasive data emerging from modern brain imaging techniques and the application of molecular biology methods to animal models of compulsive drug use indicate that this position is no longer tenable. The integration of a number of new technologies has allowed investigators to combine behavioral and neurobiological approaches to more completely evaluate multiple aspects of this difficult problem.

The following 16 chapters detail advances in the biology of substance use disorders, concentrating on those occurring during the 1990s, the decade of the brain. The section concentrates on advances most relevant to neuropsychopharmacology, integrating neurobiology, behavioral biology, and pharmacology. Knowledge of the pathophysiology of drug use disorders has greatly increased with the identification and cloning of receptors for the major drugs of abuse. There is also a much greater understanding of the brain circuits involved, including those common to different classes of drugs. The efficacy of treatment has also increased through the availability of effective medications for alcohol, heroin, and nicotine, as well as behavioral approaches used with cocaine abusers. Also, there is greater acceptance of the chronic disease model, which focuses on functional improvement as the realistic goal of treatment, rather than “cures.”

The terminology used in this section deserves some comment. There is general agreement that there are degrees of severity ranging from occasional drug use to a dangerous but moderately severe state called “abuse” in the American Psychiatric Association Diagnostic and Statistical Manual (DSM), to a severe compulsive state known as “dependence” or “addiction.” There is disagreement, however, on the usefulness of the term “addiction” to denote this severe state that occurs only in the minority of users who lose control and become compulsive drug users with a chronic relapsing clinical course. The DSM-III Revision Committee narrowly voted not to use the term “addiction” because of its prejudicial connotations, opting instead for “dependence.” This was continued in the current version, DSM-IV. The other point of view is that the term “dependence” creates confusion because it is already used to designate the state marked by drug-specific withdrawal symptoms that normally occur when regular drug use is abruptly terminated (“physical” dependence). Dependence also has a long-standing use as a personality disorder descriptor completely unrelated to drug use. Most important, patients with chronic pain receiving opiates often show signs of tolerance and withdrawal symptoms without any behavior that could be categorized as abuse. Physicians who are confused by “dependence” defined as a normal response and “dependence” as a disorder have been known to mistakenly withhold pain medication to “prevent addiction.” We have opted to use the DSM terminology for the title of this section, but the reader will find that there is some inconsistency among the chapters in the use of the terms “addiction” and “dependence” reflecting the current variance in the field over proper terminology.

Neurocircuitry of Addiction

Peter W. Kalivas

Peter W. Kalivas: Department of Physiology and Neuroscience, Medical University of South Carolina, Charleston, South Carolina

Addiction can be defined as drug-induced changes in the central nervous system (CNS) that produce maladaptive alterations in spontaneous behavior and in the behavioral response to readministration of that drug. Maladaptive behaviors include those identified as criteria for addiction in the DSM-IV. In general what most psychiatric metrics describe as addiction associated behaviors is the emergence of behaviors to obtain drug reward at the expense of engaging in behaviors to seek natural rewards, ranging from biological rewards such as sex to cultural rewards such as stable personal relationships. The substitution of drug reward for natural reward suggests that the neuropathology of addiction may reside in the same neural systems that mediate the detection and acquisition of natural rewards. This postulate forms a primary premise in the search for the neurobiological basis of addiction, and has revealed a circuit consisting of interconnections among limbic cortex, basal ganglia, and brainstem nuclei that is pathologically modified by repeated drug administration. The drug-induced changes in the structure and function of this circuit are progressive, and to some extent parallel the development of the behavioral characteristics of addiction.

Over the last decade neurobiologists have come to describe the behavioral transition to addiction as a druginduced neuroplastic process (1 ,2 and 3). In parallel with the development and expression of addictive behaviors, the neurobiology of these two components of the transition to addiction can be described as: (a) the sequence of molecular events that establish the neuroplastic changes leading to addiction, and (b) the neuroplastic changes themselves. Accordingly, a number of molecular neuroplastic alterations have been identified in the brain after repeated drug administration, and some of these appear to be important in the development and/or expression of addictive behaviors. However, the process of identifying drug-induced changes is accelerating and producing a deluge of information that is proving increasingly difficult to integrate into a coherent sequence of neuroplastic changes that mediate addiction. In part the difficulty of integration arises because the veracity of each molecular neuroplastic event must be tested in animal models of addiction; a labor-intensive process often employing imprecise tools for selective *in vivo* manipulation of cell biology. Moreover, this problem is compounded by the fact that the neuroadaptations associated with use of a drug of abuse are not entirely predicated on the pharmacology of the drug. It has become increasing clear that in addition to drug pharmacology, the environmental regulation of the drug-induced changes is a critical factor in the development and expression of addiction (4 ,5 and 6).

Although a critical role for environment in the manifestation of addicted behaviors has been obvious for decades in the behavioral evaluation of addiction in humans and animal models, only recently has the drug–environment interface been directly evaluated as critical in the cellular neuroadaptations mediating addiction (7 ,8). The realization that the neuroplasticity defining addiction arises as a collaboration between repeated drug administration and environmental associations is contributing to the construction of a template to help organize and integrate the emerging tide of data that describes the cellular adaptations potentially mediating addiction. Figure 95.1 illustrates how learning to associate environmental stimuli with the molecular action of a drug impinges on brain circuitry to elicit neuroplastic changes producing addiction. Figure 95.1 is used to organize this chapter into the three current arenas of investigation into the neurobiology of addiction: (a) the molecular site of action by a drug and the immediate consequences of drug administration to intracellular signaling and synaptic transmission; (b) the circuitry involved in learning and how this integrates with the molecular action of drugs of abuse; and (c) the overall circuitry of reward that contains both molecular sites of drug action and learning circuits, and forms the site of pathologic change mediating addiction.

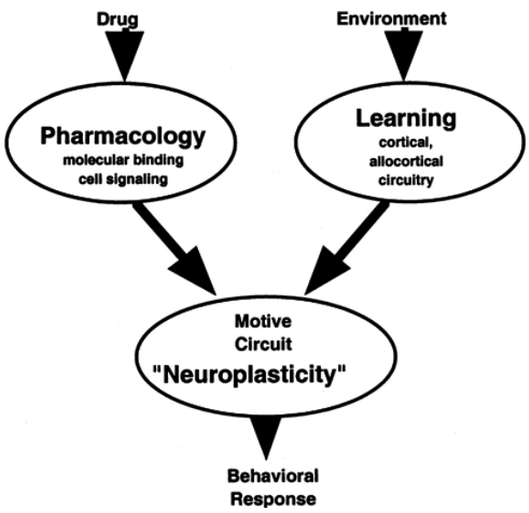

FIGURE 95.1. Collaboration between the pharmacology of a drug of abuse and environmental stimuli. Depiction of the impact that both the molecular binding site of a drug and environmental stimuli have on the neuroplasticity associated with drug addiction.

PHARMACOLOGY

Part of "95 - Neurocircuitry of Addiction "

Molecular Binding Site of the Drug

The molecular site of action and the immediate sequence of cellular events have been successfully decoded for many

drugs of abuse. Ethanol remains a notable exception where a number of candidate binding sites are currently being evaluated for a role in addiction. In contrast, for many drugs of abuse a reasonably accurate portrait of site of action has emerged. Over the last two decades a common direct or indirect action by drugs on dopamine transmission in the projection from the ventral mesencephalon (ventral tegmental area, VTA) to the forebrain has consistently been proposed and experimentally evaluated (8 ,9 ,10 and 11). This historic focus arose from studies employing lesions and the administration of dopamine receptor antagonists that converged on the potential importance of the dopamine projections in mediating natural, electrical, and drug reward. Figure 95.2 illustrates the dopamine projections most frequently evaluated in this regard and includes axon terminations in the amygdala, nucleus accumbens, prefrontal cortex (PFC), and ventral pallidum that arise from cell bodies in the VTA. Examination of the known binding sites for drugs of abuse reveals for some drugs a clear relationship between drug binding site and dopamine transmission (Fig. 95.3). Thus, amphetamine-like psychostimulants inhibit the binding of dopamine to the dopamine transporter and thereby elevate extracellular dopamine (12 ,13). Nicotine binds directly to acetylcholine nicotinic receptors on dopamine cells to increase the firing frequency of the mesocorticolimbic dopamine neurons (14). μ-opioid receptors are found in high density on presynaptic terminals of GABAergic interneurons and GABAergic axonal afferents to the VTA (15 ,16 ,17 ,18 and 19). Stimulation of these receptors inhibits the tonic and stimulated release of GABA, thereby increasing the firing frequency of the dopamine neurons. Alcohol modulates GABA-gated chloride conductance, as well as sodium and calcium conductances gated by glutamate (20 ,21). By promoting chloride conductance and inhibiting glutamate gated sodium and calcium fluxes alcohol is generally found to be inhibitory on neuronal activity. However, electrophysiologic and neurochemical studies reveal that alcohol increases dopamine cell firing and dopamine release in axon terminal fields via an action within the VTA (22 ,23 ,24 and 25). Thus,

it has been hypothesized that alcohol may act preferentially on GABAergic interneurons in the VTA to disinhibit dopamine cells. Moreover, recent evidence demonstrates that the capacity of alcohol to elevate dopamine transmission is blocked by opioid receptor antagonists (26). This indicates that alcohol is directly or indirectly increasing enkephalin release in the VTA, thereby disinhibiting dopamine cell firing. Indeed, this mechanism is likely to contribute to the therapeutic efficacy of opioid antagonist naltrexone in attenuating relapse in alcohol addiction (27 ,28).

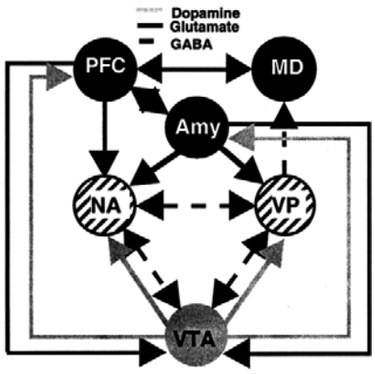

FIGURE 95.2. The circuit thought to be critical for mediating both natural and drug reward behavior. Amy, amygdala; MD, mediodorsal thalamus; NA, nucleus accumbens; PFC, prefrontal cortex; VP, ventral pallidum; VTA, ventral tegmental area.

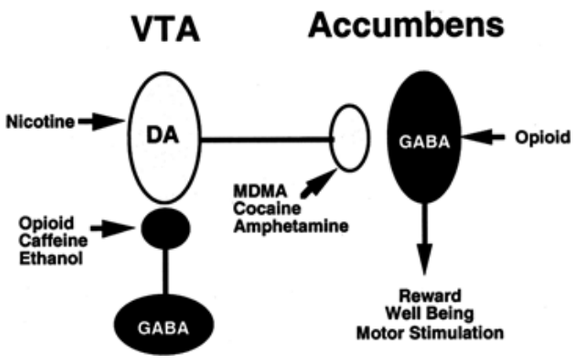

FIGURE 95.3. Sites of action by addictive drugs to augment mesoaccumbens dopamine transmission.

By inhibiting the NMDA subtype of the glutamate receptor, phencyclidine may decrease the activity of GABAergic interneurons in the VTA and thereby activate dopamine cell firing (29). Although these data strongly indicate a common action of drugs of abuse to stimulate dopamine transmission, notable exceptions exist. Of the major classes of drugs of abuse, the allosteric GABAA receptor agonists, including benzodiazepines and barbiturates, do not appear to stimulate dopamine cells or increase dopamine release (30). Also, although systemic administration of μ-opioids clearly activates dopamine transmission by disinhibiting dopamine cell activity, it is equally clear that stimulating μ-opioid receptors located postsynaptic to the dopamine projection in the nucleus accumbens is sufficient to elicit behaviors that are characteristic of addiction (31 ,32 ,33 and 34). Thus, the historic focus on dopamine transmission has identified an initial substrate for most drugs of abuse. However, the exceptions to this rule point clearly to the conclusion that, although an action on dopamine transmission may be a sufficient substrate to initiate drug-induced neuroplasticity relevant to addiction, other substrates are also sufficient.

Evaluating potential nondopaminergic substrates for initiating addiction-related neuroplasticity points most directly to modulating GABA transmission. Figure 95.2 illustrates that dopamine terminals in the nucleus accumbens synapse on GABAergic cells. Moreover, these GABAergic cells innervate GABAergic neurons in the VP. Indeed, Fig. 95.2 shows that there is a topographically organized interconnection among the nucleus accumbens, VP, and VTA that is GABAergic (35 ,36). Given the apparent importance of modulating dopamine transmission in this circuit in the neuroplasticity leading to addiction, it seems reasonable that directly modulating the GABAergic subcircuit with opioids or allosteric GABAergic agonists may also produce neuroplastic changes relevant to the development of addiction. Although substantial evidence exists for μ-opioids that this is true (31 ,32 ,33 and 34), this hypothesis has not yet been evaluated for benzodiazepines or barbiturates.

Pharmacologic Versus Physiologic Release of Dopamine

Studies in animal models measuring the *in vivo* release of dopamine with microdialysis reveal that natural rewarding or aversive stimuli increase dopamine release in the nucleus accumbens (6 ,37 ,38 ,39 ,40 ,41 and 42). However, the physiologic release of dopamine stimulated by environmental stimuli is of substantially less magnitude and duration than the pharmacologic release elicited by most drugs of abuse (22 ,43 ,44 ,45 ,46 and 47). The importance of excessive pharmacologic release of dopamine can be extrapolated from what is known about the behavioral situations that elicit physiologic activation of mesoaccumbens dopamine transmission. Dopamine release and cell firing are increased by the presentation of novel and motivationally relevant environmental stimuli (6 ,48). This has contributed to the notion that enhanced dopamine release in the nucleus accumbens signals the appearance of an important event that requires the creation and engagement of an adaptive behavioral strategy. This signal is supplied to numerous forebrain structures constituting the limbic cortex and basal ganglia (Fig. 95.2) and presumably initiates the recruitment of cortically derived memories and cognitive strategies, as well as motor output. In doing so, dopamine plays a role in initiating and establishing neuroplastic changes associated with developing behavioral strategies necessary to adapt to novel stimuli. One characteristic of the activation of dopamine transmission by environmental stimuli is that the release of dopamine diminishes with repeated exposure to the same stimulus as the organism establishes an adaptive behavioral response (40 ,49 ,50). Thus, dopamine contributes to the establishment of neuroplastic changes that mediate behavioral adaptation to relevant environmental stimuli, but may not be necessary for the expression of those behaviors. Rather, once a behavioral response to a stimulus has been established, the stimulus elicits the behavior via interactions among the limbic cortex, thalamus, and basal ganglia, with less involvement by mesocorticolimbic dopamine transmission (51 ,52). The transition from dopamine-dependent to behaviors less dependent on dopamine is illustrated in Fig. 95.4 as the transition in neural substrates mediating behavioral responding to a novel and familiar stimulus.

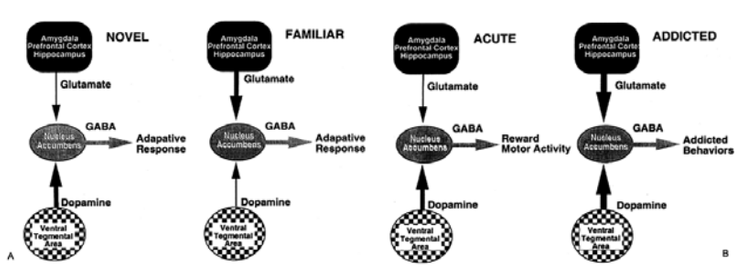

FIGURE 95.4. Changes in the role of mesencephalic versus cortical input to the nucleus accumbens with repeated exposure to natural motivational stimuli **(A)** and drug reward **(B)**. Both a novel stimulus and acute drug administration increase dopamine transmission. After repeated exposure the natural stimulus produces little or no increase in extracellular dopamine and the behavioral response to the stimulus arises primarily from cortical and allocortical interactions with the basal ganglia. Similarly, repeated drug use results in a recruitment of cortico-accumbens circuitry, but is also associated with augmented dopamine transmission. It is postulated that a portion of the pathology of addiction arises from both an overstimulated cortico-accumbens projection and a hyperresponsive mesoaccumbens dopamine projection.

Given the apparent role of dopamine release in establishing adaptive behavioral responses and the magnitude of dopamine release elicited by most drugs of abuse, it is perhaps not surprising that nonphysiologic neuroadaptations ensue, culminating in the maladaptive behaviors characteristic of addiction. Moreover, given that the physiologic release of dopamine is elicited by novel and salient environmental stimuli to facilitate the creation of enduring behavioral strategies, it is reasonable that the pharmacologic magnitude of drug-induced release would result in the addict developing potent learned associations between the dopamine-releasing drug experience and environmental stimuli. This strong association may contribute to the intense cravings that can be induced by environmental stimuli the addict has learned to associate with the drug experience.

LEARNING

Circuitry of Learning

A complete review of the current knowledge of the neural circuitry involved in learning and memory is beyond the scope of this chapter (53 ,54 ,55 and 56); however, it is clear that cortical regions receiving dopaminergic axon terminations, such as the prefrontal and anterior cingulate cortex and allocortical nuclei (including the hippocampus and amygdala) play distinct yet integrated roles in memory and learning. As illustrated in Fig. 95.2 , these cortical and allocortical nuclei have relatively dense glutamatergic projections to the nucleus accumbens and synapse on the same neurons that receive dopaminergic afferents from the VTA (57 ,58). This arrangement provides an anatomic substrate whereby learned information can be integrated and guide adaptive behavioral responding to environmental stimuli. Whether or not these glutamatergic afferents to the nucleus accumbens influence the behavioral effects of drugs of abuse and play a role in the neuroplasticity associated with the development and expression of addictive behaviors is a subject of much recent interest (13 ,59). For example, antagonists of the NMDA subtype of glutamate receptors block the development of behavioral neuroadaptations (e.g., behavioral sensitization of motor activity) to the repeated administration of most drugs of abuse, including alcohol, psychostimulants, and opioids (59 ,60). Moreover, it has been shown that drug craving induced in addicts by environmental stimuli previously paired with the drug experience is associated with metabolic activation of the anterior cingulate and amygdala (4 ,61 ,62). The apparent recruitment of glutamatergic cortical regions by a drug-associated stimulus concurrent with the manifestation of behavioral characteristics of addiction argues for a transition from primarily dopamine-dependent behaviors elicited by acute drug administration to primarily glutamate-dependent behaviors produced by drug or environmental stimuli in drug addicts. Thus, as illustrated in Fig. 95.4 , the development of addiction may consist in part of a transition from dopamine- to glutamate-dependent behaviors akin to what occurs during adaptation to biologically relevant environmental stimuli, such as food, sex, and stress. However, given the initial pharmacologic activation of dopamine transmission produced by most drugs of abuse, the ensuing recruitment of cortical glutamatergic neurons may also contain nonphysiologic constituents that contribute to the pathology of addiction. Moreover, repeated administration of most drugs of abuse, including psychostimulants, opioids, alcohol, and nicotine, increases the capacity of subsequent drug administration to release dopamine in the nucleus accumbens (2 ,63 ,65). This neurochemical reverse-tolerance or sensitization is opposite to what typically occurs with repeated exposure to motivationally relevant environmental stimuli, such as food, sex, and stress, and probably also contributes to the expression of addiction-related behaviors. Of note, the indirect measurement of dopamine release using methylphenidate-induced displacement of radiolabeled D2 receptor antagonist revealed an apparent decrease in dopamine release in cocaine addicts compared with control subjects (66). Assuming the veracity of D2 ligand displacement as an *in vivo*

measure of dopamine release (67), this indicates a potentially important distinction between data in animal models and human cocaine addicts.

NEUROPLASTICITY

Part of "95 - Neurocircuitry of Addiction "

Motivational Circuitry as a Site of Addiction Pathologies

The circuit shown in Fig. 95.2 contains interconnections among mesencephalic dopamine, cortical glutamate, and subcortical (basal ganglia) GABA neurons that can permit the transition from dopamine- to glutamate-dependent behaviors. This circuit has been a focus for research aimed at determining how the neuroplastic changes produced in various nuclei by repeated drug action at a molecular level are integrated with environmental stimuli to form the maladaptive behaviors characteristic of addiction. Studies in this regard are most numerous for psychostimulants; the findings employing this class of addictive drugs provide the primary buttresses of the model. However, emerging data with other drugs of abuse are generally consistent with this view; moreover, there is an abundance of behavioral data supporting the possibility that the neuroplastic changes elicited by repeated administration of one drug impinge on circuitry shared with a different drug of abuse. For example, the repeated administration of some drugs of abuse promotes the acquisition of addiction-related behaviors to another mechanistically similar drug of abuse (68 ,69). Similarly, a number of overlapping cellular neuroadaptations, such as changes in G proteins, tyrosine hydroxylase, and certain immediate early genes, have been identified after repeated exposure to different drugs of abuse (70 ,71 ,72 and 73). Also, a number of studies indicate behavioral and neurochemical overlap between the effects of repeated drug administration and motivationally relevant environmental stimuli (e.g., cross-sensitization and cross-tolerance to stress) (65 ,69 ,74 ,75).

Drug-Induced Changes in Presynaptic and Postsynaptic Dopamine Transmission

As described in the preceding, most addictive drugs produce significant elevations in cortical and subcortical dopamine transmission, and repeated drug-induced dopamine release causes enduring alterations in presynaptic and postsynaptic dopamine transmission. These changes have been characterized using animal models of addiction, including behavioral sensitization studies involving repeated investigator administered drug, as well as studies in which the acquisition, maintenance, and reinstatement of drug self-administration is measured (9 ,76 ,77). The majority of studies have endeavored to identify changes in nucleus accumbens dopamine transmission. However, in light of evidence implicating cortical and allocortical brain regions in addiction, more recent studies have come to focus dopamine innervation of the prefrontal cortex and amygdala. In general, in animal models the repeated administration of drugs of abuse, including amphetamine-like psychostimulants, alcohol, nicotine, and opioids, produces an enduring increase in the capacity of subsequent drug injection or an environmental stimulus, such as stress or sex, to release dopamine in the nucleus accumbens (13 ,37 ,63 ,64 and 65). The enhanced releasability may result in part from increased excitability of dopamine cells (24 ,78 ,79 and 80), but also clearly involves increased presynaptic release, as evidence by the enhanced release of dopamine from synaptosomes or after direct drug administration into the accumbens (81 ,82). Following repeated amphetamine and cocaine administration the elevated presynaptic release of dopamine arises from enhanced presynaptic calcium signaling through calmodulin kinase II (83 ,84 and 85). A number of enduring changes in postsynaptic dopamine signaling have also been identified. Most of these changes can be traced to alterations in gene expression following stimulation of the D1 receptor-signaling cascade (2 ,86). Interestingly, among the genes showing changed expression are protein products, including preprodynorphin, NAC-1, and delta-Fos-B, that appear to dampen enhanced dopamine transmission and/or the expression of behaviors potentially related to addiction, such as motor sensitization and conditioned place preference (87 ,88 and 89). This poses the likelihood that many changes produced by repeated drug administration are not necessarily promoting addictive behaviors but may constitute homeostatic alterations to minimize the impact of pathologic neuroadaptations elicited by repeated drug injection. In addition to changes in gene expression in the nucleus accumbens that affect dopamine transmission, repeated administration of psychostimulants also increases or decreases the synthesis of proteins affecting glutamate transmission that may alter postsynaptic corticofugal neurotransmission (see the following). This includes drug-induced changes in glutamate receptor subunits, as well as proteins involved in the trafficking and signaling of glutamate receptors (13 ,59 ,90 ,91).

In addition to the nucleus accumbens, more recent studies have examined the effect of repeated drug administration on dopamine transmission in the PFC. In general, repeated systemic drug administration reduces the releasability of dopamine in the PFC. Such a blunting of stimulus- or drug-induced dopamine transmission in the PFC has been most clearly shown after repeated cocaine and phencyclidine administration (50 ,92). Further implicating reduced cortical dopamine transmission, destruction of dopamine afferents to or blockade of dopamine receptors in the PFC promotes behavioral sensitization and drug self-administration (93 ,94 and 95). Moreover, the blunting of PFC dopamine transmission may be related to the cognitive dysfunction and increased impulsivity often associated with drug addiction (96).

The effect of repeated drug administration has also been evaluated in the amygdala, and in contrast with the PFC an

augmentation or no change in drug-stimulated dopamine release after repeated drug administration has been observed (97 ,98). Although the effect of repeated drug administration on dopamine release in the PFC and amygdala differs, the changes in dopamine transmission in both structures may contribute to expression of addictive behavior. Although reduced dopamine transmission in the PFC may contribute to cognitive dysfunction in some addicts (see the preceding), enhanced release of dopamine in the amygdala may contribute to the strong learned associations made between drug taking and environmental stimuli that have been repeatedly paired with drug taking. Supporting this possibility, stimulation of dopamine transmission in the amygdala increases stimulus-reward associations, whereas the inhibition of dopamine transmission blocks cue-induced reinstatement of lever pressing for cocaine (99 ,100). Thus, the sensitized release of dopamine in the amygdala may contribute to cue-induced relapse, a conclusion directly supported by imaging studies showing that drug craving in addicts is associated with metabolic activation of the amygdala (4 ,61 ,62), and in experimental animal models where drug-associated cues have been shown to increase glucose uptake or c-fos synthesis in the amygdala (101 ,102).

Prefrontal and Anterior Cingulate Cortex

As outlined above, there is an enduring change in dopamine transmission in the PFC associated with repeated administration of some drugs of abuse. Efforts to deduce the effect of dopamine transmission in the PFC have generally revealed that the actions of dopamine are state-dependent. This is reflected by distinct electrophysiologic effects of dopamine when pyramidal cells in the cortex are relatively active or inactive (e.g., up or down state) and by a biphasic dose–response effect of dopamine agonists and antagonists on cognition (103 ,104). Although the effects of dopamine are state-dependent, dopamine clearly has the capacity to modulate excitatory glutamatergic projections to the nucleus accumbens and VTA (105 ,106 and 107). Thus, the long-term alterations in PFC dopamine transmission by repeated drug use change corticofugal glutamate transmission.

A variety of emerging data indicate that glutamatergic projections to the nucleus accumbens and VTA may be altered by repeated drug administration and that this is consequential in behaviors associated with addiction. Thus, repeated cocaine administration elicits a reduction in basal extracellular glutamate in the nucleus accumbens, whereas subsequent drug exposure results in enhanced glutamate release in both the nucleus accumbens and VTA that depends on dopamine receptor stimulation (108 ,109 and 110). Moreover, the blockade of glutamate receptors in the nucleus accumbens inhibits the expression of behavioral sensitization to cocaine, as well as the capacity of systemic cocaine to elicit drug craving using a reinstatement model of craving in rodents (108 ,111). Also, lesions of the PFC have been shown to block behavioral sensitization to cocaine and morphine, as well as increase extracellular glutamate produced by cocaine in cocaine-pretreated subjects (13 ,112). Taken together with the imaging data in human cocaine addicts showing an association between cocaine craving and metabolic activity in the anterior cingulate cortex (4 ,61), the data to date point toward a critical role in addiction for neuroadaptations in glutamate transmission in the projection from the PFC to the mesoaccumbens dopamine system. Moreover, recent studies may indicate a prepotent role in cocaine addiction for glutamate over dopamine in the nucleus accumbens, although a role for this projection has been more difficult to demonstrate for some drugs of abuse, notably amphetamine (59).

Amygdala-Thalamo-Cortical Circuit

There is substantial evidence for a role by the amygdala in mediating the conditioning of behavior to obtain a natural or drug reward (99 ,113 ,114). Thus, pharmacologically inhibiting neurotransmission within the amygdala prevents the capacity of a cocaine cue to elicit drug-seeking behavior in rodents, and amygdala lesions blunt the expression of conditioned place preference produced by many drugs of abuse. There are two likely connections from the amygdala that are mediating the relationship between learned associations and rewarding stimuli. The first is an interconnected relationship with the amygdala, mediodorsal thalamus, and PFC. Various data suggest that this subcircuit is critical for the formation of learned associations with rewarding stimuli (115). The second connection is among the amygdala, VTA, and nucleus accumbens. Although this subcircuit is important in unconditioned responses to most drugs of abuse (see the preceding), many studies indicate that it is critical for the expression of behaviors elicited by conditioned stimuli to obtain reward, as well as cue-induced drug relapse (114). Although both circuits probably contribute to stimulus-induced drug relapse, the relative role of each may depend on the type of stimulus. For example, relapse precipitated by a low dose of drug, especially a drug known to activate dopamine transmission, is likely to involve the dopamine projection from the VTA to the amygdala, whereas cue-induced relapse may be more involved with the influence the amygdala brings to bear on the thalamocortical projection (99 ,111).

CONCLUSION AND FUTURE DIRECTIONS

Part of "95 - Neurocircuitry of Addiction "

The last decade has witnessed the emergence of a number of seminal developments in our understanding of the circuitry mediating addiction. Primary among these is that there exists substantial overlap in the circuits mediating behavioral responses to non-drug and drug reward (Fig. 95.2 and Fig 95.4), and that the pathology of addiction arises to a great extent

from neuroplasticity within this common circuit. The second critical development is that neuroplasticity to drug reward arises from an interaction between the molecular site of drug action and environmental stimuli associated with the effect of the drug. In this way, cortical and allocortical circuitry important in learning and memory is recruited and undergoes neuroplastic alterations in response to drugs of abuse. The studies outlined in this chapter describe changes in neurotransmission and cell signaling that may be critical in changing the functional status of the circuit illustrated in Fig. 95.2 . Accompanying these intracellular and neurochemical neuroadaptations, it is also important to note the recent studies of Robinson and coworkers (116 ,117), which show that akin to normal learning, repeated exposure to psychostimulants or opioids produces morphologic changes in dendritic branching and synaptic connectivity in many nuclei (Fig. 95.2). Although neurobiologists are well engrossed in identifying neuroplastic changes in various nuclei (Fig. 95.2), there is a lag in understanding how these alterations result in a change in the function of the circuit as a whole. The circuit shown in Fig. 95.2 is highly interconnected and topographically organized (35 ,36). Thus, a change in the function of a cell group in one nucleus is likely to impact on the status of neurons in other nuclei. Predicting and experimentally evaluating these secondary interactions and how they determine the appearance of addictive behavior will be the arena of study over the next decade. This arena can be approached from molecular technologies at one end and imaging studies at the other. The imaging experiments help to define functional subcircuits within the overall reward and learning circuitry, whereas the molecular studies can identify specific cellular neuroadaptations. Using pharmacologic and genetic manipulations these specific cellular neuroadaptations can be evaluated *in vivo* animal models of addiction to determine the relevance of the changes in addictive behaviors and on cellular adaptations in interconnected nuclei within the reward and learning circuits.

As an initial foray into integrative thinking it is becoming clear that there is a distinction between the effects of acute drug and repeated administration on the circuit shown in Fig. 95.2 . In the analysis of the literature outlined in the preceding, this distinction was characterized as a transition from dopamine-dependent effects to behaviors more dependent on cortical glutamate transmission. Although this is an oversimplification based on too few experiments using too few classes of drugs of abuse, it is similar to the physiologic neuroadaptive processes associated with the development of habitual behavioral responses to previously novel motivationally relevant natural stimuli (Fig. 95.4). Moreover, involvement of cortical and allocortical brain regions in addiction imparts a mandate that future researchers to consider the neurobiology of learning and memory as an equal partner with drug neuropharmacology in developing effective therapy for addiction.

Molecular and Cellular Biology of Addiction

Kathy L. Kopnisky

Steven E. Hyman

Kathy L. Kopnisky and Steven E. Hyman: National Institutes of Health, Bethesda, Maryland.

Addiction to alcohol, tobacco, and illegal drugs represents a substantial burden to societies worldwide. In terms of health-related outcomes, addiction results in enormous direct medical costs, premature mortality (tobacco alone may be responsible for 450,000 deaths yearly in the United States), and disability. In terms of broader social costs, addiction results in crime, negative impacts on families, derailed lives, and personal suffering. The major categories of drugs most likely to produce addiction are psychostimulants (including cocaine and amphetamines), opiates, ethanol, nicotine, marijuana, and phencyclidine-like drugs. Understanding the molecular and cellular actions of addictive drugs is obligatory if we are to better understand pathophysiology and develop potent pharmacotherapies to treat addiction. Of course, the molecular and cellular information presented in this chapter cannot be applied directly to the behavioral expression of addiction without putting it into the context of systems level neuroscience described in other chapters.

Acutely, addictive drugs are both rewarding (i.e., interpreted by the brain as intrinsically positive) and reinforcing (i.e., behaviors associated with drug use tend to be repeated). With repeated use, however, addictive drugs produce molecular changes that, within a vulnerable brain, promote continued drug-taking behavior in a manner that becomes increasingly difficult to control. The central feature of addiction is compulsive drug use—the loss of control over the apparently voluntary acts of drug seeking and drug taking. Once it has taken hold, addiction tends to follow a chronic course with periods of abstinence (that may or may not follow treatment), followed by relapse to active drug use. Even after extended periods of drug abstinence, the risk of relapse remains high. From the point of view of developing treatments, a central problem in addiction research includes understanding the molecular processes that lead to compulsive use and the long-term risk of relapse.

Addiction (defined as compulsive use) is not the only long-term effect of addictive drugs. Both addictive and many nonaddictive drugs may produce tolerance and dependence. Tolerance refers to the diminishing effect of a drug after repeated administration at the same dose, or to the need for an increase in dose to produce the same effect. Dependence represents an adaptive state that develops as a homeostatic response to repeated drug administration. Dependence is typically unmasked when drug taking stops, leading to withdrawal symptoms. Withdrawal symptoms may even emerge during active drug use as a result of tolerance, helping to drive increasing dosages or shorter intervals between doses.

Among the addictive drugs, ethanol and opiates produce dependence that has a somatic component, manifested by somatic symptoms during withdrawal, such as hypertension, tremor or seizures for ethanol, and hypertension, lacrimation, and abdominal cramps for opiates. All addictive drugs, including the psychostimulants, can produce an emotional–motivational component of dependence, manifested by symptoms such as dysphoria, anhedonia, and drug craving.

Tolerance and dependence may be prominent features accompanying addiction, but are not required. Indeed, when produced by addictive drugs, tolerance and withdrawal symptoms tend to resolve within days to weeks and therefore cannot account for the persistence of drug addiction (as manifest by the tendency to relapse) for many years. Indeed, both tolerance and dependence can occur with nonaddictive drugs as well. For example, B-adrenergic agonists inhaled for asthma, many antihypertensive drugs, and shorter-acting serotonin selective reuptake inhibitors may produce dependence and withdrawal symptoms on cessation, but do not produce compulsive drug seeking and drug taking. Based on these considerations, the molecular mechanisms underlying tolerance and dependence, and those responsible for addiction may overlap, but cannot be identical.

One other long-term effect of addictive drugs, best documented for psychostimulants, is sensitization, in which repeated administration of a drug elicits escalating effects of a given dose. Sensitization can be operationally defined as a leftward shift in the drug's dose–response curve (1). Because behavioral sensitization to drugs in animal models can be quite long-lived, it has been considered by some to be a model for long-lasting aspects of human drug addiction.

Not every individual who experiments with drugs becomes addicted. Indeed, the likelihood that a person will experiment with drugs, use them repetitively, and progress to addiction, appear to be the product of complex gene–gene and gene–environment interactions, acting together with contextual variables, such as drug availability. Factors related to vulnerability are discussed elsewhere in this volume. This chapter has a dual focus. First, it discusses the initial molecular targets of addictive drugs in the brain; then the molecular and cellular changes induced by drugs in the brain that might be responsible for such clinically significant aspects of drug abuse syndromes as tolerance, dependence, sensitization, and addiction. An enormous number of drug-induced molecular and cellular changes in brain function are already known, not all of which turn out to have clinical relevance. Thus, the chapter does not attempt to produce an exhaustive list of the known molecular effects of addictive drugs, but focuses on a subset of those that illustrate important principles and that can be related to the long-term effects of addictive drugs in humans.

With exceptions from a small number of human postmortem studies, most of what we know about the molecular and cellular actions of addictive drugs comes from animal models. The integration of such information about drug action in the brain with information about human risk factors is in its early stages and will benefit enormously from the eventual discovery of risk-producing alleles from human genetic studies. The discovery of alleles that confer vulnerability to drug use or addiction will help focus molecular and cellular studies of pathophysiology, as well as suggest biochemical pathways that can be exploited for treatment.

MOLECULAR TARGETS OF ADDICTIVE DRUGS

Part of "96 - Molecular and Cellular Biology of Addiction "

The overall effect of each of the addictive drugs depends on the particular neurons and circuits that express their molecular targets, and the nature of those targets. Thus, for example, morphine-like opiates are analgesic and sedating, whereas cocaine is a psychomotor stimulant; these different properties are based on differences in localization and functional properties of the proteins with which they interact, the μ-opioid receptor for morphine and the dopamine reuptake transporter (DAT) for cocaine. However, as described in other chapters in this section, addictive drugs share the ability to activate mesocorticolimbic dopamine projections that are critical substrates for both rewarding and reinforcing effects of natural stimuli. Mesocorticolimbic dopamine projections originate in the ventral tegmental area (VTA) of the ventral midbrain and project to structures that include the nucleus accumbens (NAc) (a complex structure within the ventral striatum that is the best-established substrate for reinforcement), and the prefrontal cerebral cortex. *In vivo* microdialysis studies have indicated that most if not all addictive drugs, including cocaine, amphetamines, opiates, nicotine, and ethanol, cause selective elevation of extracellular dopamine levels in the NAc, and blockade of dopamine neurotransmission in this region attenuates most measurable reinforcing and rewarding effects of addictive drugs (2 ,3). The powerful control over behavior exerted by addictive drugs is thought to result from the brain's inability to distinguish between the activation of reward circuitry by drugs and natural activation of the same circuitry by useful behaviors (e.g., behavioral related to eating or reproduction). Any activity, whether related to drug taking or survival, that activates this circuitry tends to be repeated; however, activation of reward circuitry by addictive drugs can be much more reliable and powerful than activation triggered by natural reinforcers, facilitating repetitive drug use, and with it, the initiation of molecular mechanisms that may produce tolerance, dependence, sensitization, and compulsive use. Although the mesocorticolimbic dopamine system is a site of convergence for the rewarding effects of virtually all major classes of addictive drugs, these drugs act by very different mechanisms.

Psychostimulants

The best-characterized and most widely abused psychostimulants are cocaine and the amphetamines. The details of their mechanisms of actions differ, but both result in increases of extracellular dopamine and other monoamines and produce similar effects on behavior. In humans, psychostimulants increase alertness and produce a sense of well being. In animal studies, psychostimulants produce a dose-dependent increase in locomotor activity at low doses and stereotypies at high doses. If cocaine or amphetamine is used repeatedly, some acute drug effects may diminish (tolerance), whereas others are enhanced (sensitization).

Cocaine and amphetamines produce their effects by potentiating monoaminergic transmission through actions on dopamine, serotonin, and norepinephrine reuptake transporters (4). These proteins normally transport previously released neurotransmitter back into the presynaptic nerve terminal, and thereby terminate transmitter action. Cocaine binds to these transporters and competitively inhibits their functioning, thereby increasing the duration of action of neurotransmitter released into the synaptic cleft. Amphetamines and related drugs increase dopamine, serotonin, and norepinephrine neurotransmission by acting as a substrate for their transporters. Amphetamines are transported into

the presynaptic terminal where they cause neurotransmitter release by reversing the usual direction of transport (i.e., causing transmitter to move into the synapse).

Whereas psychostimulants affect all three transporters, it is their actions at the DAT that are most directly related to the reinforcing effects of psychostimulant drugs. Lesions of the dopamine system or administration of dopamine receptor antagonists, but not similar manipulations of serotonin or noradrenergic systems, markedly attenuate cocaine self-administration. The central role of the DAT in psychostimulant action is highlighted in studies using mice in which the DAT has been genetically inactivated. In the absence of the DAT, animals are insensitive to the locomotor stimulatory effects of cocaine and amphetamine (5). By contrast, animals lacking serotonin (5-HTT$^{-/-}$) or norepinephrine (NET$^{-/-}$) transporters exhibit normal locomotor responses to psychostimulants (6 ,7). Interestingly DAT$^{-/-}$ animals still self-administer cocaine and amphetamine to some degree (8), but the interpretation of this result is complex because DAT$^{-/-}$ animals have very high levels of extracellular dopamine at baseline (lacking a DAT to remove synaptic dopamine), which might magnify a psychostimulant-mediated effect on norepinephrine or serotonin. Much evidence demonstrates that the dopamine system is obligatory for psychostimulant-induced reinforcement, but the serotonin and noradrenergic systems, whose transporters are also inhibited by psychostimulants, may play a role as well.

Opiates

The opiates and their synthetic analogues are the most effective analgesic agents known, and at the same time can produce tolerance, dependence (including somatic dependence), and addiction. Physical dependence on opiates can contribute to addiction, but can also occur independently of it. For example, patients with cancer pain may become physically dependent on these drugs but do not compulsively abuse them.

Opiate drugs bind to receptors for three subtypes of receptors that normally bind endogenous opioid peptides. The three subtypes, denoted μ, κ, and δ, are members of the G protein-coupled receptor family, and all interact with G proteins of the G_i/G_o types. This coupling results in inhibition of adenylyl cyclase, activation of inwardly rectifying K^+ channels, and inhibition of voltage-gated Ca^{2+} channels. Opiate receptors thus typically mediate inhibitory responses that reduce membrane excitability and reduce likelihood of cell firing and neurotransmitter release; however, the different opiate receptor subtypes are expressed on different cells, resulting in different biological effects when stimulated. Morphine-like opiates, including heroin, are both analgesic and addictive, and interact with highest affinity with the μ-receptor.

Morphine-like opiates suppress afferent nociceptive information by acting on opiate receptors contained within a descending pathway extending from the periaqueductal gray matter of the midbrain, to the rostroventral medulla, and then to the dorsal horn of the spinal cord. These same drugs appear to produce both reward and reinforcement by means of at least two mechanisms: (a) activation of the VTA, which results in dopamine release in the NAc; and (b) direct binding to opiate receptors in the NAc, an action that is independent of dopamine. Activation of VTA dopamine neurons by opiates results from disinhibition: morphine-like opiates inhibit GABAergic interneurons in the VTA that tonically inhibit the dopamine projection neurons (9). Increased activity of these dopamine neurons produces increases in extracellular dopamine levels in the NAc. Consistent with this arrangement, the reinforcing effects of intravenous heroin can be partly attenuated by administration of an opioid receptor antagonist directly into the VTA or lesioning the dopaminergic neurons of the VTA. Opiates also produce reinforcement through direct dopamine-independent action on μ, and perhaps δ, receptors expressed by NAc neurons. Consistent with this mechanism, morphine is self-administered even in the presence of dopamine receptor blockade or following a 6-hydroxydopamine lesion that destroys dopamine neurons (10 ,11). Moreover, lesions of the NAc or pharmacologic μ-receptor antagonists applied to the NAc dose dependently reduce the reinforcing effects of heroin and morphine (12 ,13). Thus, opiates and dopamine work through different postsynaptic receptors within the NAc to produce reinforcement.

M and δ-opioid receptor subtypes, both of which are present in the VTA and NAc, may both play a role in opiate reinforcement. In contrast, κ-opioid receptor activation is not reinforcing. Activation of κ receptors can decrease dopamine release in the NAc by both presynaptic mechanisms- there are κ receptors on a subset of dopamine terminals. As a result stimulation of κ opiate receptors may produce aversive responses in both animals and humans. As will be described in the following, κ opiate receptors may play a role in the emotional–motivational aspects of withdrawal from psychostimulants.

Ethanol

Ethanol is a central nervous system depressant that produces behavioral disinhibition, euphoria, reduced anxiety, decreased motor coordination, and sedation. The major mechanisms underlying behavioral effects, including reinforcement, are thought to be facilitation of $GABA_A$ receptors and inhibition of NMDA glutamate receptors (14). At higher doses, ethanol also inhibits the functioning of most voltage-gated ion channels. The molecular mechanisms by which ethanol affects these receptors and channels are not yet certain; two types of mechanisms have been hypothesized. One possible mechanism attributes the effects of ethanol on receptors and channels to its generalized effects on cell membranes, in which it is highly soluble. Certain

ligand-gated and voltage-gated channels may be preferentially affected by ethanol because, as complex multimeric proteins, they may be particularly vulnerable to ethanol-mediated changes in their lipid environment. The alternative hypothesis is that ethanol interacts with specific hydrophobic regions of these proteins to produce allosteric changes in structure, but the convincing demonstration of such interactions is still lacking.

Whether it acts via its general effects on membranes or, more specifically, in interaction with particular regions of proteins, ethanol has been shown to allosterically regulate the $GABA_A$ receptor to enhance GABA-activated Cl^- flux. The anxiolytic and sedative effects of ethanol, like those of barbiturates and benzodiazepines, are believed to result from facilitation of the $GABA_A$ receptor, although the precise mechanism differs for each drug. For example, distinct binding sites on the receptor have been identified for barbiturates and benzodiazepines. The convergence of actions of ethanol, barbiturates, and benzodiazepines on a single receptor result in more than additive effects, which can be responsible for lethal overdoses. In addition, these agents all produce cross-tolerance, thus permitting the use of benzodiazepines in ethanol detoxification protocols.

Not all $GABA_A$ receptors are ethanol sensitive. $GABA_A$ receptor complexes are heteropentamers comprised of combinations of the various members of five distinct subunit families. The subunit combinations vary in different cell types, leading to differences in the sensitivity of $GABA_A$ receptors to ethanol in different brain regions.

Ethanol also acts as an NMDA glutamate receptor antagonist, and allosterically inhibits the passage of glutamate-activated Na^+ and Ca^{2+} currents through the NMDA receptor. Other actions of ethanol that are possibly relevant to its psychotropic effects include potentiation of the action of serotonin at $5\text{-}HT_3$ receptors, which, like NMDA receptors, are excitatory, cation-selective ion channels.

The mechanisms by which ethanol produces reinforcement are not yet known in their entirety. The reinforcing effects of ethanol are partly explained by its ability to activate mesocorticolimbic dopamine circuitry (15), with enhanced release of dopamine in the NAc. It is not known whether this effect is mediated by disinhibition of dopamine neurons at the level of the VTA or whether it occurs at the level of the NAc, nor is it known whether it is caused primarily by facilitation of $GABA_A$ receptors or inhibition of NMDA receptors. Finally, it is not know to what degree opioid, serotonin, and other systems play a role in ethanol-mediated reinforcement. Thus, for example, not only $GABA_A$ receptor antagonists but also opiate antagonists, decrease ethanol self-administration and ethanol-related behavioral effects in rats (16 ,17 and 18). The opiate antagonist naltrexone reduces ethanol self-administration in animals; moreover, naltrexone and other opioid receptor antagonists reduce ethanol consumption, relapse to active drinking, and craving clinically (19 ,20).

Serotonin also appears to be involved in ethanol consumption and reinforcement; ethanol consumption is generally curbed by experimental manipulations that increase serotonergic function, and experiments with rats selectively bred for ethanol preference suggest that strong ethanol preference is associated with reduced serotonergic function. $5\text{-}HT_3$ antagonists such as ondansetron can block both ethanol-induced dopamine release in the NAc and ethanol consumption in rats. Mice lacking $5\text{-}HT_{1B}$ serotonin receptors consume higher levels of ethanol yet demonstrate less ataxia (21).

Nicotine

Nicotine is the main psychoactive ingredient of tobacco and is responsible for the stimulant effects, reinforcement, and dependence that result from tobacco use. Cigarette smoking rapidly delivers nicotine into the bloodstream. Nicotine differs from cocaine and opiates in that it is powerfully reinforcing in the absence of subjective euphoria.

The effects of nicotine are caused by its activation of nicotinic acetylcholine receptors (nAChRs). Nicotinic AChRs are ligand-gated cation channels located both presynaptically and postsynaptically. Presynaptic nAChRs facilitate neurotransmitter release. The reinforcing effects of nicotine depend on an intact mesolimbic dopamine system; nicotine-induced increases in locomotor behavior are also blocked by destruction of mesolimbic dopamine nerve terminals or cell bodies (22). Moreover, nicotine increases dopamine neurotransmission and energy metabolism in the nucleus accumbens (23).

Nicotinic AChRs containing α6 and B2 subunits are highly expressed in VTA dopamine neurons, and seem to be involved in both nicotine-induced dopamine release and reinforcement and in nicotine-induced locomotor activation (24 ,25). Systemic nicotine self-administration is disrupted when nicotinic receptor antagonists are administered directly into the VTA but not when they are administered into the NAc. Nicotine may also have some ability to stimulate dopamine release in the NAc, however, mediated by presynaptic nAChRs located on dopamine terminals within the NAc. Nicotinic AChRs on VTA dopamine neurons are normally activated by cholinergic innervation from the laterodorsal tegmental nucleus or the pedunculopontine nucleus.

Nicotine may also affect reinforcement via the opioid peptide system. Not only dopamine antagonists, but also opiate antagonists, block nicotine-induced behaviors and self-administration (26 ,27). These findings suggest a role for endogenous opioid systems in the reinforcing effects of nicotine, and raise the possibility that such antagonists may be of use in the treatment of nicotine addiction.

Cannabinoids

δ-9-Tetrahydrocannabinol (THC) is the major psychoactive compound contained in marijuana. THC produces effects

in humans that range from mild relaxation, euphoria, analgesia, and hunger to panic attacks. Reinforcing effects of cannabinoids comparable to those of other addictive drugs have not been demonstrated in animals, but cannabinoids have been shown to decrease reward thresholds and promote conditioned place preference in rats (28 ,29). THC increases mesolimbic dopamine transmission in the NAc shell, probably via a μ-opioid receptor-mediated mechanism because μ-receptor antagonists prevent the THCinduced dopamine increases in the brain mesolimbic area (30). Cannabinoids have also been reported to inhibit excitatory glutamatergic neurotransmission in the substantia nigra pars reticulata (31).

THC binds to two cannabinoid receptors denoted CB_1 and CB_2. Of the two, only the CB_1 receptor is expressed in the central nervous system, with high levels in the basal ganglia and limbic system (32). The endogenous ligand for the CB1 receptor appears to be an arachidonic acid derivative, anandamide; however, the nature of anandamide's function in the brain remains speculative. Evidence indicates that other endogenous ligands also may bind at this receptor.

Despite ongoing debates about the addictiveness of cannabinoids in humans, there appear to be many compulsive marijuana users. Withdrawal symptoms typically are not reported with termination of long-term marijuana use, but withdrawal symptoms have been demonstrated in a laboratory setting after four days of marijuana smoking (33). Cannabinoid dependence can be demonstrated experimentally with the use of cannabinoid receptor antagonists, which precipitate profound withdrawal symptoms that are somatic and emotional–motivational. In animals chronically treated with THC, a selective cannabinoid receptor antagonist produced withdrawal symptoms that included head shakes, facial tremors, tongue rolling, biting, wet dog shakes, and ptosis (34). Neurobiologically, withdrawal effects include increases in c-fos expression in the basal ganglia systems and CRF release in the amygdala (35).

Phencyclidine-Like Drugs

Phencyclidine (PCP or angel dust) and ketamine are related drugs classified as dissociative anesthetics. These drugs exhibit psychotomimetic properties, but are distinguished from hallucinogens by their distinct pharmacologic effects, including their reinforcing properties and risks related to compulsive abuse.

The reinforcing properties of PCP and ketamine are mediated by the binding to specific sites in the channel of the NMDA glutamate receptor, where they act as noncompetitive NMDA antagonists. PCP is self-administered directly into the NAc, where its reinforcing effects are believed to result from the blockade of excitatory glutamatergic input to the same medium spiny NAc neurons inhibited by opioids, and also by increases in extracellular dopamine. In contrast, hallucinogens, such as LSD, act at $5\text{-}HT_2$ serotonin receptors.

MOLECULAR AND CELLULAR MECHANISMS OF LONG-LIVED DRUG EFFECTS

Part of "96 - Molecular and Cellular Biology of Addiction "

Homeostasis Versus Associative Learning

Diverse behaviors, symptoms, and signs of substance use disorders coexist clinically, but depending on the drug and on the stage of the disorder, these may involve multiple molecular mechanisms occurring in diverse neural circuits. Heuristically, the types of molecular mechanisms involved in the long-lived effects of addictive drugs may be divided into two major classes: homeostatic adaptations and associative learning. Homeostatic adaptations can be understood as compensatory responses of cells or circuits to excessive bombardment by a drug or to excessive drug-induced neurotransmitter stimulation (e.g., excessive dopamine stimulation). These adaptations tend to dampen drug effects, thus playing a critical role in tolerance and dependence. The adapted state of neurons or neural systems may be unmasked on drug cessation, leading to the production of withdrawal symptoms, as illustrated in the following. Homeostatic adaptations typically occur within reversible bounds, and with removal of the drug, tend to dissipate over days to weeks.

Although clinically significant, homeostatic mechanisms cannot account for the persistent tendency of addicted individuals to relapse, even years after any withdrawal symptoms have subsided. Relapse often occurs on re-exposure to cues associated with drug use, consistent with an important role for associative learning (36). Although homeostatic mechanisms are thought to represent reversible global alterations in the sensitivity of neurons or circuits to neurotransmitters or drugs, associative learning is thought to represent long-lived or permanent alterations in patterns of synaptic connectivity that encode specific information (37). The clear separation between homeostasis and associative learning that has been implied, however, is an oversimplification. For example, there is recent evidence that associative learning mechanisms and compensatory adaptations may interact. Thus, for example, associative learning mechanisms have recently been shown to play a role tolerance to opiate analgesia, that is, the expression of tolerance may be context-dependent (38). Moreover, molecular adaptations that occur as a homeostatic response to drug bombardment may alter the threshold for associative learning involving affected cells.

Recruitment of Different Molecular Mechanisms Over Time

During the earliest periods of drug experimentation, mesocorticolimbic reward circuits are activated via different

mechanisms by different classes of drugs. As noted, a shared property of addictive drugs is to promote dopamine release in multiple forebrain regions, including the NAc, but also including the dorsal striatum, amygdala, and hippocampus, in which dopamine release can act as a reinforcement signal, thus controlling learning processes (39 ,40). As drug use continues, tolerance may occur, leading to dosage escalation. Depending on the drug, somatic dependence and/or emotional–motivational dependence my sustain drug seeking and drug use in attempts to avoid the aversive state of withdrawal. The emotional–motivational aspects of tolerance and dependence may largely occur within the mesocorticolimbic circuitry itself, but molecular adaptations occur in other circuits as well in a drug-specific manner reflecting the location of the target molecules for the given drug. Sensitization to some drug effects may occur, a phenomenon that is especially well documented for psychostimulants. Sensitization may act, *inter alia*, to increase the incentive salience of the drug, and thereby contribute to compulsive drug use (41). At the same time, multiple memory systems are affected by drugs of abuse (42) and, undoubtedly contribute to sustaining active drug use and late relapses (37). What follows are examples of different molecular processes that contribute to different aspects and stages of substance use disorders. These illustrations have been chosen based on the depth of available information, and likely relevance to the clinical situation in humans.

Adaptations That Produce Tolerance and Somatic Dependence to Opiates

Opiates and ethanol produce somatic dependence and withdrawal because their targets are expressed on cells and circuits that regulate bodily functions such as autonomic activity. Tolerance and dependence are generally thought to represent homeostatic adaptations that compensate for overstimulation by a drug or neurotransmitter. During withdrawal, the overcompensated system is suddenly unopposed by the drug it had adapted to counteract. Consequently, withdrawal symptoms appear that generally are opposite to the immediate effects produced by the drug. The molecular adaptations probably responsible for some aspects of tolerance and somatic dependence are best understood for opiates (43).

With repeat administration of mu agonist opiates such as morphine or heroin, both tolerance and dependence emerge. There is a significant somatic component to heroin dependence as manifest by the classic heroin somatic withdrawal syndrome. It had initially been hypothesized that opiate dependence would correlate with significant changes in expression of endogenous opioid peptides or opioid receptors or changes in opioid receptor affinity. This has not turned out to be the case; rather opiate tolerance and dependence appear to be caused by adaptation in postreceptor signaling mechanisms in opiate receptor-bearing cells (Fig. 96.1).

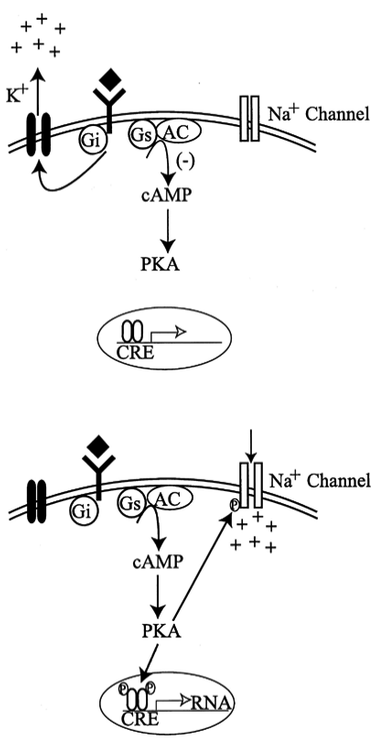

FIGURE 96.1. Mechanism of opiate tolerance and dependence in the locus ceruleus: Acute administration of opiates increases outward K^+ current, thereby hyperpolarizing locus ceruleus cells *(top)*. With chronic opiate use the cAMP signaling system is up-regulated, leading to PKA-dependent phosphorylation of the Na^+ channel. In this state, the channel is more active, allowing Na^+ ions to flow into the cell, increasingly the intrinsic excitability of the cell. Up-regulation of the cAMP system also increases CREB Ser^{133} phosphorylation and CRE-dependent gene transcription. Alterations in CRE-driven genes may contribute to the increased LC neuron excitability as well *(bottom)*.

The locus ceruleus (LC), located in the dorsal pons, is the major noradrenergic nucleus of the brain and regulates arousal, attention, and vigilance. It is involved in responses to stress, and together with other noradrenergic cell groups plays a role in regulation of the autonomic nervous system. Morphine-like opiates acutely inhibit the firing of LC neurons, but tolerance and dependence occur within the LC with continued administration. Thus, despite continued opiate exposure, LC firing rates gradually return to their basal levels. At this point, administration of an opioid receptor

antagonist, such as naloxone or naltrexone, causes a dramatic increase in LC firing rates. In animals, the period of rapid LC firing correlates with the somatic withdrawal syndrome, and drugs, such as the α_2-adrenergic receptor agonist clonidine, which inhibit LC firing, attenuate withdrawal symptoms.

Many of the adaptations that produce LC-mediated tolerance and dependence depend on the cyclic AMP (cAMP) pathway. In the LC, as in most other cell types, μ-opioid receptor activation inhibits the cAMP pathway via Gi activation and stimulates an inwardly rectifying K^+ current by means of direct interactions of the G protein βγ subunits with the channel. M-opiate receptors also inhibit a Na^+ current that is dependent on the cAMP-dependent protein kinase (protein kinase A or PKA) for its activation, and is thus dependent on an active cAMP system. Taken together, the actions of μ agonist opiates on these K+ and Na+ channels expressed by LC neurons decrease the excitability and inhibit the firing of the LC. With long-term opiate administration, however, a homeostatic compensatory response occurs: key components of the cAMP pathway become up-regulated in LC neurons; thus, for example there are increased concentrations of adenylyl cyclase and protein kinase A. This up-regulation increases the intrinsic excitability of LC neurons, by activating the cAMP-dependent Na^+ current. The activation of this current may explain why LC firing rates return to normal despite the continued presence of an opiate (an example of tolerance). These observations may also explain the dramatic increase in LC firing that occurs if an opiate antagonist such as naloxone is administered to precipitate withdrawal (illustrating dependence). The up-regulation of the cAMP pathway has increased the intrinsic excitability of the LC neuron, but as long as μ-opiate agonists continue to be administered, this excitability is counteracted.

Activation of LC neurons during opiate withdrawal owes not only to changes in intrinsic excitability, but also partly to glutamatergic projections to the LC from the nucleus paragigantocellularis of the medulla. Lesions of the paragigantocellularis, or glutamate receptor antagonists administered locally in the LC, attenuate withdrawal-induced increases in LC firing rates by approximately 50%. An up-regulated cAMP pathway also may mediate this effect, as long-term use of opiates causes up-regulation of the cAMP pathway in the paragigantocellularis and its major afferents.

The mechanisms by which the cAMP pathway becomes up-regulated are complex, and may involve both transcriptional and translational mechanisms; however, the importance of transcription factor CREB is supported by experiments in mice with a partial knockout (hypomorphic allele) of CREB. In these animals two of the major CREB isoforms, α and δ, were disrupted. After an opiate administration paradigm that would be expected to produce opiate dependence and naloxone-precipitated withdrawal, these mice exhibited markedly reduced signs of withdrawal including complete absence of sniffing and ptosis (44 ,45).

This is not the whole story, however. Opiate-induced up-regulation of PKA does not involve CREB and may be mediated posttranslationally. The inactive PKA holoenzyme is a heterotetramer composed of two regulatory and two catalytic subunits. When the regulatory subunits are bound by cAMP, the catalytic subunits are free to phosphor late substrate proteins. However, free catalytic subunits of PKA are highly vulnerable to proteolysis, whereas inactive subunits bound to regulatory subunits are proteolysis-resistant. It is currently speculated that PKA subunits accumulate in the LC during long-term opiate treatment because the enzyme is inhibited by the persistent presence of an opiate, keeping it in its inactive holoenzyme form in which subunits would be degradation-resistant. As the number of enzyme molecules increases, the kinase activity can be more readily activated by the low levels of cAMP.

Adaptations That May Produce Tolerance and Somatic Dependence on Ethanol

Like opiates, ethanol produces somatic dependence and withdrawal, although the clinical syndrome is quite distinct, and potentially more dangerous. The molecular mechanisms are less well understood than those underlying opiate tolerance and dependence, but the comparison is instructive. There is some evidence that homeostatic adaptations occur in response to ethanol that decrease $GABA_A$ receptor expression and increase NMDA receptor expression on some neurons. The decrease in receptors for the major inhibitory neurotransmitter and the increase in excitatory receptors would make neurons intrinsically more excitable. With removal of ethanol, a drugs that facilitates $GABA_A$ receptor-mediated Cl- currents and inhibits NMDA receptors, a state of increased neural excitability would be unmasked (Fig. 96.2) leading to withdrawal symptoms such as agitation, tremor, hypertension, and seizures. The decrease in $GABA_A$ receptor function is possibly due in part to decreased $GABA_A$-1 subunit expression in the striatum, cortex, and hippocampus (46). Conversely, chronic ethanol appears to increase the number and function of NMDA receptors (47). During withdrawal, glutamate release is increased for up to 36 hours in the NAc, hippocampus, and striatum (48). Overall, there is increasing evidence to suggest that that the neuronal hyperexcitability evident during ethanol withdrawal result from the combination of reduced $GABA_A$ receptor-mediated inhibition and increased glutamatergic excitation (Fig. 96.2).

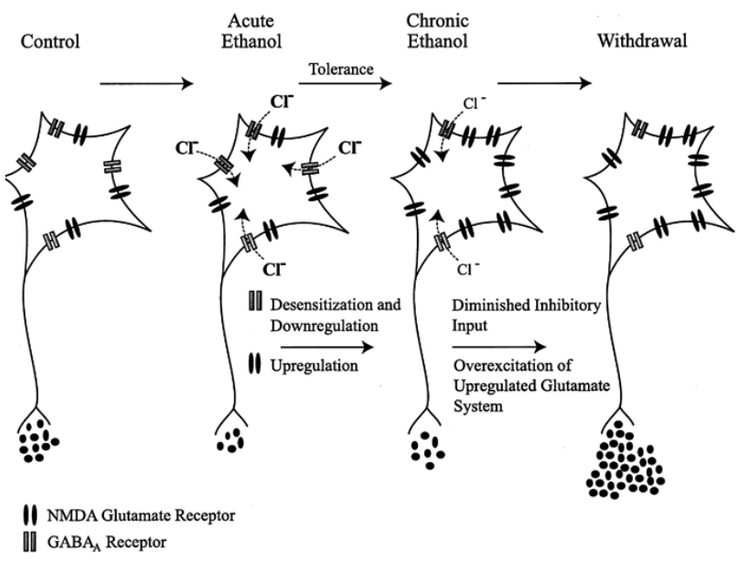

FIGURE 96.2. Hypothetical scheme to explain increased neuronal excitability with ethanol withdrawal: Acute ethanol exposure increases chloride conductance via the $GABA_A$ receptor and inhibits NMDA glutamate receptors, thereby reducing neuronal excitability and glutamate release. With chronic ethanol exposure, there is putative down-regulation of $GABA_A$ receptor subunits and possibly up-regulation of NMDA receptors. On ethanol withdrawal, inhibitory input from ethanol is removed; therefore, excitatory influences are relatively unopposed. The neurons release increased quantities of glutamate, which may act on up-regulated receptors. The unopposed cellular hyperexcitability can promote seizure activity as groups of neurons become overexcited.

Adaptations That Produce Emotional and Motivational Aspects of Dependence

An emotional and motivational component of dependence has been hypothesized to reflect neural adaptations to excessive

dopamine release within brain reward pathways. Emotional and motivational aspects of dependence are inferred in humans from the dysphoria, anhedonia, and, anxiety that may accompany withdrawal from psychostimulants (49) and other addictive drugs. One animal model for emotional–motivational aspects of dependence is elevation of brain stimulation reward thresholds. Direct electrical stimulation of brain reward pathways is both rewarding and reinforcing. Acute administration of addictive drugs decreases the level of stimulation necessary to achieve rewarding levels of stimulation. However, if drugs are repeatedly administered and then withdrawn, there is a marked increase in the threshold for achieving reward, as if the brain reward pathways are in a state of decreased responsiveness (50). Based on this and other models, it has been hypothesized that reduced mesolimbic dopaminergic activity is associated with the emotional–motivational aspects of dependence and withdrawal; however, brain reward circuitry is complex, and it is to be expected that many adaptive processes occur that contribute to dependence. For example, relevant adaptations likely occur both in NAc and in VTA neurons. Indeed there is evidence of up-regulation of the cAMP pathway with chronic administration of addictive drugs both in NAc neurons and in the GABAergic interneurons that innervate dopaminergic neurons of the VTA. Up-regulation of the cAMP pathway in VTA interneurons during withdrawal could lead to increased GABA release and consequently to reduced firing of the dopaminergic cells on which they synapse. Such activity might partially account for the reductions in dopaminergic neurotransmission from the VTA to the NAc observed during early phases of withdrawal and that are believed to contribute to withdrawal symptoms.

One mechanism that could contribute to aversive states that occur with psychostimulant withdrawal is up-regulation of the neuropeptide dynorphin. In the dorsal and ventral striatum, levels of prodynorphin mRNA and dynorphin peptides increase significantly following repeated administration of psychostimulants (51 ,52). A significant increase in prodynorphin mRNA is observed after rats self-administer cocaine (53) and, in postmortem studies of cocaine-dependent human drug abusers, there is a marked induction of prodynorphin, but not other peptide mRNAs in the striatum (54).

Dynorphin peptides are relatively selective for the κ opiate receptor, and exert inhibitory actions in the nervous system via the G protein, Gi. Stimulation of κ opiate receptors on dopamine terminals within the dorsal and ventral striatum appears to decrease dopamine release. Consistent with this, activation of κ receptors is associated behaviorally

with an aversive dysphoric syndrome both in humans (55) and rats (56). Thus, increases in dynorphin peptides produced by chronic cocaine or amphetamine administration may inhibit dopamine release and contribute to emotional–motivational aspects of psychostimulant withdrawal.

Regulation of prodynorphin gene expression by psychostimulants has been shown to be dependent on D1 dopamine receptor stimulation (57) because selective D1 receptor agonists inhibit it. Moreover, the prodynorphin gene is expressed in the striatum in D1 receptor bearing cells (58). D1 receptors are coupled to G_s/G_{olf}, and thus stimulate adenylyl cyclase to produce cAMP, which in turn activates PKA. PKA can then phosphorylate numerous substrates including CREB, a transcription factor that binds cAMP response elements (CREs) in numerous genes. Indeed, cocaine and amphetamine (59) have been shown to induce phosphorylation of CREB in striatal neurons via a D1 receptor-mediated mechanism, and the prodynorphin gene has been shown to be CREB regulated in these same cells (60). Thus, at the same time that D1 receptor stimulation acutely contributes to the acute rewarding effects of cocaine and amphetamine, it also initiating a cascade of homeostatic events that eventually yield compensatory adaptations to excess dopamine stimulation. One of these adaptations is induction of dynorphin peptides (Fig. 96.3).

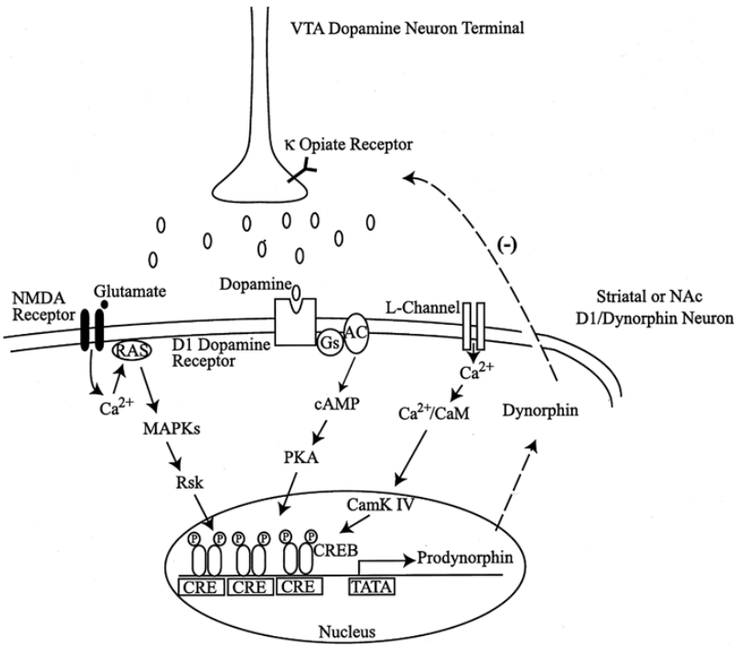

FIGURE 96.3. Dynorphin gene regulation by psychostimulants: implications for central motive states. Cocaine and amphetamine increase levels of dopamine in the nucleus accumbens and dorsal striatum. D1 receptor stimulation by dopamine leads to activation of the cAMP pathway, phosphorylation of CREB and ultimately the transcription of CRE-regulated genes such as c-fos and prodynorphin. Glutamate, via the NMDA receptor, as well as L-type calcium channels similarly contribute to CREB phosphorylation and CRE-driven gene expression in these dopaminoceptive neurons. Release of dynorphin inhibits dopamine release by binding to its presynaptic target, the κ opiate receptor, on DA nerve terminals. The dynorphin negative-feedback mechanism for controlling dopamine levels also contributes to aversive feelings and dysphoria due to its actions at the κ opiate receptor.

Corticotropin Releasing Factor May Also Contribute to Emotional–Motivational Aspects of Withdrawal

One type of adaptation that occurs outside the mesocorticolimbic dopamine system that may contribute to aversive states, and thus drug seeking, is up-regulation of corticotropin releasing factor (CRF). This neuropeptide is expressed in the hypothalamus, central nucleus of the amygdala, and other brain regions. In the hypothalamus CRF has been shown to be critical in the initiation of stress hormone cascades that culminate in the release of cortisol from the adrenal cortex. CRF released in the central nucleus of the amygdala has been implicated in anxiety states. Several studies have implicated CRF systems in the mediation of many of the angiogenic and aversive aspects of drug withdrawal. Increased release of CRF, particularly in the central nucleus of the amygdala, occurs during withdrawal from ethanol, opiates, cocaine, and cannabinoids. CRF antagonists have reversed at least some of the aversive effects of cocaine, ethanol, and opiate withdrawal in laboratory animals.

Alterations in Expression of Transcription Factors May Impact Diverse Neuronal Processes

Drug-induced changes in expression of transcription factors may lead to the altered expression of specific target genes, which in turn may affect both homeostatic adaptations and associative learning. In addition to regulating the peptide precursor gene, prodynorphin, D1 receptor-mediated stimulation of CREB induces a large number of immediate early genes (IEGs) including several that encode transcription factors, including c-fos, fras, junB, and zif268 (61 ,62 ,63 and 64). One interesting finding is that one CREB regulated transcription factor, ΔFosB, a truncated isoform of Fos B has a long half-life compared to all other members of the Fos family of transcription factors. Unlike other members of the Fos family, ΔFosB is only slightly induced by acute stimulation, but because it is long lived, it begins to accumulate with repeated stimulation, including repeated administration of addictive drugs (65). Thus, long-term, but not short-term, administration of cocaine, amphetamine, opiates, nicotine, or PCP induces ΔFosB in the NAc and dorsal striatum. Of all known molecules that exhibit altered levels following drug stimulation, ΔFosB is the longest lived currently known. Accumulation of ΔFosB represents a molecular mechanism by which drug-induced changes in gene expression can persist for weeks—even after drug use has been discontinued. The biological significance of ΔFosB induction will be better understood following identification of the genes that it regulates. Certain AMPA glutamate receptor subunit-encoding genes are among the candidates. Even though ΔFosB is stable, it is ultimately degraded; thus, by itself it cannot mediate the lifelong changes in behavior that accompany addiction.

Associative Learning

Both humans and animals readily learn to self-administer addictive drugs; behaviors that require the specific recognition of drug-associated cues, and the performance of complex action sequences. Cues associated with drug administration acquire motivational significance as illustrated by the conditioned place preference paradigm; for example, rats will choose to spend more time in a location in which they have passively received an injection of psychostimulants than in another location paired with saline injection (66). Associative learning also appears to play a role in psychostimulant sensitization. If, for example, a rat is taken from its home cage to a novel “test” cage for intermittent amphetamine injections, the sensitized locomotor response to a challenge dose is much greater if the challenge is also given in that test cage than if given in a different environment (67 ,68). Such context dependence can dominate the behavioral effects with sensitization expressed in the drug-associated location, no sensitization at all in a different environment (69 ,70). In drug-addicted humans, late relapses appear to involve associative learning, as they often occur after encounters with people, places, or other cues previously associated with drug use (71 ,72). As described, conditioned responses to drug-associated cues persist far longer than withdrawal symptoms (36), and can occur despite years of abstinence from drugs.

At a systems level, context-dependent sensitization in animal models and cue-conditioned relapse in humans suggests that the brain stores specific patterns of drug-related information. Homeostatic responses that increase or decrease the gain on the overall responsiveness of dopaminergic or other neurotransmitter systems in the brain could not mediate selective responsiveness to specific contexts or cues. Thus, general homeostatic mechanisms are not adequate to explain these phenomena. Elsewhere it has been argued that core features of addiction arise from the inappropriate recruitment of molecular mechanisms normally responsible for associative learning (37). On this view, the persistence of drug addiction reflects the persistence of the memory for this learned experience in the form of altered patterns of synaptic connectivity.

At the molecular level, stimulation of dopamine D1 receptors in multiple brain regions, including striatum, promotes activation of the transcription factor CREB (59 ,73) and a transient burst of altered gene expression (74). The induction of multiple transcription factors by this mechanism has already been described. Other psychostimulant induced IEG products that have been described in the striatum include *homer-1a, narp, arc*, and many others (62 ,74 ,75). Some of the genes induced by dopamine and psychostimulants in the striatum have been hypothesized to play

a role in hippocampal LTP, making it tempting to speculate that they may ultimately have a role in synaptic remodeling in the striatum (76 ,77 ,78 and 79). Indeed, D1 receptors have been shown to be required for normal hippocampal long-term potentiation (LTP), an important model of synaptic plasticity. For LTP in the CA1 region of the hippocampus to persist for more than 2 or 3 hours ("late-phase" LTP; L-LTP) there must be increases in postsynaptic cAMP, phosphorylation of CREB, gene transcription, and protein synthesis (64 ,80 ,81 and 82). The requirement for activation of gene expression seems to be transient, because blockers of transcription or translation disrupt hippocampal L-LTP if they are given within a few hours of the LTP-inducing stimulus, but not if given later (83). Activators of the cAMP cascade, including D1 agonists, can induce L-LTP (84 ,85). D1 receptor blockade inhibits hippocampal L-LTP (85 ,86 and 87), and D1-knockout mice do not show L-LTP (88). Therefore, D1 receptor activation in the hippocampus may act to gate synaptic plasticity, helping to determine whether changes in synaptic strength are long lasting or merely transient.

A role for dopamine receptors in the modification of synaptic strength fits well with the idea that increases in extracellular dopamine can act as a reinforcement learning signal in striatum (89). LTP (and also LTD, long-term depression) is found at corticostriatal synapses *in vivo* (90) and *in vitro* (91 ,92). Some groups have found that striatal LTP can be modified by dopamine receptor stimulation (91 ,93 ,94). Moreover, based on genetic manipulations, CREB has been implicated in both invertebrate and vertebrate models of synaptic plasticity and long-term memory (80 ,81 and 82 ,95). Moreover, changes in striatal synaptic physiology and synaptic structure occur in response to psychostimulant administration (96). At the systems level, dorsal regions of striatum appear to be involved in the learning and execution of complex automatized behavioral sequences, particularly in response to external cues. Ventral striatal areas are involved in acting on the motivational significance of such cues. Thus drug-induced synaptic plasticity in both regions may contribute to drug use through consolidation of drug-taking and -seeking behaviors. Many questions remain, but the central outstanding issue is the identification of genes transiently induced by addictive drugs, the products of which produce stable remodeling of synapses.

CONCLUSION

Part of "96 - Molecular and Cellular Biology of Addiction "

All of the initial molecular targets of drugs of abuse have been characterized and cloned. However, the molecular biology of processes relevant to tolerance, dependence, sensitization, and most important, compulsive drug use, and late relapse, are in their relatively early stages. Striking progress has been made in identifying large numbers of molecular changes initiated by drugs of abuse, but coherent biological implications of these changes can currently be described for only a few situations, such as somatic dependence on opiates. Even for more difficult problems, however, powerful tools are on the horizon. It is imperative, for example, to investigate the mechanisms by which dopamine excess might produce long-lived pathological associative memories that could underlie compulsive drug use and late relapse. Fortunately, in the very near future, a complete set of mammalian genes will be available in arrays, and similar collections of proteins will follow, albeit with some delay. Given these reagents, we will be limited only by our neurobiological imaginations.

DEFINITIONS AND VALIDATION OF ANIMAL MODELS

Part of "97 - Recent Advances in Animal Models of Drug Addiction "

Definitions of Drug Addiction

Drug addiction is defined as a compulsion to take a drug with loss of control in limiting intake (33). It is considered a chronic disorder because the risk of relapse remains high even after completion of treatment and prolonged abstinence. In 1968, the term drug dependence replaced that of addiction in the nomenclature of the World Health Organization and the American Psychiatric Association. Defined as a cluster of cognitive, behavioral, and physiologic symptoms indicative of an individual continuing substance use despite significant substance related problems, this term has become the accepted diagnostic term for compulsive use of a psychoactive substance. When defined as described, it is analogous to the term addiction. However, this term should not be confused with physical or psychic dependence, conditions in which the cessation or reduction of drug usage results in a withdrawal syndrome. Withdrawal and tolerance often are associated with compulsive drug use; however, they are not required for drug addiction. Although individuals suffering from chronic pain may develop tolerance to the analgesic effects of an opiate and experience withdrawal symptoms, they do not exhibit signs of compulsive drug-seeking behavior.

The concept of reinforcement has provided the cornerstone for current theories and animal models of drug addiction. A reinforcer is defined operationally as “any event that increases the probability of a response” and often is used interchangeably with “reward.” In general, drugs function as positive or conditioned reinforcers by virtue of their rewarding effects, and reward often connotes additional attributes of a drug (e.g., pleasure) that cannot be easily defined operationally.

This chapter reviews animal models currently used to examine the neurobiological basis of drug addiction and the role of reinforcement processes in its initiation, maintenance, and reinstatement. Emphasis is place on more recently developed models, and where possible, the models are evaluated in terms of reliability and predictability to the human condition. Potential pitfalls to consider when interpreting data also are discussed.

ANIMAL MODELS OF THE POSITIVE REINFORCING EFFECTS OF DRUGS

Part of "97 - Recent Advances in Animal Models of Drug Addiction "

Drugs of abuse function as positive reinforcing stimuli; this action has provided the framework for currently used animal models of addiction. It is also clear that humans and experimental animals will readily self-administer these agents in the absence of a withdrawal state. Earlier models of drug reinforcement used operant paradigms in nonhuman primates; however, many of these same paradigms now are utilized in rodents. The use of these rodent models, together with the development of modern neurobiological techniques, has provided important information regarding the neurobiology of addiction (11 ,15 ,36 ,45 ,51).

Operant Intravenous Drug Self-Administration

Drugs of abuse are readily self-administered intravenously by experimental animals, and, in general, drugs that are self-administered correspond to those that have high abuse potential. However, that not all drugs abused by humans are self-administered by experimental animals (e.g., hallucinogens). Furthermore, there are species- and strain-related differences in the degree to which a drug is self-administered (48 ,62). A detailed review of intravenous self-administration was presented in the previous edition (46); therefore, only key points are presented here.

For intravenous self-administration studies, the subject acquires a drug infusion by performing a discrete response. The number and pattern of responding required for each infusion is determined by the schedule of reinforcement imposed by the experimenter. Drug availability typically is signaled by an environmental stimulus. The dependent variables are the number of infusions obtained or the rate of responding during a session. In addition to the intravenous route of administration, the intragastric or oral route can be employed (see the following).

Simple Schedules

In fixed-ratio schedules, the number of responses required for drug infusion is set at a fixed number. In rodents, these schedules generally will not maintain stable responding below a certain unit dose and, within the range of doses that maintains stable responding, self-administration rate is inversely related to dose. Within the range of doses that maintains stable responding, animals increase their selfadministration rate as the unit dose is decreased. Conversely, animals reduce their rate of self-administration as the unit dose is increased. In a fixed-interval schedule, the frequency of injections is determined primarily by the interval schedule imposed and not the response rate. Therefore, the use of these two schedules can provide information regarding both the motivational effects of a drug and potential nonspecific motor effects that can confound data interpretation.

Progressive-Ratio Schedules

Progressive-ratio schedules are used to evaluate the reinforcing efficacy of a self-administered drug. In this procedure the response requirements for each successive drug reinforcement are increased and the *breaking point* (the point at which the animal will no longer respond) is determined (89). Breaking points are defined either as the largest ratio requirement that the subject completes or as the number of ratios completed by the subject per session. This value represents the maximum work a subject will perform to receive an infusion of a drug. Because the dependent measure in progressive-ratio schedules is not directly related to the rate of responding, interpretive problems associated with using rate of responding as a measure of reinforcement efficacy are avoided.

This schedule has been used to study the relative reinforcing efficacy of compounds both within and across drug classes (61) as well as the neural basis of drug reinforcement (58 ,61 ,78 ,89). Drug craving has been conceptualized as the incentive motivation to self-administer a drug that has been previously consumed; therefore, this schedule can also provide an animal model of drug craving. However, the breaking point reflects both the unconditioned (reinforcing) and conditioned incentive effects of drugs and does not allow for assessment of drug seeking in the absence of drug administration.

Multiple Schedules

Clinical definitions of drug addiction and dependence typically refer to the disruptive effects of addiction on non—drug-related activities. The use of multiple schedules of reinforcement enables the application of concepts of behavioral economics (e.g., commodities, consumption, price, and demand) to operant behavior. It also can provide a control for nonselective effects of drug reinforcement. In these procedures, self-administration of a drug is incorporated into a multiple component schedule with other reinforcers. Studies using these procedures have shown that the contingencies for concurrent reinforcers can affect behavior asymmetrically and that the response requirement for reinforcers can affect drug self-administration (12). Drugs also can function as substitutes for, complements of, or be independent from, the “price” of one another and can be interpreted in economic terms. In addition to evaluating the selectivity of manipulations that apparently reduce the reinforcing efficacy of a drug, these procedures can provide information regarding those factors affecting “loss of control,” as well as behavioral and/or pharmacologic therapies for the treatment of addiction. Behavior maintained by alternate presentation of natural reinforcers (e.g., food and water) and drugs of abuse in the same session and with the same reinforcement requirements has been reported for several species (16 ,20 ,97 ,98).

Second-Order Schedules

In a second-order schedule, completion of an individual component (or part) of the schedule produces the terminal event (drug infusion) according to another overall schedule. Typically, completion of a unit schedule results in the presentation of a brief stimulus, and completion of the overall schedule results in the delivery of the stimulus and the drug. Second-order schedules have the advantage that they maintain high rates of responding and extended sequences of behavior before any drug infusion occurs. Therefore, acute drug effects on response rates are minimized. High response rates are maintained even for doses that decrease rates when several injections are self-administered during a session (43). In addition, this schedule requires extended sequences of behavior, thus, modeling the human condition in which drug taking is preceded by a series of behaviors (e.g., procurement, preparation). Although second-order schedules are more typically used in nonhuman primate studies of addiction, their use in rodents is increasing (8 ,55 ,73).

Oral Drug-Self Administration

Oral self-administration has focused largely on alcohol because of the obvious face validity of oral alcohol self-administration

and because intravenous self-administration of alcohol is difficult to sustain in rodents (39).

Home Cage Drinking and Preference

A simple approach to studying the motivation to consume a drug is to measure the volume consumed when a drinking bottle is available in the home cage. These procedures have been particularly useful for characterizing genetic differences in drug preference, most often alcohol preference (53), and for initial studies on the effects of pharmacologic treatments on drug intake and preference. Usually a choice is offered between a drug solution and alternative solutions, one of which is often water, and the proportion of drug intake relative to total intake is calculated as a preference ratio. For two-bottle choice testing of alcohol in mice or rats, animals are singly housed and a bottle containing 10% alcohol and one containing water are placed on each cage. Most commonly, animals are allowed free choice of these drinking solutions for successive 24-hour periods with simultaneous free access to food. However, limited access to the drug can induce high drug intakes in short periods of time. Although alcohol is most often studied with these procedures, similar studies have been done with cocaine (40).

Operant Conditioning

A more “motivational” approach is to have animals work to obtain drugs for oral consumption using operant procedures. The advantages of such an approach are numerous. The effort to obtain the substance can be separated from the consummatory response (e.g., drinking) and intake easily can be charted over time. In addition, different schedules of reinforcement can be used to change baseline parameters.

For operant self-administration of alcohol, rats can be trained to lever press for alcohol using a variety of techniques all designed to overcome the aversive taste and after effects of initial exposure to alcohol. One approach involves using a sweetened solution fading procedure (80). Alcohol concentrations are increased to a final concentration of 10% over 20 days, with each concentration being mixed first with saccharin or sucrose and then presented alone. Using this approach, animals can be trained to lever press for concentrations of alcohol up to 40% (80). They will perform on fixed-ratio schedules and progressive-ratio schedules and obtain significant blood alcohol levels in a 30-minute session.

Operant self-administration of oral alcohol has also been validated as a measure of the reinforcing effects of alcohol in primates (93). Similar studies have been published with other drugs of abuse (60 ,90 ,93).

Reliability and Predictability of Self-Administration Procedures

Drug self-administration has both reliability and predictive validity. The dependent variable provides a reliable measure of the motivation to obtain drugs (e.g., the amount of work an animal will perform to obtain drug) or, in an alternative framework, in demonstrating that drugs function as powerful reinforcers. Responding maintained by drugs as reinforcers is stable across sessions and can be altered predictably by neurotransmitter antagonists. Intravenous drug selfadministration also has predictive validity. Drugs having high reinforcement potential in experimental animals have reinforcing effects in humans as measured by both operant and subjective reports (49).

Potential Pitfalls

As discussed previously, self-administration of a drug can vary as a function of the dose available, species or strain tested and the duration of self-administration sessions. It also is influenced by the availability of alternate reinforcers, the presence or absence of environmental stimuli that signal drug infusions, post-reinforcement interval, and prior history of the subject (54). In the progressive-ratio paradigm, breaking point is influenced by the size of the increment by which each ratio increases as well as the initial response requirement that starts a session. Because self-administration typically results in an inverted U-shaped curve, both leftward and rightward shifts in the dose–effect function will decrease self-administration of some unit doses but simultaneously increase self-administration of other doses. The interpretation of downward shifts in the dose–effect function also is sometimes problematic. Therefore, construction of full dose–effect functions is essential in self-administration studies. Since a given pretreatment may decrease self-administration by having nonspecific effects on behavior (e.g., sedation), the influence of a pretreatment on non-drug reinforcers should be assessed.

Conditioned Place Preference

Conditioned place preference is a classical conditioning procedure in which administration of a drug is paired with one distinct environment and administration of placebo with another. After several environmental pairings, allowing noninjected animals access to both environments and measuring the time spent in each assesses the time spent in each environment. The animal’s choice to spend more time in either environment provides a direct measure of the conditioned reinforcing effect of a drug. Animals exhibit a conditioned preference for an environment associated with drugs that function as positive reinforcers (e.g., spend more time in the drug-paired compared to placebo-paired environment) and avoid those that induce aversive states (e.g., conditioned

place aversion). This procedure permits assessment of the conditioning of drug reinforcement and can provide indirect information regarding the positive and negative reinforcing effects of drugs. Place conditioning has been used in conjunction with gene transfer and homologous recombination techniques to delineate the neural basis of druginduced reinforcement (15 ,74).

The apparatus used in conditioning experiments consists of two environments that are differentiated from each other on the basis of color, texture, and/or lighting. The distinctiveness of the environments is essential for the development of conditioning. In the unbiased design, the environments are manipulated so that animals differentiate one from the other but do not exhibit an innate preference for either of the place cues. Pairing of drug with a particular environment is counterbalanced and change in the time spent in the drug-paired environment can be directly attributed to the conditioned reinforcing effects of a drug. Although quality control experiments confirming the unbiased nature of the procedure are conducted periodically, experiments do not require a preconditioning phase to assess pretest preferences, thus preventing the potential confound of latent inhibition and decreasing the time necessary for a particular experiment.

In the biased design, animals exhibit a preference for one of the place cues prior to conditioning. A preconditioning phase, in which animals are allowed access to both environments, is necessary to determine the innate preference of each animal. The drug then is paired with the preferred or nonpreferred environment depending on whether the drug is assumed to produce aversive or positive reinforcing effects, respectively. Although this design is used often, data interpretation can be problematic because place preferences may indicate incentive motivational effects of a drug or a decrease in the aversive properties of the least-preferred environment.

Reliability and Predictability of Conditioned Place Preference Procedures

The conditioned place preference paradigm has reliability and validity. Drugs that produce conditioned preferences for the drug-associated environment are those that function as positive reinforcers in other paradigms. Conditioned aversions also are observed in response to drugs that are negative reinforcers or produce aversive or dysphoric states in human subjects (34 ,66).

Potential Pitfalls

In place conditioning studies, the drug is administered noncontingently and there is evidence that the behavioral and neurochemical effects of abused drugs differ depending on whether drug administration is controlled by the subject.

Route of drug administration, number of environmental pairings, and duration of conditioning sessions (18 ,23) can profoundly affect place conditioning and should be controlled for. Because tests of conditioning are conducted in the absence of drug, the issue of state-dependency also must be addressed.

Place conditioning now is used in many studies assessing genotype-dependent differences in drug sensitivity. However, a lack of a conditioned response may indicate a loss of the reinforcing effects of a drug or a generalized impairment of learning or memory processes required for the acquisition or performance of a conditioned response. In addition, genotype-dependent differences in the saliency of environmental cues used for conditioning may occur. Finally, issues of interpretation and latent inhibition limit the utility of biased place conditioning procedures.

Brain Stimulation Reward Thresholds

Electrical self-stimulation of certain brain areas is rewarding for animals and humans as demonstrated by the fact that subjects will readily self-administer the stimulation (69). The powerful nature of the reward effect produced by intracranial self-stimulation (ICSS) is indicated by the behavioral characteristics of the ICSS response, which include rapid learning and vigorous execution of the stimulation-producing behavior. (See ref. 28 for review.) The high reward value of ICSS has led to the hypothesis that ICSS directly activates neuronal circuits that are activated by conventional reinforcers (e.g., food, water, and sex). In bypassing much of the input side of these neuronal circuit(s), ICSS provides a unique tool to investigate the influence of various substances on reward and reinforcement processes. ICSS differs significantly from drug self-administration in that, in the ICSS procedure, the animal is working to directly stimulate presumed reinforcement circuits in the brain, and the effects of the drugs are assessed on these reward thresholds. Drugs of abuse decrease thresholds for ICSS, and there is a good correspondence between the ability of drugs to decrease ICSS thresholds and their abuse potential (47).

Many ICSS procedures have been developed over the years, but an important methodologic advance has been the development of procedures that provide a measure of reward threshold that is unconfounded by influences on motor and performance capability. These are the rate-frequency curve-shift procedure, and the discrete-trial, current-intensity procedure (28 ,47 ,64). These have been reviewed in detail previously (46) and are not discussed here.

Potential Pitfalls

Brain stimulation reward has the advantage of directly interfacing with brain reward circuits and as such eliminates any interference with consummatory-like behaviors. In addition, it is a validated and reliable measure of brain reward. Potential pitfalls, however, include the requirement for surgery

(e.g., the implantation of electrodes). The surgery itself is routine but does require specialized equipment. Another variable in this domain is the brain site selected. Some brain regions support higher rates of brain stimulation reward than others and there may be different circuits activated by different sites.

In addition, animals need to be trained for several weeks to obtain stable rates of responding or stable thresholds. This training requirement and the extensive surgical requirements virtually force the use of within-subject designs. As a result, steps must be taken to address order-effects and analyze such potential confounds.

Animal Models of the Subjective Effects of Drugs: Drug Discrimination

The use of the drug discrimination paradigm in studies of drug addiction is based on two hypotheses. First, the same components of a drug's actions subserve discriminative stimulus effects in animals and subjective effects in humans. Second, discriminative stimulus effects of drugs may contribute to drug taking in intermittent users and to relapse of addiction in former drug addicts. In this latter view, discriminative stimuli signal the availability of a reinforcer and therefore set the occasion to engage in those behaviors that enable consumption of the reinforcing drug. Evidence has been obtained that stimuli predictive of drug administration elicit drug-seeking and -taking behavior and can retard the extinction of responding for psychostimulants (24 ,87 ,97) suggesting that the discriminative stimulus effects of a drug contribute to the genesis of these behaviors.

In a typical experiment, animals are trained to emit a particular response following administration of a fixed drug dose (e.g., depression of one lever designated the drug-associated lever) and to press another lever (saline designated lever) following administration of saline under a fixed schedule of reinforcement. Most commonly, an appetitively motivated operant procedure is used in which animals are food or water deprived. Responding on the training-condition appropriate lever results in the delivery of food or water. Training is continued until the animal reliably selects the appropriate lever after drug or saline administration. Once trained, tests of stimulus generalization or antagonism are implemented to determine whether other doses of the training drug or a specific drug treatment produces stimulus effects qualitatively similar to or different from that of the training drug.

As with other operant paradigms, various reinforcement schedules (e.g., fixed-ratio, fixed-interval, differential reinforcement of low response rate) and response measures (e.g., nose poking, maze running) can be used. Dose 1 versus dose 2 and drug 1 versus drug 2 versus saline discriminations also can be employed. Details can be found in the following references (13 ,29 ,46 ,72).

Reliability and Predictability of Drug Discrimination Procedures

Drug discrimination offers both reliability and predictive validity. The dependent variable is very reliable as a measure of the interoceptive effects of drugs. Stimulus generalization gradients are stable once drug discrimination is acquired and neurotransmitter antagonists alter the stimulus effects of various drugs predictably. Drug discrimination also has predictive validity in that drugs that produce discriminative stimulus effects that generalize to known drugs of abuse have been shown to have abuse liability.

Potential Pitfalls

Generalization gradients are dependent on the dose of drug used for training. Certain neurotransmitter antagonists attenuate the discriminative stimulus effects of a drug when a low training dose is employed. However, these same antagonists fail to modify the discriminative stimulus effects of the same drug when a higher training is employed (41). Similarly, generalization to partial agonists or mixed agonists/antagonists can differ depending on the training dose employed (19); therefore, the use of multiple training doses is essential.

Different test procedures (extinction versus reinforced responding on the lever on which the first schedule requirement is completed) may yield different results depending on the variable used to measure generalization. As with all animal models, species and strain differences as well as the experimental history of an animal can alter the discriminative stimulus effects of a drug (94). Finally, subtle differences in the discriminative stimulus effects of a drug may occur depending on whether appetitive or aversively maintained responding is employed.

ANIMAL MODELS OF THE NEGATIVE REINFORCING EFFECTS OF DRUG WITHDRAWAL

Part of "97 - Recent Advances in Animal Models of Drug Addiction "

Withdrawal from chronic drug administration usually is characterized by responses opposite to the acute initial actions of the drug. Many of the overt physical signs associated with withdrawal from drugs (e.g., alcohol and opiates) can be quantified easily. However, motivational measures of abstinence have proven to be more sensitive measures of drug withdrawal and powerful tools for exploring the neurobiological bases for the motivational aspects of drug dependence.

Operant Drug Self-Administration

Drug self-administration can be conducted under conditions in which animals are rendered physically dependent

on the drug (e.g., abstinence from drug use results in a withdrawal syndrome), and the procedures are similar to those discussed in the preceding. Although it is clear that animals will self-administer drugs in the absence of withdrawal, some evidence suggests that physical dependence can increase the reinforcing efficacy of a drug. Monkeys made physically dependent on morphine show increases in their progressive-ratio performance compared to animals that do not exhibit withdrawal symptomology (101). Also, baboons in a discrete-trials choice procedure for food and heroin showed significant behavioral plasticity when allowed periodic access to heroin or food (20). In the withdrawal state, one would hypothesize that the animals would be much less likely to respond for food, even if the cost of heroin in terms of response requirements was dramatically increased. Thus, the reinforcing value of drugs may change depending on the presence or absence of a withdrawal state. The neurobiological basis for such a change is only beginning to be investigated, but much evidence has been generated to show that drug withdrawal can produce an aversive or negative motivational state that is manifested by changes in a number of behavioral measures including response disruption, increased drug intake, changes in reward thresholds, and place aversions.

Recent studies with alcohol have shown that rats with a history of self-administration of alcohol will self-administer alcohol during withdrawal in sufficient quantities to prevent withdrawal symptoms and maintain blood alcohol levels above 100 mg% (75). To assess the relationship of withdrawal severity, blood alcohol levels, and alcohol self-administration in dependent and nondependent rats, rats were trained to lever press for 10% alcohol versus water using the saccharin fadeout procedure and subjected to induction of dependence on alcohol (75). Dependent animals allowed to respond for alcohol during a second 12-hour test period showed sustained alcohol intake that maintained blood alcohol levels above 100 mg% throughout the 12-hour period, and a virtual elimination of alcohol withdrawal scores (75) (Fig. 97.1). Animals not allowed access to alcohol during withdrawal on a third test showed a precipitous drop in blood alcohol levels and a dramatic increase in withdrawal scores (75) (Fig. 97.1). These results show that rats will maintain and sustain lever pressing for alcohol during dependence if the animals have a history of lever pressing for alcohol to the point of suppressing alcohol withdrawal and maintaining blood alcohol levels.

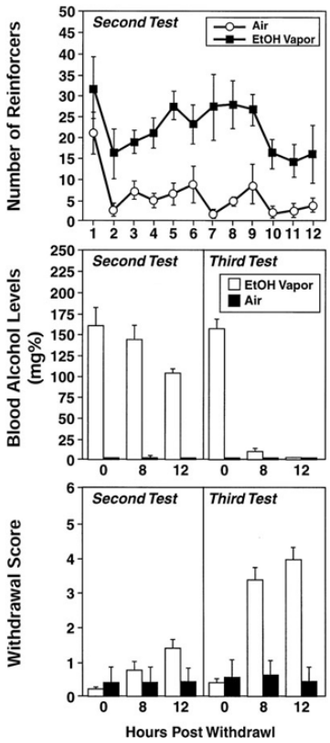

FIGURE 97.1. Operant responding for alcohol across a 12-hour test period by air-exposed and alcohol vapor-exposed rats *(top)*. In addition, blood alcohol levels *(middle)* and alcohol withdrawal severity *(bottom)* obtained during test 2 (while rats were allowed access to alcohol in the operant boxes) and test 3 (while in home cages) are shown. The animals were divided into two groups. One group of animals was assigned to 2 weeks of alcohol exposure in alcohol vapor chambers. The second group was exposed to control air. Rats then were tested in the operant boxes with access to 10% alcohol and water across two 12-hour periods separated by 4 days of vapor exposure. A third and final withdrawal phase was included after another 4 days of vapor exposure; however, animals were kept in their home cages and not allowed to respond for alcohol. Blood was collected for blood alcohol determinations, and observational withdrawal signs were rated during tests 2 and 3 at 0, 8, and 12 hours post withdrawal. Data are expressed as means ± SEM. Taken with permission from Roberts AJ, Cole M, Koob GF. Intra-amygdala muscimol decreases operant ethanol self-administration in dependent rats. *Alcohol Clin Exp Res* 1996;20:1289–1298.

Responding for Non-Drug Reinforcers

Several operant schedules have been used to characterize the response-disruptive effects of drug withdrawal (37 ,84). However, response disruption can be caused by any number of variables from motor problems to malaise and decreases in appetite, and thus other measures must be used to rule out nonspecific effects (see the following).

Conditioned Place Aversion

The conditioned place preference paradigm can also be used to characterize the conditioned aversive effects of drug withdrawal. Rodents are exposed to one environment while undergoing withdrawal and to another in the absence of a withdrawal state. During tests of conditioning, animals are allowed access to both environments and the time spent in each is determined. To date, this procedure has been used almost exclusively to study withdrawal from opiate drugs. Administration of opioid receptor antagonists to animals rendered physically dependent on morphine via implantation of morphine pellets or repeated injections of an opiate produces dose-related conditioned place aversions, an effect that can be observed after only a single conditioning session with the antagonist (27 ,34). In contrast, the administration of the same doses of antagonist to opiate-naive animals fails to produce a conditioned response. Interestingly, the minimum effective dose of an antagonist that produces conditioned place aversions in animals physically dependent on morphine is less than that producing quantifiable somatic withdrawal signs suggesting that this technique is a particularly sensitive model for evaluating the affective component of drug withdrawal. Although place conditioning typically has been used to characterize antagonist-precipitated withdrawal, more recent work indicates its utility for studies of spontaneous withdrawal (10).

Brain Stimulation Reward

ICSS thresholds have been used to assess changes in systems mediating reinforcement processes during the course of drug dependence. Although no actual negative reinforcement is measured using this technique, it is included in this section because it constitutes a model of the aversive motivational state associated with the negative reinforcement of drug abstinence in dependent animals. Acute administration of psychostimulant drugs lowers ICSS threshold (i.e., increases ICSS reward) (47), and withdrawal from chronic administration of these same drugs elevates ICSS thresholds (i.e., decreases ICSS reward) (22 ,44 ,56) (Fig. 97.2). Similar results have been observed with precipitated withdrawal in opiate-dependent rats (82). Rats showed dramatic increases in ICSS thresholds to naloxone injections that occurred in a dose-related manner and at doses below which obvious physical signs of opiate withdrawal were manifest. These doses of naloxone had no effect on reward thresholds in nondependent animals.

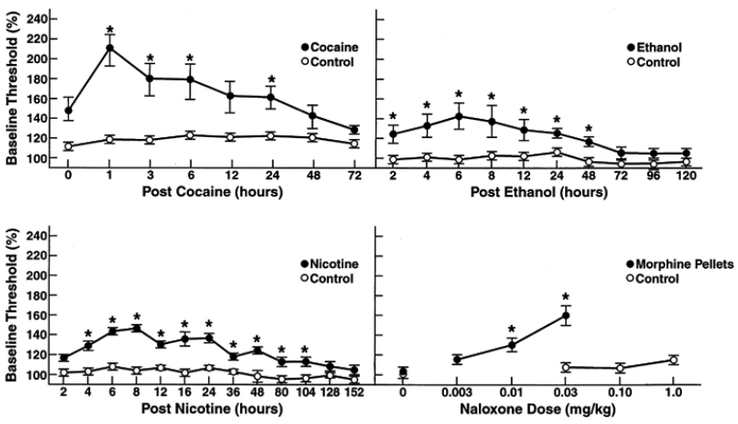

FIGURE 97.2. Changes in reward threshold associated with chronic administration of four major drugs of abuse. Reward thresholds were determined using a rate-independent discrete-trials threshold procedure for intracranial self-stimulation (ICSS) of the medial forebrain bundle. **A:** Rats equipped with intravenous catheters were allowed to self-administer cocaine for 12 straight hours prior to withdrawal and reward threshold determinations. Elevations in threshold were dose-dependent with longer bouts of cocaine self-administration yielding larger and longer-lasting elevations in reward thresholds. Taken with permission from Markou A, Koob GF. Postcocaine anhedonia: an animal model of cocaine withdrawal. *Neuropsychopharmacology* 1991;4:17–26. **B:** Elevations in reward thresholds with the same ICSS technique following chronic exposure to alcohol of approximately 200 mg% in alcohol vapor chambers. Taken with permission from Schulteis G, Markou A, Cole M, et al. Decreased brain reward produced by ethanol withdrawal. *Proc Natl Acad Sci USA* 1995;92:5880–5884. **C:** Elevations in reward thresholds during spontaneous withdrawal after termination of chronic administration of nicotine hydrogen tartrate (9.0 mg/kg per day for 7 days; *n* = 8) or saline (*n* = 6). Taken with permission from Epping-Jordan MP, Watkins SS, Koob GF, Markou A. Dramatic decreases in brain reward function during nicotine withdrawal. *Nature* 1998;393:76–79. **D:** Elevations in reward thresholds following administration of very low doses of the opiate antagonist naloxone to animals made dependent on morphine using two, 75-mg morphine (base) pellets implanted subcutaneously. Taken with permission from Schulteis G, Markou A, Gold LH, et al. Relative sensitivity to naloxone of multiple indices of opiate withdrawal: A quantitative dose-response analysis. *J Pharmacol Exp Ther* 1994;271:1391–1398. Asterisks (*) refer to significant differences between treatment and control values. Values are mean ±SEM

Drug Discrimination

Drug discrimination can be used to characterize both specific and nonspecific aspects of withdrawal. Generalization to an opiate antagonist provides a more general nonspecific measure of opiate withdrawal intensity and time course (26 ,30). Examples of a more specific aspect of withdrawal are animals that have been trained to discriminate pentylenetetrazol, an anxiogenic-like substance, from saline in alcohol-, diazepam-, and opiate-dependent animals. During withdrawal, generalization to the pentylenetetrazol cue has suggested an anxiogenic-like component to the withdrawal syndrome (14 ,21).

Ethological Measures

Animals models of withdrawal that illustrate aversive stimulus effects can be extended to observational measures, some of which may be common to withdrawal from many different drugs of abuse. Increased anxiety-like responses are observed following abstinence from cocaine, opiates, benzodiazepines, and alcohol (9 ,25 ,79 ,81 ,85). Measures used to assess anxiety-like responses during include validated animal models of anxiety such as the elevated plus-maze, light-dark test, defensive withdrawal, and defensive burying.

Advantages and Disadvantages of Animal Models of the Negative Reinforcing Effects of Drugs

The advantages and disadvantages of models used to evaluate drug withdrawal are similar to those described for the positive reinforcing effects of drugs. Clearly, each of the paradigms described has weaknesses, but when combined can provide powerful insights into the motivational effects of drug abstinence.

ANIMAL MODELS OF ESCALATION IN DRUG INTAKE

Part of "97 - Recent Advances in Animal Models of Drug Addiction "

Animal Models of Sensitization to the Reinforcing Effects of Drugs

Preclinical studies have shown that the repeated intermittent administration of psychostimulants, opiates, and alcohol can result in a long-lasting enhancement of their behavioral effects (92). This phenomenon, referred to as sensitization, has been implicated in the psychosis that occurs in some individuals following repeated psychostimulant use. A role of sensitization in both vulnerability to drug addiction and drug craving has been hypothesized (77). Both self-administration and conditioned place preference procedures have been used to evaluate sensitization to the reinforcing effects of drugs in experimental animals.

Intravenous Self-Administration

In self-administration studies, sensitization to the positive reinforcing effects of drugs is assessed. Typically, animals receive daily, noncontingent injections of a drug or placebo.

Self-administration sessions are then initiated. The rate of acquisition of self-administration and/or the number of animals acquiring stable drug self-administration then is determined. Because sensitization is defined as an increase in the potency and/or efficacy of a drug in producing a particular response following its repeated administration, the rate of acquisition of drug self-administration should be increased and the threshold dose effective in supporting self-administration should be decreased. Several laboratories have shown that the rate of acquisition of psychostimulant self-administration is increased in animals that have received noncontingent injections of these agents indicating the development of sensitization (38 ,71). The prior administration of amphetamine also increases the acquisition rate of cocaine self-administration (and, conversely, the prior administration of cocaine increases the acquisition rate of amphetamine self-administration), suggesting that cross-sensitization develops to the positive reinforcing effects of psychostimulants.

Conditioned Place Preference

The conditioning procedure used to study sensitization is identical to that described above except that the dose of conditioning drug or the number of environmental pairings used typically are those that are ineffective in producing a conditioned response in previously drug-naive animals. Animals receive repeated noncontingent administration of a drug, and place conditioning can be initiated at various time points following the cessation of drug administration. An increase in the potency of a drug provides a direct measure of sensitization (Fig. 97.3). Alternatively, by employing doses that are subthreshold and threshold for producing a conditioned response, changes in drug potency and efficacy following prior drug exposure can be determined. Using these procedures, long-lasting sensitization and cross-sensitization to the conditioned reinforcing effects of opiates and psychostimulants has been shown (50 ,52 ,88).

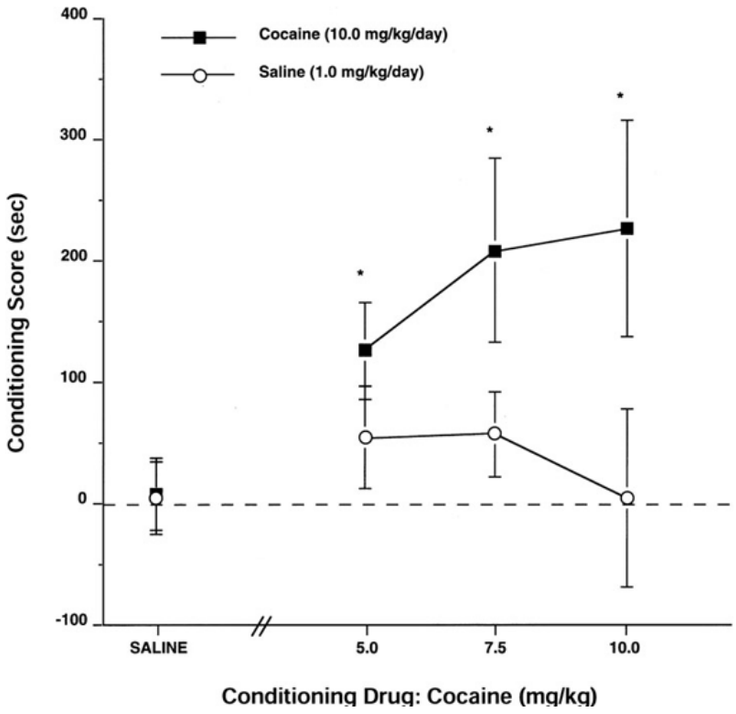

FIGURE 97.3. Sensitization to the conditioned reinforcing effects of cocaine. Rats received once daily home cage injections of cocaine or saline for 5 days. Place conditioning (two cocaine; two saline) commenced 3 days later. Cocaine was ineffective in producing a conditioned response after two environmental pairings. In animals with a prior history of cocaine, doses of cocaine as low as 5.0 mg/kg produced significant conditioned place preferences. Ordinate: Conditioning score defined as time in drug-paired environment minus time in saline-paired environment. Asterisks (*) denote significant place conditioning. Taken with permission from Shippenberg TS, Heidbreder C. Sensitization to the conditioned rewarding effects of cocaine: pharmacologic and temporal characteristics. *J Pharmacol Exp Ther* 1995;273:808–815.

Escalation in Drug Self-Administration Produced by a History of Drug Intake

A critical issue for the study of the neurobiology of addiction is to develop animal models for the transition between controlled/moderate drug intake and uncontrolled/excessive drug intake. Animal models of increased drug intake based on prolonged exposure to drug now have been described in rats for cocaine, heroin, and alcohol (1 ,2 and 3 ,76).

The pattern of drug self-administration dramatically differs depending on the duration of access. With 1 hour of access to cocaine, drug intake remained at the level of training intake and was stable over time. In contrast, with 6 hours of access per session, cocaine intake gradually escalated to levels significantly above the training baseline (Fig. 97.4). The dose–effect function was shifted up and not to the right or left (2). Abstinence of a month returned the escalated intake to pre-escalation baseline, but escalation was reinstated rapidly at a level higher than that seen before abstinence.

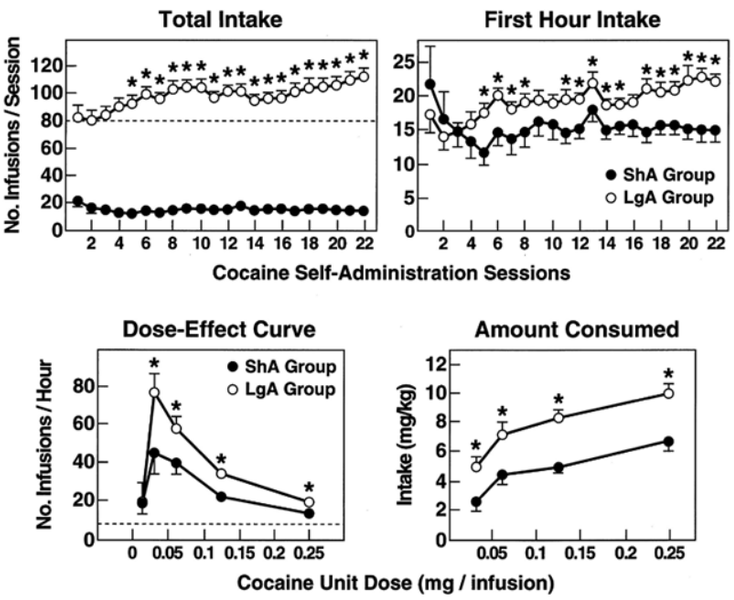

FIGURE 97.4. Reproduction of escalation of cocaine use. **A:** In Long-Access (LgA) rats (*n* = 12) but not in Short-Access (ShA) rats (*n* = 12), mean total cocaine intake (±SEM) started to increase significantly from session 5 ($p < .05$; sessions 5 to 22 compared to session 1) and continued to increase thereafter ($p < .05$; session 5 compared to sessions 8 to 10, 12, 13, and 17 to 22). **B:** During the first hour, LgA rats self-administered more infusions than ShA rats during sessions 5 to 8, 11, 12, 14, 15, and 17 to 22 ($p < .05$). **C:** Mean infusion (±SEM) per cocaine dose tested. LgA rats took significantly more infusions than ShA rats at doses of 31.25, 62.5, 125, and 250 µg per infusion ($p < .05$). **D:** After escalation, LgA rats took more cocaine than ShA rats regardless of the dose ($p < .05$). *($p < 0.05$ (Student's *t* test after appropriate one-way and two-way analysis of variance). Taken with permission from Ahmed SH, Koob GF. Transition from moderate to excessive drug intake: change in hedonic set point. *Science* 1998;282:298–300.

Similar results have been observed in rats trained to self-administer heroin intravenously. Two groups of rats were trained on 1-hour continuous access to intravenous heroin self-administration and then one group was allowed access for 11 hours continuously. In the animals with 11-hour access, intake gradually increased over time, whereas in the animals continued on 1-hour access there was no change in intake over time. The animals with 11-hour access to heroin were slower to extinguish heroin-seeking behavior.

Animals with a history of alcohol exposure sufficient to produce dependence show a similar increase in baseline alcohol intake long after acute withdrawal (76). Operant oral alcohol self-administration was established in rats and then animals were exposed to alcohol vapor chambers for a sufficient period to produce physical dependence on alcohol, detoxified, and then allowed a 2-week period of protracted

abstinence. Operant responding was enhanced during protracted abstinence by 30% to 100% and remained elevated for 4 to 8 weeks post acute withdrawal.

ANIMAL MODELS OF RELAPSE: CONDITIONED REINFORCING EFFECTS OF DRUGS

Part of "97 - Recent Advances in Animal Models of Drug Addiction "

The role of environmental stimuli in the control of drug-taking behavior is a major focus of addiction research. This interest stems from the view that any account of drug abuse must address those factors that precede and motivate drug taking, as well as those that underlie the reinforcing consequences of drug delivery. Environmental cues repeatedly paired with primary reinforcers can acquire incentive properties via classical conditioning processes (57 ,87 ,97). It has been postulated that these conditioned reinforcing effects contribute to drug craving and relapse to addiction. Indeed, human studies have shown that the presentation of stimuli previously associated with drug delivery increases the likelihood of relapse as well as self-reports of craving and motivation to engage in drug taking (17 ,68).

Positive Reinforcing Effects of Stimuli Associated with Drug Self-Administration: Conditioned Reinforcement Paradigm

The conditioned reinforcement paradigm allows characterization of the incentive value imparted on formerly neutral environmental stimuli that have been repeatedly associated with drug self-administration. In this paradigm, subjects usually are trained in an operant chamber containing two levers. Responses on one lever result in the presentation of a brief stimulus followed by a drug injection (active lever)

whereas responses on the other lever have no consequences (inactive lever) (86). The ability of the previous neutral, drug-paired stimulus to maintain responding in the absence of drug injections provides a measure of the reinforcing value of these stimuli. This procedure provides a stringent test for the conditioned incentive effects of drugs because responding for drug-associated stimuli occurs under extinction conditions (e.g., in the absence of drug). It also provides an animal model of drug craving because the incentive motivational effects of a stimulus are examined in the absence of drug taking.

Second-Order Schedules

Second-order schedules also can be used to evaluate the conditioned reinforcing effects of drugs. To assess the effects of conditioned reinforcement, the number of responses with the paired stimulus can be compared to the number of responses with a nonpaired stimulus. For example, substitution of drug-paired stimuli with nondrug-paired stimuli actually can decrease response rates (43). This maintenance of performance with drug-paired stimuli appears to be analogous to the maintenance and reinstatement of drug seeking in humans with the presentation of drug-paired stimuli (17). In rats, a decrease in responding and an increase in the latency to initiate responding occurs in response to withholding a stimulus paired with cocaine self-administration (8). The schedule can be repeated several times during a test session, resulting in multiple infusions of drug. However, drug craving in the absence of drug can be assessed by terminating sessions immediately after the first drug infusion that occurs after completion of the terminal schedule.

Extinction with and without Cues Associated with Intravenous Drug Self-Administration

Extinction procedures provide measures of the incentive or motivational effects of drugs by assessing the persistence of drug-seeking behavior in the absence of response–contingent drug availability. In this paradigm, subjects first are trained to self-administer a drug until stable self-administration patterns are exhibited. Extinction sessions are identical to training sessions except that no drug is delivered after the completion of the response requirement.

Measures provided by an extinction paradigm reflect the degree of resistance to extinction and include the duration of extinction responding and the total number of responses emitted during the entire extinction session. The probability of reinstating responding under extinction conditions with drug-paired stimuli or even stimuli previously paired with drug withdrawal can be examined.

Both stimulant and opiate self-administration have been consistently reinstated following priming injections of drug (31 ,55). Responding during extinction is greater in the presence of the conditioned stimulus than in its absence (73). Similar results have been obtained in an operant runway task (57). It is also apparent that environmental stimuli predictive of cocaine self-administration reliably elicit drug-seeking behavior in experimental animals and that responding for these stimuli is highly resistant to extinction (39 ,87 ,97).

Reinstatement of Extinguished Drug-Seeking Behavior in an Animal Model of Relapse: Use of Discriminative Stimuli

Rat models of “relapse” induced by drug-related stimuli also can involve the use of a drug-predictive discriminative stimulus (S?). This stimulus is paired with response-contingent presentation of a stimulus that has been contiguously paired with drug presentations (i.e., a conditioned stimulus, or CS) to elicit recovery of responding at a previously active lever after prior extinction of alcohol-seeking behavior. Discriminative stimuli signal the availability of a reinforcer, and thereby provide motivation to engage in behavior that brings the organism into contact with the reinforcer. A condition often associated with drug craving in humans is cognitive awareness of drug availability (63). Discriminative stimuli, therefore, may have a prominent role in craving and the resumption of drug-seeking behavior in abstinent individuals. Moreover, the response-contingent CS, acting as a conditioned reinforcer, may contribute to the maintenance of subsequent drug-seeking behavior once initiated. In fact, these contingencies can be conceptualized to resemble those associated with the relapse process in humans in that certain drug-related cues may provide the initial central motivational state to engage in drug-seeking behavior, whereas others may maintain this behavior until the primary reinforcer is obtained.

To investigate the role of drug-associated stimuli in the motivational effects of a history of cocaine self-administration, rats were trained to associate discriminative stimuli (SΔ) with response-contingent availability of intravenous cocaine versus saline (97) (Fig. 97.5). The rats then were subjected to repeated extinction sessions during which cocaine, saline, and the respective SΔ were withheld until the rats reached extinction. Subsequent re-exposure to the cocaine SΔ, but not the nonreward SΔ, produced strong recovery of responding at the previously active lever in the absence of any further drug availability. The behavioral significance of the cocaine SΔ was further confirmed by the fact that the rats initially tested in the presence of the nonreward SΔ showed complete recovery of responding when subsequently presented with the cocaine SΔ, but rats that had shown robust reinstatement ceased responding when later tested under nonreward SΔ conditions. These results support the hypothesis that learned responses to drugrelated environmental stimuli can be important factors in the reinstatement of drug-seeking in animals and provide

a powerful model for elucidating the neuropharmacologic basis for such effects that are related to the human concepts of relapse and craving (97).

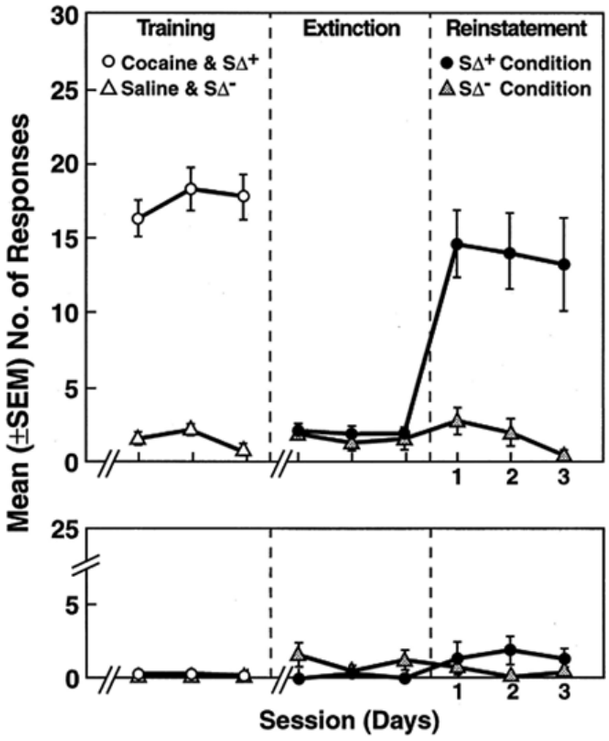

FIGURE 97.5. Lever-press responses during self-administration training, extinction, and reinstatement sessions at the active *(A)* and inactive *(B)* lever. Training phase: cocaine-reinforced responses during the final 3 days of the self-administration phase in rats (n = 15) trained to associate S?s with the availability of intravenous cocaine (S^+) versus saline (S^-). No differences were observed between responses during the first and second daily hour of cocaine availability, and responses for cocaine or saline between rats designated for testing under S^+ versus S^- conditions during the initial 3 days of the reinstatement phase. The data were, therefore, collapsed across groups and daily cocaine sessions for the purpose of this illustration. Extinction phase: extinction responses at criterion. The extinction criterion (= 4 responses per session over 3 consecutive days) was reached within 16.4 ± 3.8 days (averaged across rats designated for testing under the S^+ versus S^- condition during the reinstatement phase). Reinstatement phase: responses under the S^+ (n = 7) and S^- (n = 8) reinstatement conditions. Exposure to the S^+ elicited significant recovery of responding in the absence of further drug availability. Responding in the presence of the S^- remained at extinction levels. Taken with permission from Weiss F, Maldonado-Vlaar CS, Parsons LH, et al. Control of cocaine-seeking behavior by drug-associated stimuli in rats: effects on recovery of extinguished operant-responding and extracellular dopamine levels in amygdala and nucleus accumbens. *Proc Natl Acad Sci USA* 2000;97:4321-4326.

Cues associated with oral self-administration and availability of alcohol also can reinstate responding in the absence of the primary reinforcer (42 ,96). In addition, and consistent with the well-established conditioned cue reactivity in human alcoholics, the motivating effects of alcohol-related stimuli are highly resistant to extinction in that they retain their efficacy in eliciting alcohol-seeking behavior over more than 1 month of repeated testing (96).

Place Conditioning

Place conditioning procedures can be modified to serve as a model of relapse. Place aversions to opiate withdrawal last for over 8 weeks (94) and are resistant to extinction. Attempts to modify such conditioned effects could hypothetically contribute to knowledge of the factors that contribute to relapse or "craving." One also could envisage the use of cue- and drug-induced reinstatement of an extinguished place conditioning response as a measure of relapse (67).

Reliability and Predictability

Each of the techniques described has reliability and predictive validity. Presentation of stimuli associated with drug injection induces drug craving in humans and maintains responding in the conditioned reinforcement, second-order schedule, and extinction paradigms. The presence or absence of cues associated with drug administration alters the reinstatement of extinguished drug-seeking behavior in predictable ways.

CONCLUSIONS AND FUTURE RESEARCH

Part of "97 - Recent Advances in Animal Models of Drug Addiction "

Although it is very difficult to find an animal model of any psychiatric disorder that mimics the entire syndrome, one can reasonably validate animal models for different symptoms of mental disorders (32). In the realm of addiction research, the observation that animals readily self-administer drugs has led to arguments of face validity. Although intravenous drug self-administration meets the criteria of reliability, predictability, and face validity, it does not represent the whole syndrome of addiction (see the following). Other aspects of the addiction syndrome can indeed be modeled, but again, it is incorrect to consider any one of these an animal model of addiction. The DSM-IV criteria for substance dependence and animal models relevant to their study are summarized in Table 97.1 .

TABLE 97.1. ANIMAL MODELS FOR THE CRITERIA OF DSM-IV

DSM-IV	Animal Models
A. A maladaptive pattern of substance use, leading to clinically significant impairment or distress as occurring at any time in the same 12-month period:	
(1) Need for markedly increased amounts of substance to achieve intoxication or desired effect; or markedly diminished effect with continued use of the same amount of substance	(1) Tolerance to reinforcing effects: Cocaine Opiates
(2) The characteristic withdrawal syndrome for substance; or substance (or closely related substance) is taken to relieve or avoid withdrawal symptoms	(2) Increased: Reward thresholds: Cocaine, Opiates, Alcohol, Nicotine, Tetrahydrocannabinol Anxiety-like responses: Cocaine, Opiates, Alcohol, Tetrahydrocannabinol
(3) Persistent desire or one or more unsuccessful efforts to cut down or control substance use	(3) Conditional positive reinforcing effects: Cocaine Opiates Alcohol
(4) Substance used in larger amounts or over a longer period than the person intended	(4) Cocaine binge Opiate intake (dependent animals) Alcohol intake (dependent animals) Alcohol Deprivation Effect
(5) Important social, occupational, or recreational activities given up or reduced because of substance use	(5) Choice paradigms Behavioral economics—loss of elasticity
(6) A great deal of time spent in activities necessary to obtain substance, to use substance, or to recover from its effect	(6) Opiate self-administration during withdrawal Alcohol self-administration during withdrawal Progressive-ratio responding
(7) Continued substance use despite knowledge of having a persistent problem that is likely to be caused or exacerbated by substance use	(7) Cocaine binge toxicity

From: American Psychiatric Association, 1994.

Tolerance (criterion 1) and withdrawal (criterion 2) no longer define addiction, as illustrated by the change in criteria outlined in DSM-III versus DSM-IIIR and DSM-IV (5 ,6 and 7); however, evidence is accumulating to suggest that a common element associated with addiction is a motivational form of withdrawal that is reflected in a compromised brain reward system (see the preceding). This not only reaffirms the importance of withdrawal in addiction (e.g., criterion 2: "characteristic withdrawal syndrome") but also adds the dimension of a persistent motivational change that may be reflected in criteria 7 of the DSM-IV: "continued use

despite knowledge of having had a persistent psychological problem that is likely to be exacerbated by the substance" (Table 97.1).

The two DSM-IV criteria that are best modeled by drug self-administration are criteria 3 and 4, respectively: "the persistent desire to cut down or control substance use" and "the substance taken in larger amounts than intended." Drugs of abuse are readily self-administered by animals and, in general, drugs that are self-administered correspond to those that have high abuse potential in humans (60 ,61).

The chronic relapsing nature of drug addiction is perhaps best illustrated by criterion 3 of Table 97.1 : "persistent desire or one or more unsuccessful attempts to cut down or control substance use." Two difficult states to define that are related to relapse are craving and protracted abstinence. Presumably, such states reflect some prolonged post acute withdrawal perturbation or vulnerability to reinstatement of drug-seeking behavior and ultimately compulsive use. A residual deficit state in the reward system or sensitization of the reward system to stimuli that predict drug effects, or some combination of both, could be responsible for this vulnerability (see the preceding).

Animal models of drug craving and relapse continue to be developed but to date have reflected secondary sources of reinforcement such as conditioned reinforcement (91) or residual changes in motivational state or a combination of the two. Second-order schedules can be used as a measure of the conditioned reinforcing properties of drugs (43). Recent work suggests that reliable responding for cocaine can be obtained with a second-order schedule in rats (99). The conditioned place preference paradigm also provides a measure of conditioned reinforcement that is conceptually similar to the measures provided by the operant paradigms. More recently, stimuli that predict drug availability have been shown to be powerful cues for reinstating drug-seeking behavior (97), and a history of drug intake produces escalation in drug intake (1 ,3).

The remaining criterion for substance dependence as defined by DSM-IV can be linked to animal models by extension to the models described in the preceding. "Substance taken in large amounts or over a longer period of time than the person intended" (criterion 4) clearly is reflected in animal models of self-administration with unlimited access, or in situations of limited access where reinforcement value

is challenged by dose–effect functions or progressive-ratio procedures. “Important social, occupational, or recreational activities given up because of substance use” (criterion 5) has been demonstrated in animal models involving choice procedures (16) and involving behavioral economics paradigms (20). “A great deal of time spent in activities necessary to obtain the substance” (criterion 6) is reflected in animal models of drug self-administration during withdrawal (see the preceding). Finally, “continued substance use despite knowledge of having a persistent or recurrent physical or psychological problem that is exacerbated by the drug” (criterion 7) may be reflected in animal models of toxicity associated with chronic drug self-administration such as with cocaine, or prolonged changes in reward thresholds following chronic drug exposure (83).

Drug addiction in humans has been characterized as occurring in several stages, although progress from one stage to the next is not inevitable. The first stage is initiation or acquisition, which may lead to habitual use, physical or psychic dependence, and loss of control. An individual may stop taking a drug at any stage; however, relapse to drug taking after a period of abstinence is common. The extent to which the procedures discussed here model the human condition to the point of reliability and predictive validity requires further assessment.

Animal models of addiction are critical for advances in the study of addiction. Addiction is a chronic relapsing disorder comprised of multiple stages and multiple sources of reinforcement. As discussed, the motivating factors for the development, maintenance, and persistence of drug addiction can be broken down into four major sources of reinforcement: positive reinforcement, negative reinforcement, conditioned positive reinforcement, and conditioned negative reinforcement (100). Much progress has been made in identifying the neuronal substrates for the acute positive reinforcing effects of drugs of abuse. A more recent focus has been on the neuronal substrates for negative reinforcement and the conditioned reinforcing effects that contribute to relapse. The future challenge will be to explore the mechanisms involved in animal models of craving and relapse and to relate these mechanisms to vulnerability to addiction. A major advantage of animal models is in the translation of the human condition to the animal model (face validity) and the translation of the neurobiological measures back to the human condition in order to predict vulnerability (predictive validity).

Perhaps the best example of the translation value of animal models of addiction is the development of medications for the treatment of drug abuse (4 ,35). The opiate antagonist naltrexone long has been known to block self-administration of alcohol (4 ,95), and preclinical studies eventually led to the use of naltrexone to successfully prevent relapse in detoxified alcoholics (70).

Animal models are critical for the delineation of genetic and environmental factors that lead to and predict vulnerability to addiction. Context-independent drug administration (e.g., experimenter-administered drugs) can provide information about brain changes associated with a history of drug administration and that alter sensitivity to the effects of a drug. However, drug administration in the context of sensitive and validated animal models provides a much more powerful means of linking drug actions and sensitivities to biological and environmental perturbations. The successful implementation of procedures designed to assess functional genomic activity (e.g., screening for changes in the expression of gene activity) to the study of addiction, will require animal models that are reliable and have predictive validity if they are to contribute to our understanding of the neurobiology of drug addiction.

Vulnerability Factors for Alcoholism

Marc A. Schuckit

M. A. Schuckit: Department of Psychiatry, Veterans Affairs San Diego Healthcare System, San Diego, California.

This is an exciting and challenging time in the search for genes that have impact on the risk for alcohol abuse and dependence (alcoholism). Family, twin, and adoption studies offer solid evidence that genetic factors contribute to the risk for severe and repetitive alcohol-related life problems, and at least 30 genetically influenced characteristics are being evaluated for their possible impact on the alcoholism risk (1 ,2 ,3 and 4). Similar to other complex genetic disorders, these risk factors are heterogeneous, and combine to explain an estimated 60% of the variance, often interacting with environmental forces that contribute to the remaining 40% (1 ,2 and 3). Complicating the search for specific genetic influences even further is the probability that most of the characteristics, or phenotypes, are themselves influenced by multiple genes, and the lack of precision of the definition of the broad phenotype, alcohol abuse, or dependence (1 ,4).

This chapter reviews the progress made during the 7 years since the publication of the previous edition (5) in the search for genes that influence the risk for alcoholism. Most of the genetic studies have used variations in two approaches described in more detail in Chapter 99 , as well as in additional recent review articles (1 ,3 ,6). *Candidate gene studies* (also called case-control, association, or forward genetic investigations) begin with the hypothesis that a specific gene is related to the characteristic under study (7). If a limited number of multiple forms, or polymorphisms, of the gene are known, the proportion of individuals with and without the characteristic who have the specified polymorphism can be determined. Although this approach is an important step in identifying specific genes related to a phenotype, it is prone to false-positive results that occur if there are additional differences between groups with and without the characteristic (8). This problem, called population stratification, can be overcome by two variations of case-control studies where the relationship between the genetic marker and the characteristic, or phenotype, is evaluated among related individuals using a transmission disequilibrium or a haplotype relative risk approach (3 ,7).

The second and usually more labor-intensive technique is the *genetic linkage study*, or genome scan. This approach requires determining the presence of the phenotype and gathering blood for genotyping from either multiple generations of a large number of families or a large number of sibling pairs. The relationship between the phenotype and genetic signposts, or markers, across the 23 chromosomes is then evaluated. Unfortunately, genome scans are likely to identify only relatively powerful genes that explain a substantial proportion of the risk, and the data are best analyzed only when the mode of inheritance (e.g., dominant or recessive) is known. The potential linkage of a particular characteristic to a specific signpost helps identify areas of chromosomes of interest, after which more focused candidate gene analyses can be used to test individual genes near that marker.

This chapter describes some of the more promising results of the application of such approaches to alcohol use disorders, and briefly synthesizes the wide range of phenotypic and genotypic markers into a framework focusing on the several possible themes of potentially related characteristics described in Table 98.1 . Reflecting space limitations, emphasis is placed on genetic factors relating to alcoholism, rather than to drugs in general; most studies focus on human rather than animal work; and review articles are often highlighted rather than a series of primary data sources.

Level of response (LR)
P3/disinhibition/ASPD/type 2/B
Independent axis I disorders
Opioids
Alcohol metabolizing enzymes

ASPD, antisocial personality disorder.

TABLE 98.1. POSSIBLE BROAD FAMILIES OF RISK FACTORS

SOME SPECIFIC PHENOTYPIC AND GENETIC MARKERS OF INTEREST

Alcohol has impact on many neurochemical systems, whereas the use and consequences associated with this drug relate to many additional factors including personality traits, reinforcement, craving, and withdrawal symptoms (9 ,10). This panoply of phenomena has produced a wide range of hypotheses regarding how different phenotypes and candidate genes might contribute to the acquisition of drinking behaviors and the development of associated problems. Thus, judgment was needed to decide which potential phenotypic or genetic markers to highlight, and the reader is encouraged to turn to additional reviews (1 ,6 ,11 ,12 and 13). The information offered below is, somewhat arbitrarily, divided into results relevant to more broadly based phenotypes and those related to specific enzymes or genes.

Some Potentially Interesting Broad Phenotypes

A Low Level of Response (LR) to Alcohol

This characteristic, first proposed in 1975, reflects the need for higher doses of alcohol to produce an effect (1 ,10 ,14). The low LR to alcohol might enhance the probability of heavy drinking, encourage the formation of peer groups with similar drinking habits, and facilitate the acquisition of tolerance. LR is classically measured as the level of change in subjective feelings of intoxication, motor performance, hormone levels, and/or electrophysiologic measures observed at specific blood alcohol concentrations, but can also be evaluated by a self-report of the number of drinks required for specific effects (10 ,15 ,16). Low LRs are seen in about 40% of the estimated 700 children of alcoholics evaluated in the majority of the studies, and has been reported to characterize Native Americans, while high LRs and lower alcoholism risks have been noted for Jews and some Asian groups (17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 and 25).

A longitudinal study of 453 20-year-old sons of alcoholics and controls showed that a low LR was a significant predictor of later alcohol abuse or dependence, explaining a significant proportion of the relationship between family history and alcoholism and alcoholic outcome in that sample (14 ,15). A 10-year follow-up of 64 sons of alcoholics and controls in Denmark found a significant relationship between less alcohol-induced physiologic changes and a high risk for alcohol abuse or dependence (26), whereas a 4-year follow-up of about 100 men and women found a relationship between a lower intensity of alcohol-induced incoordination and future alcohol problems for the men (27). Finally, a 10-year follow-up of almost 400 members of Australian twin pairs confirmed the relationship of the intensity of response to the alcoholic outcome for men (28).

The LR to alcohol is genetically influenced (29 ,30 ,31 ,32 and 33). Studies in animals have identified quantitative trait loci (QTLs) associated with LR, and lower reactions to alcohol are often associated with higher alcohol intake (29 ,30). In humans, the LR is more similar in identical than fraternal twin pairs, and among first-degree relatives compared to unrelated individuals (28 ,32 ,33).

A candidate gene study reported additive relationships to LR for alleles for the γ-aminobutyric acid receptor Aα6 ($GABA_{A\alpha6}$) and the serotonin transporter gene, whereas a separate sample revealed areas of potential linkages on chromosomes 1 and 21 (32 ,33). Additional candidate genes potentially tied to LRs include neuropeptide Y (NPY), neurotensin, adenylyl cyclase (AC) systems, protein kinase, aspects of serotonin (5-HT), and the hypothalamic-pituitary-adrenal (HPA) axis. However, a low LR appears to operate relatively independently of the event-related potential (ERP) and personality variables discussed in below, and is generally independent of alcohol metabolizing enzymes, but might crossover with some EEG characteristics (see below) (19 ,24 ,34).

Low Voltage or Low Alpha and EEGs

An overall low-voltage EEG pattern and a relative paucity of synchronized EEG waveforms appear to characterize a variety of conditions including anxiety and depression (6 ,34 ,35). The importance of the EEG results reflects reports that alcohol increases alpha power, and that alcoholics might show lower amounts of alpha, higher beta activity, and/or lower voltage on the EEG overall (24 ,36). Such EEG patterns might have impact on the risk for alcoholism via several different mechanisms, including higher levels of anxiety.

Some children of alcoholics exhibit lower amounts of slower alpha and/or higher levels of faster alpha or beta EEG activity, and alcohol increases the proportion of slower alpha, whereas other offspring demonstrate lower overall EEG voltage (6 ,24 ,34 ,35 ,36 and 37). Finally, children of alcoholics demonstrate less intense, or shorter lasting EEG changes with alcohol, and there is a significant correlation between a low LR and EEG findings in the same subjects (24 ,34).

Evidence supporting genetic influences in EEG patterns includes greater similarities in identical versus fraternal twins, and a report of mendelian inheritance for slow alpha (38 ,39). Some relevant EEG characteristics might relate to genes on chromosome 20, although not all reports agree (40).

Impulsivity, the Antisocial Personality Disorder (ASPD), Types 2 and B Alcoholism

Conduct disorder (CD) in childhood and subsequent ASPD represent persisting patterns of impulsivity and difficulty benefiting from punishment, often associated with aggressive and criminal behavior. These disorders are potentially

related to personality characteristics of novelty- or sensation seeking, extroversion, neuroticism, and the absence of harm avoidance, attributes that might increase the risk for alcohol abuse or dependence (41). Related concepts that overlap with ASPD include type 2 and type B subgroups of alcoholics whose early onset and more severe course is often associated with criminality and dependence on other drugs (42 ,43).

Almost two-thirds of people with ASPD are alcoholics, although only about 20% of alcoholic men fulfill criteria for this disorder (41 ,42 and 43). There is impressive familial crossover between CD/ASPD and alcoholism, and offspring of ASPD parents are likely to have a more severe alcoholic course (44 ,45). Genetic factors are important in personality traits and some personality disorders, and ASPD and alcohol dependence are often inherited together (44 ,45 ,46 and 47).

ASPD (or CD) and substance use disorders might share the characteristic of neuronal disinhibition (41 ,48). The high levels of impulsivity and sensation seeking in CD and ASPD might, in turn, relate to aspects of 5-HT functioning, and/or to subtypes of GABA receptors (49 ,50). ASPD, or neuronal disinhibition, also appear to correlate with the ERP characteristic described in the next section (41), but neither ASPD nor the relevant ERP values correlate with a low LR to alcohol (19 ,51).

The P300 (P3) Wave of the ERP

The P300, or P3, is a positive polarity brain wave in the ERP paradigm observed approximately 300 msec after the presentation of an infrequent but anticipated stimulus (41 ,48). Diminished amplitudes or shorter latencies of this wave reflect problems in attending and interpreting subtle environmental events (48 ,52 ,53). Low P3 amplitudes are seen in schizophrenia, major depressive disorder, attention-deficit/hyperactivity disorder (ADHD), and Alzheimer's disease (6 ,52 ,53).

Adult alcoholics demonstrate small P3 waves even after extended periods of abstinence, although this might diminish with time (6 ,48 ,52). Although most investigators consider this a robust marker for adult alcoholism, a low amplitude P3 might more closely reflect states of temporary depression, a developmental delay, or aspects of CD or ASPD (41 ,52 ,53).

A relatively low amplitude P3 is seen in 20% to 35% of the offspring of alcoholics (6 ,48). A 4-year follow-up of 13 sons of alcoholics, 11 sons of nonalcoholics with family histories of alcoholism, and 12 family-history–negative controls revealed a relationship between a low P3 amplitude and delinquent behavior as well as subsequent substance use, although alcohol abuse and dependence were not directly tested (54). Another 8-year follow-up of 11 children of alcoholics and nine controls revealed lower P3 amplitudes for those four subjects who went on to develop an alcohol use disorder (55). Although neither of these investigations controlled for the potential impact of CD and ASPD, the results are consistent with the relationship between P3 amplitude and the alcoholism risk.

As is true of many electrophysiologic measures, P3 amplitudes are genetically influenced (56 ,57). Data supporting these conclusions come from twin investigations, family studies, and a genetic linkage study that highlighted findings on chromosomes 2, 5, 6, and/or 13.

There are several interesting potential crossovers between P3 amplitude and other phenotypic or genetic markers of the alcoholism risk (19 ,52 ,53). Some investigators believe that most of the variance explained by P3 relates to CD or ASPD, or that finding might reflect activities of several dopamine (DA) receptors, which, in turn, might be related to impulsiveness or CD (41 ,52 ,53 ,58). At the same time, groups demonstrating low LRs to alcohol do not appear to have smaller P3 waves (19 ,51).

Independent Major Psychiatric Disorders

Alcoholics have an elevated risk for several major psychiatric disorders (59). For some people the psychiatric symptoms are likely to be temporary manifestations of intoxication and withdrawal, and for others alcohol problems might develop in the context of poor judgment and loss of control during major psychiatric syndromes (60 ,61). With schizophrenia, bipolar manic depressive disease, and ADHD, poor judgment, feelings of alienation, and high impulsivity might increase the chance of repeated heavy drinking (62 ,63 and 64).

The anxiety disorders are a series of syndromes with different clinical symptoms (in addition to anxiety), divergent treatments, and potentially different etiologies (65 ,66). Even after controlling for the potential impact of temporary substance-induced disorders, at least two anxiety syndromes—panic disorder and social phobia—appear to be tied to alcohol dependence, whereas some others, including obsessive-compulsive disorder, are not (65).

Each of the independent major psychiatric disorders listed above is likely to be genetically influenced (66). Most have abnormalities related to the HPA axis and to neurochemical systems including DA (especially relevant to schizophrenia), 5-HT (most closely tied to schizophrenia, anxiety, and mood disorders), norepinephrine (NE) and GABA (each tied to panic and mood disorders), and NPY (in anxiety) (66). Thus, as discussed below, genes related to the relevant psychiatric disorders might indirectly increase the risks for alcoholism through the clinical manifestations of the syndrome. However, these disorders might act independently of LR (14).

The Hypothalamic-Pituitary-Adrenal (HPA) Axis

Cortisol, adrenocorticotropin hormone (ACTH), corticotropin-releasing factor (CRF), prolactin, and related hormones are important in physiologic well-being, mood, anxiety,

aggression, and reactions to stress, including alcohol withdrawal (66 ,67 ,68 ,69 and 70). Aspects of HPA functioning might relate to an alcoholic predisposition in any of several ways. These include a possible contribution to a low LR, reflections of the actions of neurotransmitters such as 5-HT or DA in the course of some psychiatric disorders, and via the opioid system.

Some alcohol-dependent men and women have high cortisol, and children of alcoholics have a differential hormonal response to alcohol, opioid antagonists, and other challenges when compared to controls with some persisting after abstinence (67 ,68). Although there is some evidence that recovering alcoholics and children of alcoholics show lower levels of HPA response to alcohol, these same groups might show higher levels of response to naltrexone, an opioid antagonist (67 ,68 and 69).

The functioning of the HPA axis is at least partially under genetic control (70). Thus, activity of this system might contribute to the alcoholism risk, perhaps indirectly through several channels described in other sections.

Other Potentially Interesting Broad Phenotypes

Additional phenomena, including other personality disorders (e.g., borderline personality disorder), additional clinical characteristics (e.g., deficiencies in neuropsychological functioning), and other psychiatric syndromes [e.g., posttraumatic stress disorder (PTSD) or generalized anxiety disorder] have also been hypothesized to be related to the alcoholism risk (6 ,11 ,71).

Thus, reflecting space constraints, this discussion is not exhaustive and the reader should consider additional review papers.

Specific Proteins and Candidate Genes Potentially Related to the Alcoholism Risk

This subsection highlights some specific genes, enzymes, and other proteins that might relate to an alcoholism vulnerability. The distinction between broad potential phenotypic markers of alcoholism (discussed above) and the more specific markers noted here is somewhat arbitrary, but might be heuristically useful.

Adenylyl Cyclase (AC) and G Proteins

These proteins include three membrane-bound components of receptors, G (or guanine nucleotide binding) proteins, and the AC enzyme that are part of a complex second messenger system that translates the impact of alcohol, neurotransmitters, and other substances on the cell membrane or receptors into changes within the cell (72 ,73). The G proteins facilitate the coupling of at least nine different isoforms of AC to cell membrane-bound receptors, which in turn affects production of 3′,5′-cyclic adenosine-monophosphate (cAMP), with the latter often used as a measure of the system's activity. This complex is affected by several neurotransmitters, and has impact on a variety of actions within the cell, including gene expression, and might impact on a variety of psychiatric disorders, including depression. G proteins come in several forms that either stimulate (G_s) or inhibit (G_i) the process.

Although results can differ when platelets or lymphocytes from patients or cells *in vitro* are used, alcohol appears to stimulate G_s. Recently detoxified alcoholics and their nonalcoholic relatives might have lower cAMP production following chemical stimulation of platelets or white blood cells, results that have been hypothesized to be related to a reduced G_s binding (72 ,74). However, AC activity is also affected by drinking and by withdrawal, and differences from controls can change depending on periods of abstinence or following the production of multiple generations of lymphocytes in cell culture (73 ,75). In the final analysis, differences between alcoholics and controls are probably both state and trait phenomena.

Regarding the latter, activity of the system appears to be genetically influenced, and it is possible the divergence in AC functioning is especially prominent in alcoholics with family histories of this disorder (75). The production of cAMP in chemically stimulated cells has also been investigated in children of alcoholics who might share lower levels of G_s-protein–stimulated cAMP production, especially if they have multiple alcoholic relatives (72 ,76).

One theory attempting to integrate these findings is that an avenue of alcoholism risk might be a low innate activity of the G_s system, with acute alcohol causing a temporary stimulation, after which abstinence from alcohol produces the opposite effect, which might lead to more alcohol intake in an attempt to compensate (77). The underlying difference has been hypothesized to involve a reduction of gene expression of the α subunit of the G_s protein (72). The process might have an impact on the development of tolerance, and, perhaps, the need for higher levels of alcohol to have an effect. Another mechanism is suggested by findings regarding the role of alcohol in decreasing neuronal excitability through enhancing G-protein–coupled inwardly rectifying potassium channels (GIRKs) (78). Perhaps these results might also tie into the actions of protein kinase and the effects of other markers such as NPY, as well as through additional neurochemical systems such as 5-HT (79 ,80).

Protein Kinase C (PKC)

These proteins encompass at least three families of enzymes that, similar to AC, have important functions in translating the effects of neurotransmitters on receptors into the cell. These calcium-activated, phospholipid-dependent proteins are widely distributed in the body, and function by phosphorylating

target proteins, including G proteins, and thus, mediating changes in intracellular signaling (81 ,82).

The direction of the impact of alcohol on PKC activity can be different with acute versus chronic administration, but in general ethanol affects the movement of this protein from the area around the nucleus to the cytoplasm (83). The changes in PKC subsequently have impact on the actions of several neurotransmitter receptors, including 5-HT and $GABA_A$, and thus, are likely to affect alcohol intoxication and tolerance.

Alcohol-dependent individuals may have higher amounts of PKC-ε, a form that might inhibit the actions of $GABA_A$ receptors, possibly tying PKC-ε to a low LR to alcohol (82). Although no data are yet available in children of alcoholics, mice genetically engineered for an absence of PKC-ε have both a high sensitivity to alcohol and lower self-administration of this drug (82). Such animals also show a decreased reaction to pain, perhaps reflecting changes in opioid activity (84). There is additional evidence that PKC-ε knockout mice have a lower intensity of reaction to alcohol, and less ability to develop tolerance to at least some effects of the drug (81).

Neuropeptide Y (NPY)

NPY is a widely distributed neurotransmitter that affects multiple receptor subtypes including Y1 (in the amygdala where NPY decreases feelings of anxiety), and Y5 (in the hypothalamus where NPY might increase appetitive behaviors) (79 ,85). NPY appears to act through G proteins, producing an inhibition of AC production, and this transmitter can facilitate the release of DA in the nucleus accumbens (86). It has been hypothesized to play a role in eating disorders, depression, anxiety, and the actions of opioids (87).

Acute alcohol intake has impact on NPY release, which in turn affects the release of DA, possibly contributing to some rewarding effects of alcohol or adding to some psychiatric symptoms (85 ,86 ,88). Chronic alcohol intake and withdrawal are associated with increased NPY in the hypothalamus, and increased responsiveness of CRF to NPY (85).

Alcohol-preferring rats have a QTL on chromosome 4 [logarithm of odds (LOD) = 8.6], which explains about a third of the enhanced alcohol intake, and which is located in an area where NPY has been mapped (89). In addition, rats bred to consume high levels of alcohol have increased NPY activity in the amygdala (perhaps reflecting levels of anxiety), along with decreased NPY in the frontal cortex and hippocampus (perhaps reflecting a lower level of satiety) (85 ,88). Mice genetically engineered for an absence of NPY drink more alcohol and have a lower intensity of response compared to wild-type mice, whereas transgenetic mice with increased NPY have less alcohol consumption and higher responses to alcohol (79 ,90). Studies have not yet been carried out in alcoholics or their offspring.

Opioid-Like Substances, Including ß-Endorphin

The opioids are endogenous proteins, including endorphins and enkephalins, as well as most of the prescription pain medications, methadone, heroin, codeine, and morphine, each of which bind to opioid receptors. Their actions diminish pain, decrease respirations, cause euphoria, and produce a decreased motility in the gut. There are a variety of opioid receptor subtypes including μ, κ, and δ, with μ most closely tied to analgesic and reinforcing effects (91). Opioids have impact on DA, 5-HT, and NPY activity, and relate to some psychiatric disorders, such as depression (92).

Acute alcohol intake results in the release of endogenous opioids, and stimulates relevant receptors (6 ,93). Aspects of tolerance and withdrawal from alcohol might relate to changes in functioning of the μ receptors, and alcohol-preferring animals have an increase in these receptors in the ventral tegmentum, along with a greater increase in ß-endorphin following alcohol (94 ,95 and 96). An exaggerated HPA response to naltrexone (an opioid antagonist) has been reported in alcoholics and their relatives, perhaps reflecting less baseline opioid functioning (97). Decreased ß-endorphin has been noted in the cerebrospinal fluid (CSF) of abstinent alcoholics, and their relatives demonstrate more release of ß-endorphin following alcohol (94 ,96). Opioid antagonists, such as naltrexone and nalmephene, can decrease the self-administration of alcohol in animals and humans, perhaps by blunting the stimulatory effect of alcohol, enhancing the sedative effects of this drug, and/or through decreased levels of reinforcement from alcohol (93 ,97 ,98). A μ opioid receptor gene might be located near a QTL for alcohol preference in mice (99), and there is a possible association between alcoholism and some of the six more known alleles of the μ opioid receptor (OPRM1), although not all studies agree (6 ,94 ,100).

The Serotonin (5-HT) Systems

The actions of this neurotransmitter, which are mediated through the 5-HT transporter (5-HTT) and more than 14 different receptors, affect HPA functioning, anxiety, impulsivity, eating behaviors, depression, and other conditions (6). Numerous drugs of abuse have impact on 5-HT systems, including alcohol, and 5-HT, in turn, also interacts with other neurotransmitters, especially DA (6). The following data suggest that different genes affecting 5-HT levels could increase the alcoholism risk through several different mechanisms.

5-HT agonists can simulate signs of intoxication, and, perhaps, feelings of craving (101). Alcoholics, especially those with aggressiveness or an early onset of their substance use disorder, may have lower levels of platelet and brain 5-HT, diminished responses to 5-HT boosting drugs, and lower levels of 5-HT metabolites in the CSF (6 ,102). Treatment with drugs that boost 5-HT in the synapse [e.g., selective

serotonin reuptake inhibitors (SSRIs)], produces a modest decrease in voluntary alcohol intake in animals and humans (6).

Alcohol preference in animals is associated with a QTL near the genes encoding for the 5-HTT (103). The s-allele may relate to nervousness, harm avoidance, and other forms of anxiety that might tie in to axis I anxiety disorders and more severe alcohol withdrawal, although not all authors agree (49 ,104). The l-allele, which might produce a protein that more rapidly takes up 5-HT from the synapse, has been tied to a low LR to alcohol and an enhanced alcoholism risk (32). Another gene that controls the production of the rate limiting enzyme in the synthesis of 5-HT, *tryptophan hydroxylase*, might also relate to lower 5-HT levels and more impulsiveness, suicidality, as well as a predisposition toward alcoholism (105).

Genes for some 5-HT receptors might be associated with higher alcohol intake either directly or through ASPD, depressive disorders, schizophrenia, or anxiety disorders. Findings include a high receptor density for 5-HT_{1A} or a decrease in 5-HT_{1B} activity in alcohol-preferring rats, with 5-HT_{1B} knockout mice demonstrating higher levels of alcohol intake (106 ,107). Turning to a second family of receptors, there is evidence of a decrease in 5-HT_{2C} receptor sensitivity in alcoholics, along with a potential increase in the density of these proteins in the hippocampus in alcohol-preferring rats (108). A third family has also been implicated through the actions of the 5-HT_3 receptor, which promotes the release of dopamine in the nucleus accumbens in the context of alcohol (6 ,109).

Children of alcoholics might have more rapid uptake of 5-HT in platelets, perhaps indicating a lower level of 5-HT in the synapse that might relate to LR (110). This is consistent with lower LR to alcohol in the offspring who have the l-allele of the 5-HTT (32). Finally, a drug that antagonizes activity of the 5-HT_3receptor, ondansetron, both decreases subjective feelings of intoxication with alcohol and decreases alcohol intake in alcoholics and their relatives (109).

The Potential Importance of Dopamine (DA)

This neurotransmitter has broad effects in the brain, including in the mesolimbic system where it functions as a mediator of reward or pleasure (6 ,111). DA impacts on the risk for heavy drinking and alcoholism through potentially diverse mechanisms including the reinforcing effects of the drug, personality characteristics, and via several psychiatric disorders.

Ethanol causes the release of DA in the mesolimbic system, affects DA neurons in the ventral tegmentum, and the reinforcement from alcohol decreases when DA antagonists are given (6 ,111 ,112). There might be a general decrease in overall DA functioning among more violent alcoholics, as evidenced by lower levels of DA metabolites in the CSF, and DA activity might also relate to personality characteristics such as novelty seeking and to ASPD (113 ,114).

These findings have led to a search for specific DA markers possibly tied to a vulnerability toward alcoholism. A decrease in the D2 receptor density has been reported in the brain of alcohol-preferring rodents and some alcoholics, as has a blunted hormonal response to D2 agonists, at least soon after withdrawal (115 ,116). Lower levels of DA in the synapse might result from a higher density of DA uptake as seen in alcohol-preferring primates, although possibly reflecting withdrawal, the opposite was reported in the striatum in a small sample of nonviolent alcoholics (116 ,117).

Although it is not clear whether they are functional, several alleles of the Taq1A marker for the D2 DA receptor (DRD2) have been reported to be linked to alcoholism, especially severe early-onset problems, and thus possibly to ASPD (6 ,118). However, results relating to this candidate have not been replicated in genome scans, and there are as many nonconfirmatory studies as there are positive ones (6 ,119). Additional interest has been expressed regarding the D4 receptor and several alleles of the DA transporter, but with conflicting results (120 ,121).

GABA, Norepinephrine (NE), and Monoamine Oxidase (MAO)

This subsection briefly reviews several markers that might relate to the alcoholism risk. GABA, a ubiquitous inhibitory neurotransmitter, has an important role in several conditions possibly related to the alcoholism risk including anxiety, mood disorders, schizophrenia, and aggressive behaviors (32 ,66). There are multiple GABA receptors, with special interest for alcohol intoxication or withdrawal for the estimated 13 or more subunits for the $GABA_A$ receptor complex (6 ,32 ,122). Alcohol-dependent men and women have a decreased density of $GABA_A$ receptors, and might show decreased responses to lorazepam in frontal brain regions and in the basal ganglia, while demonstrating abnormal responses to a benzodiazepine antagonist flumazenil (123 ,124). A diminished response to brain depressants might occur with a common mutation of the $GABA_{A\alpha 6}$ receptor, which might also reflect a low LR to alcohol (32 ,122). In addition, a possible predisposition toward alcohol dependence might link to an area of chromosome 4 near genes noted to have an impact on GABA functioning (32 ,125).

Monoamines, including 5-HT, NE, and DA, are metabolized in part by MAO. Alcoholics, especially those with concomitant ASPD, might demonstrate low MAO activities, perhaps reflecting alternate forms of genes, although this finding might be an artifact of recent smoking (126).

Finally, alcoholics, especially those with multiple alcoholic relatives, might have a blunted hormonal response to drugs that have impact on NE, especially during withdrawal and early abstinence (127). Thus, NE might also increase the alcoholism risk through vulnerability for panic and other anxiety disorders.

Alcohol-Metabolizing Enzymes

The best-documented genetic factors related to alcoholism involve genes controlling the two prominent alcohol-metabolizing enzymes, alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH). As discussed in Chapter 99 , Asian men and women who lack the low k_m, mitochondrial ALDH (i.e., have the homozygous ALDH2-2, 2-2 genotype) and who, thus, produce very high levels of the first breakdown product of alcohol (acetaldehyde), have almost no risk for alcohol dependence (11 ,12 ,128). Heterozygotes with the ALDH2-1, 2-2 genotype produce higher acetaldehyde levels than Asians with ALDH2-1, 2-1, and have an enhanced level of response to alcohol and lower risk for alcoholism. For ADH, individuals carrying the genotypes that are associated with more rapid metabolism of alcohol (e.g., those with ADH2-2, 2-3, or 3-1 alleles) more rapidly produce acetaldehyde and have a diminished alcoholism risk, especially if these genotypes are associated with the relevant ALDH markers described above (129 ,130). The ADH enzyme forms appear to exert less influence on the alcoholism risk, but are applicable to a broader range of ethnic and racial groups.

Thus, ADH and ALDH enzyme patterns have several potential mechanisms associated with an altered risk for alcohol dependence. These include an aversive reaction to alcohol related to very high levels of acetaldehyde in ALDH2-2 homozygotes, whereas individuals who are heterozygotes for ALDH2-2 and those with more rapid metabolism of alcohol through ADH forms might decrease their risk through an increased intensity of reaction to alcohol, not necessarily an overall more aversive response (25).

AN ATTEMPT TO SYNTHESIZE THESE DATA

Part of "98 - Vulnerability Factors for Alcoholism "

Background

This chapter has briefly reviewed many genetically influenced characteristics that may be relevant to the alcoholism risk. However, it is unlikely that there are 30 or so independent genetically influenced trait markers for alcoholism, and thus the findings are likely to represent a more limited number of overarching phenomena, or families of risk factors.

As in the selection of markers of interest, the identification of possible families of findings, or domains, requires subjective judgment. Initially, I was tempted to highlight a separate domain for 5-HT and another for DA markers, and I recognize that it is possible that the functioning of the HPA axis might be a core mediator of risk by itself. However, I believe that most of these markers might function as correlates of several different mechanisms through which broader domains of influence operate. Therefore, I propose that the majority of the genetically related markers of the alcoholism risk might fall into about five relatively independent overarching categories (Table 98.1). The specific markers are summarized in Table 98.2 .

	LR	Disinhibition	Axis II	Opioids	ALDH/ADH
Broad markers					
EEG alpha	X		X		
Voltage	X		X		
HPA	X		X	X	X
5-HT levels		X	X	X	
DA levels		X	X	X	
Neuropsychiatric		X	X		
Genes/proteins					
AC	X		X		
G protein	X		X		
PKC	X			X	
NPY	X		X	X	
$5\text{-HT}_{1A/1B/2C}$	?	?	?		
5-HT_3	X				
5-HTT	X	X	X		
TOH		X	X		
DRD2		X			
D4		X			
DAT		X			
$GABA_A$	X	X	X		

AC, adenylyl cyclase; ADH, alcohol dehydrogenase; ALDH, aldehyde dehydrogenase; DA, dopamine; DAT, dopamine transporter; DRD2, dopamine receptor D2; GABA, γ-aminobutyric acid; HPA, hypothalemic-pituitary-adrenal axis; 5-HT, serotonin; LR, level of response; NPY, neuropeptide Y; PKC, protein kinase C.

TABLE 98.2. POSSIBLE FAMILIES OF RISK FACTORS

A Domain Related to a Low LR to Alcohol

A low LR is a useful place to begin to demonstrate how some of the literature might be synthesized. Although the central aspect of this family of findings might be altered 5-HT or HPA axis functioning, it is equally plausible that a low LR to alcohol is the characteristic that pulls together the other findings.

Theoretically, a low LR to alcohol might reflect the final phenotypic path through which many different markers operate. Dampened responses to alcohol in children of alcoholics have been observed for several hormones, electrophysiologic measures, subjective feelings of intoxication, and motor performance. This array of findings might reflect altered second messenger and intracellular signaling actions that are less sensitive to alcohol-induced neurochemical changes, including genes that affect G proteins, AC, and PKC. Other mechanisms that might independently affect the LR to alcohol might include genes that have impact on NPY, GABA, 5-HT, and DA. The subsequent diminished effect of alcohol on neurons might also function to produce less change in the EEG and HPA axis responses, thereby helping to mediate the reaction to alcohol overall (24 ,67).

Other components of some of these same systems, including DA, 5-HT, DA, and HPA functioning, are also likely to function through additional mechanisms as mediators of several other domains of risk factors. For example, alternative aspects of these systems might have impact on disinhibition, independent psychiatric disorders, and opioid system functioning. As discussed further below, most of those additional attributes are likely to be distinct from those that relate to a low LR. It is hoped that the identification of specific genes linked to LR will help pinpoint which of these neurochemical systems contribute most to this domain.

A Domain Encompassing Disinhibition, a Low P3 Amplitude, ASPD, and Early-Onset and More Severe Subtypes of Alcoholism

A low P3 amplitude of the ERP and aspects of CD and/or ASPD characterize a substantial minority of young children of alcoholics; aspects of this domain are genetically influenced, and these phenomena relate to the future alcoholism risk. Although low LR appears to be relatively specific for the alcoholism risk (19 ,24), the disinhibition domain might enhance the risk for all substance use disorders (41 ,48 ,52). Theoretically, these markers might be associated with poor judgment and impulsive behavior, which both increase the risk for ingesting substances and for problems learning how to control their use.

This potential domain appears to operate independently of a low LR and alcohol-metabolizing enzymes, and there are few data that would link these phenomena to the opioids and major axis I psychiatric disorders (14 ,53). It is possible that one childhood psychiatric disorder, ADHD, might also fit into the disinhibition domain, and other investigators might believe that some anxiety disorders might fit here as well.

A number of neurochemical markers described above might fit together under a general heading of disinhibition. These include several DA-related genes (e.g., DRD2, and DRD4 receptors), the DA transporter, and aspects of the DA function tied to sensation seeking, novelty seeking, as well as early-onset and severe alcoholism (6 ,58). Aspects of 5-HT might also be relevant, with the major finding here (as opposed to the LR domain where only the 5-HTT might contribute) being low 5-HT functioning overall, and genes having impact on tryptophan hydroxylase (6 ,102). Several additional findings that are discussed in more detail in other publications might also apply to this domain, including cognitive difficulties with executive cognitive functioning, which might cross over with CD, ASPD, and the substance use disorders.

Independent Axis I Major Psychiatric Disorders as a Potential Domain of Risk

The central hypothesis for this domain is that genes that contribute to the development of some psychiatric disorders might indirectly increase the risk for heavy drinking and alcohol-related problems. The axis I disorders most closely tied to an elevated alcoholism risk are schizophrenia and bipolar manic depressive disorder as described above (60 ,61 ,64). An enhanced alcoholism risk might also be associated with panic disorder and social phobia, and possibly PTSD or generalized anxiety disorder. Each relevant condition is itself a complex genetic disorder, with separate, but perhaps overlapping, sets of genes. Furthermore, it is possible that different environmental events add to or detract from the risk for each of these conditions.

For this discussion, it is not essential to determine if the individual with schizophrenia, for example, is drinking to decrease the symptoms of their underlying and independent disorder (although this contention is not well supported) (63 ,131), or if the problems were a result of the combination of poor judgment, a large amount of free time, and living in a heavy drinking environment. In either case, the search for genetic factors in alcoholism might be more efficient if the potential impact of genes related to these independent disorders is considered. Once genetic markers for an additional characteristic (such as LR) have been found, they can be tested in these more complex subjects to determine whether it adds further to the risk.

The core characteristics of this domain might only indirectly relate to independent psychiatric disorders. It is possible that the predispositions toward both alcoholism and a

psychiatric disorder might operate through the same genes that have impact on the 5-HT, DA, or the HPA systems. Or the relationships could reflect transmission disequilibrium for the genes having impact on the alcoholism risk and those related to some of the psychiatric disorders. The answer to these questions might be more easily addressed once specific genes linked to the alcoholism risk and those linked to the relevant independent psychiatric disorders have been identified.

A Possible Domain Related to the Opioid System

A low level of activity of endogenous opioids could alter the intensity of reinforcement from alcohol (93 ,94). The markers reported above, as well as characteristics potentially related to the opioid systems, might form a domain that appears to be relatively independent of other risk factors. The decision to place opioids in a separate family of findings rests with evidence of high levels of alcohol dependence among opioid-dependent individuals, the closer than expected relationship between alcohol and opioid consumption in animals, and my subjective judgment that opioid systems are likely to function primarily as a characteristic subsumed under a separate global domain.

There is crossover between this hypothesized domain and the functioning of the HPA axis, and 5-HT, DA systems. Thus, it is possible this is not a separate domain of influence, but the possibility of a relatively unique impact is worth considering.

The Importance of Alcohol-Metabolizing Enzymes

Both the genetic control and the impact on drinking behaviors for alcohol-metabolizing enzymes have been well established (18 ,128). The risk for alcohol dependence among individuals with the ALDH2-2, 2-2 genotype is close to zero. ALDH2-2, 2-1 heterozygotes have significantly lower levels of risk as, apparently, do some people who have the more efficient ADH2-2, 2-3, and 3-1 alleles. The mechanisms through which the relevant genes are likely to operate include an aversive effect of alcohol at high acetaldehyde levels (as seen with ALDH2-2 homozygotes), and possibly through an enhanced LR to alcohol (for ALDH2-2, 2-1 heterozygotes and the relevant ADH alleles).

Despite some crossover with LR for ALDH heterozygotes, it is likely that the alleles controlling these alcohol-metabolizing enzymes operate as a relatively separate domain of risk. Few, if any, data tie these alleles to disinhibition or axis II major psychiatric disorders, and a strong link to opioid systems seems unlikely. However, it is possible that some of the impact of acetaldehyde might operate through elevations in HPA hormones, and the accompanying neurochemical changes might have impact on second messenger or other intracellular signaling systems.

CONCLUDING REMARKS

Part of "98 - Vulnerability Factors for Alcoholism "

During the 7 years since publication of the previous edition, there have been exciting developments regarding the study of complex genetically influenced disorders. Progress in the studies of the genetic factors in alcohol dependence has been important because this is one of the most prevalent major psychiatric conditions, and is associated with substantial morbidity and mortality.

Some readers will be most interested in the citations from publications over the prior decade regarding the broad phenotypic or more focused genotypic markers described here. It is also hoped that some will also benefit from considering the hypothesis that many of these markers of risk can be grouped together into overarching phenomena including a low LR disinhibition, independent axis II psychiatric disorders, the opioid system, or alcohol-metabolizing enzymes.

The idea of searching for central themes among the markers is potentially more important than whether any of the hypothesized domains survive the test of time. It is possible that several of the families of findings discussed here would have been better subsumed under changes in the HPA axis, that findings related to specific neurochemical systems might each represent separate domains of influence, and that some of the hypothesized domains might be epiphenomena operating under the umbrella of genes that affect the levels of functioning in specific neurochemical systems. However, as is true of all fields of science, it is important to outline possible examples of a generic approach, in the hope of stimulating additional research to determine the most appropriate domains of influence.

Molecular and Cellular Genetics of Alcohol Addiction

Mary-Anne Enoch

David Goldman

Mary-Anne Enoch and David Goldman: Laboratory of Neurogenetics, National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health, Bethesda, Maryland.

Worldwide, in societies where moderate alcohol consumption is accepted as a pleasurable pastime and even an enhancer of health and well-being, it has historically been observed that a sizable minority is unable to keep within safe limits of consumption. Such individuals may abuse alcohol or become dependent. Alcoholism is today among the most pervasive psychiatric disorders. In the United States, the lifetime prevalence of alcohol dependence, the severe form of alcoholism, is 8% to 14% (1). The ratio of alcohol dependence to abuse is 1.5:1. Individuals often maintain a pattern of alcohol abuse without dependence for many years (2). Serious drinking frequently begins in adolescence, and approximately 40% of alcoholics develop their first symptoms of addiction between the ages of 15 and 19 years (3). As discussed in this chapter, heritability studies suggest that an individual's genotype confers a particular level of vulnerability, or risk. Comparative studies across populations suggest that sociocultural factors determine differences in thresholds above which an individual is likely to go beyond social drinking and slip into abuse or addiction. Is the development of alcoholism due to a unique set of biochemical and neurobiological determinants or are the causes of addiction common to many substances? Are there preexisting behavioral traits that predispose to alcoholism? These are some of the questions addressed by this chapter.

GENETIC INFLUENCES ON ALCOHOLISM: HERITABILITY STUDIES

Part of "99 - Molecular and Cellular Genetics of Alcohol Addiction "

Alcoholism is a heterogeneous disease in which the expression of genetic vulnerability is modified by environmental factors. Some of the environmental influences are uniquely experienced by the individual (nonshared) and some are shared among different individuals within the family. Numerous studies have shown that alcoholism is familial. In the National Comorbidity Survey of 5,877 individuals, it was found that alcohol use disorders aggregate significantly in families with an odds ratio of 1.93 (4). To have an alcoholic parent is a significant risk factor for the development of the disease; children of alcoholics are five times more likely to develop alcohol-related problems than children of nonalcoholics (5). It has been shown that the transmission of the vulnerability to alcoholism from parents to their daughters is due largely or entirely to genetic factors (6).

Studies of heritability, a measure of the genetic component of variance in interindividual vulnerability, indicate that genetic influences are substantially responsible for the observed patterns of familiality. Adoption studies have shown that alcoholism in biological parents predicts alcoholism in children even when the child is reared by unrelated adoptive parents (7 ,8). Large, well-constructed twin studies (8 ,9 and 10) have demonstrated that genetic factors are important in determining vulnerability to alcoholism, particularly in the more severe forms of the disease (11).

Over the past few years, several heritability analyses have been performed using the population-based Virginia Twin Registry. A study of 1,030 U.S. Caucasian female twin pairs demonstrated that whether using narrow, intermediate, or broad definitions, the concordance for alcoholism was consistently higher in monozygotic (MZ) than dizygotic (DZ) twin pairs, and the heritability of alcoholism in women is 0.50 to 0.60 (6 ,9). In a study of 3,516 U.S. male twins, it was found that 0.48 to 0.58 of the variation in liability for both alcohol abuse and dependence was attributable to additive genetic factors with the remainder attributable to nonshared environmental factors, which is most accurately labeled as "other," including as it does other sources of variance such as measurement error (12). The results of these two studies were confirmed in a recent analysis of 5,091 U.S. male twins and 4,168 female twins from the same registry (13). This study also added the information that the genetic sources of variability are partially, but not

completely, overlapping in men and women. Compared with the expected genetic correlations of 0.5 for same-sex DZ twin pairs, heritability was 0.20 to 0.24 [95% confidence interval (CI) = 4% to 45%] for opposite-sex pairs. Although the heritability value of approximately 0.5 for alcohol dependence in men and women was replicated in an analysis of 2,685 male and female twin pairs from the Australian twin registry (10), no evidence was found for sex differences in sources of genetic influence. It may be that the relatively small number of opposite sex pairs—592—in the Heath et al. (10) study compared with the larger number—1,428—in the Prescott et al. (13) study limited the power to find a difference.

GENETIC HETEROGENEITY IN ALCOHOLISM

Part of "99 - Molecular and Cellular Genetics of Alcohol Addiction "

Although there is good evidence for substantial heritability for alcoholism, individual differences in clinical presentation suggest variation in origins of vulnerability. Alcoholics vary in their drinking patterns, the severity of their symptoms, and in behavioral, physical, and psychiatric sequelae. Vulnerability may reside in personality or psychiatric traits that predispose to alcohol-seeking behavior, differential response to the effects of alcohol, or differential predisposition to addiction. Vulnerability factors found in some, but by no means all, alcoholics include attentional deficits reflected by low amplitude of the P300 event-related potential (14), anxiety reflected by the low-voltage alpha EEG trait (15), and diminished subjective response to alcohol (16).

COMORBIDITY OF ALCOHOLISM AND OTHER PSYCHIATRIC DISORDERS: GENETIC DIATHESES?

Part of "99 - Molecular and Cellular Genetics of Alcohol Addiction "

Alcohol dependence is often comorbid with other psychiatric disorders, including drug abuse, major depression (MD), anxiety disorders (ADs), and bulimia nervosa (BN), or antisocial personality disorder (ASPD) (17 ,18). Lifetime co-occurrence is more common among women than men and is positively associated with the persistence of alcohol dependence in both men and women (18). Population comorbidity, in which two disorders may be observed to co-occur in excess, may be due to shared causation. A strength of genetic epidemiologic studies is their ability to detect evidence of shared genetic and familial environmental causation.

Severe alcoholism, suicidality, and impulsivity tend to coexist in the same individuals, usually male. The relative risk of alcoholism is significantly increased in males with either ASPD, attention-deficit/hyperactivity disorder, or childhood conduct disorder, and there is evidence of co-inheritance of ASPD and alcoholism. Alcoholism in women is associated with anxiety and affective disorders (18) and increased neuroticism (10). These data notwithstanding, a recent evaluation of the co-inheritance of alcoholism and other disorders revealed that the inheritance of alcoholism is remarkably distinct. Female twins from the Virginia Twin Registry were evaluated for alcoholism, MD, BN, phobia, generalized anxiety disorder (GAD), and panic. Alcoholism emerged as the one disorder with a large disease-specific genetic component: approximately 75% of the genetic variance. In addition, smaller components of the genetic liability to alcoholism also loaded onto a factor common to MD and GAD as well as a factor common to phobia, panic, and BN (19).

COMORBIDITY OF ALCOHOLISM WITH OTHER SUBSTANCE ABUSE: GENETIC DIATHESES?

Part of "99 - Molecular and Cellular Genetics of Alcohol Addiction "

Alcohol, cocaine, opiate, and tobacco (nicotine) dependency co-occur more often in the population than would be expected from their frequencies (20). This raises the possibility that there may be substance-general, as well as substance-specific, components to the heritability of alcoholism (21).

Both alcoholism and drug disorders are familial; two large studies have evaluated the familial aggregation of alcohol and drug dependence (22 ,23). Both studies found that relatives of drug-disorder probands across a wide range of substances, including opioids, cocaine, and cannabis, had a greater rate of drug disorders themselves than relatives of controls. However, this comorbidity occurred largely independently from cotransmission of alcoholism, suggesting that the transmission of alcoholism and other drug disorders is largely independent.

The strongest evidence of a shared, as well as a specific, addictive tendency is between alcohol and nicotine. It has long been observed that there is a relationship between smoking and alcoholism. More than 80% of alcoholics smoke cigarettes and 70% are heavy smokers, compared with 30% of the general population who smoke and 10% who smoke heavily (24). In a multivariate genetic analysis of the use of tobacco and alcohol in 774 MZ and 809 DZ male and female twin pairs from the Virginia Twin Registry, the univariate heritability of alcohol consumption was 0.60 in men and 0.47 in women, and the heritability of tobacco use was 0.49 in men and 0.51 in women. Tobacco use had a stronger loading on this shared genetic factor (0.56 in males, 0.49 in females), than alcohol consumption (0.12 in males, 0.19 in females) (25). However, the precise level of the co-inheritance is less certain than the existence of co-inheritance, and the level of genetic sharing may depend on how the phenotypes are determined. In an analysis of 2,220 MZ and 2,373 DZ U.S. male twin pairs from the National Academy of Sciences–National Research Council’s World War II Twin Registry, a heavy smoking, heavy alcohol genetic factor accounted for 0.45 of the heritable

variance in heavy drinking and 0.35 of the heritable variance in heavy smoking (26), and substance-specific genetic influences contributed 0.22 of the total heritable variance in heavy smoking and 0.55 for heavy alcohol use (26). A study of 3,356 male twin pairs from the U.S. Vietnam Era Twin Registry found a substantial genetic correlation (*r* = 0.68) between alcohol and nicotine dependence. Of the total variance in risk for alcohol dependence, 0.26 was common with the genetic influence on nicotine dependence (27).

THE NEUROBIOLOGY OF ALCOHOL ADDICTION

Part of "99 - Molecular and Cellular Genetics of Alcohol Addiction "

The essential features of addiction are loss of control over consumption, compulsion to obtain the next stimulus, and continuation of abuse despite knowledge of negative health and social consequences. Tolerance and dependence are due to neuroadaptations. Processes of reward and reinforcement play their most crucial role at the start of the path to addiction, after which long-lasting or permanent neuroadaptations occur. It is likely that genetic variation in this neurobiology predisposes some individuals to a pattern of increased craving and loss of control.

Addictive substances affect a range of neurotransmitter systems in different regions of the brain. However, a pathway that appears to be crucial to the action of all addictive drugs is the mesolimbic dopamine system, which originates in the ventral tegmental area (VTA) of the midbrain and projects to the nucleus accumbens (NAC), with projections also to the limbic system and the orbitofrontal cortex (28). The amygdala, hippocampus, and medial prefrontal cortex send excitatory projections to the NAC. The mesolimbic dopamine pathway is associated with the ability to feel pleasure. Serotoninergic neurons originating in the dorsal and median raphe nuclei project to mesolimbic structures, including the VTA and NAC, and may exert inhibitory control on mesolimbic dopamine neuron activity (29) (see Chapter 95).

Alcohol, psychostimulants, opiates, and nicotine (as well as tetrahydrocannabinol and phencyclidine) exert their primary reinforcing or reward effects by releasing dopamine (DA) in the NAC. The acute reinforcing actions of psychostimulant drugs is mediated both by the blockade of DA binding to its transporter, preventing the reuptake of DA from the synaptic cleft (20), and by interaction with multiple DA receptors including D1, D2, and D3 (28). Cocaine blocks the reuptake of serotonin (5-HT) and norepinephrine in a similar fashion. A functional down-regulation of 5-HT_3 receptors in the NAC may contribute to cocaine tolerance (30), whereas chronic alcohol intake increases the sensitivity of 5-HT_3 receptors (31). Chronic cocaine and alcohol administration also disrupts the endogenous opioid system (20). Nicotine's reinforcing effect is through activation of nicotinic receptors in the VTA, ultimately leading to release of dopamine in the NA (32), but the rewarding effects are also mediated by the cholinergic and serotoninergic neurotransmitter systems. The acute reward effects of opioids are enhanced by activation of μ (and possibly also δ) receptors in the VTA.

Enhanced γ-aminobutyric acid (GABA), glutamate, dopaminergic, opioid peptide, and serotoninergic neurotransmission have been associated with acute ethanol administration, and potentially mediate some of alcohol's reinforcing effects (33). In contrast to opioids, which bind to specific receptors, ethanol appears to act on a variety of targets within the cell membrane in a less specific manner, inducing effects on neurotransmitter and neurohormone membrane receptors and receptor-gated and voltage-activated ion channels as well as modulating neurotransmitter release (34). Alterations in calcium channels may be a major component of the changes that occur in the physical dependence on ethanol (35).

GABA is the major inhibitory neurotransmitter in brain. The development of tolerance may be related to ethanol-induced adaptive changes in the $GABA_A$ receptor system. $GABA_A$ receptors are the primary site of action of benzodiazepines and barbiturates, which are used in the treatment of alcohol withdrawal symptoms.

Increasing evidence suggests that ethanol's inhibition of the glutamatergic neurotransmitter pathways, especially at the level of the postsynaptic *N*-methyl-D-aspartate (NMDA) receptor, may be an important cause of its neurotoxic effects (36). Glutamate is the major excitatory brain neurotransmitter with up to 40% of all synapses being glutamatergic (36). Inhibition of GABAergic interneurons mediated via ethanol's effect on the NMDA receptor may result in disinhibition of forebrain glutamatergic neurons that augment dopamine release (37). Changes in the NMDA receptor system may underlie intoxication and withdrawal symptoms (38) as well as "blackouts" (36). Homotarrine (Acamprosate), a structural analogue of glutamate and an NMDA-receptor antagonist, has been shown to almost double the abstinence rate in recovering alcoholics (39).

Some of the rewarding effects of ethanol result from activation of μ opioid receptors in the VTA and/or δ receptors in the NAC by the ethanol-induced release of endogenous β-endorphin from terminals of the VTA and NAC as well as release of enkephalins from intrinsic enkephalin neurons in the NAC (34). The success of the opioid antagonist naltrexone in modifying drinking behavior, controlling craving and preventing relapse in alcoholics indicates that opioid receptor-mediated mechanisms are activated by alcohol (34 ,40).

The co-inheritance of nicotine and alcohol dependence (27) may relate to the finding that ethanol enhancement of DA release in the NAC appears to require activation of nicotinic receptors in the VTA. Neuronal nicotinic acetylcholine receptors are structurally related to $GABA_A$receptors (41).

Activation of these nicotinic receptors may enhance ethanol reinforcement and voluntary intake (42).

Some studies have implicated involvement of the serotonin receptors 5-HT_3 and possibly 5-HT_4 in DA release in the NAC (31 ,43). 5-HT_3 is the only known serotonin receptor that directly gates an ion channel and hence ethanol directly potentiates the effects of serotonin at this site (44). Chronic alcohol intake increases the sensitivity of 5-HT_3 receptors (31) and results in enhanced GABAergic activity. The 5-HT_3 antagonist ondansetron has been shown to reduce alcohol consumption in alcoholics (45).

GENETIC STUDIES OF ALCOHOLISM IN HUMANS

Part of "99 - Molecular and Cellular Genetics of Alcohol Addiction "

In a heterogeneous disease such as alcoholism it is likely that there are different environment-related thresholds and different genes and gene variants. In addition there could be additive or nonadditive (epistatic) interactions between variants of multiple genes. Classic genetic analyses in rodents show that certain alcohol-related phenotypes (e.g., alcohol sensitivity) can be polygenic. On the other hand, human data showing an approximately 2:1 MZ/DZ twin ratio of concordance for alcoholism and high recurrence rates in first-degree relatives of alcoholics followed by a progressively decreasing risk in proportion to relatedness are compatible with additivity of inheritance, and do not favor multiple genes. The alcoholism genes identified so far—*ALDH2* and *ADH2*—were discovered individually but act additively when they co-occur (vide infra).

To dissect the multiple genetic influences on alcoholism vulnerability, it may be necessary or useful to consider several phenotypes representing different aspects of the disease. Attempts have been made to classify alcoholics into more homogeneous clinical groups by severity (dependence or abuse), withdrawal signs, tolerance, medical sequelae, or latent class phenotypes. Cloninger (46) divided alcoholics on a clinical and genetic epidemiologic basis into type 1 (milieu-limited, later onset) and type 2 (early onset, male dominated, associated with ASPD), thus linking premorbid personality with alcoholism vulnerability and identifying an alcoholism subtype, type II, with a stronger genetic predisposition. This classification is supported by a study involving the National Comorbidity Survey of 5,877 people in which Kendler et al. (4) demonstrated that there are two underlying dimensions of liability for alcoholism, drug disorders, ASPD, MD, and GAD that are familially transmitted with moderate specificity: (a) chronic dysphoric symptoms of anxiety and depression, and (b) acting-out behaviors and harmful substance use.

Genetics Of Alcohol Metabolism

At the present time, the genes for alcohol metabolism are the only genes that are known to have a major impact on the development of alcoholism. One gene variant (allele) is protective and the other is a vulnerability allele. Alcohol dehydrogenase (ADH) metabolizes ethanol to acetaldehyde, a toxic intermediate, which is in turn converted to acetate by aldehyde dehydrogenase (ALDH). Approximately half the population of Southeast (SE) Asian countries such as China, Japan, and Korea have functional polymorphisms at four different genes: *ADH2, ADH3, ALDH1*, and *ALDH2*. Across populations, the ALDH2-2 variant appears on a similar genetic background (haplotype) and thus has probably had the same evolutionary origin (47). The most important variants are ALDH2-2 (Glu_{487}-Lys_{487}) and ADH2-2 (Arg_{47}-His_{47}). ALDH2-2 dominantly inactivates *ALDH2*, the ALDH that is mitochondrially localized and responsible for most acetaldehyde metabolism in cells. ADH2-2 is a superactive variant. Allelic variation at ADH3 apparently exerts no independent effect on the risk for alcoholism; however, ADH3-1 is in linkage disequilibrium with ADH2-2 (48 ,49) and is thus also predictive of vulnerability. ADH2-2 and ALDH2-2 raise the levels of acetaldehyde by increasing the rate of synthesis, by decreasing the rate of metabolism, and by interacting additively, but not synergistically (50). The result is that ingestion of even small amounts of ethanol produces an unpleasant reaction characterized by facial flushing, headache, hypotension, palpitations, tachycardia, nausea, and vomiting (51). In an analogous fashion, disulfiram, used in the treatment of alcoholism, and some antiprotozoal drugs such as metronidazole, inhibit *ALDH2* and thereby cause a flushing reaction after alcohol consumption. Therefore, the protective effect of *ALDH2* genotypes can be regarded as analogous to protection with disulfiram, as this flushing reaction, severe in homozygotes but milder in heterozygotes, deters individuals with the protective alleles from becoming alcoholic. The allele frequency of the dominantly acting ALDH2-2 is 0.3 in Japanese and Chinese, and hence about one in two individuals experience flushing after alcohol consumption. Their risk of alcoholism is reduced about four- to tenfold. Approximately 10% of Japanese are ALDH2-2/ALDH2-2 homozygotes. Thus far, only one alcoholic ALDH2-2/ALDH2-2 homozygote has been observed across a series of studies in which several hundred alcoholics have been genotyped, and that individual is the focus of a report (52).

The genetic influence of *ALDH2* variants on alcohol consumption is modified by environment. Tu and Israel (53) found that acculturation accounted for some of the variance (7–11%) in alcohol consumption for SE Asian males born in North America, although the *ALDH2* polymorphism predicted two-thirds of the alcohol consumption and excessive alcohol use. Also, there are large differences in the prevalence of alcohol dependence in populations that have similar *ALDH2* allele frequencies. The frequencies of the *ADH2* and *ALDH2* variants are similar, but the prevalence of alcoholism is 2.9% in Taiwan and and 17.2% in

Korea, suggesting that there are interactions with other genetic and environmental factors (54).

The *ADH2* genotype has been shown to be an independent factor contributing to the risk of alcoholism (50) and acts additively with the ALDH2-2 variant (Table 99.1). A pilot study found that the ADH2-2 allele accounts for 20% to 30% of the alcohol intake variance between two groups of light-drinking and heavy-drinking Israeli Jews, and suggests that the relatively high frequency of the ADH2-2 allele might contribute to the generally perceived lower levels of alcohol consumption and increased sensitivity to alcohol observed among Jews (55 ,56).

ALDH2	*ADH2*	Protective Factor
*2/*2	*2/*2, *1/*2, or *1/*1	High
*2/*1	*2/*2 or *2/*1	
	*1/*1	
*1/*1	*2/*2	
	*2/*1	
	*1/*1	None

ADH, alcohol dehydrogenase; ALDH, aldehyde dehydrogenase.

TABLE 99.1. THE RELATIONSHIP OF ALDH2 AND ADH2 GENOTYPES AND THE RISK FOR ALCOHOLISM IN SOUTHEAST ASIANS (48)

The ADH2-3 allele is a high activity variant identified in approximately 25% of African-Americans, which increases the rate of ethanol metabolism (57). In one report, the presence of ADH2-3 in African-American mothers drinking during pregnancy was associated with a lower rate of alcohol-related birth defects (58).

DETERMINING THE GENETIC BASIS OF VULNERABILITY TO ALCOHOLISM

Part of "99 - Molecular and Cellular Genetics of Alcohol Addiction "

Genetic analysis of complex disorders is complicated by the fact that any single gene is likely to account for only a small part of the variance. To detect subtle genetic effects, large samples are needed. The four methods (59) most widely used are (a) linkage analysis: the inheritance pattern of phenotypes and genotypes are elucidated in pedigrees; (b) allele sharing methods: affected relatives are compared to detect excess genotype sharing; (c) association (case-control) studies: unrelated affected and unaffected individuals are compared; (d) analysis of inbred, transgenic, and gene-knockout animals (principally mice and rats).

Linkage analysis has been successfully employed in finding major genes in diseases such as Huntington's disease, but it has limited power to detect genes of modest effect (60). An alternative approach is to employ an endophenotype as a trait specific marker, e.g., the low-voltage alpha EEG trait that is associated with alcoholism and anxiety disorders (15). Such endophenotypes may be influenced by variation at fewer genes. The brain is relatively inaccessible, so it has been more difficult to obtain biochemical and physiologic measures that identify more specific genetic subtypes as was done decades ago for certain other common, broadly defined diseases (e.g., anemia). Association studies of candidate genes, although laborious, have far greater power for untangling the genetics of complex diseases than linkage analysis (60). New approaches, including TDT (transmission disequilibrium test) analysis (61 ,62) and ethnic matching using informative markers (63), have been used to avoid the problems of population stratification, i.e., ethnic mismatching of cases and controls.

Rodent Models: Quantitative Trait Locus Analyses

Rodent strains are inbred to produce large numbers of genetically identical animals that can be maintained under controlled environmental conditions and intercrossed when required. The neurobiology of reinforcement and reward was elucidated largely through behavioral and anatomic studies in rodents. Several behavioral traits in rodents are continuous and polygenic. Each of the multiple genes responsible for such quantitative traits is termed a quantitative trait locus (QTL). Several QTLs may influence one trait, one QTL may affect several traits, and these QTLs can be individually mapped, with the ultimate goal being to identify genes that play a role in human addiction to alcohol. The knockout of an individual gene in the mouse can reveal a potential role for the equivalent (homologous) gene in the human.

Several QTLs for alcohol-associated behaviors have been identified in mice by using recombinant inbred strains that differ widely with respect to many alcohol-related traits, and by follow-up studies using interstrain crosses and congenics. The behaviors for which QTLs have been mapped include acute and chronic alcohol withdrawal sensitivity, alcohol consumption, and alcohol-associated hypothermia. Buck et al. (64) have shown that 68% of the genetic variability for genes influencing alcohol withdrawal severity can be assigned to QTLs on mouse chromosomes 1, 4, and 11. The locus on chromosome 11 accounted for 12% of the genetic variability in withdrawal liability and was near the genes for the γ_2, α_1, and α_6 subunits of $GABA_A$ receptors. Furthermore, a γ_2 subunit polymorphism has now been found to be genetically correlated with alcohol withdrawal severity in mice (65). QTLs for alcohol-induced hypothermia, alcohol consumption, and certain responses to amphetamine and morphine are located on chromosome 1 (66) and also on chromosome 9 near the serotonin $5\text{-}HT_{1B}$ receptor and dopamine D2 receptor genes (67). These genetic interrelationships between different phenotypes indicate that the same genes influence different alcohol-associated behaviors, that several genes may affect one phenotype, and that some loci

for drug abuse are not drug specific. This is also evident in studies of mice in which specific genes that map to the QTL regions or candidate genes located elsewhere in the mouse genome have been knocked out. 5-HT_{1B} knockout mice drink twice as much ethanol, are less intoxicated, and show enhanced aggression compared with normal mice (68). On chronic exposure to alcohol they show less evidence of tolerance. These mice also work harder to self-administer cocaine and show an increased locomotor response, behaving as if already sensitized to the drug (69).

The dopamine-related genes that have been knocked out in mice are the DRD4 dopamine receptor, which is located at the site of one of the alcohol QTLs, the D1 and D2 dopamine receptors, the dopamine transporter, and VMAT2 (the vesicular transporter). The DRD4 knockout mice appear to be supersensitive to ethanol, cocaine, and amphetamine (70). Mice lacking the D2 receptor consume less alcohol than normal mice (71). VMAT2 knockout mice have a pronounced supersensitivity to cocaine, amphetamine, and ethanol (72).

For morphine preference, three loci identified on murine chromosomes 1, 6, and 10 are apparently responsible for nearly 85% of the genetic variance in this trait (73). The μ opioid receptor gene is located at the site of the largest QTL, and this QTL also affects consumption of alcohol and cocaine (73).

QTL analysis in rodents has limitations. Frequently the result is a large genomic region of interest rather than a gene. There may be functional compensation in knockout mice during development. Mice and humans may not share the same functional variants at the same allele; for example, the ALDH2-2 allele is not even present in all human populations and is not found in mice. Another problem is that behaviors in mice cannot be freely extrapolated to humans; for example alcohol preference in mice may well be taste preference (74). However, QTL analyses in mice are useful for the identification of candidate genes and gene regions.

GENETICS OF REWARD NEUROCIRCUITS, AND NEUROCIRCUITS REGULATING IMPULSE CONTROL

Part of "99 - Molecular and Cellular Genetics of Alcohol Addiction "

Candidate Gene Approach: Case-Control Association Studies

A logical approach to understanding vulnerability to alcohol addiction is to look directly for variants in genes involved in neurotransmitter pathways implicated in ethanol use. Of particular interest is the reward pathway, incorporating serotoninergic, GABAergic, dopaminergic, opioid, and glutamatergic neurotransmission, and the largely serotoninergic impulse-control pathway. Genes for neurotransmitter metabolizing enzymes, transporters, and receptors are good candidates. Because of the complexity of causation of alcoholism, any genetic determinants of vulnerability to alcoholism and sensitivity to alcohol's effects are likely to be subtle.

Serotonin

Serotonin is involved in behavioral inhibition and is a target for the pharmacologic treatment of alcoholism. Selective serotonin reuptake inhibitors play a limited role in modifying craving for alcohol and also modify other comorbid behaviors such as depression and anxiety.

Pathologically low levels of serotonin may contribute to impulsivity and ASPD; for example, a group of criminal, alcoholic Finns was shown to have low cerebrospinal fluid (CSF) 5-hydroxyindolacetic acid (5-HIAA), the lowest levels being found in those who had committed impulsive crimes (75). These are the alcoholics who would be most likely to have a serotonin gene variant affecting function.

Serotonin Transporter

The availability of brainstem serotonin transporter, measured by (I-123) β-CIT and single photon emission computed tomography, has been found to be significantly reduced in alcoholics, and correlated with ratings of depression and anxiety during withdrawal (76). A functional polymorphism, 5-HTTLPR, in the serotonin transporter promoter region (77) has been associated fairly consistently with anxiety/dysphoria (77 ,78). Several association analyses have shown that the s-allele, which reduces transcriptional efficiency, is increased in French alcoholics (79), severely affected German alcoholics (80), and early-onset, violent Finnish alcoholics with ASPD (81). However, neither linkage nor association for the s-allele was found in a family-based TDT analysis of U.S. alcoholics from the COGA (Collaborative Study on the Genetics of Alcoholism) data set, some with withdrawal symptoms (82). A Japanese association study of alcoholics with withdrawal seizures was also negative (83), and in a small study the long allele was found to be associated with reduced sensitivity to alcohol, i.e., with individuals who may be more vulnerable to developing alcoholism (84). Population stratification may be a problem with these association studies as allele frequencies have been shown to vary in European-American, African-American, and Japanese populations (85).

Serotonin-Metabolizing Enzymes

A tryptophan hydroxylase (TPH) intron variant that affects splicing is associated with reduced 5-HIAA and suicidality in impulsive alcoholics (86 ,87).

Serotonin Receptors

Several serotonin receptors are known to be abundant in the NAC: 5-HT_{1B}, 5-HT_{2C}, 5-HT_3, 5-HT_4, and 5-HT_6. There are as yet few published studies in which these serotonin receptors have been genotyped in humans.

Studies in rats suggest that activation of 5-HT_{1B} receptors

in the NAC may be inhibitory on the behavioral effects of elevated mesolimbic dopamine transmission (88) by primarily modulating the activity of glutamatergic hippocampo-accumbens pathways and only secondarily altering NAC DA levels (89). In a large sib-pair linkage analysis of Finnish alcoholic criminal offenders, significant evidence of linkage and association of antisocial alcoholism to *HTR1B G861C* was found, and this was also observed in a Southwest American Indian tribe, suggesting that a locus predisposing to antisocial alcoholism may be linked to *HTR1B* at 6q13-15 (90).

Activation of 5-HT_{2C} receptors inhibits DA release in the NAC (91). However, the functional Cys23Ser polymorphism does not appear to be associated with alcohol dependence (92).

5-HT_3 receptors may be involved in several facets of alcohol-seeking behavior, alcohol intoxication, and addiction (93); however, at the present time there are no published studies on the role of 5-HT_3 variants in alcoholics.

GABA Receptors

Cross-tolerance of benzodiazepines with ethanol and their effectiveness in treating alcohol withdrawal suggests that $GABA_A$ receptors play a key role in alcohol's effects. The $GABA_A$ receptor exists as a number of subtypes that are composed of combinations of at least 14 different subunits. Preliminary studies indicate that the Pro385Ser substitution in $GABA_A\alpha6$ may play a role in benzodiazepine sensitivity (94) and may be associated with a lower level of response to the acute effects of alcohol (84). Several studies have found associations between $GABA_A\alpha6$ and alcohol dependence (84 ,95) and antisocial alcoholism (96). Differences in allele frequencies between alcoholics and controls have been found in $GABA_A\alpha3$ but not in a $GABA_A\alpha1$ (97). There are positive (95) and negative (96) association studies for $GABA_A\beta2$ and alcohol dependence.

Dopamine

Dopamine is involved in arousal, reward, and motivation. Structural variants, some altering function or level of expression of gene product, have been found in the dopamine transporter (DAT) and in several dopamine receptor genes (*DRD2, DRD3*, and *DRD4*). At the present time, no role for variation in dopamine-related genes in alcoholism has been consistently demonstrated. The controversial association of a *DRD2* dopamine receptor polymorphism with alcoholism has been replicated in some case-control studies but not in numerous others (98), nor was it supported in two very large family linkage studies (99), one of which used the functionally impaired 311Cys variant. These family studies were not subject to the potential problems of ethnic stratification inherent in some of the *DRD2* case-control association studies (100). Two recently discovered transcriptionally significant promoter polymorphisms offer promising tools for understanding the roles of *DRD2* (101) and DAT (102) in alcoholism.

Opioid Receptors

Three endogenous opioid receptors (μ, δ, and κ) are the targets of the major opioid peptides (β-endorphin, enkephalins, and dynorphins, respectively). The rewarding properties of μ- and δ-receptor ligands are brought about by activation of the mesolimbic dopamine system. Activation of κ receptors is dysphoric. Human and animal studies implicate the opioid system, particularly the μ opioid receptor, in both initial sensitivity or response to alcohol, and in the rewarding or reinforcing effects of alcohol. Subjects at high risk for alcoholism have been shown to have lower basal plasma β-endorphin levels but a more pronounced release after exposure to ethanol (103). Some studies have found associations of the gene encoding the μ opioid receptor, OPRM1, with some form of drug dependence (104). However, association and sib-pair linkage analyses of Asn40Asp, a μ opioid receptor polymorphism, in 100 U.S. Caucasians, 324 Finnish Caucasians, and 367 American Indians showed no significant association, even though the study had 80% power to detect a small to moderate effect of OPRM1 variation on alcohol dependence (105). Findings were also negative from a large study of German alcoholics (106) and a study of 891 drug- or alcohol-dependent subjects from African-American, European-American, and Hispanic origins (107).

NMDA Receptors

At the present time there are no published studies on the role of NMDA variants in alcoholism. Such studies would be of interest because of the role of NMDA receptors in reward, intoxication, and withdrawal, and potentially for the pharmacogenetics of acamprosate.

Nicotinic Receptors

Two classes of neuronal nicotinic acetylcholine receptor (nAchR) subunits (eight α and three β) have been identified (108). The most abundant receptor subtype in brain is composed of β_2 and α_4 subunits (109). Several lines of evidence, including drug preference in knockout mice (110), suggest that the nAchR β_2 subunit gene (*CHRNB2*) is involved in the reinforcing properties of nicotine. However, none of the *CHRNB2* variants found so far in humans has been associated with nicotine dependence (109). This gene has yet to be genotyped in alcoholics.

Whole Genome Linkage Scans

The power of the genetic linkage analysis approach has been greatly improved by the recent collection of very large, carefully

phenotyped, family and population data sets such as that of COGA, a multicenter, family genetic study and the National Institute on Alcohol Abuse and Alcoholism (NIAAA) Southwestern Indian family sample. Two studies utilizing these data sets have detected evidence of linkage of alcoholism to several chromosomal regions, with some convergent findings (111 ,112). In the Southwestern American Indian population isolate, suggestive evidence was found for linkage of alcohol dependence to the ADH region on chromosome 4q and to two regions harboring neurogenetic candidate genes. Those locations were chromosome 11p, in close proximity to the *DRD4* dopamine receptor and tyrosine hydroxylase gene (the rate-limiting enzyme in dopamine biosynthesis), and chromosome 4p, near a GABA receptor gene cluster (111). In the COGA families, which derive from the cosmopolitan, diverse population of the United States, modest evidence was also found of linkage to the ADH region on 4q. There was also evidence of linkage to chromosomes 1 and 7, and to chromosome 2 at the location of the opioid receptor gene (112). In addition, there was evidence of linkage of the P300 event-related potential alcoholism-associated trait to chromosome 6q in the region of a glutamate receptor (GRIK2), and to chromosome 2q near the location of two acetylcholine receptors (113).

DISCUSSION

Part of "99 - Molecular and Cellular Genetics of Alcohol Addiction "

There is abundant evidence of substantial heritability (0.5 to 0.6) of both broad and narrow definitions of alcoholism in men and women. Although the quantitative role of genetic risk factors is approximately equal in both sexes, the lower concordance of opposite-sex pairs suggests some gender-specific action of genes.

Genetic vulnerability to alcoholism may originate in personality or psychiatric traits that predispose to alcohol-seeking behavior, differential response to the effects of alcohol, or differential predisposition to addiction. Studies of the co-inheritance of alcoholism and other psychiatric disorders are beginning to emerge. There is evidence of co-inheritance of ASPD and alcoholism in men. Although alcoholism is associated with anxiety and affective disorders in women, it has been shown that 75% of the genetic variance of alcoholism is disease specific. Alcohol, nicotine, and other substance abuse disorders have been noted to co-occur, yet recent studies have shown that the transmission of alcoholism is largely independent of that of other drugs of abuse with the exception of nicotine, with which there is a substantial (0.68) genetic correlation.

The mesolimbic dopamine system is fundamental to the neurobiology of addiction. We are only at the very beginning stages of understanding the complexities of ethanol's interactions with this system. Enhanced GABA, glutamate, dopaminergic, opioid peptide, and serotoninergic neurotransmission have been associated with acute ethanol administration and potentially mediate some of alcohol's reinforcing effects. Genetic variants in the serotoninergic system—5-HT_{1B}, TPH, and possibly 5-HTTLPR—have been associated with alcoholism, particularly in males with antisocial, impulsive features. Several studies have found associations between $GABA_A\alpha 6$ and alcohol dependence. There have been no conclusive genetic findings in the dopaminergic or opioid systems to date.

Future studies are likely to focus on finding genetic variants in the neuroreceptors and ion channels that have been demonstrated to be affected by ethanol, including $GABA_A$ receptors, NMDA receptors, non-NMDA glutamate receptors, 5-HT_3 receptors, voltage-gated calcium channels, and neuronal nACh receptors. Of particular interest will be functional genetic variants that are directly capable of altering reward, tolerance, and withdrawal, thereby predisposing individuals to addiction to alcohol.

Ethanol Abuse, Dependence, and Withdrawal: Neurobiology and Clinical Implications

John H. Krystal

Boris Tabakoff

John H. Krystal: Department of Psychiatry, Yale University School of Medicine, VA Alcohol Research Center, VA Connecticut Healthcare System, West Haven, Connecticut.

Boris Tabakoff: Department of Pharmacology, University of Colorado School of Medicine, Denver, Colorado.

Ethanol produces a striking array of behavioral effects in humans that are dependent on the dose of ethanol administered, whether ethanol levels are rising or falling, and the rate of change of ethanol levels (1). The euphoric, stimulant, and anxiolytic effects of ethanol contribute to its wide recreational use, whereas its sedative effects contribute to its consumption as a nonprescription hypnotic. Yet, at intoxicating doses, ethanol clouds memory and judgment (2), slows information processing and reaction time (3), impairs coordination (4), and disinhibits impulsive or aggressive behavior (5). Perhaps, then, it is not surprising that some of the most damaging consequences of ethanol abuse reflect the impact of ethanol intoxication on behaviors, such as driving, that place a high demand on these cognitive functions (6).

With chronic administration, ethanol produces both adaptation and neurotoxicity in the brain, accounting for tolerance and dependence. The ethanol withdrawal syndrome (7) includes anxiety, insomnia, and symptoms of sympathetic nervous system arousal. With more severe levels of dependence and repeated episodes of withdrawal, abstinence may be associated with substantial sympathetic arousal, agitation, perceptual changes, confusion, and seizures. These symptoms may emerge together in the context of delirium tremens, a potentially life-threatening complication of ethanol dependence that generally develops within the initial week of sobriety. Another syndrome, alcoholic hallucinosis, may develop during any phase of the cycle of intoxication and withdrawal. It is associated with persisting hallucinations that may or may not remit with extended sobriety.

Acute and protracted abstinence are important contexts for treatment to ensure the medical safety of recovering patients and to prevent their relapse to ethanol use. Although the most severe consequences of withdrawal appear during the initial week of sobriety, protracted components of withdrawal persist for many months (8). Protracted withdrawal symptoms include insomnia, anergia, and depressed mood. The effort to rid oneself of withdrawal symptoms may be an important motivator for relapse to ethanol use. As will be reviewed later, this phase of recovery is also associated with gains in cognitive function, cortical activity, and brain structure.

Nutritional deficits complicate the natural history of alcoholism (9). If thiamine-deficient individuals ingest glucose before thiamine repletion, the resulting demand on thiamine pyrophosphate-dependent metabolic processes compromises neuronal metabolic functions and may produce cell death associated with the Wernicke-Korsakoff syndrome (10). This eponym refers to a constellation of learning and memory impairment, psychosis, and motor findings.

This chapter provides a brief and selective overview of the basic and clinical neuroscience of alcoholism. Ethanol is now known to have multiple specific actions in the brain that contrast with the historical focus on its nonspecific perturbation of neuronal membrane bulk lipids (11 ,12). This chapter discusses the acute and chronic effects of ethanol at its protein targets in the brain, and the neural circuitry of human alcoholism that has become the focus of structural and functional neuroimaging studies.

MOLECULAR TARGETS OF THE ACTION OF ETHANOL: RELEVANCE TO INTOXICATION AND DEPENDENCE

Part of "100 - Ethanol Abuse, Dependence, and Withdrawal: Neurobiology and Clinical Implications "

Amino Acid Neurotransmission

Glutamate

Glutamate Receptors as an Ethanol Target in the Brain

Glutamate is the major excitatory neurotransmitter in the central nervous system (CNS) and glutamate utilizes both

ionotropic and metabotropic receptors to transduce its signal. The ionotropic receptors, receptor-gated ion channels, include the *N*-methyl-D-aspartate (NMDA) α-amino-3-hydroxy-5-methyl-4-isoxazoleproprionate (AMPA), and kainate receptors (13). NMDA receptors are gated by membrane potential and the simultaneous binding of both glycine and glutamate (14). Ethanol at concentrations as low as 5 mM (20 mg%) inhibits ion flux through the NMDA receptor-gated ion channels, making NMDA receptors one of the highest affinity ethanol targets in the brain (Fig. 100.1) (see ref. 15 for review). It shows lower affinity for AMPA and kainate glutamate receptors (15).

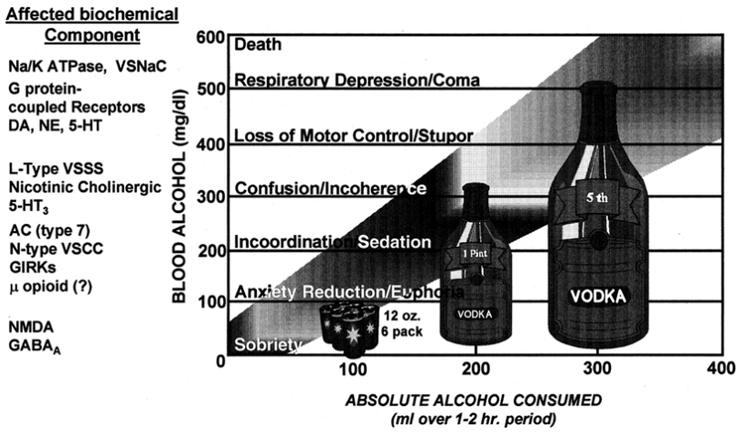

FIGURE 100.1. The relative potency of ethanol for its protein targets in the brain. Shown is the relationship between amounts of alcohol consumed and neurotransmission, neuroexcitatory components, and behavioral actions.

Ethanol effects on the NMDA receptor function are dependent on the concentration of glycine and the phosphorylation status of the receptor. In cultured cerebellar granule cells, ethanol lowered the NMDA receptor affinity for glycine, and ethanol effects were partially reversed by raising glycine levels (16). A protein kinase C (PKC)-mediated phosphorylation event may gate the effects of ethanol on glycine affinity at the NMDA receptor (16). Other protein kinases (e.g., tyrosine kinases such as Fyn and Src) may also play a role in ethanol's actions on the NMDA receptor (17).

Regional variations in NMDA receptor subunit composition contribute to distinctions in ethanol effects on NMDA receptor function across brain regions (see ref. 14 for review). Functional NMDA receptors are composed of an NR1 subunit, with at least eight splice variants, and one NR2 subunit from among the four known subtypes (NR2 A–D). The relative affinity of ethanol for NMDA receptor subtypes may be important to its dose-related effects in the brain (18), but this issue remains under intensive investigation (19).

The inhibition of NMDA receptor function by ethanol has direct neuroprotective consequences (20). NMDA antagonist effects of ethanol may influence its modulation of the release of other neurotransmitters (21 ,22), perhaps reflecting the capacity of low-dose NMDA antagonism to preferentially attenuate the activation of local inhibitory circuits (23).

The subjective effects of ethanol are tested in animals by measuring their ability to discriminate the effects of ethanol and other drugs. NMDA antagonists substitute for ethanol in these experiments, where they resemble the effects of higher doses of ethanol than ethanol doses that are most similar to the effects of γ-aminobutyric acid (GABA) agonists (24). Supporting the importance of the NMDA site, WSP (withdrawal seizure prone) and WSR (withdrawal seizure resistant) mice differ in their NMDA receptor density in several brain regions (25) and in their capacity to discriminate ethanol from other substances (26).

NMDA Receptor Adaptations with Ethanol Tolerance and Dependence

Multiple lines of evidence implicate NMDA receptor up-regulation as a mechanism contributing to acute ethanol withdrawal. Chronic ethanol administration up-regulates

NMDA receptor number, particularly in the cerebral cortex and hippocampus (27). During acute ethanol withdrawal, NMDA receptor increases are associated with tremors, anxiety, ataxia, and convulsions (27). Similarly, the increased hippocampal NMDA receptor density in WSP mice is related to their increased expression of withdrawal seizures relative to WSR mice (25). Additionally, NMDA antagonists given during withdrawal suppress withdrawal seizures (28). Lastly coadministration of the ganglioside GM_1 and ethanol prevents NMDA receptor up-regulation and the display of withdrawal seizures (29).

NMDA receptor up-regulation is subunit specific. In cultured cells and whole animals, chronic ethanol administration increases the levels of the NR2A and NR2B protein subunits and their subunit messenger RNA (mRNA) levels (30). Some, but not all, studies also suggest that NR1 subunit protein level increases may be accompanied by increases in NR1 mRNA levels (31). In cultured cells, the increases in NMDA receptor subunit proteins are associated with increased NMDA receptor function (32).

The consequences of NMDA receptor up-regulation during dependence are compounded by increases in glutamate release associated with the initiation of abstinence (33). Perhaps as a result, ethanol withdrawal is associated with seizures and neurotoxicity (see ref. 34 for review).

Glutamate: Clinical Correlates

Glutamate and the Complex Discriminative Stimulus Effects of Ethanol

As is seen in Fig. 100.2 , the NMDA antagonist, ketamine, produced dose-related ethanol-like effects in recently detoxified alcoholic patients (35). As with the preclinical studies (24), both the intensity and the degree of similarity of the ethanol-like effects of ketamine were greater at a higher subanesthetic dose (0.5 mg/kg) than at 0.1 mg/kg. Ketamine did not stimulate ethanol craving in patients, although craving was associated with the ethanol-like effects of another NMDA antagonist dextromethorphan (36).

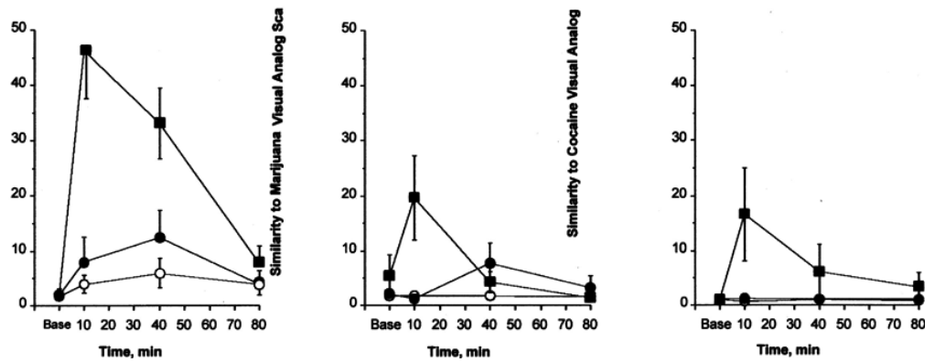

FIGURE 100.2. Similarity of the effects of placebo (*open circles*), ketamine 0.1 mg/kg (*solid circles*), and ketamine 0.5 mg/kg (*solid squares*) to ethanol (**left**), marijuana (**middle**), and cocaine (**right**) in alcoholic patients (n = 20). Values are expressed as mean ± standard error of the mean (SEM). Ketamine effects were significantly more similar to ethanol than both marijuana and cocaine by post-hoc contrast (F1 = 6.7, p = .02). (Data are from ref. 70.)

Clinical studies examining the interactive effects of ketamine and other drugs may provide insights into the NMDA antagonist component of ethanol effects in the brain. The NMDA antagonist-induced euphoria does not yet appear dopamine dependent. For example, the euphoric properties of ketamine are not blocked by haloperidol pretreatment (37) or markedly potentiated by amphetamine pretreatment (38). These findings parallel clinical findings describing the lack of interaction of ethanol and amphetamine (39). In contrast, the euphoric effects of ketamine (40), like ethanol (41), are attenuated by pretreatment with the μ opiate receptor antagonist naltrexone. Ethanol may possess actions at other brain targets that attenuate the dysphoric properties arising from its blockade of NMDA receptors including the facilitation of $GABA_A$ receptor function (42) or blockade of voltage-gated cation channels (43 ,44).

Glutamatergic Dysregulation in Ethanol Dependent Patients: Relationship to the Familial Risk to Develop Alcoholism

Postmortem studies of brain tissue from ethanol-dependent individuals suggest that the B_{max} or K_d of NMDA receptors are increased in cortical structures alcoholics (45 ,46). *In vivo*, ethanol withdrawal increases cerebrospinal fluid (CSF) glutamate levels. The combination of increased glutamate release during withdrawal and NMDA receptor up-regulation promotes withdrawal-related neural plasticity and neurotoxicity (47). With repeated episodes of withdrawal, patients show increased seizure risk (48) and hyperreflexia (49).

NMDA receptor function in recovering ethanol-dependent

patients also may shift the reward valence of the NMDA antagonist component of ethanol response from dysphoria to euphoria, promoting further alcohol use. Recently detoxified ethanol-dependent patients show reductions in their sensitivity to the perceptual, mood, and cognitive effects of ketamine (50) and the glycine-B partial agonist D-cycloserine (51). In contrast, preliminary data suggest that these patients exhibited preserved euphoric responses to ketamine relative to a healthy comparison group (Krystal, unpublished data). Thus, NMDA receptor alterations associated with ethanol dependence might contribute to relapse to ethanol use in two ways: (a) by contributing to the signs and symptoms of ethanol withdrawal, and (b) by enhancing the rewarding properties or reducing the dysphoric properties of ethanol during the early phases of relapse to ethanol use.

Healthy individuals at increased familial risk for developing alcoholism, relative to a “family history negative” group, show reductions in the dysphoric effects of NMDA receptor antagonists resembling the changes seen in ethanol dependent patients (52). Thus, inherited differences in NMDA receptor function may contribute to alterations in the set point for sensitivity to ethanol effects that promote the development of the abuse of ethanol. Further research is needed to clarify the impact of ethanol dependence and alcoholism vulnerability on glutamatergic function.

The mechanism through which ketamine sensitivity is altered in individuals at increased familial risk for alcoholism is not yet clear. In individuals without a family history of alcoholism, antagonism of voltage-gated cation channels clearly reduces the dysphoric effects of ketamine and may enhance its euphoric effects (43 ,44); i.e., these pretreatments may produce changes in the reward valence of ketamine effects that are similar to the alterations associated with a family history of ethanol dependence. The genes underlying altered ketamine response in individuals at risk for alcoholism are not yet known.

Acamprosate: A Putative Glutamatergic Pharmacotherapy for Alcoholism

Acamprosate is a homotaurine derivative without ethanol-like behavioral effects that reduces alcohol consumption in animals (53). This drug is a promising agent for treating alcoholism (54 ,55). It reduces NMDA receptor function, contributing to its capacity to suppress ethanol withdrawal (56). However, it also has promotes some NMDA receptor-mediated effects (57). The site of action of acamprosate is not known and the mechanisms related to its efficacy are not fully understood.

GABA

GABA Receptors as Targets for Ethanol Action

Ethanol produces sedative-hypnotic effects that resemble other drugs that facilitate $GABA_A$ receptor function, particularly muscimol, benzodiazepines, and barbiturates (15). The similarity between the behavioral effects of GABA agonists and ethanol is dose-dependent, with the greatest similarity between these drug classes observed with relatively low training doses of ethanol (15).

Ethanol has effects at the $GABA_A$ receptor at concentrations of 10 to 100 mM. In one study, ethanol acted similarly to benzodiazepines by potentiating the effects of GABA (58), whereas in another study ethanol resembled barbiturates by increasing the entry of chloride without the addition of GABA (59). The microsac preparation employed in these studies, however, would be expected to contain certain sufficient amounts of endogenous GABA to influence their interpretation.

Ethanol actions at $GABA_A$ receptors vary across brain regions and may be related to the differential expression of $GABA_A$ receptor subunits (60). This receptor is composed of five subunits that associate to form a Cl^- channel. Subunit families (e.g., α, ß, γ, δ) and isoforms within each family (e.g., α_1–α_6) have been identified (61). Variation in subunit composition imparts functional distinctions in $GABA_A$ receptor subtypes relevant to ethanol action (61). For example, isoforms of the γ subunit [i.e., α_{2S} or α_{2L} (62)] that differ in their sensitivity to PKC isoforms differ in their sensitivity to ethanol (63). However, studies now question the importance of these particular $GABA_A$ receptor subunits (64). Some of these differences between studies may reflect the importance of a particular PKC isoform, PKC-ε.

The adenylyl cyclase signaling system and protein kinase A (PKA) also modulate ethanol’s actions at $GABA_A$ receptors. Ethanol potentiates GABA inhibition of cerebellar Purkinje cell firing, but only when there is concomitant stimulation of ß-adrenergic receptors (65) and activation of PKA (66).

Chronic Actions of Ethanol on $GABA_A$ Receptor Function

Changes in the levels of $GABA_A$ receptor subunits occur in animals treated chronically with ethanol (67). It consistently decreases the mRNA and protein for the α_1 subunit of the $GABA_A$ receptor, whereas other subunits may show no change or even increases (67). *In vitro* studies form ethanol-treated animals demonstrated a reduced ability of ethanol to potentiate GABA-mediated chloride flux, suggestive of the development of ethanol tolerance (58). *In vivo*, hyperexcitability, fear behaviors, and convulsions during acute ethanol withdrawal may reflect decreases in GABAergic neurotransmission (68). WSP and WSR mice, noted earlier to differ in NMDA receptor regulation, also differ in predicted directions with respect to their $GABA_A$ receptor characteristics and their vulnerability to withdrawal seizures (69).

GABA: Clinical Correlates

GABA Systems and Alcoholism Vulnerability

To date, the genes underlying the GABA-related vulnerability for

alcoholism are unknown. A haplotype relative-risk study did not find evidence associating either the α_1- or α_3-subunit genes with alcoholism, although suggestive data supporting further study was obtained for the latter gene in an association study (70). The strongest tie between $GABA_A$ receptor involvement and the vulnerability to alcoholism has come from studies evaluating ethanol and benzodiazepine effects in populations at high-risk for developing alcoholism. Most (71 ,72), but not all (73), studies found that male offspring of alcoholics have reduced sensitivity to the cognitive, behavioral, and motor effects of both benzodiazepines and ethanol. Similarly, individuals at risk for alcoholism exhibited blunted cerebellar metabolic inhibition, but not cortical metabolic inhibition, following a dose of lorazepam (74). However, there may be greater sensitivity to or preference for the euphoric effects of benzodiazepines in this population (71), although these effects are not uniformly replicated (75). The rewarding effects of alcohol and benzodiazepines in humans may be increased in anxious individuals, who tend to experience more pronounced anxiolytic effects of these drugs (76).

Clinical Evidence of GABA Dysregulation in Alcoholism

GABAergic regulation differs in alcoholic and nonalcoholic populations. GABA levels are reduced in plasma, CSF, and brain in recently detoxified alcoholics during the first month of detoxification (77 ,78). In patients, low plasma GABA levels predicted relapse (79), perhaps because low GABA levels were associated with protracted abstinence symptoms. These changes may in part reflect ethanol dependence and withdrawal-related effects on the levels or function of enzymes regulating GABA synthesis and degradation (80).

Reductions in $GABA_A$ receptor binding in postmortem and antemortem neuroimaging studies may reflect the combined effects of vulnerability, ethanol dependence, and alcoholism-related neurotoxicity. Some postmortem studies found reductions in $GABA_A$/benzodiazepine (BZ) binding, but other studies had conflicting results (81 ,82 and 83). Variability between studies may reflect a compensatory up-regulation in BZ/$GABA_A$ binding that follows alcoholism-related neurotoxicity (84) or the failure to employ ligands that differentiate between subtypes of $GABA_A$ receptors. *In vivo*, positron emission tomography (PET) and single photon emission computed tomography (SPECT) neuroreceptor imaging has provided evidence of reductions in BZ binding (Fig. 100.3) (85 ,86). Neurotoxicity contributed to, but did not account for, reductions in BZ receptor binding in patients (87). Reductions in BZ binding may be consistent with evidence of reduced regional brain metabolic sensitivity to lorazepam in ethanol-dependent individuals (88). However, metabolic blunting did not rapidly recover with sobriety (89), raising the possibility that this deficit reflected genetic vulnerability or irreversible toxicity.

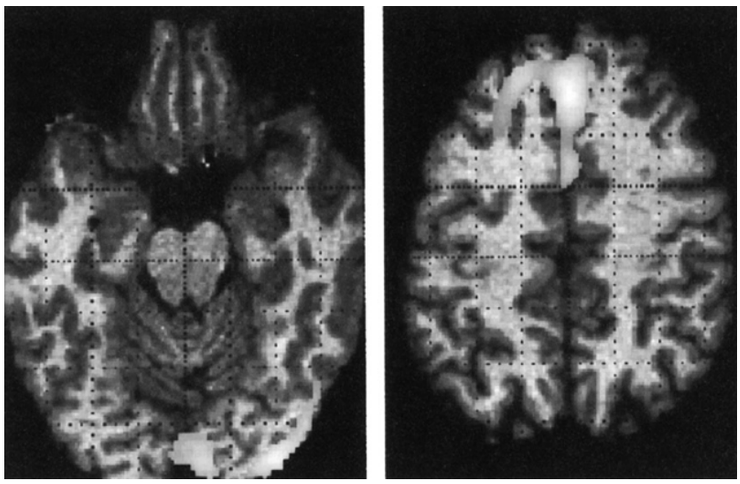

FIGURE 100.3. Transaxial slice of regions where benzodiazepine receptor distribution volume in alcoholic patients was significantly lower than in comparison subjects based on a statistical parametric mapping analysis (*yellow*). Single photon emission computed tomography (SPECT) data were superimposed on an MRI template. (From Abi-Dargham A, Krystal JH, Anjivel S, et al. Alterations of benzodiazepine receptors in type II alcoholics measured with SPECT and [123I]iomazenil. *Am J Psychiatry* 1998;155:1550–1555, with permission.) See color version of figure.

Psychopharmacologic studies also implicate GABA systems in withdrawal and relapse. Clearly, drugs facilitating $GABA_A$ receptor function including BZs, barbiturates, and anticonvulsants suppress acute ethanol withdrawal (90).

The BZ antagonist flumazenil may reduce ethanol intoxication in humans at doses greater than required to antagonize BZ effects (91). However, this drug does not produce ethanol withdrawal symptoms in ethanol-dependent individuals (92). It is not yet clear whether flumazenil exposure during ethanol withdrawal alters the course of recovery from ethanol dependence.

Neurosteroids

There is growing interest in the role of neuroactive intermediates in sex steroid synthesis and metabolism in alcoholism (93). Allopregnanolone, a coagonist of the steroid anesthetic site of the $GABA_A$ receptor, shares discriminative stimulus properties with ethanol and suppresses the ethanol abstinence syndrome in animals (94 ,95). Allopregnanolone also may potentiate the effects of ethanol (96). Allopregnanolone levels, like those of its precursor progesterone, vary markedly during the menstrual cycle. In the late luteal phase, drops in allopregnanolone levels may contribute to premenstrual mood disturbances (97) and increase the intensity of the discriminative stimulus properties of ethanol (98). These factors may increase ethanol consumption during this phase of the menstrual cycle (99). Supporting this view, higher allopregnanolone levels in the late luteal phase are associated with reduced triazolam self-administration in women (100). Thus, cyclical variation in neurosteroid levels may be a focus for future pharmacotherapies for female alcoholics.

Voltage-Sensitive Calcium Channels (VSCCs)

Preclinical Studies

In the brain, VSCCs play a major role in gating synaptic calcium influx and thereby modulating a range of calcium-dependent intracellular processes, membrane potential, and neurotransmitter release (101 ,102). There are six known VSCC classes: L-type (dihydropyridine-sensitive), N-type (“neuronal”), P-type (“Purkinje”), Q-type, R-type, and T-type (“transient”) channels (103 ,104).

Ethanol blocks L-type channels. Supporting this hypothesis, L-type VSCC antagonists show some ethanol-like effects in rats (105). Ethanol, at concentrations over 50 mM, inhibited [$^{45}Ca^{2+}$] influx in *in vitro* preparations (106). These studies suggested a wide range of L-type channel sensitivity to inhibition by ethanol, ranging from 10 to >200 mM, perhaps reflecting differences in channel subunit composition. The variability in L-type channel sensitivity to ethanol may depend on the characteristics of its subunits, post-translational modifications, and other regulatory mechanisms (107 ,108).

Chronic exposure to ethanol *in vivo* or cultured cells up-regulates L-type channels via a PKC-dependent mechanism (108). The up-regulation of L-type channels may contribute to signs of ethanol withdrawal (109 ,110), perhaps in part, by partially depolarizing cell membranes and recruiting NMDA receptors.

Electrophysiologic studies with transformed cells or pituitary neuron terminals also indicated that both N and T channels could be inhibited by an ethanol concentration of 50 mM (111 ,112). Recent evidence (113) also indicates that chronic administration of ethanol to mice up-regulates the number and function of N-type calcium channels.

VSCCs: Clinical Correlates

Ethanol actions at VSCCs may modulate its behavioral effects in humans. Despite the apparent similarities between the effects of ketamine and ethanol, ketamine produces more profound perceptual effects than ethanol at doses studied to date (114). However, the perceptual effects of ketamine are attenuated in humans by both the L-type VSCC antagonist nimodipine (44) and by lamotrigine, a drug with multiple effects on cation channels, including an antagonist action at P- and N-VSCCs (43). These studies suggest that the combination of NMDA and VSCC antagonist properties of ethanol enhance its tolerability.

The relevance of adaptations in VSCCs for the clinical phenomenology of ethanol withdrawal is not yet clear. L-channel antagonists may reduce the severity of some withdrawal symptoms, but they do not clearly suppress withdrawal seizures (115). However, the existing studies are limited by shortcomings in their study design and the selection of agents with limited CNS penetration.

Serotonin (5-HT)

5-HT systems contribute to the discriminative properties of ethanol in animals and humans. Ethanol facilitates that activity of $5\text{-}HT_{1B}$, $5\text{-}HT_{2C}$, and $5\text{-}HT_3$ receptors, and it shares discriminative stimulus properties with drugs acting at these sites (15 ,116).

The administration of the 5-HT partial agonist, *m*-chlorophenylpiperazine (mCPP), produces a euphoric effect that is perceived as ethanol-like in early-onset alcoholic patients (117 ,118 and 119). However, mCPP effects were not specifically similar to ethanol, i.e., the effects were similar to several substances of abuse (117). The two mCPP studies that administered mCPP intravenously also reported the induction of craving (117 ,119), whereas the study administering this drug orally found the opposite (120). mCPP also produced anxiety and irritability (117). The induction of dysphoria by this drug may have contributed to the elicitation of craving. Several studies report that the cortisol or prolactin response to mCPP is reduced in early onset patients (118 ,119 ,121). Further, the cerebral metabolic response to mCPP was reduced in early-onset alcoholics (122). In contrast, the euphoric responses to mCPP were enhanced in early-onset

patients relative to patients with a later onset of alcoholism (119).

The site of action of the ethanol-like effects of mCPP is not clear. Its partial 5-HT_{2C} agonist action appears to figure most prominently in its general discriminative stimulus effects (123). mCPP also has activity at 5-HT_3 (124) and 5-HT_7 receptors (125). Preliminary data suggested that ritanserin, a drug that blocks 5-HT (5-HT_{2A}, 5-HT_{2C}, 5-HT_6, 5-HT_7, 5-HT_{1D}) and dopamine (D2) receptors, reduced mCPP effects in healthy humans (125 ,126 ,127 ,128 and 129). The lack of specificity regarding the site of action of both mCPP and ritanserin limits the interpretation of the mechanisms underlying the ethanol-like and craving effects of mCPP. Also, the failure of ritanserin as an alcoholism pharmacotherapy (130) further raises concerns about the therapeutic applicability of the mCPP studies.

Molecular genetic studies further increased interest in genetic variation associated with the function of the 5-HT transporter and the regulation of central 5-HT turnover. Although the findings have not been replicated (131 ,132), two groups have associated 5-HT transporter alleles with reduced central 5-HT function or poor impulse control in alcoholic individuals (133 ,134). However, one study failed to find that alleles of the 5-HT transporter were associated with alcoholism (131). One hypothesis guiding these studies was that reduction in the efficacy or availability of synaptic 5-HT resulting from enhanced density or function of the 5-HT transporter would contribute to the constellation of behaviors associated with early-onset alcoholism (135 ,136). Alternatively, reduced density of 5-HT transporter binding in the brain might reflect reductions in the density of 5-HT terminals that might contribute to reduced central 5-HT function (137 ,138). Studies suggest that 5-HT transporter antagonists have limited efficacy for alcoholism and may make some early-onset patients worse (139 ,140). However, 5-HT–related vulnerability may be reflected in comorbid conditions. Ethanol-dependent patients with depression may benefit from treatment with 5-HT transporter antagonists (141), and patients with comorbid anxiety may benefit from the addition of the 5-HT_{1A} agonist buspirone (142).

Preclinical research suggests that ethanol stimulates 5-HT_3 receptors and that 5-HT_3 antagonists may attenuate the discriminative stimulus properties of ethanol and ethanol self-administration in animals (143). In humans, the 5-HT_3 antagonist odansetron did not robustly attenuate the discriminative stimulus effects of ethanol (144). However, a clinical trial employing odansetron found evidence of efficacy in early-onset ethanol-dependent patients (145).

Catecholamines

Dopamine

Dopamine-mediated neurotransmission has received much attention due to the involvement of dopamine in rewarding properties of ethanol and other drugs (146). Doses of ethanol that produce motor stimulation or ataxia increase the firing rate of midbrain dopamine neurons of unanesthetized rats (147). *In vitro*, ethanol added to brain slices in concentrations of 20 to 320 mM also stimulated the activity of ventral tegmental dopamine neurons (148).

Ethanol increases dopamine release in brain regions involved in the reinforcing effect of ethanol, such as the ventral tegmental area and nucleus accumbens (21). Further, rats bred to drink ethanol, compared to ethanol nonpreferring animals, show increased dopamine release associated with ethanol consumption (149). In addition, dopaminergic drugs alter ethanol self-administration in animals (150). Ethanol also has effects on dopamine release that may be mediated by opioid and nicotinic cholinergic systems (151 ,152). During ethanol withdrawal, there are reductions in dopamine release in the ventral striatum and in the nucleus accumbens (153). These decreases may contribute to withdrawal-related dysphoria. Ethanol, NMDA receptor antagonists, and L-type VSCC antagonists attenuated these dopamine deficits (153 ,154 and 155).

Norepinephrine

The locus coeruleus (LC) contains the cell bodies for the brain dorsal noradrenergic system (156). LC basal activity and activation are reduced by ethanol, an action that may contribute to sedative effects of ethanol (157 ,158). Ethanol also produced biphasic effects on norepinephrine turnover in the brain, with low doses increasing turnover and higher doses depressing turnover. The sensitivity of noradrenergic systems to ethanol effects varies among brain regions (159).

Catecholamines: Clinical Correlates

Modulation of catecholamine function modulates the stimulant and intoxicating effects of ethanol. Catecholamine synthesis inhibition, produced by α-methyl-para-tyrosine, modestly reduced ethanol intoxication in healthy humans (160). Similarly, dexamphetamine and methamphetamine pretreatment either had no effect or modestly potentiated ethanol intoxication in humans (39). In contrast, the α_2-adrenergic antagonist yohimbine potentiated the intoxicating effects of ethanol, but did not substantially alter the subjective sense of euphoria associated with intoxication (161). These data may conflict with other studies suggesting that ß-adrenergic stimulation attenuates ethanol intoxication, whereas ß-adrenergic blockade enhances intoxication (162 ,163). In recently detoxified early-onset alcohol-dependent patients, yohimbine effects have a low degree of similarity to ethanol effects and it reduced ethanol craving levels below baseline (117).

Several studies document reduced sensitivity of both dopamine and noradrenergic receptors in recently detoxified patients. Reduced sensitivity of dopamine receptors is suggested

by blunted growth hormone responses to dopamine agonists (164). These data are consistent with neuroimaging data, suggesting that the density of dopamine transporter binding is preserved but striatal D2 receptor density is decreased in ethanol-dependent patients (137 ,165). Down-regulation of postsynaptic α_2-adrenergic receptors is suggested by blunted growth hormone responses to clonidine and increased cortisol responses to yohimbine (121 ,166). In contrast, presynaptic noradrenergic activity appears to normalize rapidly following withdrawal, as measured by the CSF levels of the norepinephrine metabolite 3-methoxy-4-hydroxyphenethyleneglycol (MHPG) (167). Similarly, the presynaptic component of the noradrenergic response to yohimbine, reflected by plasma MHPG levels, is normal in patients sober for approximately 1 month (121).

Genetic studies relating catecholamine receptor alleles to the vulnerability to alcoholism have been a promising but controversial research strategy that has not yet born fruit. Initial studies suggested that D2 receptor alleles were associated with alcoholism (168 ,169). However, more definitive subsequent studies were negative (170). Reanalysis of published studies suggested that the positive findings reflected ethnic differences between the patient and control population (171). A subsequent study also suggested that D2 receptor alleles predicted an anticraving response to bromocriptine (172). However, studies using dopamine agonists to treat alcoholism have so far had limited promise (173 ,174). A tentative association between versions of the D4 receptor and novelty-seeking (175) was reported. However, this finding was not replicated, and studies of other dopamine receptor genes to alcoholism have been negative (133 ,176 ,177 ,178 ,179 ,180 ,181 and 182).

Opiates

Preclinical Studies

Ethanol modulates opioid neuropeptides in regionally specific ways. Acute ethanol administration to animals or ethanol perfusion of cultured pituitary or hypothalamic tissue increased (183) or had no effect on (184) tissue content or release of ß-endorphin. Ethanol also raised enkephalin and dynorphin levels in some brain regions in some studies (183 ,185). Chronic ethanol administration to rodents decreased pituitary ß-endorphin processing and reduced hypothalamic mRNA levels of the peptide precursors proopiomelanocortin (POMC) and prodynorphin (186 ,187).

In vitro, ethanol has a biphasic effect on µ opioid receptor binding. Ethanol concentrations, in the range of 10 to 25 mM, produce a small, but significant, increases in the binding of µ receptor ligands, whereas higher concentrations of ethanol inhibit ligand binding to the µ receptor (188). Under physiologic conditions, the µ receptor may be more sensitive to ethanol-induced inhibition than the δ receptor (189). Chronic ethanol administration reduces the density and function of striatal and accumbens µ opioid receptors (190). In contrast, chronic ethanol administration also modulates the binding and function of δ opioid receptors (191 ,192).

Opiates: Clinical Correlates

Naltrexone appears to reduce the rewarding effects of ethanol and ethanol consumption in social drinkers (41 ,193). Also, naltrexone maintenance appears to reduce the pleasurable aspects of ethanol consumed during treatment for alcoholism (194 ,195). This property appears to contribute to the capacity of opiate antagonists to reduce ethanol consumption in alcoholic patients (196 ,197).

The contributions of endogenous opiate systems to the rewarding effects of ethanol are further supported by evidence of abnormalities in these systems in alcoholic patients. However, the current data do not yield a clear picture of these abnormalities. Postmortem studies have described both increased µ-receptor density (198) and decreased µ-receptor affinity (199). CSF and plasma studies have also suggested the existence of reductions in ß-endorphin levels and ethanol-stimulated increases in plasma ß-endorphin levels (200 ,201). Naltrexone reductions in ethanol effects appear to be particularly evident in individuals at high risk for developing alcoholism (202). These data suggest a genetic component underlying the efficacy of naltrexone treatment for alcoholism. To date, there have been negative studies evaluating the association of the proenkephalin A gene and µ opiate receptor gene with alcoholism (203 ,204).

THE NEURAL CIRCUITRY OF ALCOHOL ABUSE AND DEPENDENCE: INSIGHTS FROM NEUROIMAGING AND NEUROPSYCHOLOGY

Part of "100 - Ethanol Abuse, Dependence, and Withdrawal: Neurobiology and Clinical Implications "

Structure (Computed Tomography, Magnetic Resonance Imaging, Postmortem)

Preclinical studies describe alcoholism-related neurotoxicity. These toxic effects appear to reflect a combination of the neurotoxic effects of ethanol, the interaction of ethanol with nutritional deficiencies, and the neurotoxic consequences of ethanol withdrawal (205). In rats, extended consumption of an ethanol diet did not produce anatomic deficits. However, ethanol withdrawal was associated with reductions in dendritic arborization and neuronal loss (206).

Brain shrinkage and neuronal loss has been documented in the brain tissue from individuals with alcoholism in both cortical and limbic regions (207). With respect to brain volume, postmortem research suggests that white matter loss appears to be more prominent than gray matter loss (208).

Neuronal loss appears to be primarily loss of pyramidal neurons, with relative sparing of interneurons (208). Another study was unable to replicate neuronal loss using uniform sampling and unbiased neuron counting methods (209). However, even when neurons are extant, they may exhibit structural deficits consistent with neurotoxicity (210). Generally, cortical and limbic brain shrinkage and neuronal loss may be more prominent in individuals whose alcohol dependence is complicated by Wernicke's encephalopathy and Korsakoff's psychosis (211). The Wernicke-Korsakoff syndrome has been associated with abnormalities in frontal cortex, as well as in several subcortical structures including the thalamus, hippocampus, mamillary bodies, and amygdala (10).

Structural neuroimaging studies are consistent with the findings in postmortem research. Cortical and limbic volumetric losses in ethanol-dependent patients have been described using computed axial tomography (CAT) and magnetic resonance imaging (MRI) (212 ,213). Gray and white matter volumetric losses are progressive with heavy drinking and are most prominent in frontal and temporal cortex (213 ,214 and 215). Ethanol-dependent individuals also show sulcal and ventricular enlargement (215), as well as hippocampal volume reduction (216). Reductions in the volume of the corpus callosum has also been described (217). Brain atrophy documented in structural neuroimaging studies is most more prominent with advancing age in adults (Fig. 100.4) (218). This age-related effect may reflect an age-related vulnerability

to ethanol in older populations, the interaction of aging processes, and the neurotoxicity of alcoholism, i.e., the “premature aging of the brain” (219), as well as the accumulated impact of long-standing alcoholism on older populations. Thus, atrophy may not be detectable in young healthy ethanol-dependent populations (220). In contrast, ethanol-dependent adolescents show hippocampal volumetric changes not seen in the studies of healthy young adults (221). The study in adolescents raises the possibility that adolescents show disruptive effects on brain development or an increased sensitivity to the neurotoxic effects of ethanol.

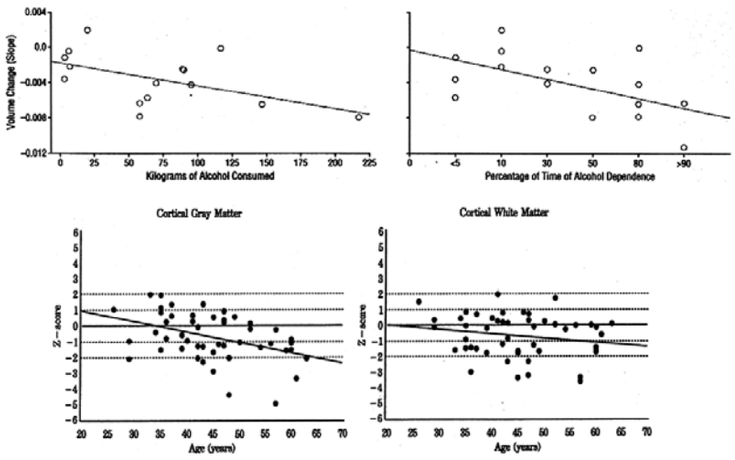

FIGURE 100.4. The **top two panels** illustrate the relationship between drinking severity and duration with gray and white matter volume loss in ethanol-dependent patients. The **bottom two panels** illustrate the interaction between alcoholism and volume loss with age. **Top figures**: The relationship between cortical gray matter rate of change and the amount of alcohol consumed during the follow-up period (*left*) (Spearman rho = -0.52, p = .04) and between the cortical gray matter rate of change and the estimated amount of time during past 5 years that alcoholic patients (group 1) met *Diagnostic and Statistical Manual of Mental Disorders*, third edition revised (DSM-III-R) criteria for alcohol dependence during the follow-up period (*right*) (Spearman rho = -0.53, p =.04). One alcoholic patient who reported 950 kg of alcohol consumption is omitted from the **left panel** so as not to distort scaling. The *darker circle* represents two patients with overlapping values. (From Pfefferbaum A, Sullivan EV, Rosenbloom MJ, et al. A controlled study of cortical gray matter and ventricular changes in alcoholic men over a 5-year interval. *Arch Gen Psychiatry* 1998;55:905–912.) **Bottom figures**: Cortical gray (*left*) and white matter (*right*) volume changes with age in ethanol-dependent patients. Data from individual ethanol-dependent patients are expressed as age-corrected Z-scores plotted as a function of age. (From Pfefferbaum A, Lim KO, Zipursky RB, et al. Brain gray and white matter volume loss accelerates with aging in chronic alcoholics: a quantitative MRI study. *Alcohol Clin Exp Res* 1992;16:1078–1089, with permission.)

Over the initial years of sobriety, there is recovery in the volumes of gray and white matter and reductions in sulcal and ventricular volume (222). There are differences in the rate of particular brain regions and particular tissue types with regard to the rate of recovery (222 ,223). The relatively rapid recovery of white matter volume with sobriety does not appear to reflect the return of tissue water displaced by ethanol, i.e., tissue rehydration (224).

Nutritional status, neurologic complications of ethanol withdrawal, and hepatic function appear to be related to findings in structural neuroimaging studies. Ethanol withdrawal seizures have been linked to neurotoxicity in these patients (225). Supporting this association, temporal cortex white matter loss was particularly associated with ethanol withdrawal seizures (226). Although cortical atrophy has been described in ethanol-dependent patients with good nutritional status (227), the Wernicke-Korsakoff syndrome and hepatic cirrhosis are generally associated with more prominent MRI volumetric deficits in cortical and limbic structures than ethanol-dependent patients who are otherwise healthy (228).

To date, there has been very little study of structural factors that might predispose individuals to develop alcoholism. One risk factor, antisocial personality disorder, appears to be independently associated with reductions in frontal cortex gray matter volume (229). Thus, the observation that frontal gray matter volume loss is present in young ethanol-dependent patients could reflect a combination of the vulnerability to alcoholism and atrophic effects of ethanol dependence (214).

Magnetic Resonance Spectroscopy

Magnetic resonance spectroscopy (MRS) has been applied to the evaluation of structural deficits in alcoholic patients in a limited fashion. Proton-MRS ([^{1}H]MRS) enables the measurement of N-acetyl-aspartate (NAA), a constituent of viable neurons. One study found reductions in the NAA/creatine ratio in the frontal cortex and cerebellum of ethanol-dependent patients (230 ,231). A phosphorus-MRS ([^{31}P]MRS) study found reductions in phosphodiester and phosphocreatine levels in cortical white matter in ethanol-dependent patients (232).

Findings From Functional Neuroimaging

Functional neuroimaging studies described reductions in cortical blood flow and metabolism associated with ethanol withdrawal. There is a limited understanding of the extent to which these studies also reflect genetic or alcohol-related structural abnormalities. Studies of ethanol intoxication suggest that it reduces cortical metabolism in humans (233). Clinical studies of withdrawal, mostly conducted during or following medications for detoxification, predominately describe reductions in regional cerebral perfusion or glucose metabolism in frontal and temporal cortex (234 ,235). More pronounced deficits were observed in patients with evidence of cortical atrophy based on structural neuroimaging (236), years of ethanol use, age (237), and multiple ethanol detoxifications (238). Cerebral perfusion and metabolic deficits may attenuate over the initial months of sobriety (237), and improvement may continue over several years (239). Antisocial personality (240), a risk factor for developing alcoholism, but not family history of alcoholism (241), was associated with more pronounced volumetric deficits.

Across several studies, reductions in resting frontal cortical perfusion and metabolic rate is associated with reduced performance on cognitive tests that engage the frontal cortex (242). Similarly, cerebellar metabolic deficits are associated with behavioral evidence of cerebellar dysfunction (236).

Behavioral Studies

The most profound cognitive deficits associated with alcoholism are the memory impairments arising from nutritional deficiency, as in Korsakoff syndrome (10), or hepatoxicity, as in hepatic encephalopathy (243). Although the most severe consequences of alcoholism for cognition may not reflect the direct toxic effects of ethanol on the brain, many patients exhibit cognitive deficits independent of these factors that reflect the combined impact of age, familial vulnerability for alcoholism, adaptations to ethanol effects on the brain, perhaps degree of liver injury (244), presence of comorbid depression, and ethanol-related neurotoxicity (245). Cognitive function is further compromised in those patients who continue to drink, due to the direct effects of ethanol on cognition (246).

The familial vulnerability to alcoholism and traits associated with that vulnerability are associated cognitive deficits and educational achievement (247). Although reductions in attention, planning, visual-spatial learning, and impulse control have been described in children of alcoholics (248), these findings are not universal (249). These findings may be largely accounted for by comorbid traits such as antisocial personality, similar to both MRI and event-related potential (ERP) findings in alcohol dependent patients (250 ,251). Consistent with this view, the familial risk for cognitive deficits associated with alcoholism is particularly associated with poor prognosis of the parent in alcoholism treatment,

a characteristic of antisocial alcoholism (252). Familial history of alcoholism appears to compound the negative consequences of social drinking on cognitive function (253). However, children of alcoholics exhibit attenuated impairment in attention and memory relative to individuals with a familial alcoholism history (254). Thus it is possible that cognitive responses to ethanol may also contribute to the risk for making the transition from social drinking to alcoholism.

Although traits associated with the vulnerability to alcoholism contribute to cognitive deficits seen in ethanoldependent patients, they do not account for the deficits in patients (255). Ethanol-dependent patients show many impairments in cognitive function. Deficits in the level of performance and efficiency of verbal skills, learning and memory, problem-solving and abstracting, and perceptual-motor skills have been described (256). Cognitive deficits may reflect in part the degree of neurotoxicity related to alcoholism. For example, young ethanol-dependent patients may show normal brain volumes on MRI and normal cognitive function (257 ,258). With repeated episodes of ethanol withdrawal and advancing age, cognitive deficits become more pronounced (259).

Cognitive function improves over the initial year of sobriety; however, the domains of cognitive function do not recover at the same rate and recovery may be partial (260 ,261). Poor cognitive function at the time that treatment is initiated appears to predict improved alcohol-related treatment outcomes (262). However, progress in treatment may be reflected in improved cognitive function (263). Consistent with the view that treatment may modulate cognitive recovery, some cognitive deficits in recovering patients appear to respond to cognitive rehabilitation (264).

In summary, the behavioral studies describe the display of deficits in cognitive functions that may have implications for circuitry dysfunction in alcoholism: executive function deficits associated with the prefrontal cortex, visual-spatial deficits associated with the parietal cortex, and learning/memory deficits that may involve the hippocampus and related temporal cortical structures. Overall, these studies are consistent with the findings related to reduced tissue volume on MRI, reductions in cortical metabolism with fluorodeoxyglucose (FDG)-PET (242), and information processing deficits in ERP studies (265). This overlap implies a connection between alterations in brain structure, function, and behavior related to alcoholism.

THE INTERPLAY OF THE NEURAL CIRCUITRY AND NEUROCHEMISTRY OF ALCOHOLISM: IMPLICATIONS FOR TREATMENT

Part of "100 - Ethanol Abuse, Dependence, and Withdrawal: Neurobiology and Clinical Implications "

Ethanol has multiple specific effects on amino acid, monoamine, and neuropeptide neurotransmitter systems, and these effects contribute to its complex array of behavioral effects in animals and humans. Direct effects of ethanol on excitatory and inhibitory neurotransmission also are modulated by direct and indirect effects of ethanol on ion channels. Further, the cellular consequences of exposure to ethanol are modulated by ethanol-sensitive regulatory enzymes, such as PKA and PKC.

The diversity of ethanol targets in the brain and frequent co-localization of the neural circuitry bearing the sites of ethanol action raise the possibility of convergent mechanisms underlying the rewarding effects of ethanol in the brain. In this regard, there is growing evidence that the interplay of the prefrontal cortex (PFC) and limbic structures including the nucleus accumbens (NAc) and amygdala generally plays an important role in reward (266 ,267). Ethanol has many component actions that directly inhibit the output of the NAc including NMDA receptor antagonism, GABA facilitation, and enhancement in 5-HT and dopamine release (267). Drugs that antagonize the inhibitory effects of ethanol in the NAc, such as naltrexone (268), may play an important role in the treatment of alcoholism even if μ opiate receptors are not a major site of action for many of the behavioral effects of ethanol.

Abnormalities in PFC development may be an important factor influencing the vulnerability to alcoholism, in part by altering the interplay of PFC and NAc that underlies reward. As noted above, the vulnerability to alcoholism, particularly in the case of individuals with antisocial personality disorder or impulsive traits, appears to be associated with behavioral, physiologic, and structural evidence of PFC dysfunction. An important and unanswered question is, How does PFC dysfunction contribute to the vulnerability to alcoholism? Hypotheses have been presented that suggest that alcoholism is just one of several forms of impulsive behavior that these individuals fail to inhibit due to a general deficiency in behavioral inhibition or as a consequence of the failure to anticipate the negative consequences of alcoholism (269 ,270).

These cognitive hypotheses may be complemented by a reward dysfunction hypothesis resting on a consideration of the impact of PFC dysfunction on mechanisms underlying reward. The PFC input into limbic structures responsible for reward is critical to the experience, anticipation, and seeking of reward (271 ,272). The activation of PFC outputs to limbic structure causes a release of glutamate that may serve to activate, for example, the GABAergic output neurons of the NAc, and this action opposes direct effects of ethanol (268). From this perspective, PFC activation serves as a “brake” on reward mechanisms. In fact, it is tempting to think of this PFC-NAc interplay as a pathway contributing to the capacity of human judgment to restrain impulsive reward-related behavior. Yet abnormal PFC input would also be expected to disturb NAc function with respect to both the processing of rewarding stimuli generally and drugs of abuse in particular. Thus, it may not be surprising that

the familial vulnerability to alcoholism is associated with both PFC functional deficits and alterations in the capacity of drugs representing multiple component actions of ethanol (GABA, NMDA, opiate) to generate rewarding or aversive experiences in humans. If so, then genes controlling corticolimbic neurodevelopment and genes encoding the individual targets or intracellular mediators of ethanol action may provide a diversity of potential foci for the study of the genetics of alcoholism.

The cellular adaptations to chronic ethanol underlie tolerance to ethanol effects and withdrawal symptoms that develop upon the initiation of abstinence. As reviewed in this chapter, acute withdrawal symptoms reflect an enhancement of glutamatergic function and a deficit in GABAergic function. When examined beyond these generalizations, the neurobiology of ethanol dependence appears to be complex. For example, dependence-related adaptations may be reflected in absolute numbers of receptors in binding studies or perhaps changes in receptor subunit composition. Also, protracted withdrawal may produce functional changes in the opposite direction of acute withdrawal. Withdrawal is a critical juncture in the treatment of alcoholism because withdrawal symptoms may present an immediate medical risk, motivate relapse to ethanol use, induce withdrawal-related neuroplasticity that can increase risk for subsequent withdrawal-related medical complications, and may promote neurotoxicity. In light of these issues, novel treatments for withdrawal aim to achieve multiple therapeutic objectives (273).

Suchitra Krishnan-Sarin, Stephanie S. O'Malley: Department of Psychiatry, Yale University School of Medicine, New Haven, Connecticut.

Alcoholism remains one of the most common and significant medical problems in the United States and internationally. For example, in the United States, over 4% of the general population is alcohol dependent and another 5 to 10 million people drink hazardously at least several times per month (1). The economic and medical costs of alcoholism and alcohol abuse continue to escalate. Most recent figures put the economic costs of alcohol-related expenses at $176 billion annually in the United States (2). This includes the economic costs of increased health care expenses, lost productivity at work, and legal expenses. Similarly, although there have been some reductions in the number of motor vehicle deaths attributed to excessive alcohol drinking, the overall number of alcohol-related annual deaths is 105,000 in the United States (3).

Current psychosocial approaches to alcohol addiction are moderately effective, with perhaps as many as half the patients receiving treatment becoming abstinent or significantly reducing episodes of binge drinking (4). In the past two decades significant progress has been made in understanding the pharmacology of alcohol and why some people become dependent. This has led to the development of several medications that have been shown in research studies to improve treatment outcomes. This chapter reviews some of the possible neurobiological mechanisms involved in alcohol reward and dependence, and how medications can affect these systems to facilitate treatment. We introduce future directions for research such as the use of combinations of medications that may have additive or synergistic effects on improving treatment, and discuss the role of psychosocial support to facilitate the effectiveness of pharmacotherapy.

PHARMACOLOGIC TREATMENTS FOR ALCOHOL DETOXIFICATION

Part of "101 - Alcoholism Pharmacotherapy "

The first step in the pharmacologic treatment of alcoholism is to help patients safely detoxify from alcohol. Although historically, alcohol detoxification has occurred in inpatient setting, increasingly alcohol detoxification is being conducted in ambulatory settings. Except in the case of medical or psychiatric emergencies, outcome studies generally show that successful detoxification can safely and effectively be carried out in ambulatory setting using medications such as benzodiazepines (5 ,6). In addition, the use of anticonvulsants has received recent interest.

Benzodiazepines

Benzodiazepines are γ-aminobutyric acid (GABA) agonists that metaanalysis of placebo-controlled double-blind studies have consistently shown to be safe and effective (7). Benzodiazepines differ widely in their pharmacologic half-life, and this has been a factor in the choice of which benzodiazepines to use for detoxification. For example, one popular approach is to use a benzodiazepine with a long half-life such as chlordiazepoxide as a loading dose and let the benzodiazepine self-taper (8). The advantage of this technique is that the dose can be administered in the physician's office, which precludes problems with patience noncompliance. A second approach is to use shorter acting benzodiazepines and titrate the dose depending on symptoms. In a recent study, oxazepam was used as needed depending on the severity of withdrawal symptoms as assessed by the Clinical Institute Withdrawal Assessment for Alcohol-revised (CIWAA-R). As needed oxazepam resulted in effective alcohol withdrawal management with a lower total amount of oxazepam over a shorter duration compared to routine dosing (9).

Anticonvulsants

Several anticonvulsants have been used instead of benzodiazepines for alcohol withdrawal. Anticonvulsants have the

advantage of no abuse potential and a theoretical advantage of reducing kindling, a sensitization of withdrawal symptoms that occurs after multiepisodes of alcohol withdrawal. In one randomized study comparing valproate, a GABAergic agent, with phenobarbital, both medications were effective in reducing withdrawal symptoms, and there were no reliable differences between mediations with the exception of less hostility in the phenobarbital group (10). Carbamazepine has also been used as an alternative to benzodiazepines to attenuate alcohol withdrawal symptoms (11). Although its mechanism of action remains unknown, research generally shows that carbamazepine is as effective as benzodiazepines. Disadvantages of carbamazepine include a rather narrow therapeutic window, the need to monitor serum levels, and hepatotoxic effects. For patients with a history of alcohol withdrawal seizures, however, anticonvulsants such as carbamazepine may be a useful alternative to benzodiazepines (12).

PHARMACOLOGIC TREATMENTS TO REDUCE ALCOHOL RELAPSE

Part of "101 - Alcoholism Pharmacotherapy "

Disulfiram

The aversive agent disulfiram has been available for the treatment of alcoholism since 1949. Disulfiram works by inhibiting the liver enzyme that catalyzes the oxidation of acetaldehyde, a toxic by-product of alcohol, resulting in an aversive reaction to alcohol consumption. In this way, disulfiram is thought to deter drinking by making the negative consequences of drinking more certain, immediate, and aversive than they would be otherwise. Provided that the patient takes the disulfiram, the decision about whether or not to drink is probably shifted toward abstinence when faced with opportunities to drink based on the knowledge of the disulfiram-ethanol interaction. In randomized controlled clinical trials, however, disulfiram has not been shown to be effective in the absence of supervision of ingestion, probably due to poor compliance (13). With supervision and positive contingencies for taking disulfiram, however, the effectiveness of disulfiram appears to be enhanced (14). As an alternative to behavioral methods for enhancing compliance, pharmacologic methods such as implants have been developed. However, these efforts have been unsuccessful perhaps because these implants have not yielded adequate disulfiram blood concentration required to produce a reaction to alcohol (15 ,16).

Opioid Antagonists

Background

The role of the alcohol-induced activation of the endogenous opioid system in the reinforcing effects of alcohol has been well established in dozens of animal models of alcohol drinking (17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 ,29 ,30 ,31 ,32 and 33). These studies have consistently demonstrated that alcohol enhances the release of endogenous opioids, and alcohol preference is reduced when opioid receptors are blocked.

Alcohol increases the release of opioid peptides *in vivo*, particularly in rats and humans with a genetic predisposition for excessive alcohol drinking (34 ,35). For example, Gianoulakis and colleagues (34) have found that in humans peripheral levels of ß-endorphin increase in family history–positive subjects following a moderate dose of alcohol, whereas there is no increase in ß-endorphin for social drinkers without a family history of alcoholism. Moreover, Froehlich and colleagues (36) have also demonstrated that alcohol-induced ß-endorphin responses both prior to and following alcohol administration are significantly heritable.

Genetic preference for alcohol drinking has been shown to be associated with differences in opioid receptors and opioid peptides (37 ,38). Nonpreferring (NP) rats exhibit differences in the densities of µ opioid receptors in certain brain reward regions compared to alcohol-preferring rats. Transgenic mice lacking ß-endorphin have been shown to exhibit decreased preference for alcohol compared with wild-type mice (39).

Nonspecific and specific opioid antagonists have been found to reduce alcohol self-administration in rodents and monkeys (19 ,22 ,25 ,31 ,40 ,41 ,42 and 43). Preclinical studies have also evaluated the efficacy of antagonists specific for the µ and δ opioid receptors in reducing alcohol drinking. The µ opioid receptor antagonist ß-funaltrexamine (ß-FNA) and the δ opioid receptor antagonists naltrindole (NTI) and naltriben (NTB) have all been shown to reduce alcohol drinking (17 ,18 ,41). Recent evidence also suggests a role for the δ opioid receptors in mediating the aversive effects of alcohol as indicated by an increase in conditioned taste aversion in alcohol preferring (P) rats in the presence of the δ opioid receptor antagonist NTI (44).

Taken together, these preclinical studies in animals and humans support the model that alcohol drinking is reinforcing at least in part because of its effects on enhancing the release of endogenous opioids. The use of opioid antagonists as an effective agent in the treatment of alcoholism is strongly predicted by these preclinical studies.

Pharmacokinetics, Pharmacodynamics, and Safety

Naltrexone, an opioid antagonist, was originally developed for use in the prevention of relapse in detoxified opiate addicts. Naltrexone has a half-life of approximately 4 hours, and 6-ß-naltrexol, its major metabolite, has a half-life of 12 hours. Rapidly absorbed, naltrexone reaches peak plasma levels between 60 and 90 minutes. Naltrexone undergoes first-pass hepatic metabolism, and there is some evidence of dose-related hepatotoxicity at doses four to five times higher than the currently recommended 50-mg daily dosage.

In alcohol-dependent patients, adverse events reported by at least 2% of those participating in an open-label safety study were nausea (10%), headache (8%), dizziness (4%), nervousness (4%), fatigue (4%), insomnia (3%), vomiting (3%), anxiety (2%), and somnolence (2%) (45). In addition to these new-onset adverse events, naltrexone is contraindicated for patients who are currently opioid dependent, are in acute opioid withdrawal, or require opioid analgesics for management of pain, and those with acute hepatitis or liver failure. Special considerations are involved in the management of medical emergencies requiring pain management because naltrexone is an opioid antagonist. Although there has been little formal research on drug–drug interactions, with the exception of opiate-containing medications, subjects on naltrexone who were on concurrent treatment with antidepressant therapy did not experience any increase in adverse events relative to those not on antidepressant therapy in the aforementioned safety trial.

Efficacy

Naltrexone is currently approved for use in the treatment of alcoholism in the United States, Canada, and many European and Asian countries. The efficacy of naltrexone has been tested in several double-blind placebo controlled trials (Table 101.1).

TABLE 101.1. DOUBLE-BLIND, PLACEBO-CONTROLLED TRIALS OF OPIOID ANTAGONISTS FOR THE TREATMENT OF ALCOHOL DEPENDENCE

In general, these studies have been 12 weeks in duration, with one study (52) reporting on a 6-month follow-up period. Samples have been composed primarily of male subjects (ranging from 71% to 100%) without other complicating psychiatric or substance abuse problems, although there have been smaller studies in specialized populations, including those who use cocaine and alcohol (53) and older alcoholics (50). The behavioral interventions provided in conjunction with naltrexone include day-hospital treatment, cognitive behavioral therapy, and supportive therapy. These studies have tested the efficacy of a 50-mg daily dose against placebo; although several studies in progress are evaluating the utility of higher doses (e.g., up to 100 mg daily). The majority of studies, which have found naltrexone to be superior to placebo in treatment outcomes, have initiated treatment in subjects following a period of abstinence ranging from 5 to 7 days (46 ,47 and 48 ,51). Other ongoing studies are testing whether an opioid antagonist can be effectively used in a treatment sample to help subjects reduce and possibly initiate a period of abstinence or effectively control binge drinking.

The most consistent finding in the studies of alcohol-dependent subjects is that naltrexone decreases the risk of drinking at hazardous levels and the percentage of drinking days. In three studies, this finding was observed in the overall sample (46 ,48 ,51), and an additional investigation found that naltrexone significantly reduced hazardous drinking in a secondary analysis of subjects who were good treatment compliers (47). In contrast, no evidence of efficacy was found in a recent randomized study (54) comparing placebo,

naltrexone 50 mg daily, and nefazodone. In this investigation, naltrexone therapy was associated with a higher incidence of adverse effects, poorer medication compliance, and greater attrition than placebo, leading the authors to suggest that adverse events may limit the effectiveness of naltrexone.

Although the optimal duration of therapy with naltrexone is unknown, efficacy data are available for 12 weeks. A 6-month follow-up study (55) found that subjects who had originally been treated with naltrexone for 12 weeks were less likely to experience a day of heavy drinking during the follow-up period or to meet criteria for a diagnosis of alcohol dependence than subjects treated with placebo during that time period. However, there was evidence that the effects of naltrexone appeared to decline over time, raising the question of whether longer-term therapy may be needed. In this regard, initial evidence supporting the potential value of longer-term naltrexone therapy for some patients has been reported at scientific conferences.

Nalmefene, a newer opioid antagonist that is structurally similar to naltrexone, has also been reported to reduce the risk of relapse to heavy drinking. In a 3-month double-blind pilot study, there was initial evidence of reduced risk of heavy drinking among subjects treated with 40-mg doses of nalmefene compared to 10-mg or 0-mg doses (49). In a larger double-blind study (56) in which patients were randomized to placebo, 20 mg daily or 80 mg daily, lower relapse rates were observed for patients treated with nalmefene (combined across the 20-mg and 80-mg doses).

Since the initial published reports of naltrexone for use in alcoholism, several smaller studies have been conducted evaluating its potential in special populations of alcoholics. For example, the use of naltrexone in treating individuals with comorbid alcohol and cocaine use disorders have included one open-label study using 150 mg of naltrexone per day (57) that showed a positive effect for naltrexone, and one double-blind, placebo-controlled study using 50 mg of naltrexone per day in 64 subjects, which was negative (53). Pending additional research with larger samples at higher doses, naltrexone treatment does not appear indicated for the management of individuals with concurrent cocaine and alcohol use disorders. A small study in older alcohol-dependent men suggests that it may be efficacious (50), and in an open-label trial it was found to be helpful for adolescents (58).

The finding of reduced risk of relapse following a lapse has led to considerable interest and research into possible mechanisms underlying this effect. In the clinical trials, alcohol-dependent subjects retrospectively reported feeling less “high” (59) and lower levels of craving and incentive to continue drinking (60). Fixed alcohol dose administration studies in non–alcohol-dependent subjects suggest that naltrexone may attenuate some of the positive mood altering effects (e.g., stimulation), but not the aversive effects of alcohol (e.g., cognitive impairment, sedation) (61 ,62). High rates of nausea have been noted in alcohol administration studies in non–alcohol-dependent subjects maintained on naltrexone, suggesting that naltrexone may make alcohol more aversive in some subjects, particularly at higher doses of alcohol and naltrexone (63). These fixed alcohol dose administration studies involve rapid consumption of large amounts of alcohol. Interestingly, nausea in interaction with alcohol has not been a common complaint in the clinical trials. This suggests that these alcohol-dependent individuals either may be less vulnerable to nausea or may limit their alcohol intake (both the rate of consumption and the amount consumed) to levels that do not cause nausea in interaction with naltrexone. Direct evidence that naltrexone treatment is associated with reduced speed of drinking and the number of drinks consumed has been obtained using ad libitum drinking paradigms (64). Evidence that naltrexone reduces craving or urge to drink is also accruing from this body of research (63 ,64).

Summary

The evidence suggests that naltrexone 50 mg daily is efficacious in reducing the risk of heavy drinking and in increasing the percentage of days abstinent. Although the hypothesized effect of naltrexone on reduction of craving has been somewhat elusive in the clinical trials, laboratory studies provide support for this hypothesis. Additional studies are under way to test the optimal duration of therapy and the efficacy of alternative doses. Although the side-effect profile of naltrexone is acceptable, efforts to minimize adverse events should be investigated given that these events are associated with reduced compliance with therapy, and compliance has been linked to treatment outcome (65).

Acamprosate

Background

Ethanol has also been shown to alter levels of, and have high affinity for receptors of, two other neurotransmitters, glutamate and GABA. *In vitro* studies indicate that ethanol inhibits function of the glutamatergic *N*-methyl-D-aspartate (NMDA) receptor by inhibiting ion flux through this ionotropic receptor. Both *in vitro* and preclinical *in vivo* studies have also demonstrated that ethanol modulates NMDA-mediated release of other neurotransmitters such as acetylcholine, dopamine, and norepinephrine. Microinjections of glutamate antagonists into the nucleus accumbens of rats not dependent on alcohol has been shown to significantly decrease self-administration of alcohol. In preclinical studies, chronic alcohol administration results in an up-regulation of NMDA receptors, and NMDA antagonists given during withdrawal from alcohol have been shown to suppress withdrawal seizures. Clinical studies indicate that increased cerebrospinal fluid (CSF) levels of glutamate during

ethanol withdrawal may be associated with the development of seizures, and that repeated withdrawals increases the risk of seizures. Similarly, ethanol has also been shown to modulate the GABA system particularly $GABA_A$receptor function. Chronic administration of ethanol results in decreases in the messenger RNA (mRNA) and protein for the α subunit of the $GABA_A$receptor. GABA levels are also found to be reduced in the brain and CSF of recently detoxified alcoholics. Moreover, drugs that modulate $GABA_A$ receptor function such as benzodiazepines, barbiturates, and anticonvulsants have been shown to suppress the symptoms of ethanol withdrawal. Given the above evidence, there has been increased interest in examining the effects of agents that alter gluatamate and GABA function on alcohol drinking.

Acamprosate (calcium acetyl-homotaurine), a homotaurine derivative is a structural analogue of GABA and an upper homologue of taurine. It displays high binding capacity with GABA receptors, and it also shows functional activity in direct and indirect tests of GABA activity (66). Studies suggest it also inhibits NMDA receptors and reduces glutamate concentrations, particularly in the nucleus accumbens (67 ,68). A number of preclinical studies have shown that acamprosate produces dose-dependent decreases in alcohol consumption, with complete suppression of drinking seen at a dose of 400 mg/kg. It has also been shown that acamprosate diminishes reinstatement of alcohol drinking in the alcohol-dependent rat.

Pharmacodynamics, Pharmacokinetics, and Safety

Acamprosate has low bioavailability (10%), is not metabolized by the liver, and is primarily excreted through the kidney, with an excretion half-life of 18 hours (69 ,70). Acamprosate has an excellent safety profile. The most common adverse effect distinguishing acamprosate from placebo is diarrhea; other reported side effects that may be associated with acamprosate are rash and changes in libido. Drug interaction studies indicate that acamprosate does not interact with a variety of medications prescribed to individuals with alcohol dependence (e.g., antidepressants, anxiolytics, disulfiram, hypnotics, or neuroleptics) (69).

Efficacy

Acamprosate is approved for use as a treatment for alcohol dependence in most European countries and in many Latin American countries as well as in Australia, South Africa, and Hong Kong. The efficacy of acamprosate has been evaluated in over ten published placebo-controlled trials ranging from 3 to 12 months, with follow-up periods ranging from 0 to 12 months following the discontinuation of therapy (Table 101.2).

NR, result not reported.
Adapted from Garbutt et al., JAMA Vol. 281, 14:1318–1325.

The treatment period generally began following completion of inpatient detoxification. With respect to dose, earlier studies typically adjusted the dose of acamprosate for body weight, whereas more recent studies have used a fixed dose of 1,998 mg/day, with two 333-mg tablets given three times per day (six tablets per day). The nature of the concurrent behavioral interventions was not specified and typically was that used by a particular site. The primary outcome measures included retention in treatment and measures of abstinence, such as rate of abstinence preceding study visits, continuous abstinence (i.e., completing the study without having a drink), or a measure of cumulative abstinence duration (e.g., total number of days abstinent or percentage of days abstinent during treatment the study). Information about the actual quantity of alcohol consumed on a nonabstinent day was rarely reported.

Summarizing across the studies in Table 101.2 , the majority of studies find an advantage of acamprosate over placebo on measures of total abstinence, time to first drink, and/or cumulative abstinence duration (71 ,72 ,73 and 74 ,77 ,78 ,79 ,80 and 81). For example, in an early 12-week trial, Lhuintre et al. (71) found that abstinence rates for patients treated with acamprosate were nearly double (61%) that of patients treated with placebo (32%). Paille et al. (74) demonstrated that the effects of acamprosate on measures of abstinence were dose dependent. Specifically, point prevalence measures of abstinence at 6 months were 18.6% in the placebo group, 27.7% in the 1.3-g/day condition, and 34.7% in the 2-g/day condition. Similar dose effects were found on retention in treatment. In a study of 272 severely dependent alcoholics who had been abstinent 14 to 28 days prior to acamprosate treatment, 43% of the acamprosate-treated patients were continuously abstinent compared to 21% of those who received placebo over the course of 48 weeks (75). Although overall abstinence rates were lower in a different sample of severely dependent alcoholics with only 5 days of abstinence pretreatment (76), differences in abstinence rates were found favoring acamprosate over placebo during the 360-day treatment period. The advantage of acamprosate over placebo continued once acamprosate was discontinued after 6 and 12 months of active treatment.

At this time, there is no information available about the optimal duration of treatment with acamprosate. Although the duration of treatment has varied across studies (e.g., 3 to 12 months), there are no studies that have examined the effect of treatment periods of different lengths or the value of continued acamprosate in treatment responders. Given that differences between acamprosate and placebo appear to emerge after 2 to 3 months of treatment and generally persist after treatment is discontinued, studies addressing the potential value of short- versus long-term treatment are warranted to guide clinical practice.

Whether results comparable to those obtained in European

studies will be obtained in the United States is of great interest. A 21-site, 6-month, double-blind, placebo-controlled trial has recently been conducted to determine safety and efficacy of acamprosate in 601 U.S. alcoholdependent patients (82). This study tested the efficacy of a 2-g daily dose against placebo and includes an exploratory 3-g dose, given the absence of rate-limiting side effects. In contrast to European studies in which patients were randomized into study treatments following inpatient detoxification, the U.S. study allowed for randomization at as early as 2 days of abstinence. The results of this study are not published as of this time.

Summary

The evidence suggests that acamprosate can have a positive effect on measures of abstinence from alcohol following inpatient detoxification. These effects appear to be dose dependent, favoring the higher doses of acamprosate that have been tested. Although it is hypothesized that the efficacy of the acamprosate is due to its effects on conditioned withdrawal and withdrawal-related craving (83 ,84 and 85), ratings on analogue scales of craving have not distinguished acamprosate and placebo-treated patients in the clinical trials to date. In addition, the potential effect of acamprosate on alcohol reward and drinking following a lapse in abstinence is not understood at this time, because the majority of studies collected information on abstinence only, and there are no laboratory studies examining the interactions of acamprosate and alcohol. The results of the U.S. trial, however, may provide additional information because daily reports of drinking quantity were obtained.

Serotoninergic Medications

Background

The use of medications that affect the serotonin (5-HT) system was initially anticipated by clinical observations regarding similarities between alcoholism and mood, anxiety, impulse control, and antisocial personality disorders. Given

the presumed relationship between these various disorders and a dysfunction in the serotonin system, this clinical observation led to speculation that alcohol dependence was also related to some serotonin dysfunction. Several lines of preclinical research in animals and social drinkers support the notion that alcohol drinking compensates for some deficiency in serotoninergic activity. Most of these have consistently shown certain precursors to reducing alcohol drinking. More specifically, studies conducted in animals selectively bred for high alcohol drinking (HAD) or low alcohol drinking (LAD) behavior indicate that tissue content of serotonin and its metabolite 5-hydroxyindoleacetic acid are substantially lower in certain brain regions of the alcohol-preferring (P) animals compared with NP and in the HAD compared with the LAD rats (86). Smith and Weiss (87) have recently shown that ethanol-naive P rats have higher basal levels 5-HT release compared with NP rats, whereas chronic alcohol treated P rats had decreased extracellular levels of 5-HT in comparison to NP rats. However, although acute administration of alcohol results in increased levels of serotonin in the brain and periphery of alcohol-naive animals, this release is not altered by a genetic predisposition toward high alcohol drinking (88).

The evidence on densities of serotonin receptors in rats with a genetic predisposition to alcohol drinking is controversial. Alcohol-preferring (P) rats have higher 5-HT_{1A} binding and lower 5-HT_{1B} and 5-HT_2 binding in several brain regions when compared with NP rats (89). In contrast, the replicate HAD and LAD lines do not display the same differences in receptor densities, and in the alcohol-drinking fawn-hooded rats the densities of 5-HT_{1A} receptors were lower and those of the 5-HT_2 receptors higher compared to that of LAD Wistar rats (see ref. 90 for review). Preclinical studies indicate that 5-HT_{1A} agonists and serotonin reuptake inhibitors reduce ethanol intake in P and HAD rats as well as in unselected rat lines (86 ,91). In contrast, the role of the 5-HT_2 and 5-HT_3 receptor systems in alcohol drinking behavior is controversial (see ref. 90 for review). Although some studies indicate that ethanol drinking is reduced by both 5-HT_2 receptor agonists and antagonists, other investigators report no effects with antagonists of 5-HT_2 receptors. Similarly, the role of the 5-HT_3 receptor system in mediating ethanol drinking is also controversial, with reductions in drinking seen in paradigms using continuous access to alcohol, but little efficacy being observed in paradigms using limited access to alcohol. In contrast, studies using serotonin uptake inhibitors such as fluoxetine reported robust decreases in alcohol drinking in the P rats (86 ,92).

Pharmacodynamics, Pharmacokinetics, and Safety

There are currently five Food and Drug Administration (FDA) approved selective serotonin reuptake inhibitors (SSRIs) available today: fluoxetine (Prozac), fluvoxamine (Luvox), paroxetine (Paxil), sertraline (Zoloft), and citalopram (Celexa). SSRIs have in common the ability to block the reuptake of serotonin, and this functionally enhances serotoninergic activity. Fluoxetine is characterized by a long plasma half-life with a range of 1 to 4 days and its active metabolite norfluoxetine has a half-life of up to 2 weeks. In contrast, the half-life of the other SSRIs varies between 21 hours for paroxetine and 36 hours for citalopram (93). The long half-life for fluoxetine offers some pharmacokinetic advantage for patients who are less compliant with taking their medications, and fluoxetine has less of a discontinuation syndrome compared to the shorter duration SSRIs paroxetine and sertraline (94). SSRIs are inhibitors of cytochrome P-450 isoenzymes, with paroxetine an especially strong inhibitor of the P-450-2D6 isoenzyme, whereas fluvoxamine is an especially potent inhibitor of P-450-1A2. Thus there are important drug–drug interactions when SSRIs are combined with medications that are metabolized by the P-450 system. Despite their common mechanism of action, there are important pharmacokinetic and pharmacodynamic differences. Despite their name, SSRIs are not completely selective in affecting just serotonin reuptake. For example, sertraline and to a lesser extent fluoxetine are relatively potent dopamine reuptake inhibitors, and the various SSRIs can also block the reuptake of norepinephine (95). In addition, the SSRIs also antagonize muscarinic and histaminic receptors leading to anticholinergic and sedative side effects. Of the most disturbing side effects to SSRIs, initial nausea and sexual dysfunction are the most common.

Efficacy

None of the SSRIs is currently approved for the treatment of alcoholism. The results of several placebo-controlled double-blind studies using SSRIs for the treatment of alcohol dependence have led to conflicting results. In an Italian study with 81 subjects randomized to placebo, fluvoxamine, or citalopram, both of the SSRI groups showed a higher incidence of continuous abstinence compared to the placebo group (96). Similarly, in a Finnish study of 62 randomized subjects, citalopram was more effective then placebo in alcohol drinking outcomes (97). These studies are not consistent with two American trials. For example, in a 12-week trial using fluoxetine in a general sample of alcohol-dependent subjects, there were no overall differences between the medication and placebo groups (98). At doses of up to 60 mg per day in a group of 101 subjects who also received weekly sessions of relapse prevention therapy, fluoxetine did not reduce any measure of alcohol drinking.

Although the overall results of SSRIs for alcoholism treatment are generally negative, there may be subtypes of patients who benefit from treatment with SSRIs and other serotoninergic medications (Table 101.3). For example, in a study of 51 alcoholics with severe comorbid major depression,

subjects randomized to fluoxetine experienced less depression and less alcohol drinking than placebo-treated subjects (99). At 1-year follow-up the results for both depression and alcohol continued to favor the fluoxetine group (100).

TABLE 101.3. DOUBLE-BLIND, PLACEBO-CONTROLLED TRIALS OF SEROTONINERGIC AGENTS FOR THE TREATMENT OF ALCOHOL DEPENDENCE

Given that there may be important subgroups of alcoholics who self-medicate with alcohol, Kranzler and colleagues (102) subsequently reanalyzed their data after using a k-cluster technique to identify type A and type B alcoholics. Type B alcoholics are thought to reflect some underlying serotoninergic dysfunction because they tend to be more impulsive, have more emotional distress, and have increased severity of alcohol dependence. Contrary to the prior predictions, type B alcoholics drank more when given fluoxetine compared to placebo subjects (102). There were no medication differences in type A alcoholics. Similarly, Pettinati and colleagues (103) found that in a 14-week placebo-controlled trial of sertraline (200 mg per day), there was no main effect of sertraline on any alcohol drinking measure, but a significant alcoholic subtype by medication interaction. Subjects with presumed serotoninergic dysfunctions (type B) treated with sertraline tended to drink more than placebo-treated subjects, whereas the less severe type A subgroup of alcoholics showed a favorable response to sertraline in several drinking measures.

Other Serotoninergic Medications (Buspirone, Ritanserin, Ondansetron)

There are a variety of other medications that affect the serotonin system but work through different mechanisms than the reuptake inhibitors. The results are mixed and suggest that these medications may be effective only for certain subtypes of alcoholics.

Buspirone

The results of buspirone, a serotonin 1A partial agonist, on alcohol drinking are mixed and may depend on the subgroup of alcoholics studied (104 ,105 ,106 ,107 and 108). As Table 101.3 shows, in a general sample of alcoholics buspirone shows little evidence of clinical efficacy. In anxious alcoholics,

however, studies consistently show that buspirone reduces anxiety in subjects and may reduce alcohol drinking and, in one study, days in which alcohol was craved (107).

Ritanserin

In a large multicentered placebo-controlled trial, 493 subjects were randomized to receive placebo or one of three doses of ritanserin, a 5-HT_2 receptor antagonist, with a treatment duration of 6 months. The results of the study showed no differences between the placebo group and any of the three medication groups (109).

Ondansetron

More encouraging are the results of the 5-HT_3 antagonist ondansetron. A 6-week placebo-controlled study of 71 patients, found that 0.5 mg/d but not 4 mg/d of ondansetron reduced alcohol intake, although this effect was at the level of a trend (p = .06) (110). Johnson and colleagues (111) found that among early-onset alcoholics (onset prior to age 25), 4 µg/kg reduced the intensity of drinking compared to placebo. Among subjects receiving ondansetron, the percent of days abstinent was about 70% compared to 50% for those subjects treated with placebo (111). There were no differences between the medication and placebo groups for late-onset alcoholics.

Summary

Although there are suggestions that serotoninergic mechanisms are involved in excessive drinking, the results of using serotoninergic medications for alcoholism treatment are inconsistent. An understanding of which patients may be helped by which serotoninergic medications is complicated by the heterogeneous nature of alcohol-dependent patients and the subtle pharmacokinetic and pharmacodynamic differences among serotoninergic medications. The finding that some subtypes of alcoholics may do worse while taking serotoninergic medications is of considerable clinical interest, because many alcoholic-dependent patients may be taking a serotoninergic medication to treat a comorbid psychopathology. Given the widespread use of SSRIs and other serotoninergic medications, it is likely that there are more alcoholics patients taking serotoninergic medications than those taking all the medications specifically approved for the treatment of alcohol dependence combined. Rather than improve their drinking status, use of these medications may be interfering with alcohol recovery in some patients.

Tricyclic Antidepressants (TCAs)

The tricyclic antidepressants (e.g., impramine, desipramine, amitriptyline) represent a rather large class of medications that have been used for several decades to successfully treat mood and anxiety disorders. This class of medications, like the SSRIs, blocks the reuptake of serotonin but are far less specific in their actions. They also block the reuptake of norepinephine and dopamine, and antagonize muscarinic and histaminic receptors to varying degrees. The effect of TCAs on antagonizing muscarinic receptors and histaminic receptors give TCAs substantial anticholinergic and sedative effects. These anticholinergic effects include dry mouth, constipation, and tachycardia. The antihistamine effects include drowsiness and sedation. The TCAs are metabolized in the liver by the cytochrome P-450-2D6. Thus TCAs can interact with medications that are also metabolized by the P-450 system. Of note, alcohol can induce liver enzyme activity and reduce plasma TCA levels.

Efficacy

Studies using TCAs for the treatment of comorbid depression and alcohol dependence have generally shown that TCAs effectively reduce symptoms of depression but have little effect of alcohol drinking. For example, Mason and colleagues (112) tested the effectiveness of desipramine in a double-blind, placebo-controlled trial of 71 alcohol-dependent subjects with (28 subjects) or without (41 subjects) concurrent symptoms of depression (112). Overall, desipramine did not reduce alcohol drinking, but it was effective in reducing depression scores in those subjects with coexisting depression. Similarly, McGrath et al. (113) studied a group of 69 subjects with a history of depression that either predated or occurred independently of alcohol abuse. In this double-blind, placebo-controlled study, imipramine combined with relapse prevention therapy was effective in improving depression but had little effect on alcohol drinking. Among subjects who showed a good clinical response on depressive symptoms, there was evidence that imipramine was associated with greater reductions in alcohol drinking compared to placebo. In summary, the results of these small-scale studies provide suggestive evidence that there is a subgroup of patients with coexisting depression who may benefit from TCAs.

Lithium

The use of lithium for the treatment of alcoholism was suggested on the basis of clinical observations that many patients with mood disorders, particularly bipolar disorder, report alcohol use as a way to control mood instability. Early small-scale trials of lithium in the treatment of alcoholics were encouraging (114). For example, there were some data that among patients who received therapeutic levels of lithium, there were improved treatment outcomes (115). However, in a large multicenter placebo-controlled trial with 457 male alcoholics involving both depressed and nondepressed alcoholics, there were no significant improvements in alcohol drinking outcomes overall or in the depressed subgroup (116).

Similarly, in a recent double-blind, placebo-controlled study there were no significant reductions in alcohol drinking for a general population of alcoholics (105). Based on these larger, well-designed studies, the use of lithium to treat alcoholism does not receive empirical support. Its use in controlling bipolar symptoms may still be important for those with coexisting bipolar disorder and alcoholism.

Combination Therapy

Research on rational combinations of medications to treat alcoholism is an area that is rapidly developing. Given that the acute and chronic effects of alcohol involve a number of neurotransmitter systems, a therapeutic approach targeting more than one system may be more effective than monotherapy. In addition, medications may be combined to target distinct aspects of the process of relapse (craving, abstinence, and/or relapse following an initial lapse in abstinence) in order to help a larger number of individuals with alcohol dependence. Finally, combination therapy with efficacious agents may permit the use of lower doses of one or both medications, thereby potentially improving tolerability and compliance with treatment and maximizing treatment outcome.

A number of preclinical studies using rodent models have examined the effect of combining naltrexone and other agents thought to alter alcohol intake, including fluoxetine (117 ,118 and 119), a thyrotropin-releasing hormone analogue TA-0910 (120), the calcium channel blocker isradipine (121), the 5-HT_3 antagonist ondansetron (122), and the 5-HT_{1A} antagonist WA-100635 (123). The majority, but not all (121), of these studies have found at least an additive effect of combining naltrexone with these agents. Whether or not similar effects will be obtained in human subjects is under investigation for the combination of naltrexone and ondansetron (124) and the SSRI sertraline, with very small preliminary reports suggesting some optimism for continuing to investigate these approaches to combination therapy (124 ,125).

The possibility that disulfiram can be used to augment the efficacy of acamprosate has been evaluated in secondary analyses of a double-blind, placebo-controlled study (126). In this study, 118 Swedish subjects were randomized to either acamprosate or placebo, and disulfiram use was permitted on a voluntary basis. Comparisons of subjects who took disulfiram in combination with either acamprosate (*n* = 24) or placebo (*n* = 22) and those who received acamprosate or placebo only indicated that combined use of acamprosate and disulfiram was associated with the highest number of continuous abstinent days compared to the other three groups. These findings are of interest; however, they must be interpreted cautiously because subjects taking disulfiram were self-selected, differed from those who did not use disulfiram on a number of measures, and had much more frequent contact with the treatment program due to the fact that disulfiram administration was supervised.

There is considerable interest in the potential effect of combining acamprosate and naltrexone for the treatment of alcohol dependence. These agents target different neurobiological systems altered by alcohol drinking and dependence, and have been found to influence different aspects of the relapse process. Acamprosate has been shown to have its primary effect on measures of abstinence, whereas naltrexone is most noteworthy for its effect of reducing the risk of relapse following a lapse in abstinence. Finally, these two medications are eliminated through different pathways (hepatic metabolism for naltrexone and excretion for acamprosate). Preliminary data supporting the safety of this combination derived from laboratory studies of normal volunteers (56) and alcohol-dependent subjects (124). A large-scale multisite evaluation of the efficacy of these two medications alone and in combination when provided with behavioral interventions of different intensities is planned (127).

PHARMACOLOGY AND INTERACTION WITH BEHAVIORAL INTERVENTIONS

Part of "101 - Alcoholism Pharmacotherapy "

Psychosocial Treatment Approaches

Medications for the treatment of alcoholism are generally given in the context of psychosocial treatment. There are a variety of psychosocial approaches to alcoholism treatment and little evidence that one type of treatment is superior to others. Project MATCH (Matching Alcoholism Treatments to Client Heterogeneity) provides the clearest presentation of our state-of-the-art psychosocial treatments (4). In this large multicentered study, over 1,700 subjects were randomly assigned to motivational enhancement treatment (MET), cognitive behavioral treatment (CBT), or twelve-step facilitation (TSF). The results clearly demonstrate that subjects presenting for treatment and receiving some type of psychosocial intervention general reduce their alcohol consumption. For example, alcohol was consumed on about 75% of the days prior to starting treatment and then with treatment was consumed on less than 25% of days. These were few differences between the three psychosocial conditions and limited evidence that one type of treatment was better for a particular type of patient (4).

Inspection of the various double-blind studies on the effectiveness of medications to reduce alcohol drinking generally shows that the psychosocial interventions alone have a dramatic effect in reducing alcohol drinking. For example, as shown in the project MATCH data, it is common for baseline drinking to occur on the average of 60% to 75% of days prior to starting the study and for placebo subjects to reduce drinking to less the 20% of the days (46 ,47 and 48 ,51). The additional benefit of pharmacotherapy is thus an

adjunct to the considerable benefit of participating in a clinical trial that includes a psychosocial intervention.

Special Issues in the Use of Psychopharmacology in the Treatment of Alcoholism

Despite the convincing clinical treatment research results, the clinical use of medications for the treatment of alcoholism lags behind the pharmacotherapy of other psychiatric disorders. With the exception of medications that treat alcohol withdrawal symptoms, the medications presented here do not provide any immediate relief of symptoms. The long-term beneficial effects have been shown in terms of reductions in slips from abstinence or relapses to heavy drinking, but to the individual patient these outcomes are difficult to attribute to the use of a medication. A successful outcome for the medication is the absence of some adverse clinical event that may or may not happen in the future. In contrast, medications used to treat other psychiatric disorders do provide relief of emotional distress even if the relief is delayed by several weeks, as is the case for antidepressants in the treatment of mood disorders. In general, there are no obvious rewarding properties of taking a medication to treat alcoholism. Coupled with the fact that the immediate effect of drinking alcohol is to feel good or reduce some unpleasant feeling, it makes it a challenge to help patients become and remain compliant with taking their prescribed medication.

Given the lack of easily experienced positive effects from taking medications for alcoholism, it is not surprising that medication compliance is an important factor in the efficacy of medications. For example, in a 12-week, double-blind, placebo-controlled trial using naltrexone in conjunction with addiction counseling, with a total sample of 98 randomized subjects, naltrexone had a modest effect in reducing alcohol relapse rates. However, among subjects who took at least 80% of their prescribed medication, the relative effectiveness of naltrexone was much improved, as 52% of placebo subjects relapsed compared to 14% of the naltrexone subjects (47).

Compliance-Enhancement Techniques

To enhance motivation to remain in treatment and comply with taking medication, several behavioral interventions have been implemented. For example, the BRENDA approach, developed at the University of Pennsylvania (128), incorporates various behavioral strategies such as giving people feedback, developing an empathic therapeutic relation, working collaboratively with the patient to develop treatment goals, and continuing to assess treatment adherence.

A comparison of compliance rates of patients treated with the BRENDA approach to historical compliance rates at the Treatment Research Center at the University of Pennsylvania (103) suggests that BRENDA can enhance treatment and medication compliance. A randomized controlled study is currently under way to directly compare the BRENDA approach to cognitive behavioral therapy and simple physician medication management.

Integration of Behavioral and Pharmacotherapies

In a sense all pharmacotherapy studies are combined behavioral and pharmacotherapy studies. The effectiveness of medication is superimposed in a context of behavioral treatment. Thus, all the studies reported here reflect the additional benefits of an active medication group superimposed on the benefit of a behavioral treatment. The behavioral treatment intervention of subjects presenting for treatment has rather large effects as reflected on the improvement seen in the placebo groups in pharmacotherapy trials.

It remains to be determined how the behavioral interventions interact with pharmacotherapy, but there is a potential for additive or even synergistic effects of combining behavioral and pharmacologic treatments. Just as different medications may address different biochemical mechanism to improve treatment outcome, the integration of medications with psychosocial interventions can address different aspects of recovery. As discussed above, behavioral strategies can enhance medication compliance and treatment retention, thus giving the medication a better chance to be effective. Similarly, pharmacotherapy can reduce the chance of relapse to clinically significant drinking and increase the chance the patient will stay in treatment sufficiently to learn new behavioral coping skills. For example, a medication such as naltrexone can act immediately to reduce the severity of a slip and a return to hazardous drinking. When combined with cognitive and behavioral strategies to cope with triggers for relapse, the synergistic effects of the combined approach can be seen when the naltrexone is stopped, as the patient can now rely on learned skills to avoid and cope with a lapse.

CONCLUSION

Part of "101 - Alcoholism Pharmacotherapy "

The past two decades have shown dramatic changes in the understanding of the pharmacology of alcohol. From understanding alcohol’s nonspecific effects on membranes to alcohol’s specific effects on neurotransmitter systems and second messengers, dramatic advances in the field have led to newer more effective treatments. Recent understanding of the pharmacology of alcohol has led to the development of new medications that improve treatment outcome and help show why some people are vulnerable to becoming addicted to alcohol. Of the new medications, the opiate antagonist naltrexone and acamprosate offer the most immediate promise. For specific populations, serotoninergic medications, tricyclic antidepressants, and mood stabilizers offer

hope for treatment. The use of these medications alone or in combinations remains fertile avenues for research. Finally, special challenges are involved with the clinical use of medications for alcoholism treatment. Psychosocial treatments designed to improve motivation to remain in treatment and adhere to the medication regimen are important adjuncts to pharmacologic treatment. The use of the compliance-enhancing techniques can be safely and effectively integrated into primary care models, thus bring addiction treatment to a wide range of health care providers. Ultimately, the intensity and/or nature of the behavioral intervention may interact with the effects of medication to determine the ultimate outcome of treatment. Given dramatic reductions in the availability of intensive treatment, such as inpatient rehabilitation, and the fact that few individuals seek specialized alcoholism treatment, the availability of effective pharmacotherapies should extend the range of patients who can be successfully managed with less intensive behavioral interventions and increase the probability that individuals with alcohol dependence are identified in primary care settings and offered treatment.

Pathophysiology and Treatment of Cocaine Dependence

Thomas R. Kosten

Thomas R. Kosten: Department of Psychiatry, Yale University School of Medicine, VA Connecticut Healthcare System, West Haven, Connecticut.

PHARMACOTHERAPY TARGETS IN STIMULANT DEPENDENCE

Part of "102 - Pathophysiology and Treatment of Cocaine Dependence "

Pharmacotherapy can help to initiate abstinence and prevent relapse among the estimated 2 million stimulant-dependent users (1). These 2 million dependent users include some of the residual of long-term users from the peak of this epidemic 15 years ago, but a steady stream of new users and casualties is also accumulating. Between 1991 and 1998 the 30-day prevalence of cocaine abuse among eighth, tenth, and twelfth graders had increased more than twofold (1). Casualties from stimulant use also continue to accumulate, cocaine involvement in emergency room accident and violence cases remains prominent, and recent National Institute of Justice figures show that male and female arrestees in major cities display 40% to 80% cocaine-positive urines (2). These emergency room episodes have remained stable after a 78% increase from 1991 to 1994. Now localized epidemics of amphetamine abuse are developing, particularly in the western United States. The dangers associated with stimulant use are enormous and include increased risk of HIV infection, possible detrimental effects on the unborn and newborn, increased crime and violence, as well as medical, financial, and psychological problems. Because of these consequences, the task of identifying, characterizing, and developing treatments is more important than ever.

Models of Treatment: Neurobiological

To initiate abstinence among stimulant abusers, pharmacotherapy can be directed toward the abnormalities that stimulant dependence appears to create in normal neurobiology. This medication role in renormalizing these alterations parallels the role of medications for initiating abstinence from alcohol or opioids, where pharmacotherapy can reduce the harm from seizures or widespread physiologic withdrawal symptoms. Although discontinuation of stimulant dependence is not associated with severe medical complications, abstinence initiation does produce symptoms of dysphoria (3). These symptoms can be pharmacotherapy targets, and more broadly the disrupted cognition of stimulant abusers can be targeted to facilitate behavioral and cognitive psychotherapies, which have demonstrated efficacy for these disorders. Thus, in addition to abstinence initiation and relapse prevention to stimulant use, surrogate targets include withdrawal symptoms such as craving and dysphoria as well as cognitive impairment, which can result from disrupted neurobiology. Because depressive symptoms are relatively common among stimulant abusers in the early phases of abstinence, antidepressants for stimulant abusers were one of the first interventions studied in controlled trials. Although these medications have a checkered history of failures and successes, some recent data suggest that the depressed stimulant abuser may benefit from antidepressants (4 ,5). This benefit includes reductions in stimulant abuse as well as the depressive symptoms, and is consistent with the recent findings among depressed alcoholics and older studies in depressed methadone maintained patients (6). However, stimulants may induce a depressive syndrome, and these secondary or drug-induced depressions are less clear targets for pharmacotherapeutic intervention (5 ,6).

A useful concept in treatment of these patients is renormalization of disrupted neurobiology. Abnormalities in neurotransmitter receptors and transporters that have been noted in animal models have been confirmed in human neuroimaging studies of the dopamine neurotransmitter systems (7 ,8). Neuroendocrine challenge studies show functional defects consistent with these neuroimaging findings, and norepinephrine systems that stimulants might also disrupt show parallel pharmacologic-challenge abnormalities such as lowered thresholds for yohimbine induction of panic attacks (9 ,10 and 11). These three neurotransmitter systems show

the direct actions of chronic stimulants, but other neurotransmitter systems are indirectly affected including glutamate, γ-aminobutyric acid (GABA), and κ opioid systems (12). Abnormalities in any of these systems are appropriate targets for pharmacotherapy and have been targeted by clinical trials using a range of available agents that are reviewed below.

Although reversible abnormalities in neurotransmitter systems offer the potential for renormalization with subchronic treatment, maintenance treatment may be essential for irreversible changes or genetic predispositions. Examples of such abnormalities among stimulant abusers have been suggested for the postsynaptic dopamine receptor, which may be irreversibly down-regulated compared to normal individuals and even symptomatically resemble Parkinson's disease. Among candidates for genetic predispositions are polymorphisms in the dopamine transporter (DAT) associated with paranoia such as tandem repeats at the SLC6A3 site (13). Recently, the homozygous 10 tandem repeat, which along with the 9 repeat are the most common variants, has also shown a functional correlate of reduced DAT binding in humans (14). A critical association relevant to cocaine abusers is the up-regulation of the DAT after chronic cocaine in many abusers (7). Those who possess this 10 repeat polymorphism are not likely to have their DAT become up-regulated and therefore be successful candidates for medications that target postsynpatic dopamine targets rather than the dopamine transporter. Thus, patients with identified genetic polymorphisms in the DAT could be given more effectively targeted maintenance pharmacotherapies to prevent relapse.

Abnormalities in cerebral blood flow also appear to be common among stimulant abusers and may contribute to cognitive dysfunction (15 ,16). The basis for these perfusion defects appears to be a combination of platelet abnormalities leading to "sticky" platelets and vasospasm from repeated vasoconstriction induced by repeated stimulant use (18). The pharmacotherapies developing for stroke including antiplatelet agents such as clopidogrel and vasodilators such as the calcium channel blockers hold promise for this condition.

Finally, a way to sustain abstinence might be pharmacologic blockade with antibodies, enzymes, or receptor antagonists. The dopamine receptor antagonists such as haloperidol for the D2 receptor or Schering 39166 for the D1 receptor have not been successful, although some argument has been made that a partial agonist with its antagonism only expressed at higher doses might be effective (19). The other more peripheral approach is to prevent or at least slow the entry of stimulants into the brain using antibodies to the stimulant or augmenting the enzymes responsible for metabolic disposition of the stimulant. Because rapid entry of stimulants into the brain appears essential for their reinforcing properties, a delay in this entry might be as effective as fully preventing entry by retarding the stimulant in the bloodstream (3). Although augmenting cholinesterase activity (the enzyme that metabolizes cocaine to an inactive metabolite) remains to be clinically tested, active immunization has been studied in humans. Consistent with the animal studies, humans produced substantial quantities of antibody to an active immunization, but a reduction in cocaine use among outpatients has yet to be tested, to correlate with the reduced self-administration of cocaine observed in the animal studies (20).

CLINICAL ASPECTS OF STIMULANT USE

Part of "102 - Pathophysiology and Treatment of Cocaine Dependence "

The rewarding effects of cocaine and amphetamine are influenced by the route of administration because some routes (e.g., intravenous administration) produce more immediate onset of euphoria. The euphoria appears to depend on occupancy of the DAT (21). The preferred method of selfadministering cocaine has been snorting and, more recently, smoking. Amphetamines come in a variety of forms (e.g., pill, liquid, or powder form), but are usually taken orally or intravenously. The effects of route of administration and pharmacokinetics was extensively covered in the previous edition of this chapter (2).

Stimulant use may range from low dose to high dose and from infrequent to chronic or binge patterns. Depending on the dosage, pattern, and duration of use, stimulants can produce several drug-induced states that differ in clinical characteristics. Moderate to high doses of stimulants can produce stimulant intoxication that may or may not be pleasant. The intoxicated person may show signs of hyperawareness, hypersexuality, hypervigilance, and psychomotor agitation. Often the symptoms of stimulant-induced intoxication resemble mania. The intoxicated person should be monitored by the medical staff until the symptoms of intoxication diminish. If the intoxication does not return to baseline level within 24 hours, mania may be present and treatment for manic disorder may be required (3).

With increased dosage and duration of administration, stimulants can also produce a state of mental confusion and excitement, known as stimulant delirium. Delirium is associated with becoming disoriented and confused, as well as anxious and fearful. Extreme medical caution is needed when treating delirium because such symptoms may indicate stimulant overdose. For instance, crack cocaine addicts who overdose need careful monitoring for seizures, cardiac arrhythmias, stroke, and pulmonary complications. Overdose management has been reviewed in detail (22), but a syndrome of hyperthermia and agitation might be most safely managed with high doses of benzodiazepines (23).

During high-dose stimulant use, often seen during binge episodes, individuals can experience stimulant-induced psychosis characterized by delusions, paranoid thinking, and stereotyped compulsive behavior. When they are delusional, close clinical monitoring is essential and it may be necessary

to employ short-term treatment with neuroleptics to ameliorate the psychosis. It is more common for amphetamine than cocaine to induce psychosis, perhaps due to the difficulty in maintaining high chronic levels of cocaine in the body. Also, stimulant-induced psychosis in humans may be related to the dose and duration of administration of amphetamine, although cocaine psychosis and paranoia may be related to psychiatric predisposition (24).

Stimulant withdrawal, which occurs following cessation of cocaine or amphetamine use, can produce a wide range of dysphoric symptoms. Following binge use, individuals may initially experience a “crash” period, which is characterized by symptoms of depression, anxiety, agitation, and intense drug craving, although controlled studies have shown minimal withdrawal symptoms (3 ,8).

Treatment of stimulant abuse requires a comprehensive assessment of the patient’s psychological, medical, forensic, and drug use history. Moreover, because information obtained from chemically dependent persons may be incomplete or unreliable, it is important that the patients receive a thorough physical including blood and supervised urine samples for analysis. The clinician needs to be aware that polydrug abuse is common. Patients may ingest large amounts of one or more drugs at potentially lethal doses, and therefore it is important that the physician be aware of the dangers of possible drug combinations, such as cocaine and alcohol or heroin.

Pharmacologic intervention may be necessary during stimulant-induced drug states. For instance, neuroleptics may be useful in controlling stimulant-induced psychosis or delirium, and during withdrawal when depression may set in, antidepressants may be an appropriate choice for treatment medication. Treatment medications can be given on an inpatient or outpatient basis. However, if medications are used for outpatient treatment, it is critical to warn the patient of the potential adverse interactions between cocaine and the prescribed treatment medication. For instance, high blood pressure could result from the release of epinephrine by cocaine combined with the reuptake blockade by the tricyclic (25), although later in the course of treatment tricyclics decrease the sensitivity of the postsynaptic adrenergic receptors. Finally monitoring of treatment is essential using urine toxicologies as well as self-reports. The frequency of monitoring may be as infrequent as weekly, but three times weekly is optimal. There appears to be no advantage to quantitative over simple qualitative results based on typical cutoffs such as 300 ng/mL of benzoylecgonine for cocaine use in routine clinical practice.

HUMAN TESTING PARADIGMS FOR NEW MEDICATIONS

Part of "102 - Pathophysiology and Treatment of Cocaine Dependence "

Human Laboratory

The human laboratory setting in which cocaine or amphetamine is administered to volunteer subjects has been a critical paradigm for testing potential pharmacotherapies for stimulant dependence (12 ,25 ,26). Variations on this paradigm have used visual, tactile, aural, or cognitive cues to induce craving for these abused substances. In both experimental settings, the outcome measures have been subjective responses such as euphoria, unpleasant feelings or craving itself, as well as estimates of how much the drug is worth to the participant (e.g., dollar value). The induction of craving for more cocaine after a small to modest dose of cocaine is called the priming effect, and modulation of this priming effect can be an important role for a treatment medication in reducing relapse (27). This reduction in relapse would occur by preventing a “slip,” that is a single use of cocaine in a patient who wants to remain abstinent, from leading into a full relapse to binge cocaine usage.

To more precisely operationalize this human laboratory model, self-administration has been introduced. In that paradigm the subject can self-administer cocaine or amphetamine repeatedly within a range dictated by medical safety considerations. The subject is offered the alternative of getting cocaine or various other rewards that have a range of monetary values. The subject is thereby asked not only to estimate a worth of the cocaine, but also to actually choose to get that amount or to get the cocaine. In these paradigms the behavior of drug taking can be more clearly approximated and a medication that might block the effects of cocaine could be detected. This blocking effect would presumably lead the subject to prefer the alternative reward over the cocaine after the first test dose, when the medication is present, because the reinforcing effects of cocaine would be reduced (12). Although this model has theortical appeal and has shown the expected subject behaviors with various doses of cocaine, it has yet to be tested with an appropriate medication to judge its sensitivity for blocking agents.

In all of these paradigms, the key outcome of cocaine or amphetamine interactions with potential pharmacotherapies yields not only surrogate efficacy data, but also medical safety data. Cardiovascular measures in particular can be carefully monitored after both acute and subchronic dosing with potential medications. The baseline effects of these treatment medications can be assessed in escalating dose regimes, and then dose–response evaluations using escalating doses of cocaine or amphetamine can be examined. Subjective responses may also be important to assess dysphoric interactions between the medication and the abused drugs. These reactions might help in reducing stimulant abuse, although they might also discourage compliance with the medication. Overall, this is a powerful paradigm for medication development because of its potential to inform the clinical trials process with information about how the outpatients in a trial are likely to respond to the new medication, when a study participant uses a stimulant. Its utility as a rapid screening procedure for eliminating medications from further outpatient testing has yet to be demonstrated, but

this may be a future use of these highly controlled paradigms as we obtain gold standard agents with demonstrated efficacy in outpatient trials.

Neuroimaging

A newer technology for human laboratory assessment of potential medications is neuroimaging of either functional activity or receptor and transporter occupancy (28). Functional activity can involve either cerebral blood flow (CBF) or metabolic activity using fluorodeoxyglucose (FDG). The use of FDG as a medication development strategy has been examined in a recent study of selegiline combined with cocaine administration. In this study, selegiline reduced the euphoria from acute cocaine administration, and positron emission tomography (PET) imaging using FDG showed that the cocaine-induced changes in metabolic activity were blocked by the administration of selegiline (29). This surrogate marker provided an interesting correlate of the attenuation of cocaine's subjective effects, because other outpatient work has suggested that selegiline might reduce cocaine abuse in outpatients. Because similar studies of subjective effects alone have not had corresponding predictive validity for outpatient efficacy, these neuroimaging measures may have promise as a more rapid screening tool for medications.

Another medications development approach using neuroimaging focuses on the CBF defects that have been observed in cocaine abusers and on the neuropsychological deficits that persist even during sustained abstinence (6 ,15 ,17). As reviewed below, these CBF defects may be responsive to pharmacotherapy. The therapeutic implication is that by resolving these CBF defects, cognitive functioning might improve, and the response to cognitive behavioral therapies also might be enhanced.

Outpatient Randomized Clinical Trials

Outpatient clinical trials remain the standard approach to assessing efficacy of a medication. Although many principles of conducting randomized placebo-controlled clinical trials in psychopharmacology apply to these studies, some specific considerations are relevant to outcome measures that are not found in other areas. Urine toxicology is a most informative outcome that can be analyzed with both quantitative and qualitative approaches. The urines are typically obtained three times per week for maximum sensitivity to repeated stimulant use based on the duration that detectable metabolite levels remain after use. Analyses are most frequently done with cutoff scores of 300 ng/mL, for example, with the cocaine metabolite benzoylecgonine, with any level above this being considered an indication of cocaine use within the last 3 days. More complex analyses have been proposed using quantitative levels either directly with gas chromotography–mass spectroscopy for quantitation or immunoassays for semiquantitation. This semiquantitation can be combined with self-reported use and compared to urine levels obtained prior to the urine in question to estimate new use of cocaine, because with three times weekly toxicologies a heavy daily cocaine abuser can stop using for 2 or 3 days and yet still have a positive urine (30) (e.g., positive on Monday and Wednesday when the last use was on Sunday). Although the goal of treatment is often complete abstinence, the sensitivity of these urine tests can be enhanced by these data manipulations. Thus, self-reported decreases in stimulant use may be important as a treatment outcome even when the goal may be abstinence initiation. Treatment retention is also critical in getting toward this goal of abstinence initiation, in order to keep the patient available for intervention.

In these outpatient studies, relapse prevention is a conceptual outcome that follows abstinence initiation. Relapse as defined by recurrent use or dependence after "sustained abstinence" first requires a definition of sustained abstinence, particularly among the binge users of stimulants. These patients may use weekly or even less often in binges that last up to several days. Although meeting the criteria of the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV) for stimulant dependence, the periods of nonuse can manifest reasonable psychosocial functioning, yet each time the patient returns to a binge this return is not a relapse. Simple definitions of sustained abstinence can just be defined by a period of cocaine- or amphetamine-free urines that lasts three, four, or perhaps ten times longer than the typical inter-binge interval. For current investigations, an important prognostic stratification is evolving based on sustained abstinence; patients who are abstinent during the 2 to 5 weeks before entering a medication trial have better treatment outcomes than those who continue to use up to their entry into treatment (31). Longer-term relapse prevention has also been an area where psychotherapy may synergize with pharmacotherapy (32). For example, sustained abstinence with desipramine treatment for cocaine dependence was enhanced by relapse-prevention cognitive behavioral therapy when examined at 6 and 12 month follow-up. Relapse was significantly higher after attaining abstinence with the medication alone than with both medication and the behavioral therapy.

SPECIFIC MEDICATIONS

Part of "102 - Pathophysiology and Treatment of Cocaine Dependence "

A large number of medications have been used for a variety of cocaine-related effects, including treatment of cocaine withdrawal or cocaine craving, and initiation and maintenance of abstinence. Although many of these medications have appeared to be promising in open trials, randomized, placebo-controlled clinical trials have not shown any medications to have substantial efficacy for cocaine dependence. Many studies have included small sample sizes and have been hampered by large dropout rates. Diagnostic criteria

have varied across clinical trials (some studies enroll patients meeting diagnostic criteria for cocaine dependence or for cocaine abuse, and others do not specify patient diagnosis). Many larger studies have examined patients with primary opiate dependence on methadone maintenance. Although these patients tend to be more available for follow-up because of their need to report to a clinic daily for methadone treatment, it is likely that they are different from patients with primary cocaine use disorders. Therefore, results obtained in studies enrolling methadone-maintained cocaine abusers may not apply to other patient groups. Outcome variables differ among clinical trials, making it difficult to determine a medication's effectiveness. Studies that utilized self-reports without confirmation by urine toxicology screen may not be reflective of cocaine use by study participants.

Antidepressants

Desipramine, a tricyclic antidepressant agent, was one of the first medications to be studied as a treatment for cocaine dependence. It is one of the most extensively studied pharmacotherapies for cocaine dependence to date (4). The initial study of desipramine suggested its efficacy based on self-report primarily, and two subsequent studies in methadone-maintained samples based on urine toxicology found no difference from placebo (33 ,34 and 35). A large clinical trial examined the efficacy of desipramine and psychotherapy, alone and in combination, as a treatment for ambulatory cocaine abusers (32). In this 12-week, double-blind, placebo-controlled trial, 139 subjects were assigned to one of four conditions: relapse prevention therapy plus desipramine, clinical management plus desipramine, relapse prevention plus placebo, and clinical management plus placebo. The mean dose of desipramine was 200 mg daily and was adjusted by a nonblinded psychiatrist in response to plasma concentration (target ranges 300 to 750 ng/mL) and side effects. All groups showed significant improvement in treatment retention and a reduction in cocaine use at 12 weeks, but there were no significant main effects for psychotherapy, pharmacotherapy, or the combination. Lower severity patients (cocaine use 1 to 2.5 g/week) had improved abstinence initiation when treated with desipramine. Desipramine was significantly more effective than placebo in reducing cocaine use during the first 6 weeks of treatment. Depressed subjects had a greater reduction in cocaine use than nondepressed subjects and had a better response to relapse prevention therapy. This finding of a desipramine response among depressed patients was confirmed among the depressed patients on methadone. A subsequent study by Nunes et al. (5) also found that depressed cocaine abusers on methadone had a significant reduction in cocaine use on imipramine, but not placebo. They did not find a significant effect in the nondepressed patients. Finally, a recent study with desipramine in methadone- and buprenorphine-maintained cocaine- and opioid-dependent patients found a reduction in both opioid and cocaine abuse with desipramine (36). A recent report of desipramine in depressed cocaine abusers found no difference from placebo; however, those patients whose depression remitted also showed a substantial reduction in cocaine use (37). Thus, these tricyclic antidepressants do not have well-demonstrated utility even in the depressed cocaine abusers, who can be a substantial subgroup comprising up to 40% of those presenting for treatment (3 ,6).

Several well-controlled human laboratory and outpatient clinical trials with fluoxetine have been conducted in patients with cocaine use disorders. A double-blind, placebo-controlled, cocaine administration study examined the interaction of cocaine with fluoxetine at 0, 20, 40, or 60 mg daily on an ascending schedule (38), and found that the 40- and 60-mg doses of fluoxetine decreased subjective effects of cocaine. Fluoxetine has been utilized in outpatient clinical trials in both methadone-maintained, cocaine-dependent patients and in patients with primary cocaine use disorders. An open study in methadone-maintained, cocaine-dependent patients found that fluoxetine at 45 mg daily significantly reduced self-reported use and quantitative urine benzoylecgonine concentrations during 9 weeks of treatment (39). More recently, fluoxetine has not reduced cocaine positive urines more than placebo in either methadone-maintained or primary cocaine abusers (40). The consensus of these studies is that fluoxetine may not have a clinical role among unselected cocaine abusers, and side effects have limited its use in several studies.

Bupropion is a second-generation antidepressant that enhances dopaminergic and noradrenergic transmission, but has little effect on serotoninergic neurotransmission. Although a pilot study suggested efficacy, a large multicenter study in methadone-maintained patients showed little benefit in cocaine dependence (41).

Dopaminergic Agents (DA)

The most widely accepted explanation of cocaine-induced euphoria is that dopamine reuptake inhibition results in increased extracellular dopamine concentration in the mesolimbic and mesocortical reward pathways in the brain (42). This basis for euphoria has suggested that dopamine antagonists might reduce cocaine use, but few human laboratory studies have supported their use, and controlled outpatient trials with both D1 and D2 antagonists have not been supportive. Although a laboratory study suggested attenuation of cocaine effects by the D1 antagonist Schering 39166, a multisite outpatient trial found no dose response and no difference from placebo in cocaine use (43; Ko, personal communication, 1999). The D2 antagonists such as haloperidol and flupenthixol have had minimal effects on euphoria in human cocaine administration studies (44), and flupenthixol has not been superior to placebo in an outpatient trial (45).

Because relative DA hypofunction induced by cocaine abuse may underlie craving and withdrawal symptoms that are often observed in recently abstinent cocaine-dependent patients (3), DA agonists may be of use. Bromocriptine is an agonist with high affinity for the D2 receptor. In human studies, pretreatment with either bromocriptine 2.5 or 5 mg 2 hours prior to cocaine administration had no effect on cocaine euphoria (46). Although early work supported its use, even in an early double-blind clinical trial, bromocriptine at 5 to 7.5 mg daily was poorly tolerated, with high dropout rates (47). In another small double-blind, placebo-controlled trial Moscovitz et al. (48) gave bromocriptine 1.25 mg three times daily or placebo to cocaine-abusing patients presenting to an emergency room for minor medical complaints. They found no difference in retention (bromocriptine group 43%, placebo group 31%), but those randomized to bromocriptine had more urine toxicology screens negative for cocaine (67%) than those randomized to placebo (31%). Cocaine administration studies have found a lack of effects with pergolide (49). A placebo-controlled outpatient study of pergolide found no difference in cocaine use and significant side effects, in spite of early pilot work in 21 patients suggesting good responses in 16 of 21 patients (50). Most recently, the D1 agonist ABT431 has been examined in human cocaine administration studies and found to reduce cocaine-induced craving (51). This compound is only available intravenously, but this offers promise for related compounds such as the D3 partial agonist recently reported in the animal laboratory (19).

Amantadine increases dopaminergic transmission, but whether the mechanism is DA release, direct effects on DA receptors, or DA reuptake blockade is unclear. One study examined the effects of acute amantadine (200 or 400 mg) and chronic amantadine (100 mg twice daily for 4 days) followed by insufflation of cocaine 0.9 mg/kg (52). Although the acute 200-mg dose of amantadine was associated with a decrease in cocaine “high,” chronic administration of amantadine 100 mg twice daily was associated with increased “high” in male subjects after cocaine administration. The effectiveness of amantadine was evaluated in a double-blind, placebo-controlled trial in which 42 patients in a day treatment program were randomized to amantadine 100 mg twice daily (n = 21) to be taken over 10 days or placebo (n = 21). Urine toxicology screens showed that those who had received amantadine were significantly more likely to be free of cocaine (p <.05) at the 2-week and 1-month follow-up visits (53).

L-deprenyl is a monoamine oxidase type B inhibitor that specifically inhibits the metabolism of DA. A study in five human volunteers examined the effects of 10 mg L-deprenyl alone and in combination with cocaine, but found no attenuation of cocaine effects (54). More recently, it was found to attenuate some subjective effects of cocaine, and an outpatient trial showed reduced cocaine use reported in comparison to placebo (29; Vocci, personal communication, 2000).

Methylphenidate (MP) is a stimulant and DA agonist primarily used in the treatment of childhood attention-deficit/hyperactivity disorder. MP is a DA agonist with pharmacologic properties that include DA release, and it has similar levels of binding to the DAT as cocaine. Grabowski et al. (55) have reported that it does not increase cocaine use and retains patients better than placebo, but have not shown a reduction in cocaine use compared to placebo.

Mazindol is a DA reuptake inhibitor that is without abuse liability and it has been suggested that it might antagonize the effects of cocaine as a treatment. A report on the effects of cocaine alone and in combination with mazindol at 1 or 2 mg orally in cocaine abusing volunteers found that the combination significantly increased heart rate and blood pressure (56). Mazindol did not alter the subjective effects of cocaine. One 12-week, double-blind, placebo-controlled clinical trial of mazindol 2 mg daily in cocainedependent subjects reported no difference from placebo (57). Mazindol was also not well tolerated, with 16 of 33 patients dropping out, and the average length of treatment was 5 weeks. A similar trial in methadone maintained patients found limited efficacy for those patients who had been cocaine abstinent for at least 2 weeks before starting mazindol (58).

Nonspecific Anticraving Agents

A number of other agents have been tested to reduce the desire or craving for cocaine. The rationales have broadly involved mechanisms such as sensitization and kindling as well as neurotransmitter systems that are indirectly affected by cocaine such as the opioid, excitatory amino acid/glutamate, and GABAergic systems. For most of these approaches, outpatient clinical trials have been quite limited. Medications include GABA agents such as baclofen, opioid antagonists such as naltrexone, calcium channel blockers such as nifedipine, antikindling agents such as carbamazepine, and disulfiram. Finally, stress responses and the associated elevation of cortisol have been considered as potentially important in cocaine craving induction and as a therapeutic agent. However, a cocaine administration study showed no reduction in cocaine effects or self-administration with the cortisol synthesis inhibitor ketoconazole in spite of significant reductions in cortisol levels (59).

Carbamazepine (CBZ) is an anticonvulsant medication hypothesized to have potential as a treatment for cocaine craving and abuse because of its ability to block cocaine-induced “kindling” in rodents. A double-blind, placebo-controlled, crossover study of the interaction of 400 mg of CBZ daily for 5 days with cocaine found no effects on subjective response to cocaine (60). A double-blind, placebo-controlled study in outpatients included a 20-day, controlled, fixed-dose (CBZ 200 mg or 400 mg or placebo)

trial in 30 volunteers and found that cocaine use was unchanged (61). Another study in 183 cocaine abusers randomized to CBZ 400 or 800 mg daily or placebo showed that CBZ at 400 mg was associated with a significant decrease in cocaine-positive urines and a reduction in cocaine craving (62). However, three other double-blind, placebo-controlled studies with CBZ treatment in over 150 subjects found no significant difference in cocaine use, cocaine-positive urine samples, or depressive symptoms measured by the Beck Depression Inventory (63 ,64 and 65). Plasma CBZ levels of 5.6 ± 0.8 µg/mL were achieved by week 4 in these studies. Thus, confidence in this medication has waned.

Naltrexone is an opioid antagonist that has been examined as a treatment agent for cocaine abuse. One study examined the effects of cocaine after 10 days of treatment with naltrexone 50 mg or placebo in a double-blind, randomized, within-subjects design (66). Some cocaine-induced subjective effects were less during naltrexone than placebo administration. A placebo-controlled outpatient study of naltrexone found no efficacy (67).

The calcium channel blockers and antagonists of glutaminergic function have also been examined as anticraving agents and protective agents to minimize cardiovascular cerebral damage from cocaine. The calcium channel antagonist nifedipine has been studied and shows some promise (68). Nimodipine showed a reduction in the effects of intravenous cocaine as well as reductions in acute cocaine-related cardiovascular toxicity, but lamotrigine did not reduce cocaine effects in a similar placebo-controlled crossover study (69 ,70). Memantine, a glutamate inhibitor, showed no efficacy in reducing cocaine effects acutely (71). Outpatient placebo-controlled studies have not been done with these agents, however.

Much enthusiasm has developed for the use of agents targeting the GABA system, particularly for vigabatrin, which antagonizes the breakdown of GABA (72). Unfortunately, this agent is not available in the United States, and its side effects of bitemporal hemianopsia may preclude its use in cocaine abusers (73). However, baclofen, which is a direct agonist for the $GABA_B$ receptor, has shown some reduction in cocaine self-administration in animals and some utility in reducing cocaine abuse among humans (74). No other controlled trials have been published with this or related GABA agents, but several have gotten preliminary screenings in the National Institute on Drug Abuse (NIDA) medications development program including tiagabine, which also enhances GABA levels (Vocci, personal communication, 2000).

Disulfiram is an aldehyde dehydrogenase inhibitor used in treating alcoholism, a common coexisting problem among cocaine abusers. One study in six cocaine-dependent volunteers examined the effect of disulfiram 250 mg on responses to intranasal cocaine (2 mg/kg) using a randomized double-blind, placebo-controlled design (75). Although disulfiram induced no significant differences in cocaine "high," it decreased craving for cocaine. Plasma cocaine concentration following cocaine administration was significantly greater while on disulfiram, and this may have contributed to the decreased craving and increased dysphoria observed in some subjects. Carroll et al. (76) found that cocaine use was significantly reduced in the disulfiram group compared to psychotherapy alone, with patients who abused both alcohol and cocaine. The patients reported a significantly lower percentage of cocaine use days and fewer days of cocaine use, and fewer positive urine screens for cocaine were observed.

In surveys of cocaine abusers, 65% have reported significant problems in concentration and 57% reported memory problems, and formal testing suggests some sustained abnormalities in memory and concentration among abusers (3 ,16). Initial studies of recovering cocaine-dependent patients have revealed impairments of short-term memory, attention, and complex psychomotor and simple motor abilities, but the data are limited (16 ,77). Reaction time, motoric signs of central nervous system (CNS) dysfunction, and EEG evidence of residual CNS hyperexcitability may also persist (78).

These problems may be associated with structural or functional brain damage caused by cocaine including strokes (16). Structural imaging using computed tomographic scanning and magnetic resonance imaging (MRI) have shown enlarged ventricles and sulci in cocaine abusers (79). Functional neuroimaging studies have shown focal reductions in regional cerebral blood flow (rCBF) among chronic cocaine abusers (15 ,16 and 17). These defects also appear to be persistent for several weeks of abstinence at least, and can be associated with neuropsychological deficits (15 ,16 and 17 ,80). The ischemic damage from cocaine can lead to neuronal degeneration, as suggested by phosphorus magnetic resonance spectroscopy (^{31}P-MRS), in which abstinent cocaine abusers showed abnormally high levels of phosphomonoesters and low levels of nucleotide triphosphates compared to normals (81).

The etiology of decreases in rCBF following cocaine may involve vasoconstriction (82) and platelet abnormalities. The vasoconstriction may respond to calcium channel blockers (83). Abnormal platelets may produce thrombosis in cerebral vessels and produce blood flow alterations (18). In autopsy studies platelet-rich coronary thrombi (sometimes in otherwise normal vessels) and accelerated atheromatous lesions are found and could be ascribed to platelet activation and platelet α-granule release (16). Because platelet granule release appears to be completely inhibited by aspirin under *shear* conditions (analogous to flowing blood), and aspirin prevents thrombotic complications, a preliminary test of 4 weeks of aspirin therapy led to a 50% improvement in cerebral perfusion (16). In a placebo-controlled study that has just been completed, aspirin significantly reduced perfusion defects on single photon emission computed tomography (SPECT) imaging (84 ,85).

Peripheral Blocking Agents Targeting Cocaine Itself

Although the simplest peripheral blocking approach of passively injecting polyclonal antibodies to cocaine into a human might be useful for cocaine overdoses, these antibodies would not last very long and might be of limited use as a sustained treatment. For any type of relapse prevention, the immune response elements must remain at relatively high levels for periods of several weeks or months, which is best done by active immunization (86). However, three other approaches using catalytic antibodies, monoclonal passive antibodies, or injections of butrylcholinesterase have some promise (87). With all these peripheral cocaine-blocking agents, the amount of cocaine entering the brain is partially blocked or its rate of entry is reduced. Either of these effects can cause a very significant reduction in the high or rush from cocaine. All four of these approaches can also be combined and used together with the pharmacotherapies described above. The only approach that has been tested in humans is active immunization (86). The initial animal studies showed excellent production of a highly specific antibody to cocaine. With active immunization the amount of inhibition of cocaine entering the brain ranged from 30% to 63% at 30 seconds after cocaine injection in rats. This amount of inhibition was sufficient to extinguish cocaine self-administration in the rat model.

In the initial human study of this vaccine, it was well tolerated with virtually no side effects using a dose of 1,000 µg given with two booster injections over a 3-month period (88). The vaccine produced substantive quantities of antibody that was related to both the dose of vaccine and the number of booster injections. Thus, further studies of its potential efficacy in relapse prevention for abstinent cocaine abusers appear warranted.

PSYCHOTHERAPIES

Part of "102 - Pathophysiology and Treatment of Cocaine Dependence "

Professional Psychotherapy vs. Drug Counseling

Because of the limited efficacy of pharmacotherapy, the success of behavioral and psychotherapies is important to consider. Two major approaches have been evaluated. First, the use of professional therapies such as cognitive behavioral therapy and supportive expressive therapies has been examined. Second, contingency management as a form of behavioral therapy has gotten much attention and reasonable success. These therapies have now been extensively studied and are increasingly being examined as treatments that might be complemented by emerging pharmacotherapies. However, nonprofessional drug counseling also holds much promise and many be more readily available to community programs.

The most extensive examination of psychotherapy for cocaine dependence has been the NIDA Collaborative Cocaine Treatment Study. It was a large, multisite psychotherapy clinical trial for outpatients who met the DSM-IV criteria for cocaine dependence. For 480 randomized patients, four treatments were compared over an 18-month period. All treatments included group drug counseling. One treatment also added cognitive therapy, one added supportive-expressive psychodynamic therapy, and one added individual drug counseling. The final group had drug counseling alone. Two specific interaction hypotheses, one involving psychiatric severity and the other involving degree of antisocial personality characteristics, were examined, but no major findings related to these hypotheses have been found (88 ,89).

All of the therapies were manual guided and treatment was intensive, including 36 possible individual sessions and 24 group sessions for 6 months. Patients were assessed monthly during active treatment and at 9 and 12 months after baseline. Primary outcome measures were the Addiction Severity Index–Drug Use Composite score and the number of days of cocaine use in the past month. Compared with the two psychotherapies and with group drug counseling (GDC) alone, individual drug counseling plus GDC showed the greatest improvement on the Addiction Severity Index–Drug Use Composite score. Individual group counseling plus GDC was also superior to the two psychotherapies on the number of days of cocaine use in the past month. Hypotheses regarding the superiority of psychotherapy to GDC for patients with greater psychiatric severity and the superiority of cognitive therapy plus GDC compared with supportive-expressive therapy plus GDC for patients with antisocial personality traits or external coping style were not confirmed. Thus, compared with professional psychotherapy, a manual-guided combination of intensive individual drug counseling and GDC showed promise for the treatment of cocaine dependence (90).

Cognitive Behavioral Therapy (CBT)

In spite of these overall discouraging results, cognitive behavioral treatments have been among the most frequently evaluated psychosocial approaches for the treatment of substance use disorders and have a comparatively strong level of empirical support (91 ,92). To date, more than 24 randomized controlled trials have evaluated the effectiveness of cognitive behavioral relapse prevention treatment on substance use outcomes among adult tobacco smokers and alcohol, cocaine, marijuana, opiate, and other types of substance abusers (93). Overall, these studies suggest that the average effect size for CBT compared with control or comparison conditions is 0.36 (Feingold, unpublished data/APA presentation), which is consistent with a moderate effect. Review of this group of studies suggests that, across substances of abuse but most strongly for smoking, there is good evidence of the effectiveness of CBT compared with no-treatment

controls (93). This body of literature also suggests that outcomes in which CBT may hold particular promise include reduced severity of relapses when they occur, enhanced durability of effects, and patient-treatment matching, particularly for patients at higher levels of impairment along dimensions such as psychopathology or dependence severity. A review of this series of studies can be found in Carroll (93).

To help cocaine-dependent individuals meet the treatment goal of abstinence and relapse prevention, CBT treatment has two critical components. The first is a thorough *functional analysis* of the role cocaine and other substances play in the individual's life. A functional analysis is simply an exploration of cocaine use with respect to its antecedents and consequences. The second critical component of CBT is skills training. In CBT, a substantial portion of every session is devoted to the teaching and practice of coping skills; in fact, CBT can be thought of as a highly individualized training program that helps cocaine abusers unlearn old habits associated with cocaine abuse and learn or relearn more healthy skills and habits. Other important features of CBT are fostering the motivation for abstinence, teaching coping skills, changing reinforcement contingencies, fostering management of painful affects, and improving interpersonal functioning.

In a study comparing supportive therapy to CBT for pharmacotherapy of cocaine dependence, 121 individuals meeting DSM-III-R criteria for cocaine dependence were randomly assigned to one of the four treatment conditions: (a) CBT in combination with desipramine, (b) CBT plus placebo, (c) clinical management (ClM) plus desipramine, and (d) ClM plus placebo (33). Cocaine outcomes were comparable whether the patient received CBT or ClM, or whether the patient received desipramine or placebo, but patients with more severe cocaine use were retained longer in treatment, attained longer periods of abstinence, and had fewer urine screens positive for cocaine when treated with CBT compared with ClM. CBT also was more effective than supportive ClM in retaining depressed subjects in treatment and in reducing cocaine use (94). Thus, CBT has been useful for medication development as a platform for clinical trials because it meets the guidelines for an effective platform. Specifically, it is strong enough to hold patients in treatment, but not so strong as to eliminate the possibility for any medication effects. As counterexamples, treatments such as clinical management tend to be too weak to hold patients, although day treatments tend to produce very high rates of abstinence without any medications, but can serve as excellent means to inducing initial abstinence.

Contingency Management Procedures

Contingency management (CM) procedures are based on a behavioral perspective of drug abuse, which views drugs as powerful reinforcers maintaining high rates of behavior aimed at administering the drugs, even in the absence of physical dependence (95). In substance abusers, drugs can therefore be seen as being the predominant reinforcers exerting control over a large portion of these individuals' behavioral repertoire, whereas in nonsubstance abusers more socially acceptable reinforcers influence behavior. Thus, the goal of drug abuse treatment is to decrease behavior maintained by drug reinforcers and increase behavior maintained by nondrug reinforcers. CM procedures are one method of accomplishing this goal, by presenting rewards or incentives contingent upon documented drug abstinence (positive contingencies), withdrawing privileges contingent upon documented drug use (negative contingencies), or a combination of the two.

Higgins and colleagues (95 ,96 and 97) have demonstrated that CM procedures in combination with a community reinforcement approach (CRA) facilitate initial abstinence in primarily cocaine-dependent persons. In the first, 12-week study (95), the CM procedure consisted of vouchers with a monetary value, which were presented upon evidence of drug abstinence (i.e., cocaine-free urine) during weeks 1 to 12. The vouchers increased in value for every consecutively drug-free urine and were exchangeable for client-therapist agreed-upon retail items and activities related to treatment goals. Treatment retention was significantly higher in the behavioral treatment than standard drug counseling group. In addition, 85% of clients receiving the behavioral treatment achieved at least 3 weeks of abstinence as compared to 33% of clients receiving standard drug abuse counseling. In the second study (96), the CM procedure was modified, in that vouchers exchangeable for goods and services in weeks 1 to 12 and lottery tickets in weeks 13 to 24 were presented contingent upon documented drug abstinence. As before, treatment retention was significantly higher in the behavioral treatment than standard drug counseling group. Similarly, 68% and 42% of the clients in the behavioral treatment group achieved at least 8 and 16 weeks, respectively, of continuous cocaine abstinence as opposed to 11% and 5% in the standard drug abuse counseling group. In the third, 24-week study (97), cocaine-dependent individuals were randomized to receive either behavioral treatment without incentives or behavioral treatment with incentives (i.e., vouchers exchangeable for goods and services). The group that received the incentives showed significantly greater treatment retention (75% vs. 40%) and longer duration of continuous abstinence (11.7 vs. 6.0 weeks) than the group not receiving the incentives. Overall, the findings of these studies suggest that incentives contingent on drug abstinence can be a powerful intervention for facilitating cocaine abstinence in primary cocaine abusers, although separating the CRA effects has not been done.

This voucher system also has been examined in a 12-week clinical trial for its ability to facilitate cocaine abstinence in methadone-maintained cocaine abusers (98 ,99). The contingency group subjects achieved significantly longer durations

of sustained abstinence than yoked-controls (mean of 5.0 vs. 0.8 weeks, respectively), with 47% of contingency subjects achieving at least 7 weeks vs. 6% of controls achieving at least 2 weeks of sustained cocaine abstinence. These findings suggest that vouchers also can be used as incentives for drug abstinence in opioid-dependent cocaine abusers using a CM procedure similar to that employed by Higgins et al. (97).

There are also problems with CM. One issue with CM procedures is that the therapeutic effects tend to be impermanent following withdrawal of the intervention. This issue of continued efficacy after stopping medications has been addressed in a very limited way, mostly due to the lack of medications showing equivalent efficacy to these contingency approaches (32). Also, there are no mechanisms available to support CM in standard clinical programs, although some new approaches are being developed (100 ,101). Because vouchers are used to support treatment goals, therapists must work with patients to evaluate appropriate use of the vouchers, and treatment staff generally must assist in making voucher purchases. These restrictions impose considerable program costs over and above the costs of the vouchers. The delay between the time the reinforcement (purchase of goods or services) is provided and the time that the behavior being reinforced (abstinence, as evidenced by a drug-free urine) occurs may decrease the value to the patient (but not the actual program cost) of the reinforcement. The efficacy of CM in studies with cocaine-dependent patients also appears to be considerably more modest at best than in the earlier studies. Iguchi and his colleagues (102) compared voucher-based CM used to reinforce either drug-free urine samples (UA group) or treatment plan tasks (TP tasks) and a no-voucher standard treatment group (STD) during methadone maintenance treatment. The value of the vouchers was set considerably lower than in other studies of CM and did not increase in value for successive drug-free urine samples or completion of therapeutic tasks. The authors also did not use the CRA that Higgins has used, although their TP intervention included many of the CRA elements. There were no significant main effects of treatment group on rates of drug-free urine samples. Rates of drug-free urine samples remained relatively unchanged in either the UA or STD groups, whereas they increased over time in the TP group. Finally, CM is not effective for all patients—for example, 10 of 19 (53%) CM-treated methadone-maintained patients failed to achieve more than 3 consecutive weeks of cocaine abstinence in the study reported by Silverman and his colleagues (98 ,99), and resumption of drug use following discontinuation of CM is also a problem. Although increasing the value, schedule, or duration of the vouchers may lead to higher and more sustained rates of abstinence (103), alternatives to CM should also be explored. Considering that drug-dependent patients continue illicit drug use despite extremely high immediate and longer-term costs, increasing patient internal motivation may be more cost-effective than increasing the value of the vouchers or monetary rewards for abstinence. Of additional concern is the possibility that failure to earn vouchers may contribute to demoralization and a lack of perceived self-efficacy for succeeding in stopping drug use and thus contribute to a cycle of drug use and failure.

In summary, despite its promise, there are a number of limitations of CM for the treatment of patients with cocaine dependence: (a) CM is of limited efficacy in this population. (b) CM is labor intensive and difficult to implement. (c) CM is costly and not supported by current funding mechanisms. (d) The failure to obtain vouchers in CM may contribute to demoralization. (e) There is a possible rebound in drug use or dissipation of effects after discontinuation of CM.

CM’s potential utility as a platform for pharmacotherapy has yet to be fully explored, but recent reviews suggest it may have a modest effect size of 0.25 and that various approaches can be used to apply it in community settings (101 ,104).

SUMMARY

Part of "102 - Pathophysiology and Treatment of Cocaine Dependence "

No medications are currently approved by the Food and Drug Administration (FDA) for cocaine dependence, but we have developed several leads for medications based on our understanding of the neurobiology and clinical phenomenology of stimulants. Based on neurobiological abnormalities in dopamine receptors and transporters after chronic stimulant use, studies have examined both dopamine agonists and antagonists, but not shown clinical efficacy. Based on clinical phenomenology, antidepressants have been tried in depressed cocaine abusers who may reduce their cocaine use with desipramine, other tricyclics, serotonin reuptake inhibitors, and bupropion. Among unselected stimulant abusers these antidepressants may be quite limited, but when depressive symptoms are reduced, cocaine abstinence also appears to follow. Cerebral blood flow (CBF) defects also appear to be relatively common among stimulant abusers and to correlate with neuropsychological deficits. These CBF defects in cocaine abusers may respond to antistroke medications, and this potential for remediation builds on a rapidly evolving field of stroke pharmacotherapy. Finally, vaccines are under development that may reduce cocaine’s rewarding effects and prevent relapse among abstinent formerly dependent patients.

Methods for screening medications as potential pharmacotherapies have used human laboratory studies employing cocaine administration as a surrogate efficacy assessment. Although this method needs validation with a gold standard of medications that have demonstrated efficacy in outpatient randomized clinical trials, these laboratory settings have been helpful in assessing medical safety during cocaine interactions. Neuroimaging of cerebral blood flow and of

“receptor” binding also holds promise for medication development.

With all of these pharmacotherapies the behavioral platform for their delivery is critical in retaining the patient in treatment and maintaining compliance with the medications. As a behavioral disorder, stimulant dependence is quite responsive to contingency management using a variety of reinforcers and schedules of reinforcement. Vouchers to purchase prosocial goods and services are the most common reinforcer used to initiate and maintain stimulant-free urines (95 ,97). Reinforcement schedules are typically on a one-to-one fixed ratio initially, with a progressive increase in the ratio of reinforcement and escalation in reinforcers as longer periods of abstinence are attained. The major problem with this approach has been maintaining abstinence after the reinforcers are withdrawn completely and developing a mechanism to obtain these types of reinforcers outside of a research setting. A more typical time limited therapy for clinical programs is cognitive behavioral therapy. Cognitive behavioral therapies have been examined in conjunction with pharmacotherapy, particularly using antidepressants, and have shown interesting additive effects (32). For example, at 1-year follow-up after a 3-month treatment period, those patients who got both the pharmacotherapy and the cognitive therapy showed more sustained abstinence than those who got either therapy alone. The behavioral treatments may also be most useful for abstinence initiation, particularly the contingency management and cognitive behavioral therapy approaches (32). Overall, the long-term outcome at 1 year is substantially enhanced by the use of psychotherapy in combination with medications.

Application of Imaging Technologies in the Investigation of Drug Addiction

Nora D. Volkow

Joanna S. Fowler

Nora D. Volkow: Medical Department, Brookhaven National Laboratory, Upton, New York.

Joanna S. Fowler: Chemistry Department, Brookhaven National Laboratory, Upton, New York.

Brain imaging can be used to assess the following in the human brain: (a) morphology [computed tomography (CT) and magnetic resonance imaging (MRI)]; (b) electrical and magnetic signals [electroencephalography (EEG) and magnetoencephalography (MEG)]; (c) neurotransmission [positron emission tomography (PET) and single photon emission computed tomography (SPECT)]; (d) tissue composition [magnetic resonance spectroscopy (MRS)]; and (e) blood flow and metabolism [functional MRI (fMRI), PET, SPECT, and dynamic CT]. Table 103.1 summarizes the spatial and temporal resolution and the sensitivity for the various imaging modalities.

	Parameter Measured	Temporal Resolution	Spatial Resolution	Sensitivity
MEG	Function	1 ms	5 mm	
EEG		1 ms	10–15 mm	
CT	Structure	ms		
MRI	Structure	ms	1.0–1.5 mm	10^{-3} molar
	Function	3–5 s	mm	
	Biochemistry	10–20 min	cm	
[b]PET	Function	45 s	4 mm	10^{-2} molar

TABLE 103.1. IMAGING MODALITIES USED TO INVESTIGATE THE LIVING HUMAN BRAIN a

This chapter focuses mainly on the application of PET, SPECT, and MRI for the investigation of the effects of drugs of abuse in the human brain and their relationship with their reinforcing, addictive, and toxic effects. A brief description of these imaging techniques follows.

PET and SPECT are nuclear medicine instruments that detect and measure the spatial distribution and movement of radioisotopes in tissues of living subjects. PET measures compounds labeled with positron emitting radioisotopes and SPECT with single photon emitting radioisotopes. An advantage of the positron emitters is that some of these are isotopes for the natural elements of life (^{11}C, ^{15}O, ^{13}N), and this feature enables labeling of compounds without affecting their pharmacologic properties. Although labeling an organic compound with a single photon emitter such as ^{123}I results in a compound that is different from the parent compound, many iodine-substituted radiotracers with high biological selectivity and affinity for specific molecular targets have been developed. The positron emitters used for imaging have shorter half-lives than the single photon emitters. Both types of isotopes can be used to label ligands for specific receptor, transporter, or enzymatic systems to be used with PET or SPECT to quantify these parameters in living human brains. In addition, PET tracers such as [^{18}F] or [^{11}C]-labeled deoxyglucose (FDG, CDG) and [^{15}O]-labeled water can be used to measure regional brain glucose metabolism and cerebral blood flow (CBF), and SPECT tracers such as ^{99m}Tc hexamethylpropyleneamineoxime (HMPAO) can be used to measure CBF.

MRI is an imaging instrument that can distinguish elements in tissue on the basis of their magnetic properties. This information can be used to obtain images that reflect brain structure, brain function, or chemical composition. Information on structure in the brain can be obtained on the basis of differences in chemical composition between gray and white matter. For structural brain imaging, this is mostly accomplished by proton analysis, which enables the assessment of the water content of tissues. Information on brain function is derived from the differences in magnetic properties of oxygenated versus deoxygenated hemoglobin (blood oxygenation-dependent or BOLD contrast). During activation of a brain region, an excess of arterial blood is delivered into the area, with concomitant changes in the ratio of deoxyhemoglobin to oxyhemoglobin. Concentration on a wide variety of compounds that reflect metabolic state of the tissue and cell integrity can be obtained with MRS. MRS can also be used to measure the concentration and metabolism of compounds such as ^{13}C-glucose.

The most widespread application of imaging in the study of drugs of abuse has been its use to assess brain function, which can be done using imaging modalities that measure electrical activity, CBF, or brain metabolism. Of the modalities used for functional imaging, fMRI has the highest spatial resolution. Conversely, MEG and EEG are the imaging technologies with the highest temporal resolution, which enables the examiner to assess the temporal displacement of activation signals as they propagate in brain on the order of a few milliseconds (1).

The effect of drugs of abuse on neurotransmission has also been investigated. This effect depends on biochemical processes that occur at very low concentrations (nanomolar-picomolar range). PET and SPECT have the highest sensitivity of all currently available imaging techniques, and they can measures concentrations in the nanomolar-picomolar range, which are the physiologic concentrations at which neurotransmitter processes occur (2 ,3 and 4).

PHARMACOLOGIC PROPERTIES OF DRUGS OF ABUSE IN THE HUMAN BRAIN

Part of "103 - Application of Imaging Technologies in the Investigation of Drug Addiction "

The investigation of the pharmacologic properties of drugs entails studies of their pharmacokinetics (primarily using PET and the [^{11}C]-labeled drug) as well as their pharmacodynamics (using PET or SPECT and a radiotracer with specificity for a particular molecular or biochemical target or using PET, SPECT, and fMRI to assess brain function). Because these studies are done in awake human subjects, one can investigate the relationship between the behavioral effects of drugs and their effects on brain function and neurochemistry.

Pharmacokinetics

PET can be used to measure the absolute uptake, their regional distribution, and the kinetics of [^{11}C]-labeled drugs in the human brain. Moreover, the labeled drug can also be used to determine the target organs for the drug and thus can provide information on potential organ toxicity. Table 103.2 shows the various addictive drugs that have been labeled with a positron emitter and whose distribution has been evaluated with PET.

Drug Class	Specific Drug	Reference or Review
Psychostimulants	Cocaine	5,6
	Methylphenidate	113
	Metamphetamine	114
Opiates	Morphine	115
	Heroin	115
	Codeine	115
	Buprenorphine	116
	Methadone	117
Cannabinoids	THC	118
Nicotine	Nicotine	119–120
Caffeine	Caffeine	112
LSD	LSD	121

TABLE 103.2. DRUGS WITH ABUSE LIABILITY THAT HAVE BEEN LABELED WITH A POSITRON EMITTER (CARBON-11)

An example of the value of this strategy is its use in the investigation of the pharmacokinetics of cocaine in the human brain, as assessed with [^{11}C]cocaine (5), and a comparison with methylphenidate (MP), a drug used in the treatment of attention-deficit disorder that, like cocaine, blocks the dopamine (DA) transporter (DAT) but is much less abused than cocaine, as assessed with [^{11}C]MP (6). Cocaine and MP were found to have a large brain uptake (7% to 10% injected dose) and to have an almost identical pattern of distribution in the human brain, where they bound

predominantly to the striatum and where the specific binding for both drugs was to the DATs. Both drugs had a very fast rate of uptake, with peak concentrations in striatum achieved for cocaine between 4 and 6 minutes and for MP between 6 and 10 minutes after injection (6). However, their clearances differed; MP's clearance from striatum (half-life longer than 90 minutes from peak uptake) was significantly slower than that of cocaine's (half-life of 20 minutes from peak uptake) (Fig. 103.1). For both drugs, their fast uptake in striatum paralleled the temporal course for the experience of "high" reported by subjects given pharmacologic doses of intravenous cocaine or of MP. However, whereas for cocaine the rate of clearance paralleled the decline in the "high," for MP the "high" declined while there was still significant binding of the drug in brain (Fig. 103.1). Because it was the "rate of uptake" that was associated with the "high" for both drugs and not the presence of the drug in brain, investigators postulated from this observation that the rate of clearance may affect the propensity of a drug to promote frequent repeated administration. Although the rate at which psychostimulants enter the brain had been recognized as an important variable in their reinforcing effects (7), the relevance of their rate of clearance had not. These pharmacokinetic studies provided evidence that the rate of drug clearance is relevant in their reinforcing effects. In the case of cocaine, the fast rate of clearance enables repeated, frequent administration that is characteristic of cocaine bingeing (cocaine is taken every 15 to 30 minutes), whereas for MP, its relatively slow clearance from brain is likely to produce accumulation and toxicity that thus prevents frequent repeated administration.

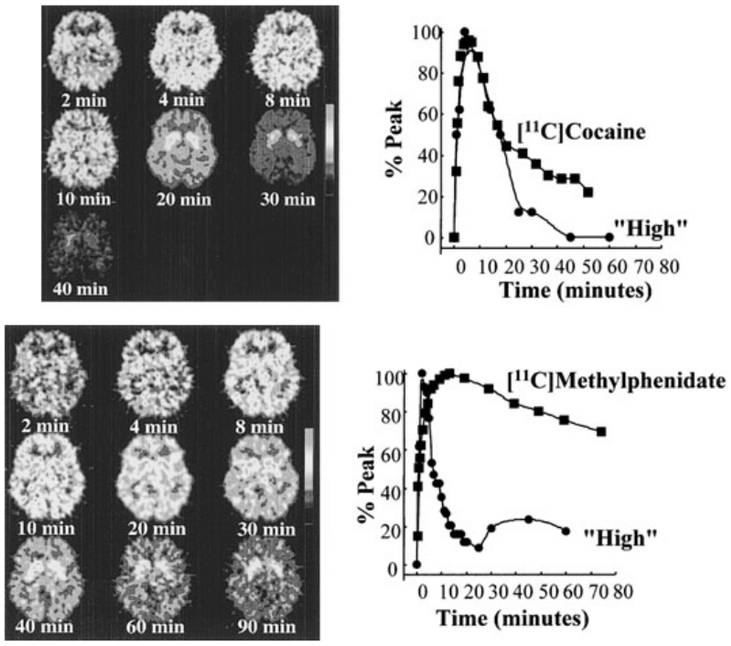

FIGURE 103.1. Left: Images at the level of the striatum obtained with [^{11}C]cocaine and with [^{11}C]methylphenidate at different times after radiotracer injection. **Right:** Time activity curves for radiotracer concentration in striatum and temporal course for the "high" expressed as a percentage from peak after pharmacologic doses of intravenous cocaine **(upper panel)** and of intravenous methylphenidate **(lower panel)**. (Modified from Volkow ND, Ding U, Fowler JS, et al. Is methylphenidate like cocaine? Studies on their pharmacokinetics and distribution in human brain. *Arch Gen Psychiatry* 1995;52:456–463, with permission.) See color version of figure.

Pharmacodynamics

Multiple parameters pertaining to the mechanisms of action of the drug of abuse can be investigated with imaging. These include measurement of the efficacy of the drug of abuse at the molecular target that is associated with the reinforcing effects of the drug of abuse (i.e., DAT for cocaine) and assessment on the effects of the drug of abuse on DA concentration and on brain function. These parameters can be assessed both in nonaddicted control subjects and in addicted patients to determine whether there are differences in the responses between them.

Drug Efficacy

The efficacy of the drug of abuse at the molecular target is illustrated with studies done to investigate the levels of DAT blockade achieved by reinforcing doses of cocaine. With PET and appropriate radiotracers, it is possible to measure the levels of DAT occupancy achieved by drugs that block DAT in human subjects reproducibly (8). The levels of DAT occupancy by different doses of intravenous cocaine were assessed with PET and [^{11}C]cocaine in active cocaine abusers (9). This study showed that cocaine is very effective in blocking DAT; at the doses commonly used by cocaine abusers (0.3 and 0.6 mg/kg), cocaine blocked more than 60% of the DAT. This study also showed that the higher the levels of DAT blockage, the higher the intensity of the "high," and that for cocaine to induce a "high" it had to block more than 60% of DAT function. A similar study done with intravenous MP showed that the ED_{50} (the dose required to block 50% of the DAT) was half that of cocaine (MP, 0.075 mg/kg; cocaine, 0.13 mg/kg) (10). As for cocaine, the magnitude of the DAT occupancy was significantly associated with the intensity of the "high," a finding corroborating the importance of DAT blockade in the "high." The differences in the ED_{50} between cocaine and MP are compatible with differences in their affinities for DAT (the inhibition constant or K_i of DA uptake corresponds to 640 and 390 nM, respectively) (11). In analyzing the implications of the similar *in vivo* efficacy for DAT blockade by cocaine and MP, regarding the low abuse potential of MP, it is important to emphasize that the similarities were observed after intravenous administration, which

is not the route of administration used in the treatment of attention-deficit/hyperactivity disorder. Because the rapidity of drug effects is an important variable in the reinforcing effects of drugs of abuse (12) and routes of administration affect drug pharmacokinetics, the results with intravenous MP cannot be extrapolated to oral MP.

The high levels of DAT occupancy achieved by cocaine and MP contrast with the results obtained for other drugs of abuse such as benzodiazepines. SPECT studies measuring the levels of receptor occupancy by the benzodiazepine drug lorazepam showed that only a few receptors are occupied at pharmacologic doses (13), findings that support the notion that in humans there is a “reserve” of benzodiazepine receptors.

Effects on Dopamine Concentration

Because the ability of drugs of abuse to increase extracellular DA concentration is considered crucial for their reinforcing effects, the estimation of DA changes becomes particularly relevant. PET and SPECT enable one to carry such measures in the human brain using radioligands that bind with relatively low affinity to DA D2 receptors (i.e., [^{11}C]raclopride, [^{123}I]IBZM) and compete with DA for binding to DA receptors. For this purpose, subjects are scanned twice, at baseline and after administration of the drug of abuse, and the difference in the binding of the radioligand between both conditions is mostly a reflection of drug induced changes in extracellular DA. Studies to measure changes in DA concentration induced by drugs of abuse in the human brain have been carried out for amphetamine, cocaine, and MP (14 ,15 and 16). These studies showed that these three psychostimulant drugs significantly increase extracellular DA, and, in the case of intravenous MP, the magnitude of druginduced DA changes was closely correlated with the intensity of the self-reports of “high.” In fact, for intravenous MP, the changes in DA were a better predictor of the “high” than the levels of DAT blockade, a finding that indicates that the effects of DAT blocker drugs are not only a function of the levels of DAT blockade but also of the amount of DA being released by the terminal (17).

Effects on Regional Brain Function

The most widely used imaging approach for the investigation of drugs of abuse has been to assess the effects of acute drug administration on brain glucose metabolism or CBF. This allows analysis of the brain regions that are most sensitive to the effects of the drug, and because the studies are done in awake human study subjects, it allows an analysis of the relation between regional changes in metabolism or flow and the behavioral effects of the drug. Although most drugs of abuse decrease regional brain glucose metabolism, their effects on CBF are increased by some drugs and decreased by others. This discrepancy between metabolism and CBF is probably an indication of the vasoactive properties of many of these pharmacologic agents, a property that is relevant for understanding their toxicity as it relates to cerebrovascular disease. The discrepancy could also reflect the finding that changes in metabolism reflect an average of the changes that occur over the uptake period of FDG (30 to 35 minutes), whereas those from blood flow reflect activity that occurs between 2 and 5 seconds for fMRI and 60 seconds for PET and [^{15}O]water.

CHRONIC EFFECTS OF DRUGS OF ABUSE IN THE HUMAN BRAIN

Part of "103 - Application of Imaging Technologies in the Investigation of Drug Addiction "

Imaging studies have been done to assess neurochemical and functional changes in the brain of addicted subjects that are associated with the process of addiction as well as changes associated with drug toxicity. Functional imaging strategies have also been used to assess the brain region involved in drug-related states such as drug craving. (See Chapter 110 .)

Drug Toxicity

Drug toxicity can be assessed with imaging techniques for brain as well as for other organs. Toxicity from drugs has been documented in abusers of cocaine, methamphetamine, and ecstasy, and the findings from these studies are covered under the subsection of the drug class. In addition, the ability to label the drug with a positron emitter and to follow its distribution in the human body and the availability of radiotracers that allow one to monitor organ function provide a mechanism for evaluating potential toxicity of drugs to organs other than brain. For example, PET studies done with [^{11}C]cocaine have shown significant accumulation in human heart (18), a finding leading to the question whether this could be associated with cocaine’s cardiotoxic properties. Cocaine was shown to induce a long-lasting inhibition of the norepinephrine transporter in heart using 6-[^{18}F]fluoronorepinephrine or [^{11}C]hydroxyephedrine (19 ,20). Cocaine is a local anesthetic, and its accumulation in heart could result in direct myocardial toxicity. At the same time, inhibition of the norepinephrine transporter by cocaine interferes with a protective mechanism of the heart to remove circulating catecholamines. Thus, these two separate mechanisms operating in parallel are likely to contribute to the highly cardiotoxic properties of cocaine.

Cocaine

Toxicity

Studies using PET and [^{15}]-labeled water provided the first documentation of abnormalities in CBF in cocaine abusers

(Fig. 103.2) (21). The patchy distribution of these CBF defects in brain suggested that they were secondary to cocaine's vasoactive effects (e.g., vasoconstriction, and platelet aggregation), rather than its regional neuroactive properties. These imaging findings, which appeared as defects seen with small strokes and hemorrhages, corroborated clinical reports of strokelike symptoms associated with cocaine use. These PET findings were subsequently replicated in several SPECT studies of CBF in chronic cocaine abusers (reviewed in ref. 22). More recent studies with MRI documented hyperintense lesions in white matter suggestive of subclinical anoxic vascular events in cocaine abusers that were also ascribed to the vasoactive effects of cocaine (23 ,24). The vasoconstricting effects of cocaine in human brain were corroborated by MRI studies showing significant reductions in cerebral blood volume (23%) (25) and CBF after acute cocaine administration (26).

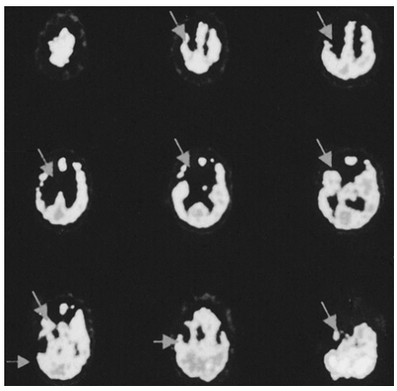

FIGURE 103.2. Brain images obtained with PET and [^{15}O]water to measure cerebral blood flow in a cocaine abuser. Note the regional decreases in blood flow *(arrows)*. (Modified from Volkow ND, Mullani N, Gould KL, et al. Cerebral blood flow in chronic cocaine users: a study with positron emission tomography. *Br J Psychiatry* 1988;152:641–648, with permission.) See color version of figure.

Using MRS, it is possible to assess tissue composition differentially for neurons and glial cells in brain. This information can be used, in turn, to determine whether there is neuronal damage or glial proliferation. In cocaine abusers, MRS studies reported increases in total creatine (+7%) and myoinositol (+18%) in white matter but no changes in *N*-acetyl aspartate, which is a marker for neuronal content (27). This finding was interpreted as reflecting alterations of nonneuronal but not of neuronal cells in cocaine abusers.

Brain Glucose Metabolism and Function

In contrast to the marked defects in CBF reported in cocaine abusers, the functional changes as assessed with brain glucose metabolism are not as pronounced and vary significantly as a function of detoxification. Also different from the patchy distribution of the CBF defect are the decrements in metabolism that tend to localize to cortical projections of the DA system. In recently detoxified cocaine abusers (less than 1 week), brain glucose metabolism was reported to be significantly higher in orbitofrontal cortex and in striatum than in control subjects (28). Metabolic activity was highest in subjects tested during the initial 72 hours after withdrawal, and cocaine abusers who had the highest brain metabolic values had also the highest subjective ratings for craving. In contrast, cocaine abusers tested between 1 and 4 months of detoxification showed significant reductions in metabolic activity in prefrontal cortex, orbitofrontal cortex, and anterior cingulate gyrus (Fig. 103.3) (29). Thus, the orbitofrontal cortex, which is hypermetabolic during early cocaine discontinuation, becomes hypometabolic with protracted cocaine withdrawal.

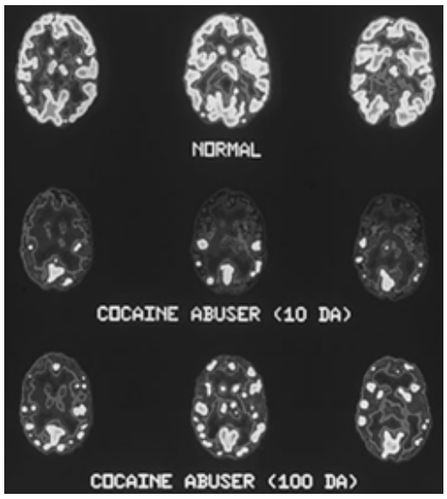

FIGURE 103.3. Images at the level of the striatum obtained with PET and FDG to measure regional brain glucose metabolism in a control subject and in a cocaine abuser tested at two different time points of the detoxification. Notice the marked reduction in metabolism in the frontal cortex. See color version of figure.

In addition to the studies measuring resting metabolism or CBF, the effects of pharmacologic challenges in cocaine abusers have been compared with controls. Intravenous cocaine was found to reduce brain glucose metabolism in cortical and subcortical brain regions as measured by FDG PET (30). In contrast, an fMRI study of acute cocaine administration revealed widespread activation in various cortical and subcortical brain regions, and the temporal course paralleled that of cocaine-induced "rush" (31). Because other acute pharmacologic interventions used to study cocaine abusers were for the most part chosen to target a specific neurotransmitter system, these aspects are discussed under the appropriate neurotransmitter headings.

Dopamine System

Ii has been hypothesized that decreased DA activity could underlie cocaine addiction (32). PET studies done to assess whether there are changes in DA brain activity in cocaine

abusers have used a multitracer approach to assess the relationship between levels of DA D2 receptors and regional brain metabolism in cocaine abusers during early cocaine withdrawal and after cocaine detoxification. Studies in cocaine abusers tested during early cocaine withdrawal (less than 1 week) revealed significant decreases in DA D2 receptor availability when compared with controls (Fig. 103.4) (33).

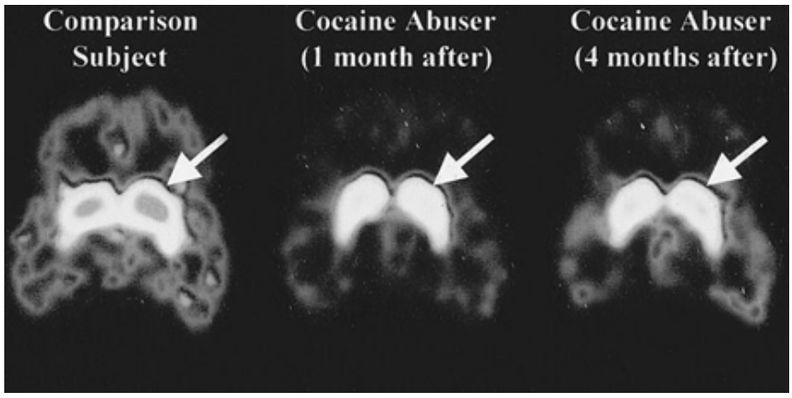

FIGURE 103.4. Images at the level of the striatum obtained with PET and [^{18}F]NMSP to measure dopamine D2 receptors in a control subject and in a cocaine abuser tested at two different time points of the detoxification. Notice the marked reduction in dopamine D2 receptors during both early and protracted detoxification. See color version of figure.

Studies in cocaine abusers tested between 1 and 4 months of detoxification also showed significant reductions in DA D2 receptor availability as assessed with [^{11}C]raclopride (34). The reductions in DA D2 receptor availability persisted on repeated testing 3 months after completing the inpatient detoxification program. In these patients, the reductions in DA D2 receptors were significantly correlated with metabolic activity in prefrontal cortex, orbitofrontal cortex, and cingulate gyrus (34). Lower values for D2 receptors were associated with lower metabolism in orbitofrontal cortex, cingulate gyrus, and prefrontal cortex, a finding suggesting an association between DA activity and the function of these frontal brain regions. The persistence of the decreased D2 function raise the question of long-term cocaine-induced changed versus preexisting DA system deficits that could increase vulnerability to cocaine dependence.

Abnormalities in orbitofrontal cortex and cingulate gyrus have also been reported for patients with obsessive-compulsive disorders (35), with whom cocaine abusers share the compulsive quality of their behaviors. In patients with obsessive-compulsive disorders, this feature manifests itself in specific behavioral rituals, and in cocaine abusers, it manifests as an obsession to procure the drug and in the repetitive pattern of cocaine self-administration. In laboratory animals, destruction of the orbitofrontal cortex leads to the emergence of repetitive behaviors that cannot be easily terminated (36), and a similar syndrome can be generated by the destruction of the mesocortical DA pathway (37). Thus, it has been postulated that DA-mediated dysregulation of the orbitofrontal cortex and the anterior cingulate gyrus may be one of the mechanisms responsible for the compulsive administration of cocaine during a “binge” and for the loss of control experienced by the drug abusers when exposed to cocaine or cocaine-related cues (38).

Studies in cocaine abusers to assess the DA terminal have mostly used ligands for the DAT. The results from studies are not consistent; PET studies done with [^{11}C]cocaine as a DAT ligand in actively abusing as well as in detoxified cocaine abusers have failed to show changes in DAT availability (reviewed in ref. 39), whereas SPECT studies done with [^{123}I]β-CIT showed significant DAT increases (17% to 25%) during states of acute (up to 96 hours) drug abstinence (40). Studies with [^{18}F]6-fluorodopa (6-FDOPA), which is an index of DA synthesis that also serves as a marker of the DA terminal, revealed significant reductions in recently detoxified cocaine abusers (11 to 30 days) when compared with control subjects or early abstinent cocaine addicts (1 to 10 days) (41). Reasons for the disparity between these studies are likely to reflect not only differences in the subjects studied but also differences in the effects of cocaine on the targets studied (i.e., it is possible that cocaine increases the expression of DAT while decreasing the synthesis of DA in the terminal). The discrepancies between the two types of DAT studies could reflect differences between the radiotracers and the models used. Because of the disparities, the effects of cocaine on the DA terminal are still not clear. However, because no study has documented reductions in DAT in cocaine abusers, this provides with evidence that cocaine does not induce degeneration of the DA terminal in humans.

Studies in cocaine abusers to assess DA release by the DA terminal have been done using PET and the DA D2 radioligand [^{11}C]raclopride. Studies to assess DA release were performed with and without administration of MP, which is a drug that, like cocaine, blocks DAT. In humans, the measures of MP-induced DA changes are reproducible (42), and they are similar in magnitude to those induced by equivalent doses of cocaine (43). Studies comparing the changes in [^{11}C]raclopride binding between cocaine abusers and control subjects showed that the response of cocaine abusers was 50% lower than that of controls. The “high” induced by intravenous MP was also more intense in controls than in cocaine abusers, whereas in cocaine abusers but not in controls, MP induced intense cocaine craving. This finding indicates that cocaine-dependent patients release less DA in the striatum and have a blunted “high” relative to controls when they are given MP. These results provide evidence that cocaine addiction does not imply an enhanced pleasurable response nor is there a sensitized DA response to the drug. Rather, the reduced DA release and blunted “high” are compatible with cross-tolerance between cocaine and intravenous MP.

The marked decrease in DA brain function in the cocaine abusers (reduction in DA D2 receptors, DA synthesis, and release) may lead to a decrease in activation of DA-modulated

reward circuits that are important in drive and motivation. Thus, one could postulate that the decreased in DA activity in cocaine abusers may make normal reinforcers less effective, and these patients may be taking the drug to compensate for the decreased stimulation of DA reward pathways. The decrease in DA function may also contribute to the dysphoria and the anhedonia experienced by these patients during cocaine withdrawal. Thus, strategies to enhance DA brain function in cocaine abusers may help these individuals to engage in activities that may help them to avoid a relapse.

GABA System

Cocaine enhances DA brain activity, and DA signals are transferred by γ-aminobutyric acid (GABA)ergic pathways (44). These make the GABA pathways a particularly susceptible target for cocaine's effects. PET studies have shown significant reductions in striatal DA D2 receptors in cocaine abusers (33 and 34). Because D2 receptors are predominantly located on GABA cells (45), reductions of these receptors suggest involvement of GABA pathways in cocaine abusers. The GABA system has been evaluated in cocaine abusers with functional imaging techniques. These studies assessed the brain regional responsivity to GABA stimulation in cocaine abusers and controls (46). Brain responsivity to GABA stimulation was assessed by measuring the brain metabolic responses to lorazepam, a drug that facilitates GABA neurotransmission. Although plasma lorazepam concentration was significantly higher in controls that in drug abusers, lorazepam-induced sleepiness in cocaine abusers was significantly more intense than in controls. Lorazepam reduced whole-brain metabolism, the decrements were greater in drug abusers (21±3 %) than in controls (13±7 %), and the differences were largest in striatum, thalamus, and parietal cortex. Because lorazepam-induced sleepiness was correlated with changes in thalamic metabolism, this finding suggests that the increased sedation in cocaine abusers results from the enhanced sensitivity of the thalamus to lorazepam. These results support the notion of disruption of GABA activity in the brain of cocaine abusers. The extreme sedative effects observed for some of the cocaine abusers after lorazepam administration should alert clinicians to potential untoward reactions in the use of these drugs in active cocaine abusers.

MRS was used to assess the concentration of GABA levels in brain comparing cocaine abusers and controls (47). GABA measurements were localized to the occipital cortex (volume, 9 cc). The cocaine abusers showed a significant decrease (23%) in GABA in comparison with controls. In contrast, macromolecule levels were not significantly different between controls and cocaine abusers. These data corroborate an involvement of cerebral GABA levels in cocaine abusers.

Opioid System

The endogenous opioid system has been implicated in the reinforcing actions of cocaine and other addictive drugs. μ-Opioid receptor binding was measured in cocaine-dependent subjects using PET and [^{11}C]carfentanil (48). μ-Opioid binding was increased in several brain regions of the cocaine addicts in proportion to the severity of cocaine craving experienced at the time. The up-regulation of μ-opioid receptor binding persisted after 4 weeks of detoxification. These findings provide evidence for the involvement of the opioid system in cocaine addiction.

Alcohol

Imaging studies in patients with alcoholism have been done to measure CBF, brain glucose metabolism (baseline and with pharmacologic challenges), benzodiazepine receptors, DA D2 receptors, and DATs and serotonin transporters in brain.

Brain Metabolism and Cerebral Blood Flow

Most of the nonstructural imaging studies have been done to investigate brain metabolic and CBF changes in patients with chronic alcoholism with and without neurologic impairment (reviewed in refs. 49 and 50). Patients with alcoholism and Korsakoff encephalopathy showed decreased metabolism in prefrontal, parietal, and temporal cortices, and patients with alcoholism and neurologic symptoms other than Korsakoff encephalopathy showed decreased metabolism in frontal and parietal cortices. Studies in patients with alcoholism who have no evidence of neurologic impairment have also consistently shown evidence of frontal abnormalities (reviewed in ref. 51). Decrements in metabolism were most accentuated in the older patients with alcoholism with longer histories of alcohol consumption. The degree of brain metabolic recovery with detoxification was evaluated with PET in patients with alcoholism who were evaluated at different times of the detoxification (52 ,53). These studies showed that brain metabolism increased significantly during detoxification, predominantly during the first 16 to 30 days of detoxification. However, decreased metabolic activity in orbitofrontal cortex persisted (Fig. 103.5) (9). Most PET studies in patients with alcoholism have been done in male patients, and little is known about changes in female patients with alcoholism. One PET study measured regional brain metabolism in recently detoxified female patients with alcoholism and compared it with that in age-matched female controls (54). This study showed no differences between patients with alcoholism and female control subjects. These results did not support a higher toxicity for the effects of alcohol in the female than in the male brain, in which most studies have consistently reported lower metabolism in the frontal region. However, this study was confounded

by the finding that the severity of alcohol use in these female patients with alcoholism was less than that of the male patients with alcoholism previously investigated in PET studies. The female subjects in this study were mostly premenopausal, and thus the lack of metabolic abnormalities may have reflected not only the lower alcohol severity but also the protective effects of estrogens.

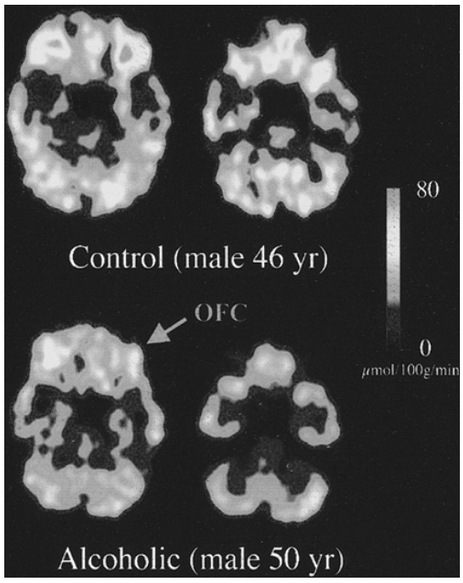

FIGURE 103.5. Images at the level of the orbitofrontal cortex obtained with PET and FDG to measure regional brain glucose metabolism in a control subject and in detoxified patient with alcoholism. Notice the reduction in metabolism in the orbitofrontal cortex. See color version of figure.

In addition to the studies measuring resting metabolism or CBF in patients with alcoholism, multiple studies have been done comparing regional brain metabolic and CBF responses to various pharmacologic challenges between control subjects and patients with alcoholism. Because most of the pharmacologic interventions were chosen to target a specific neurotransmitter system, we will discuss the findings from these studies under the neurotransmitter heading. In the case of alcohol, which is believed to exert its effects through multiple neurotransmitter systems, its effects on brain glucose metabolism (55 ,56) and CBF (57) were evaluated with PET. Such studies showed that acute alcohol administration decreased brain glucose metabolism (Fig. 103.6). When compared with controls, patients with alcoholism showed a significantly larger reduction in metabolism despite showing less subjective response to the intoxicating properties of ethanol (55). In control subjects but not in patients with alcoholism, the subjective response to the intoxicating effects of ethanol was significantly correlated with the brain metabolic decrements (55). This seemingly paradoxic response in patients with alcoholism was interpreted as reflecting their tolerance to ethanol-induced decrements in metabolism.

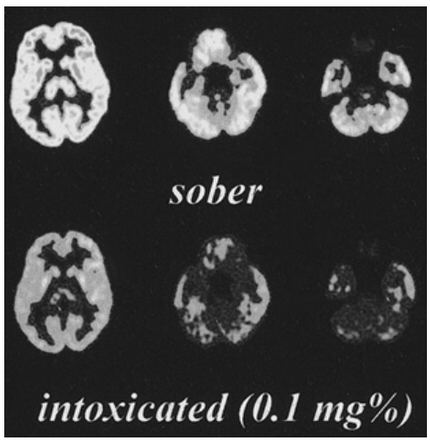

FIGURE 103.6. Images at the level of the striatum and of the orbitofrontal cortex and cerebellum obtained with PET and FDG to measure the effects of acute alcohol administration (1 g/kg orally) on brain glucose metabolism in a control subject. Notice the marked reduction in metabolism during alcohol intoxication. See color version of figure.

GABA System

The effects of benzodiazepines, which facilitate GABA neurotransmission, on brain glucose metabolism (58 ,59 and 60) and CBF (61) have also been evaluated with PET. Such studies have shown that, similar to ethanol, benzodiazepines decrease brain glucose metabolism, and the effects are more pronounced in the occipital cortex, the area of the brain with the highest density of benzodiazepine receptors (62). Benzodiazepines also decrease CBF, and as for metabolism, the largest changes are observed in the occipital cortex. Studies comparing the response to benzodiazepines between control subjects and patients with alcoholism showed a significantly lower response in the orbitofrontal cortex in patients with alcoholism than in controls (46 ,53). The blunted response to lorazepam in orbitofrontal cortex persisted after detoxification, a finding suggesting that it was not the result of withdrawal and that hypoactivity in this brain region may in part reflect abnormal GABAergic function (benzodiazepines facilitate GABAergic neurotransmission).

Imaging studies have also been done to measure changes in benzodiazepine receptors using PET and [^{11}C]flumazenil in patients with alcoholism. One study showed that although there were no changes in the levels of receptor between controls and patients with alcoholism, the latter had a significantly larger variability for B_{max} (receptor concentration) measures than controls (63). However, more recent studies have consistently reported significant decreases in

benzodiazepine receptors in patients with alcoholism, predominantly in frontal brain regions including cingulate gyrus and orbitofrontal cortex (64 ,65), but also in cerebellum (66). The reductions in benzodiazepine receptors in patients with alcoholism reported by these imaging studies are consistent with postmortem studies and may indicate either a toxic effect of alcoholism on benzodiazepine receptors or a vulnerability factor for developing alcoholism. The reductions in benzodiazepine receptors in the orbitofrontal cortex of patients with alcoholism could account for the blunted response to benzodiazepines reported in this brain region (53 ,59).

Dopamine System

DA D2 receptors were evaluated in patients with alcoholism with PET and [^{11}C]raclopride and showed significant reductions in DA D2 receptor availability when compared with controls (67 ,68). No significant correlations were found between DA D2 receptor availability and days of detoxification (1 to 68 weeks). One of these studies also measured DATs in a subgroup of the alcoholics in whom reductions in DA D2 receptors were detected and reported no changes in DAT availability (68). This finding was interpreted as evidence of GABAergic involvement in patients with alcoholism because DA D2 receptors in striatum are mainly localized in GABA cells.

DAT availability in patients with alcoholism has been measured by various PET and SPECT studies. The results have not been consistent. SPECT studies with [^{123}I]β-CIT reported that a group of violent patients with alcoholism had increases (8%) and nonviolent patients with alcoholism had decreases in DATs (25%) when compared with controls (69). SPECT studies in nonviolent patients with late-onset alcoholism have also reported a reduction in DATs (70). However, a PET study done with [^{11}C]D-threo-MP and a SPECT study done with [^{123}I]β-CIT showed no changes in DATs in patients with alcoholism (71 ,68). These discrepancies are likely to reflect in differences in the time since detoxification. One SPECT study showed that whereas DAT levels were significantly reduced in patients with alcoholism within the first few days of last alcohol use, the levels returned to normal 4 weeks after detoxification (72). PET studies with 6-[^{18}F]-FDOPA (a marker for the DA synthesis in the DA terminal) in patients late-onset (type 1) alcoholism showed higher striatal 6-[^{18}F]-FDOPA uptake in the patients with alcoholism than in the controls, a finding that was interpreted as a compensatory mechanism to low postsynaptic DA function (73).

Serotonin System

The effects of m-chlorophenylpiperazine (mCPP), a mixed serotonin agonist-antagonist drug, on brain glucose metabolism was compared in patients with alcoholism and in controls. This study showed that mCPP-induced activation in thalamus, orbitofrontal cortex, caudate, and middle frontal gyrus was significantly blunted in patients with alcoholism when compared with controls (74). This finding was interpreted as reflecting a hyporesponsive striatothalamoorbitofrontal circuit in patients with alcoholism. The abnormal response to mCPP suggests an involvement of the serotonin system in the abnormalities seen in this circuit in patients with alcoholism.

The availability of serotonin transporters, which serve as markers for the serotonin terminals, was measured with SPECT and [^{123}I]β-CIT in patients with alcoholism. This study showed a significant reduction in the availability of brainstem serotonin transporters in patients with alcoholism that was significantly correlated with lifetime alcohol consumption and with ratings of depression and anxiety during withdrawal (75). As for the prior study, this finding provides evidence of a role for serotonin in alcoholism and in its involvement with depressive symptoms during withdrawal.

Opioid System

The effects of an oral naltrexone challenge on CBF in patients with alcoholism during detoxification was studied with SPECT and HMPAO. At baseline, patients with alcoholism showed lower CBF in left orbitofrontal cortex and prefrontal cortex than controls. After naltrexone, a significant regional CBF decrease was found in basal ganglia and the left mesial temporal region, which are structures rich in opioid receptors. These results were interpreted as supporting the involvement of the opioid system in alcohol dependence (76).

Spectroscopic Studies

Patients with alcoholism had a significant reduction of the cerebellar *N*-acetylaspartate–to-creatine ratio, which was interpreted as reflecting neuronal loss and a reduction of the choline-to-creatine ratio, which was interpreted as reflecting cell membrane modification or myelin alterations (77).

Subjects at Risk of Alcoholism

The regional brain metabolic response to lorazepam was evaluated in subjects with a positive family history of alcoholism (FHP) and was compared with that of subjects without a family history of alcoholism (FHN) (78). At baseline, FHP subjects showed lower cerebellar metabolism than FHN, and when challenged with lorazepam, they also showed a blunted response in cerebellum and in anterior cingulate gyrus. Lorazepam-induced changes in cerebellar metabolism were significantly correlated with motor impairment. The blunted cerebellar sensitivity to benzodiazepines in FHP could account for the decreased sensitivity to the motor effects of alcohol and benzodiazepines in FHP subjects.

The decreased cerebellar baseline metabolism in FHP subjects as well as the blunted cerebellar response to lorazepam challenge may reflect disrupted activity of benzodiazepine-GABA receptors in cerebellum of FHP subjects.

Opiates

The effects of morphine on brain glucose metabolism were evaluated in polydrug abusers (79). This study showed that morphine reduced glucose metabolism by 10% in whole brain and by about 5% to 15% in telencephalic areas and the cerebellar cortex. Morphine-induced metabolic decrements were not significantly related to subjective measures of euphoria. The effects of acute fentanyl, a synthetic opiate, on CBF were measured with PET and [^{15}O]water. Fentanyl administration was associated with significant increases in regional CBF in cingulate, orbitofrontal, and medial prefrontal cortices, as well as caudate nuclei, areas known to be involved in reward and addiction (80).

Resting CBF was measured with SPECT and ^{99m}Tc-HMPAO in heroin abusers tested 1 week after opiate discontinuation and then retested 2 weeks later (81). The initial scans demonstrated significant CBF defects in the frontal, parietal, and temporal cortices. Two weeks later, the SPECT scans showed improvement. The results from this study provide evidence that long-term use of opiates results in perfusion abnormalities that are partially reversible with short-term abstinence.

Dopamine System

Using PET and [^{11}C]raclopride, opioid-dependent subjects were found to have lower DA D2 receptor availability than controls. Naloxone-induced withdrawal in opioid-dependent subjects did not change [^{11}C]raclopride binding, a finding indicating that withdrawal does not alter synaptic DA in the striatum as measured by this method (82).

Opioid System

To date, there have been no published studies of opioid abusers using these opiate receptor radioligands to study heroin abusers (see earlier).

Spectroscopic Studies

Phosphorus magnetic resonance spectroscopy (^{31}P MRS) at 1.5 T was performed on polysubstance abusing men (cocaine and heroin dependence) (83). The phosphorus metabolite signal expressed as a percentage of total phosphorus signal was 15% higher for phosphomonoesters, 10% lower for nucleotide triphosphates (ß-NTP), and 7% lower for total nucleotide phosphates in polydrug abusers compared with controls. These findings were interpreted as suggesting that long-term drug abuse or withdrawal results in changes in cerebral high-energy phosphates and in phospholipid metabolites.

Marijuana

Marijuana is the most widely used illicit drug of abuse in the United States. Despite its widespread use, the mechanisms by which ð^{9}-tetrahydrocannabinol (THC) (the main psychoactive substance of marijuana) exerts its psychoactive effects are still not known. Relatively few imaging studies have been done to assess the effects of acute and chronic marijuana use in the human brain.

Brain Metabolism and Cerebral Blood Flow

SPECT studies assessed the effect of THC intoxication on CBF in chronic marijuana users (84 ,85). Acute marijuana administration led to decreases in CBF in subjects who were not experienced marijuana smokers, whereas it increased CBF in subjects who were experienced smokers. In a more recent study, these investigators extended these findings to a larger groups of subjects and documented increases in CBF in anterior cingulate gyrus and in the insula in marijuana users (86). Interpretation of the effects of THC on CBF is confounded by the vasoactive properties of THC (87). Thus, it is difficult to separate the effects of THC that are related to its action on nervous tissue from those that are related to its vasoactive effects. This problem is obviated when using deoxyglucose to measure brain glucose metabolism because this agent is insensitive to fluctuations in CBF (88).

The effects of THC on regional brain glucose metabolism have been evaluated in nonabusing controls (89) as well as in marijuana abusers (90). The whole-brain metabolic response to the effects of THC was variable among individuals; some subjects had increases, some had decreases, and some did not show change. Despite these variable responses in whole-brain metabolism, there was a very consistent pattern of metabolic activation by THC. That is, under THC intoxication, most of the subjects showed activation of the cerebellum. The cerebellar activation by THC was significant both for the absolute and for the relative measures. In marijuana abusers, THC also increased metabolism in the anterior cingulate gyrus and in the orbitofrontal cortex. A more recent study assessing the effects of marijuana on CBF also reported an increase in cerebellar flow during intoxication (91). The highly localized concentration of cannabinoid receptors in the cerebellum (92) supports involvement of the cannabinoid receptors in the metabolic and CBF response during THC intoxication. Activation of the cerebellum by THC could explain the disruption in motor coordination and proprioception during THC intoxication. Cannabinoid receptors are also localized in other discrete areas, namely, hippocampus, substantia nigra, pars reticulata,

and globus pallidus. These are too small to be measured with the spatial resolution of the PET instrument used.

SPECT studies compared CBF in subjects with attention-deficit disorder who had a history of marijuana abuse with those who did not (93). Decreased perfusion in the prefrontal cortex was seen in both marijuana users and nonusers. However, the marijuana users also demonstrated marked decreased activity in the temporal lobes, which was ascribed to chronic marijuana use.

Cannabinoid Receptors

Attempts to investigate THC in the living brain with PET by using the labeled drug with a positron emitter have been unsuccessful because of the highly lipophilic nature of THC. This was also a limitation for δ^8-tetrahydrocannabinol, an analog of δ^9-THC, which was labeled with ^{18}F. Its uptake and distribution showed widespread uptake in the baboon brain with no particular pattern of localization (94). This pattern of distribution mainly reflected nonspecific binding because pretreatment with δ^8-THC did not affect the uptake of [^{18}F]δ^8-THC in brain. A promising alternative may be the use of THC antagonists with high receptor affinities (95).

Cigarettes and Nicotine

Even though there are 45 million cigarette smokers in the United States and there are 400,000 deaths per year associated with smoking, surprisingly little is known about the neurochemical actions of tobacco smoker exposure on the human brain, and very few imaging studies have been performed. The acute administration of intravenous nicotine has been reported to reduce brain glucose metabolism (96). In addition, PET studies with [^{11}C]nicotine have shown that cigarette smokers have increased binding in brain that could reflect the up-regulation in nicotinic receptors sites reported in smokers (97).

Monoamine oxidase A and B (MAO A and B) have been examined in the human brain (98 ,99). MAO breaks down neurotransmitter amines like DA, serotonin, and norepinephrine, as well as amines from exogenous sources. It occurs in two subtypes, MAO A and MAO B, which can be imaged *in vivo* using [^{11}C]clorgyline and [^{11}C]L-deprenyl-D2 and PET. Using these ligands, it was shown that cigarette smokers have a reduction in brain monoamine oxidase B (MAO B) of about 40% relative to nonsmokers and former smokers, and smokers have a 28% reduction in brain MAO A relative to nonsmokers. It is known that nicotine does not inhibit MAO B at physiologically relevant levels. MAO A and B inhibition is associated with enhanced activity of DA, a neurotransmitter involved in reinforcing and motivating behaviors and in movement as well as decreased production of hydrogen peroxide, a source of reactive oxygen species. Inhibition of MAO by cigarette smoke could be one of the mechanisms accounting for the lower incidence of Parkinson disease in cigarette smokers. MAO A and B inhibition by smoke may also account for some of the epidemiologic features of smoking that include a higher rate of smoking in persons with depression and addiction to other substances. In this regard, it is noted that MAO A inhibitors are effective in the treatment of depression.

Ecstasy

The toxicology of the popular illicit drug ecstasy, 3,4-methylenedioxymethamphetamine (MDMA), is covered in Chapter 108 . Studies in laboratory animals have shown that ecstasy induces neurotoxicity to serotonergic neurons. Ecstasy users imaged with the PET ligand [^{11}C]McN-5652 (for 5-hydroxytryptamine transporters), showed decreased global and regional brain 5-hydroxytryptamine transporter binding compared with controls (100). SPECT studies with [^{123}I]β-CIT (a radioligand for DAT and serotonin transporters) confirmed the reductions in serotonin transporters in ecstasy users (101) and provided preliminary evidence of serotonergic neurotoxicity by ecstasy in humans.

Because the cerebrovasculature is regulated partly by the serotonergic system, it was questioned whether ecstasy would affect CBF in humans. For this purpose, CBF was measured with SPECT in ecstasy users tested at baseline and after receiving MDMA (102). Abstinent ecstasy users showed no baseline CBF changes when compared with controls. However, within 3 weeks after MDMA administration, CBF remained decreased in the visual cortex, the caudate, and the superior parietal and dorsolateral frontal regions compared with baseline values. These reductions were interpreted as reflecting transient effects of MDMA on the serotonergic system or the indirect effects of its metabolites on the DA system.

PET and FDG were also used to measure regional brain glucose metabolism in ecstasy users (103). Ecstasy users showed altered activity in amygdala, hippocampus, and Brodmann's area II, findings interpreted as suggesting a long-term effect of ecstasy on brain function.

Spectroscopic studies with proton MRS done in ecstasy users showed normal *N*-acetyl compounds in all brain regions but showed increases in myoinositol concentration (+16.3%) and the myoinositol-to-creatine ratio (+14.1%) in parietal white matter (104). The finding of a normal *N*-acetyl concentration was interpreted as a lack of neuronal injury in recreational ecstasy users, and the increase in myoinositol was seen as an increase in glial content.

Methamphetamine

Methamphetamine is a particularly problematic drug not only in that it is highly addictive but also because animal

studies have shown that it is neurotoxic to DA cells (105). Because the pattern and doses of methamphetamine administered to laboratory animals differ from those used by drug abusers, imaging studies have been performed to determine whether similar pathologic features occur in human methamphetamine abusers. The data in humans are very limited: a postmortem study of 12 methamphetamine abusers (106) and two PET studies, one of six (107) and the other of 15 methamphetamine abusers (108). Both reported reductions in brain DATs. Moreover, for one of the studies, the reductions in DAT were associated with motor slowing and memory impairment and were present even in patients who had been detoxified for more than 11 months (108). These results provide evidence that methamphetamine, at the doses administered by humans, damages the DA terminals, that these effects are long lasting, and that the damage from methamphetamine is functionally significant.

Spectroscopic studies were done with proton MRS in abstinent methamphetamine abusers and showed that the concentration of *N*-acetylaspartate, a neuronal marker, was reduced significantly (-5 to -6%) in the basal ganglia and frontal white matter of methamphetamine users compared with controls (109). The frontal white matter (*N*-acetylaspartate) correlated inversely with the logarithm of the lifetime methamphetamine use. The methamphetamine users also showed significantly reduced total creatine in the basal ganglia (-8%) and increased choline-containing compounds (+13%) and myoinositol (+11%) in the frontal gray matter. These findings were interpreted as providing evidence of long-term neuronal damage in abstinent methamphetamine users.

Caffeine

Caffeine is an antagonist of the G-protein–linked adenosine receptors. Caffeine is a mild stimulant when taken orally, but it has marked effects when administered intravenously, including olfactory hallucinations.

Despite the widespread consumption of caffeine and the potential for confounding effects in studies of other drugs of abuse, caffeine appears to be the subject of only a single PET CBF study. Caffeine (250 mg), given either intravenously or orally, produced an approximately 30% decrease in global CBF measured using [^{15}O]water, without significant regional differences (110). The effect of caffeine lasted for at least 45 minutes. The original purpose of this study was to examine whether patients with panic disorder exhibited a difference response from control subjects, but no differences were found.

The effects of caffeine on regional brain metabolism, as assessed by the changes in brain lactate, were measured with MRS (111). The response of heavy caffeine users was compared with that of caffeine-intolerant persons. Subjects were studied at baseline and 1 hour after caffeine (10 mg/kg). The caffeine-intolerant group but not the heavy caffeine users showed significant increases in brain lactate. Reexposure of the regular caffeine users to caffeine after a caffeine holiday resulted in rises in brain lactate similar in magnitude to those seen in the caffeine-intolerant group. These results provide evidence of caffeine tolerance in the human brain and do not support the role of lactate as a mediator of caffeine intolerance.

Studies using [^{11}C]caffeine showed that its binding in brain was mostly nonspecific, as was expected because of caffeine's low affinity and lack of selectivity for adenosine receptor subtypes (112). Intravenously administered [^{11}C]caffeine resulted in very fast uptake and clearance from brain, contrasted with the slow brain uptake when [^{11}C]caffeine was given orally through a nasogastric tube (brain uptake was increasing even after 2 hours at the end of the study).

CONCLUSION

Part of "103 - Application of Imaging Technologies in the Investigation of Drug Addiction "

Brain imaging using virtually all available methods has proved useful in evaluating the effects of abused drugs. Much has been learned about the mechanisms of action in human subjects as well as the potential for toxic effects. Among the consistent findings across the various drugs of abuse are the following:

1. The pharmacokinetic properties of drugs of abuse affect their reinforcing effects.
2. Many of the drugs of abuse have vasoactive effects, which, in the case of cocaine, can result in cerebrovascular disease.
3. The orbitofrontal cortex and the anterior cingulate gyrus have consistently been shown to be abnormal in addicted subjects, a finding implicating a role in the process of drug addiction.
4. The availability of DA D2 receptors is reduced in most drug abusers who have been investigated. Because DA D2 receptors modulate reward circuits, this could be one of the mechanisms that contributes to drug self-administration.

As new ligands and new methods are developed, an improved understanding of the mechanisms of addiction can be expected.

Molecular and Cellular Neurobiology and Pathophysiology of Opiate Addiction

Mary Jeanne Kreek

Mary Jeanne Kreek: Laboratory of the Biology of Addictive Diseases, Rockefeller University, New York, New York.

In the years 1994 to 2001 (since the last edition of this book went to press), innumerable and important advances have been made in our understanding of the molecular and cellular neurobiology, as well as pathophysiology, of opiate addiction. Clearly, the greatest advances have come about ultimately because of the first successful cloning of a specific opiate receptor, the δ receptor, achieved in late 1992 by two groups working independently, using expression cloning in a cell line that is known to express the δ-opioid receptor (1 ,2). The reports of the groups of Evans and colleagues from Los Angeles and Kieffer and colleagues from Strasbourg, France, followed by the cloning of μ- and κ-opioid receptors of rodents and in humans by Yu, Uhl, and others, opened new doors for both animal and basic clinical research studies, as well as human molecular genetics studies (1 ,2 ,3 ,4 and 5). Other notable technologic advances have been made recently and are continuing to be made. Possibly the most dramatic of these, from which we will undoubtedly see novel and unexpected findings over the next few years, is the development of microarray technology, to determine the changes in levels of gene expression of literally thousands of genes simultaneously (although not yet with the sensitivity required to detect changes in mRNA levels reflecting gene expression of many neuropeptides and most neuroreceptors), and also even newer microarray technology for identification and screening for human polymorphisms, including single nucleotide polymorphisms (SNPs) (6 ,7). By using these new findings and technologies, as well as by building on earlier and current best techniques, profound advances have been made in each of three areas, of which only a few may be covered briefly herein.

Many of these varied advances have been collated and placed in perspectives of our earlier knowledge in several thoughtful reviews, such as selected reviews of preclinical research (6 ,8 ,9 ,10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 ,18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 and 26), basic clinical research (27 ,28 ,29 ,30 and 31), and molecular biology and genetics (32 ,33 ,34 and 35). All these advances have and will continue to make further revelations concerning each of the addictions, and in particular, for this discussion, opiate addiction.

PRECLINICAL STUDIES OF CHRONIC ADMINISTRATION AND WITHDRAWAL EFFECTS OF OPIATES IN DIVERSE AND NOVEL ANIMAL MODELS

Part of "104 - Molecular and Cellular Neurobiology and Pathophysiology of Opiate Addiction "

Neuropeptide and Neurotransmitter Systems Primarily Affected

Opioid Peptides and Receptors: Molecular, Cell Biological, and Signal Transduction Alterations, and Possible Implications for Pathophysiology of Opiate Addiction

After the definitive discovery of specific opioid receptors in 1973, research began to address what had been a long-standing hypothesis, later apparently to be disproved. The hypothesis was that tolerance to opioids depended on down-regulation or decreased availability of, and thus access to, μ-opioid receptors after chronic μ-opioid agonist (e.g., heroin or morphine) exposure. Later, this could be considered to result from “desensitization” of μ-opioid receptors while still on the cell surface (i.e., phosphorylation or uncoupling of the receptors from their G-protein–coupled signal transduction mechanisms essential for the effects after binding), or, alternatively, to result from a decrease in numbers of receptors on the cell surface (i.e., actual down-regulation), which could be caused either by a long-hypothesized, but only recently documented phenomenon, that of endocytosis or internalization of receptors, or by a decrease in the reappearance

of receptors at the cell surface once internalized (36 ,37 ,38 ,39 ,40 ,41 ,42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 and 52). Moreover, a significant decrease in production of new receptors could contribute to a so-called down-regulation. Although the terms *down-regulation* and *up-regulation* have been used loosely with inadequate definitions, the overall concept that chronic μ-opioid agonist administration may cause reduced capacity to bind, or increased capacity to bind, or to have no effect, but each alternative with reduced capacity of activated receptors to have an effect (or “tolerance”), has persisted, and repeatedly studied, with conflicting results. The earliest studies to address this issue of impact of chronic opioid administration effects on binding were conducted to elucidate the well-documented and accepted phenomenon of tolerance, both in cell systems and in whole animals. Morphine was the most common opiate used to determine whether opioids down-regulated or otherwise altered opioid-receptor–binding sites.

Later, the effects of specific opioid antagonists on opioid-receptor binding or density were also conducted, primarily using naltrexone. The binding of opioid antagonists, of course, does not involve coupling; that is, no $G_{i/o}$-protein–coupled signal transduction mechanisms are involved, because the opioid antagonists (according to most current theories) do not activate receptors, but rather prevent activation by endogenous or exogenous opioids. The effect of chronic administration of primarily μ-opioid-receptor antagonists to up-regulate the binding capacity, or density, of μ-opioid receptors has been well established. There is now essentially a consensus from many and diverse studies that the chronic administration of opioid antagonists, primarily naltrexone, will cause a significant up-regulation or increase in density of μ-opioid receptors (53 ,54). There has, however, been some controversy regarding whether opioid antagonist treatment and the resultant up-regulation of μ-opioid receptors leads to a sensitized state, that is, a state in which an opioid agonist would have a greater than usual effect on any system. This has been addressed both in animal models and in humans, with some conflicting results.

From the very beginning of the documentation of the existence of specific opiate receptors, in 1973, although numerous studies have used several different opioid agonists, primarily morphine, given by different regimens, ranging from intermittent injections to repeated pellet implantation, to a few studies using chronic administration by pump, there have been conflicting study results and no consensus on the effects on μ-opioid-receptor binding or density. The results reported from studies conducted in living adult animals, for the most part, have shown no overall net changes in μ-opioid-receptor–binding capacity, that is, no overall changes in opioid-receptor density, as measured by quantitative autoradiography or by classic homogenate binding assay studies, and, more recently, no overall changes in μ-opioid-receptor mRNA levels. The original studies, conducted in living adult animals by the groups that included those who first defined opioid receptors, showed no alterations of opioid receptors during chronic morphine exposure, and this finding altered their initial hypothesis, that such chronic exposure to an opioid agonist would cause down-regulation of receptors (55 ,56 and 57). Subsequent studies using diverse ligands and dosing regimens continued to give varied results, with up-regulation of μ-opioid receptors, down-regulation of μ-opioid receptors, and no change of μ-opioid-receptor density or binding after chronic μ-opioid-agonist administration all reported. The prevailing concept for receptor-agonist ligands and, in this case, specifically agonists for the μ-opioid-receptor system, has been that persistent activation of receptors would generally lead to down-regulation, and conversely, the persistent deprivation of receptors of specific ligands would generally lead to persistent lack of activation of receptors and thus to up-regulation. However, the results are complex and conflicting.

From 1996 to 2000, several intriguing articles appeared concerning the effects of opioid-agonist administration on receptor internalization (44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 and 52). In addition, further and relevant studies on signal transduction, primarily through G-protein–coupling mechanisms, but also alternative mechanisms, appeared and extended our earlier knowledge and may ultimately explain some of the apparently conflicting results concerning receptor binding and density (12 ,13 ,14 and 15 ,18 ,19 ,20 and 21 ,23 ,24 ,34 ,36 ,37 ,38 ,39 ,40 ,41 ,42 and 43).

Starting with the early seminal work of Aghajanian in the late 1970s, chronic morphine administration to whole animals was shown to alter, at a cellular level, the function of neurons, specifically in the locus ceruleus, and also to lead to tolerance and physical dependence (12 ,18 ,20 ,24). These changes included initially the well-established acute inhibition by morphine of adenylyl cyclase, as well as resultant inhibition of the cyclic adenosine monophosphate (cAMP)–dependent cascade, followed by, during chronic morphine treatment, a compensatory increase of activity of adenylyl cyclase, with an increase in the cAMP-dependent cascade, including increases in protein kinase A and increases in phosphorylated proteins, as well as of the cAMP-dependent response element binding protein, or CREB (18 ,20 ,24). Nestler and Aghajanian hypothesized that this up-regulation of the entire cAMP pathway in the locus ceruleus represents a compensatory change to oppose or offset the initial inhibitory effects of morphine and thus could be considered to be one component of tolerance (18 ,20). They also suggested that these increases in the cAMP pathway components could contribute to opiate dependence and thus withdrawal, because these changes could be involved in a variety of functions once no longer opposed by morphine (18 ,20). This concept is of particular relevance because this up-regulation of the entire cAMP pathway during chronic morphine exposure has been shown to occur predictably in the locus ceruleus of all strains and species of rodents studied to date. Because the locus ceruleus is the major noradrenergic nucleus of the brain, diverse noradrenergic functions that are known to be activated in opiate

withdrawal could be affected. Nestler and other groups showed that although these changes occur uniformly in the locus ceruleus neurons, and in a few other brain regions, particularly in the nucleus accumbens, this type of change in the nucleus accumbens is strain dependent, and also such changes do not occur in many other brain regions in any strain or species (12, 18, 20, 24) . They also do not occur in the gastrointestinal tract. Nestler and others did not find a down-regulation of μ-opioid receptors during chronic morphine treatment in the locus ceruleus (18, 20, 24) . They did, however, report an uncoupling of the μ-opioid receptor from its G-protein–coupled inwardly rectifying potassium channels during chronic morphine exposure, with a resultant reduction in the maximal outward current and documented decreased efficiency along with decreased potency of the opioid. This is intriguing in the context of findings of the laboratories of Yu and Kreek, who reported that after binding of the long, 31-residue, endogenous opioid ß-endorphin to the variant μ-opioid receptor coded by the very common SNP, A118G, there is enhancement of activity of these G-protein–coupled inwardly rectifying potassium channels (58) .

Almost all groups, again starting with the earliest work of Aghajanian, as well as more recent work of Nestler and others, have suggested that the locus ceruleus may be primarily involved in expression of opioid physical dependence and thus in opioid withdrawal (20) . Selley and Childers et al. studied the effects of chronic morphine treatment on opioid-receptor–coupled G-protein activity in membranes from the locus ceruleus and showed that chronic morphine treatment decreased the inhibitory G-protein activity in the locus ceruleus and yet did not produce any detectable desensitization, a finding suggesting a potential adaptation at that level (40) . Chronic morphine treatment decreased both basal and opioid stimulated guanosine triphosphatase (GTPase) activity and yet caused no changes in the percentage of stimulation by an opioid agonist. All these results were extended by binding assays using [^{35}S]GTPγS (40) . In further studies, it was found that long-term heroin self-administration also similarly altered the opioid-receptor–activated G proteins in specific brain regions, primarily in specific brainstem nuclei (42) . Decreased μ-opioid-agonist–stimulated [^{35}S]GTPγS binding was observed in the locus ceruleus and in a few related regions during long-term heroin self-administration. These findings were similar to those previously described in animals treated with morphine on a long-term basis (40) . Moreover, the decreased μ-opioid-stimulated [^{35}S]GTPγS binding was found in two additional regions, the thalamus and the amygdala, which may be of importance for the reinforcing effects of drugs of abuse and thus self-administration (42) .

All these scientists mention that the neuronal and molecular basis of opioid tolerance and dependence remains unclear. The opioid receptors involved have all been cloned and have been documented to be part of the G-protein–coupled family of seven transmembrane receptors; there has been further documentation of receptor phosphorylation, desensitization, and uncoupling from G proteins, as well as new studies documenting internalization (endocytosis) of opioid receptors (36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51 and 52) . However, studies in animals continue to produce very conflicting results concerning the effects of chronic opiate administration on opioid-receptor binding and density or number. Similarly, despite documentation by many groups that cellular adaptations may be directly involved in the development of tolerance and dependence, the mechanisms have yet to be fully elucidated. Moreover, multiple other neurotransmitter systems have been implicated, in particular the *N*-methyl-D-aspartate (NMDA)–receptor complex and its ligands.

Chronic morphine administration, with resultant changes in G-protein–coupled signal transduction mechanisms and changes in downstream effectors, such as increases in CREB and phosphorylated CREB, and also other changes such as increases in and accumulation of chronic FRAs (Fos-related antigens), are all nonspecific. For instance, diverse stimuli such as cocaine, opiates, opiate withdrawal, nicotine, other drugs of abuse, and stress have been shown to cause increases in chronic FRAs (12) . CREB is one component of the enhanced cAMP response and is a transcription factor; chronic FRAs have now been identified as isoforms of ΔFosB, which is a splice variant of the *fosB* gene. Each of these enhanced or altered transcription factors can change the levels of expression of many specific genes and in specific brain regions. These increases in CREB and in chronic FRAs, both results of chronic morphine administration, may yield enhanced or altered gene transcription elements and, in turn, changes in levels of expression of specific genes and in specific brain regions. The increases in chronic FRAs after long-term morphine administration occur exclusively in the striatum, whereas the increases in chronic FRAs seen after stress occur in the prefrontal cortex (20) . However, these components are also transient. For instance, Nestler found that chronic FRAs probably persist for only a few weeks after accumulation during chronic opiate or cocaine administration and thus require repeated exposure to a drug of abuse for reappearance or for persistence. These increased and accumulated amounts of CREB and chronic FRAs are tangible examples of neuroplasticity of the brain and document one type of change that may occur and persist with chronic exposure to a drug of abuse. As Nestler warned, however, they are but two of probably many such changes and, although related to specific addiction related phenomena, are not the sole cause of any of the three distinct and separable phenomena of tolerance, physical dependence, or addiction. Moreover, all the resultant gene expression changes that occur, related to CREB and ΔFosB, and that may contribute to an atypical activator protein 1–type transcription factor, are nonspecific changes, with respect to the causative agent. In addition, these transient, but gene-specific, changes in gene expression can

occur in specific brain regions after specific times of exposure to, or withdrawal from exposure to, a drug of abuse such as morphine (but also cocaine and other drugs of abuse).

Direct effects of these transcription factors have been studied only to a limited extent. Nestler hypothesized that the documented increases in amounts and phosphorylation of CREB in the locus ceruleus caused by chronic morphine administration may be directly involved in the regulation of the entire cAMP pathway through the CREB effects as a transcription factor on gene expression (18). His group showed that application of CREB antisense oligonucleotides applied to the locus ceruleus of opiate-dependent rats decreases the opiate withdrawal-induced increases in neuronal firing that are usually seen (18). Further, the laboratory of Nestler showed that accumulation of chronic FRAs during chronic morphine treatment, related to the transient early gene protein products Fos and Jun, which, in turn, join to form a major gene transcription factor, activator protein 1, may play a role in the effects of morphine and also of stimulants (18). For instance, Nestler's group showed in *fosB* knockout mice, in which chronic FRAs are presumed not to be formed or accumulate, an enhanced locomotor response to cocaine (12). Using an effective construct involving both a tetracycline transactivator gene to allow regulation of gene expression and the gene encoding ΔFosB that then can be delivered to a specific brain region, Nestler's group conducted further studies of the effects of drugs of abuse. This gene construct allows overproduction of ΔFosB by the gene insertion, the overexpression of which can be prevented by administration of a tetracycline congener, but it be started again by stopping treatment with the tetracycline congener. The overexpression can be both brain region specific and time specific (12). To date, enhancement of ΔFosB in the striatum has been shown to alter the behavioral response to cocaine (12). Using a different transgenic approach, a viral vector may be used to deliver a desired gene to a specific brain region to yield overexpression. Carlezon and Nestler and their colleagues used such a delivery system to achieve overexpression of the NMDA-receptor component, $GluR_1$, with overexpression in different specific brain regions; in some brain regions, and with this region-specific overexpression, they were able to document increases in opiate reward and, in other brain regions, increases of aversion to opiates (59).

There is an increasing consensus that the reinforcing effects of drugs of abuse, along with possibly physical dependence, are not directly related to tolerance, and they also may not be directly related to any changes in receptor density, number, desensitization, internalization, G-protein uncoupling, or other effects on signal transduction mechanisms. These findings are further supported by the report of Bohn, Lefkowitz, Caron, and colleagues that, in studies in ß-arrestin knockout mice, one sees enhancement and persistence of the antinociceptive effects of morphine (60). Furthermore, Bohn and colleagues reported that no tolerance develops to the antinociceptive effects of morphine during chronic administration, but they also said that there apparently is no impact on physical dependence in the ß-arrestin knockout mice (61).

Dopamine, Other Neurotransmitters, Neuropeptides, and Their Receptors: Molecular, Cell Biological and Signal Transduction Alterations, and Possible Implications for Pathophysiology of Opiate Addiction

The early work of many groups showed that opiates, like most other drugs of abuse, appear to act to enhance dopaminergic tone and through that enhancement achieve some, most, or all of their reinforcing effects. Moreover, through a variety of studies, primarily conducted in animals using either surgical lesions or specifically directed neurotoxins, and also other specific chemicals to enhance or decrease dopaminergic function, along with ultimately microdialysis techniques, researchers showed that enhancement of dopamine tone in the mesolimbic-mesocortical dopaminergic system in particular is associated with the rewarding or reinforcing effects of most or all drugs of abuse. The seminal work by Johnson and North documented unequivocally that one action of μ-opioid agonists, exerted through μ-opioid receptors localized in the ventral tegmental area, is on inhibitory GABAergic interneurons and is one of inhibition of those neurons (62). Thus, by inhibiting these inhibitory neurons, which normally put a brake on the dopaminergic neurons in the ventral tegmental area, the result is activation of the dopaminergic neurons, with enhanced release of dopamine in the nucleus accumbens, as well as in the amygdala and probably in all other regions of the mesolimbic-mesocortical dopaminergic fields (62).

Although many investigators have attributed the reinforcing effects of all drugs of abuse, including heroin and morphine, to actual or presumed enhanced dopamine levels in the nucleus accumbens, through this indirect action for opiates, and for cocaine, through a direct blockade of the dopamine reuptake transporter, there is increasing evidence that dopamine not only is not essential for the reinforcing effects of heroin and morphine, but also does not play a central role in the reinforcing and rewarding effects of opiates.

Studies have been conducted in animals with deletion of the dopamine transporter gene, which many researchers had hypothesized would eliminate cocaine self-administration because of the very high constant levels of dopamine and the lack of further effects by superimposed cocaine (63). This was found to be not the case (63). The dopamine transporter knockout mice were found unequivocally to self-administer cocaine, although the acquisition of that behavior was slower than in the wild-type mice (64). Thus, even for cocaine, dopamine clearly plays a role in the rewarding effects,

but it is not the sole component, nor are changes in dopamine levels essential for the reinforcing effects of cocaine (63 ,64). In that same animal model, the dopamine reuptake transporter knockout mice, it has been found, however, that morphine is more avidly self-administered than in wild-type mice, a finding suggesting a positive interaction between the persistently elevated levels of dopamine and morphine to enhance reward (65). Hemby and Smith and their colleagues also found a synergistic elevation of extracellular dopamine when cocaine was added to heroin in self-administration studies (66). These findings may explain, in part, the common co-dependency in humans of both heroin and cocaine addictions.

With respect to opiates, two very early studies showed that when animals were lesioned to delete the dopaminergic neurons completely in discrete brain regions by use of a neurotoxin, 6-hydroxydopamine, self-administration of morphine proceeded normally as in unlesioned animals. However, in such animals, cocaine self-administration was eliminated.

There have been conflicting results in other studies. For instance, in one study using the technique of *in vivo* fast cyclic voltammetry, it was found that heroin caused a dose-dependent increase in dopamine in the nucleus accumbens during heroin self-administration, and co-administration of a κ-agonist (U-50,488 H) with the heroin, or alternatively, intracerebroventricular administration of dynorphin A, significantly depressed the heroin-stimulated dopamine release (67). Moreover, installation of the κ-synthetic compound or natural ligand dynorphin A alone decreased basal dopamine release, as had also been shown by Claye and others (68). Studies by Xi, Fuller, and Stein thus suggested that the μ-agonist morphine activates the mesolimbic-mesocortical dopaminergic pathway and that κ-opioid-receptor activation offsets, or counterregulates, that activation (67).

However, another set of studies by Hemby, Smith and colleagues showed that systemic self-administration of heroin alone does not cause any elevation in dopamine as determined by *in vivo* microdialysis with the probes in the nucleus accumbens (69). In related studies, these investigators found, as have numerous others, that cocaine caused a striking increase in extracellular dopamine concentrations in the nucleus accumbens, and, moreover, the combination of cocaine and heroin caused a synergistic elevation (66). Their finding that heroin alone failed to cause an increase in dopamine in the nucleus accumbens complemented several earlier findings that heroin self-administration is not attenuated by administration of dopamine antagonists, as well as even earlier studies showing that integrity of dopamine pathways in the nucleus accumbens is not essential for heroin self-administration. These findings document further the early hypothesis of the Kreek laboratory, and many others, that the reinforcing properties of heroin are mediated primarily by dopamine-independent mechanisms and probably by the μ-opioid receptor itself. This hypothesis has been ultimately supported by the findings that μ-opioid-receptor deletion knockout mice have no self-administration of opiates and no rewarding effects of opiates (reviewed in ref. 33).

In another study, which used morphine pellet implantation to develop opioid tolerance and dependence, a reduction in dopamine D2-receptor mRNA levels, but no change in dopamine D1 mRNA levels, was found at the end of the 6 days of morphine exposure (70). The mRNA levels for both dopamine D1 and D2 receptors was reduced after 1 day of withdrawal, and both returned toward normal by the third day after drug withdrawal. These findings may be related to the reduction in dopamine D2-receptor binding, which has been seen in human heroin addicts, by using positron emission tomography. However, curiously in this study, but not in other studies, reductions of mRNA levels for dynorphin and enkephalin genes were found during morphine exposure. In contrast, enhanced dynorphin mRNA levels have been found at least after acute single and multiple intermittent-dose morphine administrations (71 ,72). Further studies will be needed to determine the time course of dynorphin mRNA level changes during morphine exposure. Trujillo, Akil, and their colleagues showed that chronic injection or infusion of morphine caused increases in levels of dynorphin peptides in the dorsal striatum (caudate putamen) but not in the ventral striatum (nucleus accumbens) (73).

Intriguingly, Lee, Henriksen, and colleagues found that only a few (approximately 20%) nucleus accumbens neurons seem to exhibit an inhibitory response after heroin self-administration, along with about 40% of prefrontal cortex neurons showing such inhibition (74). Thus, the multiple changes in signal transduction observed and discussed earlier, including the effects of chronic morphine administration on μ-opioid-receptor–stimulated [^{35}S]GTPγS binding changes, with reduction of [^{35}S]GTPγS binding specifically in the brainstem nuclei, including the dorsal raphe nucleus, the locus ceruleus, the lateral and medial parabrachial nuclei, and the commissural nucleus tractus solitarius, may result from a direct opiate effect or an indirect effect by alteration of the dopaminergic system (40 ,42). Similar findings were made by the group of Sim-Selley, Selley, Childers, and colleagues after chronic heroin self-administration, with the greatest decrease in μ-opioid-receptor–stimulated [^{35}S]GTPγS binding in the brainstem and the lowest alterations in binding in the striatum and cortex (42). Because the changes of dopamine D1-receptor activation would act in one direction and dopamine D2-receptor activation would act in the opposite direction on adenylyl cyclase activity, the effects on these receptors could also influence the effects of μ-opioid-receptor activation, and the changes that have been observed may result exclusively from the opioid effects acting at the μ-opioid receptors or also secondary indirect effects on dopamine receptors.

These and other findings suggest that opiates may act

directly to alter dopaminergic systems both in the ventromedial striatum, that is, the core and shell of the nucleus accumbens, and in the dorsolateral striatum, that is, in the caudate putamen region. Clearly, there are abundant μ-opioid receptors as well as κ-opioid receptors in those regions (26 ,75 ,76 and 77). Work from the Kreek laboratory showed that another drug of abuse, cocaine, when delivered in a binge pattern, which markedly enhances dopaminergic tone, causes an increase in density of μ-opioid receptors and also κ-opioid receptors in those brain regions, and it also alters basal and opioid-regulated adenylyl cyclase activity in these regions (75 ,76 and 77). There have been no similar findings with respect to increasing μ-opioid-receptor density after chronic opioid administration, however. It is not really known to what extent reinforcement or reward resulting from heroin and morphine occurs because of activation directly in these areas, especially the nucleus accumbens and possibly also the amygdala, as contrasted to indirect effects on the ventral tegmental area. The effects on dopamine in each of these different locations and also the different mechanisms involved have not yet been fully elucidated using a model of chronic, high-dose, intermittent but evenly spaced opiate administration, mimicking the human pattern of heroin or morphine abuse and addiction, and also after withdrawal, as well as during reexposure after such opiate administration. During chronic binge pattern cocaine administration, a pattern mimicking the human condition, there is a progressive lowering of basal, as well as cocaine-stimulated, dopamine levels in the extracellular fluid of the caudate putamen and in the nucleus accumbens (78). Noble and Cox clearly defined a role of the dopaminergic system in opioid-receptor desensitization in these brain regions during chronic morphine administration (39).

After chronic opiate administration, Nestler and colleagues found increases in tyrosine hydroxylase in the ventral tegmental area. This is a rate-limiting enzyme in the biosynthesis of dopamine. They also found a reduction in mean size of the ventral tegmental area dopaminergic neurons and decreased axonal transport to the nucleus accumbens (24 ,79). However, there were no changes in numbers of dopaminergic neurons and no changes in the size of nondopaminergic neurons (79). Within ventral tegmental area, infusion of brain-derived neurotrophic factor prevented this morphine-induced reduction in size of dopaminergic neurons (79). Their group also found that chronic morphine administration resulted in an increase of other components related to signal transduction, including the extracellular signal regulated kinases (ERKs), which are effectors for brain-derived neurotrophic factor in the ventral tegmental area (24). However, the time course of these changes and their persistence after morphine withdrawal have yet to be elucidated, and their relation to both physiology and the behaviors of addiction also have not yet been fully explored, although the findings suggest that neurotrophic factors may act in response to the opiate-induced changes in neural integrity, that is, the neuroplasticity after chronic opiate administration that results in impairment of normal neural integrity. Both the chronic morphine-induced injury and the counterregulatory events may alter neural growth, development, and synapse formation, signal transduction, and overall system integrity (24 ,79).

Similarly, the findings that acute and chronic morphine administration and withdrawal may enhance dynorphin gene expression and dynorphin peptides, undoubtedly events mediated in part through action of dopamine D1 receptors, often co-localized on cells with dynorphin gene expression, as well as more direct effects of enhanced transcription factors on dynorphin gene expression, may be again important counterregulatory events, which also represent examples of profound neuroplasticity of the brain. Such findings have also been made during binge pattern cocaine administration (80 ,81). Enhanced dynorphin peptides, in turn, acting at κ-opioid receptors, may reduce dopaminergic tone in many brain regions, including those involved in reward and also locomotor activity, and they may also attenuate opioid withdrawal in dependent animals or humans (6 ,8 ,9 ,10 and 11 ,16). Again, these events must be considered to be a direct result of neuroplasticity and are counterregulatory, the attempt to attenuate, modulate, or even brake the events caused by the rapid changes in dopaminergic tone brought about especially by stimulants such as cocaine, but also to a lesser extent also by opiates.

The changes in signal transduction mechanisms after chronic heroin or morphine administration are undoubtedly primarily the result of the effects of chronic opioid administration. However, because there are also significant changes in dopaminergic tone with enhanced signaling through the dopaminergic pathways, owing to indirect or direct activation of dopamine release, the changes in signal transduction observed may also result from enhanced activation of the dopaminergic neurons, as stated earlier. D1- and D5-type dopaminergic receptors enhance adenylyl cyclase activity, an effect similar to that occurring in the locus ceruleus after chronic, but not acute, morphine administration, in most strains of rodents studied, and also in the nucleus accumbens in some strains of some species. In contrast, activation of the dopaminergic D2 receptors causes a reduction in adenylyl cyclase activity, such as observed during acute morphine administration in all brain regions of strains and species of rodents studied, as well as in all cell systems studied, and an effect that continues to pertain in some specific regions of the brain and other parts of the body during chronic opioid administration. Thus, the observations of alterations in the downstream events of the adenylyl cyclase changes may be the cumulative response of chronic morphine administration on μ-opioid-receptor activation and also of dopamine on dopaminergic D1- and D2-receptor systems.

More recently, the findings of Crain and Shen showed the ability of very small amounts of specific opioid antagonists,

in fact, to enhance the analgesic effects of the μ-opioid-receptor agonists and to prolong the opioid-agonist effects both in animal models and in humans (82). Crain and Shen hypothesized that, although most μ-opioid receptors are coupled with inhibitory $G_{i/o}$ protein, a small proportion may be coupled at the stimulatory G_s protein, which can be suppressed with small amounts of opioid antagonists. These findings of enhanced morphine analgesia are, in part, very similar to the findings of Bohn, Caron, Lefkowitz, and colleagues, in mice with deletion of ß-arrestin (60). These researchers also showed that ß-arrestin is important in several distinct functions, including events leading to the internalization of an agonist bound μ-opioid receptor, which, after the phosphorylation of the bound form, binds to ß-arrestin, along with binding by G-protein–receptor kinases (60). This event of ß-arrestin binding has been described as potentially part of the process that desensitizes, that is, leads to G-protein uncoupling of the μ-opioid receptors, as well as being actually involved in the internalization of endogenous and some exogenous agonist-bound μ-opioid receptors (44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 and 52 ,60). The role of internalization in the development of tolerance and the independent process of dependence remain unclear because there are many conflicting results, including the finding that most exogenous opioid ligands, including morphine, that do not induce prompt internalization of μ-opioid receptors once bound, clearly lead to the development of both tolerance and physical dependence (44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 and 52). In sharp contrast, methadone and etorphine do lead to prompt internalization of μ-opioid receptors, just as do all the natural endogenous opioid peptides such as Met-enkephalin and ß-endorphin (44 ,45 ,46 ,47 ,48 ,49 ,50 ,51 and 52). Intriguingly, in the mice with deletion at the ß-arrestin-2 gene, enhanced morphine analgesia was seen, and further studies revealed that tolerance does not develop to morphine effects, and yet objective signs reflecting the development of physical dependence are present after chronic morphine administration (60). These studies again dissociated the development of tolerance from the development of physical dependence. The studies of the group of Crain, as well as the studies of the group of Caron and Lefkowitz, suggested that either deletion of ß-arrestin or suppression, by opioid antagonists in very small doses, of opioid receptor coupled to G_s, the stimulatory G-protein pathway, will enhance opioid analgesia and also may attenuate or prevent development of tolerance. It is not known whether blocking of the $G_s$coupling alters the development of physical dependence, however. In possibly related studies, Jeziorski and White showed that the NMDA antagonist, MK-801, prevents development of behavioral sensitization during chronic morphine administration, whereas dopamine-receptor antagonists prevent expression, but not development, of sensitization (83). Sensitization has been suggested to be related to drug reward or craving. Possibly in contrast, Churchill, Roques, and Kalivas found that dopamine depletion, such as may happen during chronic opiate, as well as chronic cocaine, administration, augments opioid-induced locomotion (84).

There have been only limited studies of the time course of all these dopaminergic responses during investigator-administered morphine or heroin on an intermittent basis, mimicking the human pattern of heroin abuse, or during chronic self-administration of opiates. It would be assumed that possibly, as with cocaine, one sees a progressive diminution of the responsivity, with a resultant lowering of basal level and stimulant-induced rise of absolute levels of dopamine (78). Numerous human studies suggest this may indeed happen. It has been repeatedly shown in heroin addicts that the short acting μ-opioid agonist heroin will cause a prompt increase in serum prolactin levels, resulting directly from an abrupt lowering of dopamine levels in the tuberoinfundibular dopaminergic systems (85). In humans, and to a greater extent than in rodents, prolactin release is essentially solely under tonic inhibition by dopaminergic tone in the tuberoinfundibular dopaminergic system. However, it was found that during chronic methadone treatment, there is adaptation or tolerance to this phenomenon, an attenuation, but not a complete removal or ablation of this response caused by dopamine lowering and resulting in elevation of serum prolactin levels (85). Even during long-term methadone maintenance treatment, as reported in 1978, it was found that peak plasma levels of the μ-opiate agonist methadone are related temporally to the peak plasma levels of prolactin (85). These findings suggest that the long-acting opioid methadone administered orally continues to have an impact at least on the tuberoinfundibular dopaminergic system, with a lowering of dopaminergic tone, resulting in a modest increase of prolactin levels, although not exceeding upper levels of normal. However, that attenuation occurs suggests that there may be either a lowering of dopaminergic levels and tone in the turberoinfundibular dopaminergic system of that region or, alternatively, an attenuation of responsivity of the μ-opiate-receptor system. It has been shown that the κ-opiate-receptor system similarly plays a role in modulating prolactin levels in humans (86). In normal healthy volunteers, dynorphin A causes a prompt rise in serum prolactin levels, resulting again presumably from a lowering of dopaminergic tone in the tuberoinfundibular system (86). This is a μ, but also a κ-opioid-receptor effect, as documented by use of two different opioid antagonists with different receptor selectivity (86). In preliminary studies, the Kreek laboratory showed that there is altered responsivity both in former heroin addicts and in former cocaine addicts, as well as those with combined heroin opioid and cocaine dependency (87).

Acute morphine administration has been shown to have a variety of profound effects on many other neurotransmitters; this group comprises fast-acting neurotransmitters including excitatory amino acids such as glutamate and slower-acting neurotransmitters such as norepinephrine, epinephrine, and serotonin, as well as dopamine, and a variety

of neuropeptides. Very few studies have been conducted in models using chronic heroin or morphine administration, or self-administration, using long-term, high-dose, regularly spaced intermittent administration or by long-access, high-dose, self-administration, mimicking the human pattern of heroin abuse. Further work will be central to detail the long-term effects and, also of special interest, the effects of the withdrawal and reexposure to mimic relapse. However, qualitatively and quantitatively different changes have been found during chronic morphine or heroin administration by different patterns, dose, and routes of administration.

Physiologic Systems and Behaviors Primarily Altered

Stress Responsivity: Possible Implications for Opiate Addiction

An atypical responsivity to stress and stressors existing on a drug-induced basis or possibly *a priori*, on a genetic or environmental basis, as one component of the "metabolic basis" of heroin addiction was a concept that was hypothesized by the Kreek group in 1964, and it was therefore addressed directly in our prospective studies started at that time and completed in 1972, as well as in other early basic clinical research studies (6 ,85 ,88 ,89 ,90 ,91 and 92). Several laboratories went on to study, in humans, the impact of drugs of abuse and specifically heroin, but also morphine, (as used in a single dose or on a chronic basis in the pharmacotherapy of pain), on one component of stress response, the hypothalamic-pituitary-adrenal (HPA) axis (6 ,93 ,94 ,95 ,96 ,97 ,98 ,99 ,100 ,101 ,102 ,103 ,104 ,105 ,106 ,107 and 108). Long-term studies in animal models came later, however, and were performed by many different groups (6 ,8 ,109 ,110 ,111 ,112 ,113 ,114 ,115 ,116 ,117 and 118). The initiation of these studies was predicated not only on the clinical research, which clearly documented that opiates suppress the HPA axis in humans and continue to do so during the long-term self-administration of short-acting opiates such as heroin, but also, and very importantly, that normalization of this HPA axis occurs during steady-dose long-term methadone maintenance treatment, findings that were made in rigorous studies and reported as early as 1972 (6 ,89 ,90). Studies reported from the late 1970s onward have documented that the endogenous opioids clearly play a tonic modulatory role of inhibiting the hypothalamic-pituitary part of the HPA axis (reviewed in ref. 9). Further more recent studies in humans have shown that this modulation is effected by both μ- and κ-selective opioid ligands (108).

In the middle to late 1980s, several groups began to study the concept that stress and the response to stress, as well as novelty and risk-seeking, may contribute to self-administration of drugs of abuse, including opiates, and parallel studies showed that drugs of abuse including opiates, cocaine, and alcohol perturb components of the stress-responsive systems in animal models. The initial studies measured primarily specific behaviors after assessment of the relative response to novelty or to risk and used different strains of rats, as well as mice. Similarly, more recent studies looked not simply at the acute effects of drugs of abuse, but also at the subacute and chronic effects of drugs of abuse and the impact of withdrawal from such drugs on components of the stress-responsive axis. Even more recent studies went on to study levels of gene expression and the impact of exposure to drugs of abuse over a defined time course of exposure on gene expression, first on "early gene response" and then, more recently, on changes of expression of many other specific genes, in particular, components of stress-responsive axis (6 ,8 ,9 ,109 ,110 ,111 ,112 and 113).

The interactions of the dopaminergic system on the HPA axis as well as the effects of catecholamines on this axis have been studied in both animal models and in humans. It is clear that opiates, like cocaine but to a much lesser extent, cause an elevation in dopaminergic tone, especially in the mesolimbic-mesocortical dopaminergic system. However, as discussed earlier, several groups have shown that although this is a reproducible phenomenon, the mesolimbic-mesocortical dopaminergic system is not essential for heroin or morphine self-administration, and animals that have received lesions abolishing this mesolimbic-mesocortical dopaminergic system readily self-administer opiates such as morphine. This finding is in sharp contrast to that which pertains for cocaine self-administration in which lesions of the mesolimbic-mesocortical dopaminergic system abolish cocaine self-administration. Thus, the role of dopamine in the well-established acute morphine activation of the HPA axis in rodents is of interest, but it may be a related, but not central, component of the mechanism underlying self-administration. More recent studies performed in transgenic mice have had a deletion or knockout of DARPP-32, an obligatory component of the signal transduction mechanisms after activation of primarily dopaminergic D1 receptors; a profound attenuation of the well-established cocaine effect of enhancing hormones of the HPA axis, including adrenocorticotropic hormone (ACTH) and corticosterone levels, was found (110). Parallel studies using this model to explore the impact of this deletion on the well-established acute morphine activation of this axis have yet to be conducted.

Of great interest for many years, and not always recognized by research groups, has been the finding that rodents have the opposite response to acute opiate administration than do humans; that is, activation of the HPA axis occurs. Studies in drug-naive healthy humans, as well as in formerly opiate-dependent healthy humans, and in active heroin addicts have shown that the first, or initial, acute administration of a short-acting opiate, such as morphine or heroin, as well as the first or initial acute administration of a long-acting opioid, such as methadone, will cause suppression of the stress-response systems. Further, in humans, chronic self-administration of short-acting opiates, such as heroin, leads to a continuing suppression of this HPA axis. In contrast,

many rigorous studies have shown with chronic administration of a long-acting opioid, such as methadone, which allows steady-state profusion of μ-opioid receptors in humans and which is provided during methadone maintenance treatment of heroin addiction, one sees normalization of this axis (6 ,8 ,9 ,85 ,89 ,90 ,91 ,92 ,93 ,94 and 95 ,100 and 101).

Zhou et al. modeled this phenomenon in rodents and found that whereas acute intermittent morphine administration causes activation of the HPA axis, delivery of methadone by pump to achieve a steady state, paralleling the situation in humans receiving chronic methadone treatment for management of opiate addiction or chronic pain (with pump delivery essential because methadone has a half-life of 90 minutes in the rat), yields neither alterations in any component of the HPA axis nor alterations in ACTH or corticosterone levels seen (111 ,112). When administered on a chronic basis in humans or in rodents, short-acting opiates such as heroin and morphine cause suppression of the HPA axis and with no sustained activation in rodents. During either spontaneous or naloxone-precipitated withdrawal, one sees activation of the hormones of the HPA axis in all species studied.

Recently, an animal model was designed to mimic more closely the human pattern of heroin administration, with multiple short-acting opiate (morphine) administrations given at evenly spaced intervals over a single day; activation of the HPA axis with elevation of levels of ACTH and corticosterone was found (111). In addition, as part of this initial study of the effects of acute intermittent morphine, but given in a mode more closely similar to that in the human heroin addict, the impact of a superimposed stress on the effects of morphine was also studied (111). A modest stress of water restriction was applied that, like acute morphine, also significantly increased the ACTH levels. However, when morphine was concomitantly administered to the animals undergoing modest water restriction, morphine attenuated the stress-induced elevation of ACTH and corticosterone levels of this axis (111). These findings may have enormous implications for the human condition, in which morphine or heroin may act immediately to attenuate any activation of the HPA axis caused by any one of numerous types of environmental stressors. Rigorous studies have now been conducted showing that another drug of abuse, cocaine, not only causes elevation of ACTH and corticosterone levels, but also initially enhances corticotropin-releasing factor mRNA levels; however, it was also found that chronic binge pattern cocaine administration led ultimately to an attenuation of the still elevated plasma levels of ACTH and corticosterone by 14 days, and at that time corticotropin-releasing factor mRNA levels were significantly lower than basal levels (109). Recently, Zhou and colleagues made similar findings with respect to acute versus chronic ethanol treatment (113).

Various studies in humans, from the Kreek laboratory, and in animal models, by Stewart, Shaham, and Erb and many other investigators, further documented that stress and stressors, in addition to cues of drug use, and “priming,” or reexposure to a drug, may play an important role in relapse to self-administration of drugs of abuse (99 ,103 ,104 ,114 ,115 ,116 ,117 and 118). Moreover, various studies (99 ,103 ,104 ,114 ,115 and 116), such as the work of Piazza and LeMoal, showed that animals with a greater response to novelty or stress and also animals with higher basal levels of the stress-responsive hormone, corticosterone, may more readily begin to acquire self-administration of a drug of abuse, at least of low-dose psychostimulants such as cocaine (reviewed in ref. 116).

Other studies have documented unequivocally that each of the major drugs of abuse highly significantly not only alter the hormone levels of the HPA axis, but also causes alterations of levels of expression of genes of that axis, as well as of similar stress-responsive genes in other parts of the brain, not directly involved in the HPA axis (109 ,112 ,113). Corticotropin-releasing factor, indirectly and directly measured, for instance in the work of Weiss and Koob, was shown to play a potentially very important role in particular aspects of withdrawal from drugs of abuse and in relapse (6 ,8 ,9 ,89 ,90 ,95 ,99 ,103 ,104 ,117 ,118).

Studies in Novel Animal Models

Since the mid-1990s, investigators have increasingly developed and used animal models that more closely mimic human patterns of drug abuse and emulate the pharmacokinetic situation that pertains during treatment of addictions, such as the pharmacotherapy of heroin addiction, which has been successful primarily by using long-acting, specific μ-opioid-receptor–directed agonists, and also a partial agonist, including methadone, L-α-acelytmethadol (LAAM), and more recently buprenorphine (with its abuse potential minimized by the addition of the non–orally bioavailable antagonist naloxone).

One of the earliest of these animal models that closely parallels a human pattern of addiction was the development of the binge pattern cocaine (investigator) administration model. This model mimics the most common pattern of human abuse, that is, multiple self-administrations of cocaine either by the intravenous route of administration or by inhalation (smoking) of the freebase form, known as crack (75 ,76 ,77 and 78 ,80 ,81 ,119 ,120) This model has uniquely allowed identification of molecular neurobiological changes, including increases in μ-opioid-receptor density that has subsequently been identified in human cocaine addicts (75 ,77 ,121). Animal models mimicking the most common human pattern of heroin addiction have really just begun to be used (111). Heretofore, most of the subacute and chronic models used morphine, the major metabolite of heroin, not heroin itself, and they also used morphine pellet implantation, to develop tolerance and dependence with ease and predictability (with such morphine pellets usually implanted every 1, 2, or 3 days, and most commonly using

the NIH-NIDA developed 75-mg morphine pellets developed by the National Institutes of Health and National Institute of Drug Abuse). Although extremely useful and convenient for many studies, this pellet (prolonged exposure, followed by slow withdrawal) approach does not give the features that have been shown in many studies to be profoundly different from when “steady-state” (pump) or “on-off” (intermittent injections) are used. Thus, increasingly, investigator administration models are being developed in which the human pattern of heroin addiction may be mimicked, that is, with heroin or morphine administered at equally spaced intervals during the animal’s awake period, three to six times every day, and with opiate withdrawal over the sleep period, which is most common for the heroin addict.

Similarly, because methadone, the most widely used and efficacious of the μ-opioid agonist treatments for heroin addiction, has, in fact, a very short-acting pharmacokinetic profile in rodents (90 minute half-life in the rat and 60 minutes half-life in the mouse, as contrasted with a 24 hour half-life in humans, and with an even long-acting half-life of the active l(R) enantiomer in humans), to mimic the human situation for treatment in rodents, one must administer methadone in a steady state, using pump technology (122 ,123 ,124 ,125 and 126). When this has been done, very different findings may have been made than when methadone has been administered intermittently, and thus it behaves in the rodent as a short-acting μ-agonist (112).

Over the past several years, it is has also been recognized that whereas opiates and also other drugs of abuse may cause innumerable acute effects, ranging from enhanced early gene expression (e.g., cfos and related Fos peptide changes) to later changes in other gene expressions and resultant neurochemical and behavioral changes, most of these changes disappear, become attenuated, or are altered by opposing or counterregulatory events after subacute or chronic short-acting opiate administration in an on-off pattern, in which setting, for instance, both dynorphin expression and κ-opioid-receptor gene expression become elevated (71 ,72). Increasing numbers of basic laboratory investigators are therefore focusing on studies of subacute and chronic effects of opiates, as well as other drugs of abuse, and then are proceeding to study those effects that persist during and after withdrawal of opiates (and other drugs of abuse) and into the abstinence period, to determine the point of no return or very slow return to normal status and thus the critical turning point in the development of relentless drug self-administration or addiction. Thus, models also have been developed and studies conducted to attempt to model human craving and relapse (or resumption of drug exposure or self-exposure), including the use of cue-induced, stress-induced, and small amounts of drugs of abuse-induced (priming) challenges, as well as in investigator-administered drug. Relevant molecular and neurobiological effects also are being conducted.

Most of these models mentioned earlier are investigator-administered models. There have also been several parallel studies attempting to modify long-existing, self-administration models to more closely parallel the human pattern of drug abuse and addiction (8 ,127 ,128 ,129 and 130). For various important and valid research reasons, self-administration studies, which use rats, mice, or nonhuman primates, primarily have been conducted using short sessions (usually, 1 to 3 hours in length) and in special cages to which each animal is moved for such studies, to provide the repeated cueing of a novel drug-related environment. Some studies, notably by the groups of Koob and Ahmed, Miczek and Tornatzky, and Mantsch et al., are starting to use much longer sessions of self-administration and also with very different unit doses of drug to be self-administered, with the resultant findings of different patterns of acquisition, extinction, and relapse that are probably more relevant to the human disorders of addictions (127 ,128 ,129 and 130).

Most studies since the mid-1980s years also have used relatively low to very low unit doses of the drug to be self-administered (although much higher unit doses were used effectively in some very early studies). These low doses have been used to allow evaluation of the reinforcing or rewarding properties of the drug by measurement of the number of responses, or work performed, and thus willingness to work to receive a unit dose of drug and also thereby to evaluate perturbations, either pharmacologic or behavioral, that may reduce that level of work. However, in human drug abuse and addiction, much larger unit doses of drugs of abuse (heroin or cocaine) are self-administered, and for opiates especially, with longer intervals between self-administrations. Thus, the bolus effect of a very rapid onset of action of a large amount of a short-acting drug such as heroin (or cocaine), self-administered either intravenously or by inhalation with sublimation of freebase drug, is achieved. It has been shown that the rapid rate of rise of amount of drug at a specific site of action, such as the μ-opioid receptor for heroin, is more closely related to the reinforcing effects, and also the rapid offset of drug action is related to the withdrawal or abstinence effects of a drug of abuse. Thus, higher unit dosages of drugs, such as are self-administered in the human situation, will have greater positive and negative reinforcing effects than small doses (8). Numerous small doses may, in fact, more closely begin to model a maintenance or steady-state mode, although the sessions are often too short to be analogous to desired treatment. A few groups are now using much longer sessions of self-administration and also, in some studies, higher unit doses of drug (primarily cocaine, but also heroin or morphine), with the expectation of longer self-administration dosing intervals and much larger total doses self-administered, thus probably with greater impact on molecular, cellular, and neurobiological features and, importantly, a greater magnitude and also qualitatively different and relevant behavioral changes (127 ,128 ,129 and 130).

BASIC CLINICAL RESEARCH

From the mid-1960s, the Kreek group hypothesized that there is a metabolic basis to addictive diseases, and an atypical responsivity to stress and stressors may contribute to the persistence of and relapse to addiction to heroin and also addictions to other specific drugs of abuse. Furthermore, it was hypothesized that such an atypical responsivity to stress and stressors may exist *a priori* on either a genetic or an early environmentally induced basis and may contribute to the initial acquisition of an addiction (6 ,85 ,88 ,89 ,90 and 91). Therefore, prospective studies, which were started in 1964 at the beginning of research on use of the long-acting opioid methadone in the pharmacotherapy of heroin addiction linked with behavioral treatment, included studies to assess the HPA axis component of the stress-responsive system, because this is one critically important component and one that can be evaluated in living humans; additional special studies were also conducted (6 ,85 ,89 ,90 and 91). Those very early studies documented an atypical responsivity of the stress-responsive HPA axis in heroin addicts, with suppression of all aspects of this axis by chronic self-administration of the short-acting opiate heroin, including reduction of plasma levels of hormones and alterations in the feedback control mechanisms, and also abnormal gonadal function with an impact on reproductive biology (6 ,85 ,89 ,90 ,91 and 92). Further, those early prospective studies on the effects of the long-acting opioid methadone, contrasted to the physiologic and pharmacologic effects of short-acting opiates, such as heroin, showed normalization during chronic methadone treatment of diverse physiologic functions disrupted by chronic heroin abuse, with gradual normalization of the stressresponsive HPA axis function over a 3- to 4-month period during steady moderate to high-dose treatment with the long-acting opioid methadone (6 ,8 ,9 ,10 ,85 ,89 ,90 ,93 ,94 ,95 ,96 ,97 ,98 ,99 ,100 ,101 and 102).

Studies also showed reduced responsivity to a chemically induced stress during cycles of heroin addiction and normalized neuroendocrine function of the HPA axis including a normal response to a chemically induced stressor during methadone maintenance treatment (6 ,85 ,89 ,90 and 91). However, further studies that we initially performed in 1983 and 1984 (95 ,99) showed a hyperresponsivity to a chemically induced stressor in medication-free and illicit drug-free former heroin addicts. A hyperresponsivity to an induced stressor, not only in drug- and medication-free former heroin addicts, but also in active cocaine addicts, who were using cocaine alone, and in methadone-maintained persons who continue to be addicted to cocaine was subsequently documented (95 ,98 ,99 ,103 ,104).

Other very important clinical research studies that have been conducted have shown, for instance, that activation of the stress-responsive HPA axis may precede, rather than follow, the signs and symptoms of opiate withdrawal (105 ,106 and 107). The activation of the HPA axis may drive the onset and may contribute to the severity of withdrawal symptoms, rather than result from the unpleasant or noxious qualities of these signs and symptoms (105 ,106 and 107). In addition, further studies of the continuing disruption of the HPA axis during naltrexone treatment and the lack of normalization of the assumed disruptions by heroin of HPA axis function during short-term buprenorphine treatment have been reported (10 ,28 ,96 ,97 ,102).

The Kreek laboratory hypothesized that natural sequence, but shorter, dynorphin A_{1-13} administered intravenously would result in prompt induced elevation of serum prolactin levels in normal healthy volunteer subjects. This was hypothesized because of two sets of previous findings. First, it is well-known that μ-opioid-receptor agonists will effect a rise in serum prolactin levels. Moreover, it has been shown that even during long-term methadone treatment, tolerance or adaptation is not fully developed to this prolactin-releasing effect of methadone (85). The mechanism for this is also known. In humans, prolactin release is essentially completely under tonic inhibition by dopamine. Therefore, an elevation in prolactin levels indicates a spontaneous or induced reduction in dopaminergic tone in the tuberoinfundubilar dopaminergic system. Other studies by several groups showed that synthetic small compounds that are κ agonists may reduce dopaminergic tone in rodents, and Claye et al. showed that the natural peptide dynorphin A_{1-17} instilled into the nucleus accumbens results in a reduction of dopaminergic tone in rats (68). In a study of healthy human volunteers, it was shown that a dose-dependent elevation of serum prolactin levels occurs in response to intravenous administration of dynorphin A_{1-13} (86). Further studies using two different opioid antagonists documented that this effect was mediated by the κ- as well as μ-opioid receptors. It was also shown that females, who have significantly higher basal prolactin levels, responded to a significantly greater extent to this natural peptide κ-opioid-receptor agonist challenge with respect to elevations in serum prolactin levels (86).

In other studies, Specker and Pentel and colleagues found attenuation of opiate withdrawal symptoms in heroin addicts given dynorphin A_{1-13} (131). These studies build onto much earlier studies, which were not well controlled but which suggested that dynorphin peptides may attenuate some of the signs and symptoms of opiate withdrawal. In studies conducted in patients with chronic pain, dynorphin A_{1-13} was shown to augment the analgesia provided by the usual μ-opioid agonists (morphine or methadone), a finding suggesting a positive interaction between the μ- and κ-opioid-receptor agonists and a possible novel approach for providing pain relief (132). All these findings suggest that one could consider clinical research studies using a κ-opioid agonist along with a μ-opioid agonist in a pharmacotherapy of opiate addiction (11).

In another area of basic clinical research related to the neurobiology of heroin addiction or its treatment, imaging

techniques, using positron emission tomography or the related technique of single photon emission computed tomography, with studies of glucose metabolism or blood flow to assess activation or depression of activity of specific brain regions, as well as some studies using ligands directed toward specific types of receptors, including recently the opiate receptors, have been conducted in humans and reported (133 ,134). In addition, some studies using magnetic resonance imaging and functional magnetic resonance imaging have begun to contribute to our information about withdrawal from heroin addiction (135). We hope that, in the future, such imaging studies will contribute even further to our understanding of the neurobiology of the development of and relapse to opiate addiction and will also potentially be able to be related to the apparent normalization of function that can occur during long-acting μ-opioid receptor agonist treatment with methadone, or alternatively with l-α-acelytylmethadol (LAAM) and possibly also (but yet to be studied) with the buprenorphine-naloxone combination. The implications of all of this basic clinical research for treatment have been considered further in reviews (10 ,11 ,27 ,28 ,29 ,30 and 31).

Finally, the first successful cloning of the genes of the specific opiate receptors, starting in late 1992, led to studies to identify polymorphisms of the human opioid receptor and peptide genes and as well as of other genes that have been shown to be affected by drugs of abuse, and specifically for this discussion, by short-acting opiates used illicitly. Many such polymorphisms, including primarily SNPs of the μ-opioid receptor as well as of related genes, have been identified recently (6 ,7 ,32 ,58 ,136 ,137 and 138). Studies of potentially functional changes resulting from those polymorphisms, especially SNPs in the coding region of the genes resulting in amino acid changes, and thus in resultant peptide differences, have been initiated (32 ,58). In addition, a few groups are now studying human molecular genetics of the specific addictive diseases, including heroin addiction. In fact, an epidemiologic study by Tsuang et al. suggested that heroin addiction may have an even greater relative risk attributable to heritable factors than any other addiction, including alcoholism (139).

MOLECULAR BIOLOGY AND GENETICS

Part of "104 - Molecular and Cellular Neurobiology and Pathophysiology of Opiate Addiction "

The completion of cloning of the genes of the endogenous opioid system, following the first reports of the cloning of the δ-opioid receptor in late 1992, allowed the expansion of many types of studies, as well as the initiation of new studies. All the genes of the endogenous opioid system in rodents, as well as in humans, now may be included in molecular neurobiological studies, such as studies of quantification of levels of gene expression (mRNA levels). It is now also possible to look for polymorphisms, including SNPs, in human genes of the endogenous opioid system, as well as genes of related neurotransmitter, neuropeptide, and receptor systems (as discussed earlier). Since 1994, new technologies for such studies have been developed, and during the next decade, undoubtedly, they will be able to be used for novel discoveries of heretofore unrecognized genes and gene products involved in the acquisition, persistence, and relapse to addiction (6 ,7 ,32 ,58 ,136 ,137 and 138). These include use of microarray technologies for measuring gene expression (although to date, these arrays are relatively insensitive and cannot yet detect, let alone measure with precision and accuracy, the small changes, usually less than 50% to 100% increase or decrease, that may be expected in integrated neurobiology for genes of low-abundance encoding neuropeptides and their receptors, such as those of the endogenous opioid system). Nevertheless, use of microarray technology, and with the developing informatics to analyze the vast amounts of the expected resultant data, will undoubtedly reveal novel gene systems involved in the specific addictive diseases. In addition, microarray technology and other new approaches are beginning to be used for the identification of already recognized polymorphisms, including SNPs, and they may be able to be used in the future for the identification of novel polymorphisms (6 ,7 ,32).

The completion of the cloning of the endogenous opioid system has permitted the development of appropriate gene deletion, so-called knockout mouse models (reviewed in refs. 33 ,34 and 35). The single most important and relevant finding with respect to opiate addiction has been the documentation, first by Kieffer and colleagues, that there is no opiate-induced reward, as measured by conditioned place preference in the μ-opioid-receptor knockout mice; in addition, these mice show essentially no self-administration of ethanol (33 ,140). All investigations have shown that μ-opioid-receptor knockout mice have no analgesic response to conventional μ-opioid-receptor agonists such as morphine (reviewed in refs. 33 ,34 and 35). Cloning of these genes also permitted the further use of knock-down, or antisense modeling, as well as gene enhancement using appropriate constructs for gene delivery. Many laboratories have initiated work for conditional knockout or knock-in enhancement of gene expression, with control of time of onset of the deletion or enhancement, as well as in some models, specific brain region–dependent changes.

SUMMARY

Part of "104 - Molecular and Cellular Neurobiology and Pathophysiology of Opiate Addiction "

Many exciting developments stemmed from the initial cloning of each of the three opioid receptors—δ, μ, and κ—in 1992 and 1993, and the subsequent cloning of each of those genes in humans in 1994. Subsequently, many studies have been and can be conducted, using classic techniques, as well as other new modern techniques, such as microarray technology. Various studies on the impact of opiates on gene expression as well as signal transduction systems and integrated physiologic function have been conducted.

Moreover, novel animal models have been developed. Possibly most excitingly of all, further basic clinical research studies have been performed, including studies identifying many polymorphisms of human genes of the endogenous opioid systems. These studies have already given, and will continue to give, increased insights into the pathophysiology as well as molecular and cellular neurobiology and related behavioral changes of opiate addiction, and all these studies have continued to teach us about the enormous capability of the brain to change through neural plasticity.

Paul J. Fudala: Department of Psychiatry, University of Pennsylvania, Philadelphia, Pennsylvania; Department of Behavioral Health Service, Veterans Affairs Medical Center, Philadelphia, Pennsylvania.

George E. Woody: Substance Abuse Treatment Unit, VA Medical Center, Philadelphia, Pennsylvania.

Currently, numerous effective pharmacologic and behavioral therapies are available for the treatment of opioid addiction, and these two types of therapies often are combined to optimize patient management. Newer therapeutic options may take various forms. For example, methadone maintenance is an established treatment modality, whereas the use of buprenorphine and naloxone in an office-based setting represents a new variation on that theme. Clonidine has been used extensively to ameliorate opioid withdrawal signs, whereas lofexidine is a structural analogue that appears to have less hypotensive and sedating effects. The depot dosage form of naltrexone, currently under development, may increase compliance with a medication that has been an effective opioid antagonist but that has been underused secondary to patient nonacceptance. In almost every treatment episode using pharmacotherapy, it is combined with some type of psychosocial or behavioral treatment. Recent research has documented the value of these additional treatments and has provided insight into the ones that are the most effective. This chapter reviews current and experimental treatments for opioid addiction with an emphasis on some of the newer, more promising, and interesting therapies.

TREATMENT PARADIGMS

Part of "105 - Current and Experimental Therapeutics for the Treatment of Opioid Addiction "

Long-Term, Short-Term, Rapid, and Ultrarapid Opioid Detoxification

Detoxification from opioids, for most patients, is only the first phase of a longer treatment process. Most patients seeking treatment have been addicted to heroin or other opioids for 2 to 3 years, some for 30 years or more. Thus, treatment usually involves changes in patients' lifestyles. Although generally ineffective in producing sustained remission unless combined with long-term pharmacologic, psychosocial, or behavioral therapies, detoxification alone continues to be widely used and studied. It is sometimes the only option available for patients who do not meet United States Food and Drug Administration (FDA) criteria for, do not desire, or do not have access to agonist medications such as methadone or methadyl acetate (L-α-acetylmethadol or LAAM).

The detoxification process may include use of opioid agonists (e.g., methadone), partial agonists (e.g., buprenorphine), antagonists (e.g., naloxone, naltrexone), or nonopioid alternatives such as clonidine, benzodiazepines, or nonsteroidal antiinflammatory agents. In many cases, one or more medications are combined, such as naloxone with clonidine and a benzodiazepine. The choice of detoxification medication and the duration of the process depend on numerous factors including patient preference, clinician expertise and experience, type of treatment facility, licensing, and available resources. Ultimately, however, the goal of detoxification is the achievement (and maintenance) of a drug-free state while minimizing withdrawal. Unfortunately, however, detoxification for some patients appears to be used in a punitive manner or as an expedient means to achieve a drug-free state rapidly with no follow-up pharmacologic or behavioral therapy.

Opioid detoxification paradigms are frequently categorized according to their nominal duration: long-term (typically 180 days), short-term (up to 30 days), rapid (typically 3 to 10 days), and ultrarapid (1 to 2 days). These temporal modifiers provide only a coarse description of the paradigm; they do not provide other important information such as the medications used or whether postdetoxification pharmacologic (e.g., naltrexone maintenance), psychosocial, or behavioral therapy is provided. However, some general guidelines typically apply.

The most common detoxification protocols, and those for which the most data are available, are the long-term (typically 180 days) and short-term (up to 30 days) paradigms involving the use of methadone. Unfortunately, these strategies have not generally been associated with acceptable treatment response using relapse to opioid use as an outcome criterion. For example, one study reported that more than half the patients participating in a 180-day detoxification program were using opioids illicitly during the medication-taper phase of the protocol (1). Six-month follow-up indicated that 38.5% of the urine samples (n = 26) tested negative for illicit opioids, only three of 31 patients reported remaining free of illicit opioids for the entire 6 months before follow-up, and 22 participated in some other form of treatment (2). Results from more rapid detoxification evaluations using short- or even intermediate-term (up to 70 days) medication-tapering protocols are even less encouraging and have an unfortunately low success rate. However, provision of additional services such as counseling, behavioral therapy, treatment of underlying psychopathologies, job skills training, and family therapy to address concomitant treatment needs can improve outcome, although success rates remain low, even with these services (3).

Rapid detoxification involves the use an opioid antagonist, typically naltrexone or naloxone, in combination with other medications (such as clonidine and benzodiazepines) to mitigate the precipitated withdrawal syndrome. The procedure is intended to expedite and compress the withdrawal process to minimize discomfort and to decrease treatment time. Ultrarapid detoxification also uses other medications, along with an opioid antagonist, to moderate withdrawal effects. However, rather than being awake as they are during the rapid detoxification process, patients are placed under general anesthesia or, alternatively, are deeply sedated. A comprehensive review of the rapid and ultrarapid detoxification literature (identifying 12 and 9 of each type study, respectively) has been published (4). Rapid detoxification studies were conducted in inpatient facilities, outpatient substance abuse treatment settings, and outpatient primary care facilities; ultrarapid ones were confined to inpatient settings. Patients included those who were heroin dependent as well as those in methadone maintenance treatment.

Only four of the studies reviewed provided follow-up beyond the initial detoxification. Retention on postdetoxification naltrexone maintenance in one rapid detoxification study was 53% at 1 month and 82% in another at 3 months. Only one of the ultrarapid detoxification studies provided follow-up information indicating that all patients (11 of 11) were taking naltrexone 30 days after detoxification (5). A more recently published study (6), in which ultrarapid detoxification was followed by naltrexone maintenance and supportive psychotherapy, indicated that 49 of 72 patients were opioid abstinent 12 months after detoxification. All these studies involved self-selected patients; thus, it is impossible to know the overall effectiveness of this type of intervention.

A major concern regarding ultrarapid detoxification in particular is the occurrence of potentially serious adverse effects, such as respiratory distress (7), or other pulmonary and renal complications (8), during or immediately after the procedure. A high frequency of vomiting has also been reported (9). The degree to which serious adverse effects occur has not yet been determined; however, there have been press reports of sudden death occurring shortly after the procedure that were not caused by relapse to opioid use and overdose.

In spite of the emerging evidence about serious adverse effects, ultrarapid detoxification may be appropriate for highly selected patients based on considerations of previous treatment history, economic factors, and patient choice. However, patients seeking this treatment must be thoroughly informed that serious adverse effects, including sudden unexpected deaths, have occurred in association with this procedure, and its use should probably be limited to inpatient settings where monitoring by anesthesiologists and other highly trained staff is available.

Buprenorphine, a μ-opioid partial agonist, has also been used as a detoxification agent. Results from inpatient (10 ,11 and 12) and outpatient (13 ,14) studies have shown that it is safe and well tolerated, and it mitigates opioid withdrawal signs and symptoms over a range of doses and detoxification schedules. Clonidine, an α_2-adrenergic agonist, has been shown to suppress many of the autonomic signs and symptoms of opioid withdrawal. It can cause pronounced sedation and hypotension but has been used with few problems when appropriate monitoring is available. It does not suppress the subjective discomfort of withdrawal, and probably for that reason, it is not well accepted by most opioid addicts.

Other α_2-adrenergic agonists have also been evaluated to find agents that are equally or more effective, but produce less sedation and hypotension than clonidine. Lofexidine, a medication that was originally promoted as an antihypertensive, has been the most thoroughly studied. When compared with clonidine, it was found to suppress autonomic signs and symptoms of opioid withdrawal equally, but with less sedation and hypotension (15 ,16 and 17). When compared with methadone dose tapering, lofexidine detoxification was associated with opioid withdrawal effects that peaked sooner, but resolved to negligible levels more rapidly (18). In another study (19), an accelerated 5-day lofexidine treatment regimen attenuated opioid withdrawal symptoms more rapidly than 10 days of either lofexidine or methadone, with similar blood pressure responses observed for the two lofexidine groups. Data regarding the potential effectiveness of guanabenz and guanfacine have also been reported, but further studies are required to assess the potential utility of these medications for detoxification treatment. In summary, recent studies have shown that lofexidine is

likely to be a useful opioid detoxification agent whose efficacy approximates that of clonidine but with fewer side effects.

Opioid Agonist Pharmacotherapy

Methadone maintenance was developed by Dole and Nyswander and has become the most commonly used pharmacotherapy for opioid dependence (20). Methadone acts as the μ-opioid receptor, and its ability to suppress opioid withdrawal for 24 to 36 hours after a single oral dose makes it an ideal medication for this purpose. Another μ-opioid agonist, LAAM, received FDA approval for maintenance treatment in 1993. LAAM is a long-acting congener of methadone that suppresses withdrawal for 48 to 72 hours and thus has the advantage of requiring less frequent clinic visits than methadone, which must be taken daily. A third medication, buprenorphine, is far advanced in the FDA approval process. It was mentioned earlier as a detoxification agent and is discussed later and in more detail because it has unique properties that are likely to result in its being used with fewer regulatory controls than methadone and LAAM.

Both methadone and LAAM are Schedule II controlled substances and can be used only for maintenance and detoxification in programs that are licensed and regulated by the FDA and the Drug Enforcement Administration (DEA). The regulations specify who is eligible for treatment, procedures that are required for its administration, the number of take-home doses permitted, and the type of medication storage security needed. Treatment programs have been inspected approximately every 3 years for the past 30 years, and violations have resulted in sanctions ranging from administrative citations to criminal prosecution.

The combination of FDA and DEA regulations has resulted in a treatment system that is separated from the mainstream of other medical care and that consists almost entirely of specially licensed and inspected clinics. Clinics are often located in old buildings that have been converted to comply with regulations but that were never intended for medical use. At the present time, it is estimated that approximately 179,000 patients are being maintained on methadone or LAAM at 940 or more sites, and this number represents only about 20% of the opioid addicts in the United States (21).

This treatment-program regulatory system has been under increasing criticism since the early 1990s. Criticism has come from both patients and treatment providers who believe that the current regulations impose unnecessary burdens and expenses, have done little to improve the quality of treatment, and impede access to care. The importance of these criticisms has been underlined by the recent increase in heroin addiction (22), by evidence that methadone maintenance reduces the incidence of hepatitis and HIV infection, and by the lack of coverage for agonist maintenance by most health insurance plans. The overall effect has been a widening gap between treatment need and availability, and lost treatment opportunities.

As a result, the Institute of Medicine and the National Institutes of Health each made recommendations for regulatory reform (23 ,24). Many of these recommendations are in the process of being carried out and include an overall reduction in regulations and transfer of oversight to accreditation bodies that are approved by the Center for Substance Abuse Treatment, rather than the FDA. Other recommendations include allowing long-term, stable patients to be treated in settings other than methadone clinics where they can receive up to 30 days of take-home medications *(medical maintenance)*, allowing take-home doses for LAAM, and allowing more clinical judgment in determining dosages and take-home schedules. Procedures to prevent diversion include careful screening of patients who receive medical maintenance, return to directly observed medication administration if illicit drug use or diversion is detected, random urine testing, and call-back procedures in which patients will be required to report to the medical treatment setting and to produce the remaining, unused take-home containers.

The appropriate agonist medication dosage has been a subject of both federal and state regulations, although there has been a gradual shift toward allowing more clinical judgment in its determination. Numerous studies have been conducted since the mid-1970s to determine the optimal dose, and, although it is clear that some patients do well on low doses of methadone or LAAM (about 20 to 50 mg), studies have consistently shown that most patients need higher doses if they are to achieve maximum benefit from agonist treatment (25). The results of these methadone dose comparison studies are generally supportive of the guidelines originally proposed by Dole and Nyswander, who recommended doses in the 80- to 120-mg per day range (20). Clear relationships between methadone blood levels and clinical response have not been observed consistently. One study found significant correlations between oral dose and methadone concentration, but only among patients who complained of low dosing (26). These findings suggest that some patients may be more sensitive to dosage changes and that clinical response, including subjective complaints, is a more important guide to adequate dose levels than specific blood levels. No controlled studies have been done examining doses higher than 120 mg; thus, the upper limits of dosing effectiveness are not well understood.

Perhaps the most important pending regulatory change is to amend the Controlled Substances Act with respect to registration requirements for practitioners using drugs approved for detoxification or maintenance that are in Schedules III, IV, and V (27). Physicians who choose to treat persons with opioid dependence under the new regulations will need to notify the Secretary of Health and Human Services in writing of their intent and to show that they

are qualified to provide addiction treatment by virtue of certification or experience. No physician would be allowed to treat more than 30 patients at one time without special approval, according to the legislation as it is now proposed.

This change in the regulations will be especially important for buprenorphine and the buprenorphine-naloxone combination (discussed later), because it will provide better access to treatment for persons who are unwilling or unable to be treated in the current methadone or LAAM system. The overall intent of the proposed regulatory reform is to better integrate maintenance treatment into the mainstream of medical care, to make it more readily available, and to improve its quality.

As mentioned earlier, these changes are likely to influence the ways in which buprenorphine is used in opioid addiction treatment. Buprenorphine is marketed internationally as an analgesic (both without naloxone and with naloxone to deter abuse) and as a treatment for opioid addiction. The most widespread use of buprenorphine is in France, where it was approved for the latter indication in 1996. In the United States, buprenorphine is currently approved only as an analgesic for parenteral administration; approval for opioid addiction treatment is pending. Buprenorphine has been used almost exclusively sublingually in addiction treatment because of its poor oral bioavailability. Most of the early clinical trials used a sublingual solution of buprenorphine formulated in a hydroethanolic vehicle, although a more commercially suitable sublingual tablet formulation is now used.

The greatest advantage of buprenorphine compared with full agonists such as methadone and LAAM is the plateau effect of μ-agonist activity. Parenteral doses as high as 12 mg intravenously (28) have been given to opioid-intolerant patients with only limited adverse effects (e.g. sedation, irritability, nausea, itching). Numerous large trials have confirmed the utility of buprenorphine for agonist maintenance therapy. These studies have included comparisons of buprenorphine with placebo (29 ,30), a buprenorphine-naloxone combination with placebo (30), and a multiple-dose comparison study (31). In one of the most recent trials (32), buprenorphine (given three times weekly) was compared with LAAM (given three times weekly) and methadone (given daily) in a 17-week study. Mean retention in treatment was higher for buprenorphine, LAAM, and high-dose methadone groups compared with low-dose methadone and for high-dose methadone compared with LAAM. Opioid-positive urine samples decreased most for the LAAM-treated group and least for low-dose methadone. Patient self-reports of opioid use did not differ among the groups, but they showed decreases of about 90% over the course of the study.

Buprenorphine has the potential to be abused and can produce addiction. However, most persons who abuse buprenorphine initiated opioid use with other drugs. Abuse may take the form of using greater than prescribed dosages for analgesia, using buprenorphine in place of a more desired but less available opioid such as heroin, or using buprenorphine for its own positive subjective effects (33 ,34). Only one study published to date has characterized the behavioral and physiologic effects of a wide range of buprenorphine analgesic doses in nonusers of opioids (35). The results indicated that buprenorphine, given intravenously, has a low abuse liability in this population.

Buprenorphine, in combination with naloxone, has less potential for abuse than buprenorphine alone (36 ,37). The therapeutic utility of combining naloxone with buprenorphine derives from the low sublingual bioavailability of naloxone compared with buprenorphine. Parenteral misuse of the combination by persons addicted to opioids would be expected to produce antagonist-like effects; thus, most opioid addicts would not be likely to inject the combination more than once. The use of the buprenorphine-naloxone combination product in an office-based setting represents an innovative alternative to the restrictive methadone or LAAM maintenance paradigm described previously. The use of this new drug combination should expand the availability of agonist maintenance treatment with a relatively low risk for abuse or diversion. In addition, the partial agonist activity of buprenorphine results in a much lower risk of overdose death than is the case with methadone or LAAM.

Antagonist Maintenance

Naltrexone is the prototypical opioid antagonist used in abstinence maintenance therapy; this drug blocks the effects of heroin and other opioids through competitive receptor inhibition. Naltrexone has no opioid agonist effects and is a competitive opioid antagonist. It is orally effective and can block opioid effects for 24 hours when administered as a single daily dose of 50 to 60 mg. Higher doses usually will not block opioid effects for 48 to 72 hours though they will provide more cross tolerance to heroin and other opioids during the 24-hour dosing period (38). Despite a favorable adverse event profile (nausea is typically the most common side effect), naltrexone is generally not favored by opioid addicts because, unlike opioid agonists and partial agonists, it produces no positive, reinforcing effects. Furthermore, it may be associated with the precipitation of an opioid withdrawal syndrome if it is used too soon after opioid use stops, an effect that can be minimized by administering a naloxone challenge test before giving naltrexone.

Although the literature on naltrexone treatment spans more than 25 years, work continues on increasing medication compliance and improving outcomes. Some of these more recent efforts include work to develop a depot form that will block opioid effects for 14 to 28 days. This dosage form is currently in phase II clinical trials. At present, a patient treated with naltrexone has only to stop the medication for 1 to 3 days to experience the full effects of subsequent opioid use. A depot dosage form of naltrexone would provide more time for patients to overcome ambivalence about stopping opioid use and could result in more long-term success than has currently been the case. Another variant

on antagonist treatment is nalmefene, an orally effective but somewhat longer-acting (about 48 hours at dosages of 50 to 100 mg per day) opioid antagonist that has been effective for alcohol treatment that may have advantages over naltrexone due to its longer duration of action. The problem will be that addicts may not take it, as has generally been the case with naltrexone (39 ,40).

Psychosocial and Behavioral Treatment

Research has called attention to the finding that, as in other substance use disorders, most patients with opioid dependence and abuse are ambivalent about stopping drug use (41 ,42). This ambivalence presents a therapeutic challenge because it contributes to varying levels of motivation to enter and remain in treatment, to early dropout, and to partial or (in some cases) nontreatment response. Studies have emphasized that treatment providers must be aware of this “normal” ambivalence and make reasonable efforts to resolve it in favor of treatment participation and cessation of drug use (42). Suggestions have been made regarding initial steps to maximize the chances for engagement in treatment and cessation of drug use. These include avoiding unnecessary delays in entering treatment, expressing a hopeful and nonjudgmental attitude, performing a comprehensive evaluation, and developing a treatment plan that is responsive to patients’ self-identified goals (41).

In addition to challenges related to ambivalence, patients often have serious problems with nonopioid substance abuse or with medical, psychiatric, legal, employment, and family or social issues that preexist or result from the addiction. Research has found that addressing these additional problems can be helpful, but they are complex and require coordination between agonist pharmacotherapy staff and other medical and psychosocial services (43 ,44).

The most common type of psychosocial service in opioid agonist treatment is individual drug counseling. Counselors are typically persons at the masters level or below who deliver a behaviorally focused treatment aimed to identify specific problems, to help the patient access services that may not be provided in the clinic (e.g., medical, psychiatric, legal, family or social), to stop substance use, and to improve overall adjustment. Functions that counselors perform include monitoring methadone and LAAM doses and requesting changes when needed, reviewing urine test results, responding to requests for take-homes doses, assisting with family problems, assessing and responding to crises, writing letters for court or social welfare agencies, recommending inpatient treatment when necessary, and providing support and encouragement for a drug-free lifestyle.

Counseling usually addresses both opioid and nonopioid use. Although nicotine (tobacco) use is not always included, the increased emphasis on adverse health effects of smoking has resulted in more attention to stop smoking at all levels, including drug counseling. Counselors and patients typically have weekly, 30- to 60-minute sessions during the first weeks or months of treatment with reductions in frequency to biweekly or monthly depending on progress. The frequency of counseling can vary widely depending on the severity of the patient’s problems, clinic requirements, and counselor workload.

The importance of regular counseling was clearly demonstrated in a study by McLellan and co-workers (43), in which patients were randomly assigned to minimal counseling (one 5- to 10- minute session per month), standard counseling (one 45-minute session per week), or enhanced counseling (standard plus on-site referral to psychiatric, medical, and family or social services). Results showed a dose–response relationship with the minimal condition doing significantly worse than standard and enhanced counseling doing the best overall; however, about 30% of patients did well in the minimal counseling condition. This study clearly demonstrated the positive benefits achieved by drug counseling and showed that, for most patients, counseling is necessary to bring out the maximum benefits of agonist maintenance.

Most counseling is individual, one on one, but some programs use group therapy exclusively. However, most programs use groups only for selected patients with focal problems such as HIV disease, posttraumatic stress disorder, homelessness, loss of close personal relationships, or not at all. Many programs encourage patients to participate in self-help groups, but ask them to be careful to select a group that accepts persons who are receiving opioid agonist maintenance treatment. Some programs have self-help groups that meet regularly on site. Counselors, like psychotherapists, can vary widely in the results they achieve (45). This variability seems more related to the ability to form a positive, helping relationship with the patient than to specific techniques (46).

Contingency management techniques are always included in drug counseling, if for nothing else than to fulfill regulations about requiring progress in treatment as a condition of providing take-home doses, and studies have shown that they can be very helpful. For example, an opportunity to receive take-home medications in return for drug-free urine tests is a powerful motivator for many patients (47). Such a contingency strategy is an example of research with a clear use in general clinical practice because it is easily applied and costs little or nothing beyond standard program costs. More flexibility in dispensing take-home doses as contingencies for positive behaviors could be a positive effect of the regulatory reforms described earlier.

Another contingency that is easily applicable and that some programs have used with positive results is requiring a negative alcohol breath test before dispensing the daily dose of methadone or LAAM. This contingency can be especially useful for patients with alcohol abuse or dependence. Maintenance, counseling, and contingency management are often combined in complex ways, as seen in the following vignette:

A 42-year-old man presented for his sixth episode of

methadone maintenance. He had a long history of alcoholism and was using cocaine regularly. He had done fairly well on methadone as far as illicit opioid use was concerned, but his clinic attendance and ability to comply with clinic rules, especially regarding take-home doses, were severely compromised by alcohol use. In the past, he would remain in treatment for about a year, then become angry over his inability to obtain take-home doses because of positive breathalyzer tests, drop out, and have a relapse to opioid use. He had frequently been offered inpatient detoxification for alcoholism but always refused because “alcohol’s not my problem, heroin’s the problem,” and he could not take time off from work (as a stockperson in a liquor store). When he presented for treatment most recently, he was unemployed (secondary to alcohol problems) and living with his parents, who were threatening to put him out because of drug use. He agreed that, as part of his treatment plan, he would go into the hospital for alcohol detoxification and stabilization on methadone and then be discharged to maintenance therapy. After inpatient discharge, he attended AA-style counseling, requested daily alcohol breath tests, and turned down an offer to return to his job at the liquor store. He remained stable for 3 years on 65 mg per day of methadone with no urine samples positive for opioids (but occasionally positive for cocaine), and he enrolled (and continued) in school.

It is clear that in such a complex but relatively typical case, a single intervention was not enough. Rather, a series of coordinated steps was necessary to achieve a positive treatment response. Although not demonstrated in this vignette, family therapy is another intervention that can be combined with agonist therapy and other psychosocial interventions, and studies have shown that it can be useful as well (48).

Although counseling and other services are effective enhancements of agonist treatment, adherence is often an issue, and clinics vary in the way they respond to this problem. Some remind patients of appointments, others do not permit patients to be medicated unless they keep appointments, and others suspend patients who miss appointments. For nonadherent patients, a very powerful contingency is requiring certain behaviors for patients to remain on the program, a procedure that is often formalized in a *treatment contract*. Here, the patient is given an option of stopping unprescribed drug use, keeping regular counseling appointments, looking for work, or correcting other behaviors that need improvement as a condition for remaining in treatment. Patients who fail are administratively detoxified, suspended for months to years, and referred to another program, although the referrals are not always successful.

The long-term effects of this form of contingency management have not been well studied. For example, relatively little is known about negative effects on patients who may have improved with methadone and counseling, but not to the degree required by the contingency, and who are subsequently discharged for failing to adhere to a treatment contract. One study done in Philadelphia (49) found that among 110 patients who were administratively discharged or dropped out of a Veterans Affairs (VA) maintenance program, 8.2% (nine of 110) died within the following year as compared with only 1% (four of 397) who remained in treatment. Among the 43 patients (from among the 110) who were discharged for failing to adhere to a treatment contract, five (11.6%) died within a year. None of these five patients were in treatment at the time of death, and all died as a result of overdoses. No overdose deaths occurred among patients remaining in treatment, and, interestingly, there were no deaths in those patients who were suspended for violating program rules (mainly drug dealing or giving a false urine specimen). These results are consistent with data from New South Wales, Australia, where there has been a sharp rise in heroin-related deaths. Although it is estimated that 20% to 30% of the heroin addicts in New South Wales are receiving methadone maintenance, only 3% of the 953 heroin-related fatalities occurred among patients receiving methadone maintenance (50). These data emphasize the fine line between contingencies maintained in programs and the dangers associated with program dismissal.

The foregoing data, when considered along with studies showing a protective effect of maintenance on acquiring HIV infection (51), have made some clinicians increasingly hesitant to suspend patients from maintenance treatment for positive urine test results alone. This caution may be especially relevant in environments where the potency of heroin is high, such as Philadelphia, where the average “bag” of heroin is now 71% pure (22).

Therapeutic communities are another psychosocial approach that is often useful for opioid addicts who have a long history of addiction and a strong motivation to become drug free. These programs are very selective, self-governing, long-term (6 to 18 months) residential settings where patients share responsibilities for maintaining the treatment milieu (cleaning, cooking, and leading group therapy). Confrontation of denial and behaviors such as lying and “conning,” combined with group support for healthy, positive change, is used to restructure character and the addictive lifestyle. Medications such as methadone, LAAM, or naltrexone are rarely used; however, medications for specific psychiatric or medical conditions are usually available after careful screening and evaluation. Patients who enter therapeutic communities are often referred by the criminal justice system. Some patients have tried, but not responded, to agonist maintenance on repeated occasions. Although dropout rates are high, studies have shown that more than 80% of patients who complete a course of treatment in a therapeutic community have a sustained remission and demonstrate significant improvement in psychiatric symptoms, employment, and criminal behavior (52 ,53).

Addressing Comorbidity

Patients seeking treatment for opioid dependence are typically dependent on one or more other substances (cocaine, alcohol, benzodiazepines, amphetamines, marijuana, nicotine), and have additional problems in the psychiatric, medical, family or social, employment, or legal areas. In fact, it is rare to find a person with only opioid dependence and no other substance abuse or without a psychiatric, medical, or family or social problem. The presence of these problems, perhaps with the exception of nicotine dependence, tends to magnify the severity of the opioid dependence and makes the patient more difficult to treat.

Among the psychiatric disorders seen in persons with opioid dependence, antisocial personality disorder is one of the most common (54). Diagnostic studies of persons with opioid dependence have typically found rates of antisocial personality disorder ranging from 20% to 50%, as compared with less than 5% in the general population. Posttraumatic stress disorder is also seen with increased frequency.

Opioid-dependent persons are especially at risk for the development of brief depressive symptoms and for episodes of mild to moderate depression that meet symptomatic and duration criteria for major depressive disorder or dysthymia. These syndromes represent both substance-induced mood disorders as well as independent depressive illnesses. Brief periods of depression are especially common during chronic intoxication or withdrawal or in association with psychosocial stressors that are related to the dependence. Insomnia is common, especially during withdrawal; sexual dysfunction, especially impotence, is common during intoxication. Delirium or brief, psychotic-like symptoms are occasionally seen during opioid intoxication (54).

The data on psychiatric comorbidity among opioid addicts and its negative effect on outcome (55) have stimulated research on the effect of combining psychiatric and substance abuse treatment. Several studies have now shown that tricyclic antidepressants can be useful for chronically depressed opioid addicts who are treated with methadone maintenance (56). Two studies have shown that professional psychotherapy can be useful for psychiatrically impaired, methadone-maintained opioid addicts, although another study found no psychotherapy effect (57 ,58 and 59). The main result in most pharmacotherapy and psychotherapy studies with methadone-maintained addicts has usually been a reduction in psychiatric symptoms such as depression, although some studies have shown reductions in substance use as well (56 ,57).

Fewer than 5% of persons with opioid dependence have psychotic disorders such as bipolar illness or schizophrenia; however, these patients can present special problems because programs typically have few psychiatric staff members. As a result, these patients are sometimes excluded from methadone treatment because of the severity of their psychotic disorders. Others are treated with methadone, counseling, and the same antipsychotic or antimanic medications used for nonaddicted patients with similar disorders. Although studies evaluating the outcome of combining opioid agonist treatment with antipsychotic or antimanic medications have not been done, there is little controversy that these medications are useful for opioid addicts with psychotic disorders, and most programs use them with little hesitation.

Women opioid addicts can present special challenges because many have been sexually abused as children, have other psychiatric disorders, and are involved in difficult family or social situations (60). Abusive relationships with addicted men are common, sometimes characterized by situations in which the man exerts control by providing drugs. These complex psychiatric and relationship issues have emphasized the need for comprehensive psychosocial services that include psychiatric assessment and treatment and access to other medical, family, and social services.

Medical comorbidity is a major problem among opioid addicts; HIV infection, AIDS, and hepatitis B and C have become some of the most common illnesses. Sharing injection equipment, including “cookers” and rinse water, and engaging in high-risk sexual behavior are the main routes of infection. Sexual transmission appears to be a more common route for HIV transmission among women than men because the HIV virus is spread more readily from men to women than from women to men. Females patients who are intravenous drug users and who also engage in prostitution or other forms of high-risk sexual behavior are at extremely high risk of HIV infection (60). Cocaine use has been found to be a significant risk factor as a single drug of abuse or when used in combination with heroin or other opioids (61).

As mentioned earlier, mortality is high, and studies have found annual death rates of approximately 10 per 1,000 or greater, which is substantially higher than demographically matched samples in the general population (62). Common causes of death are overdose, accidents, injuries, and medical complications such as cellulitis, hepatitis, AIDS, tuberculosis, and endocarditis. The cocaine and alcohol dependence that is often seen among opioid-dependent persons contributes to medical morbidity by cirrhosis, cardiomyopathy, myocardial infarction, or serious cardiac arrhythmias.

Tuberculosis has become a particularly serious problem among intravenous drug users, especially heroin addicts. In most cases, infection is asymptomatic and is evident only by the presence of a positive tuberculin skin test. However, many cases of active tuberculosis have also been found, especially among those who are infected with HIV who may have a newly acquired infection or reactivation of a prior infection as a result of impaired immune function.

After rising rapidly in the late 1970s and early 1980s, the incidence of new HIV infections among intravenous drug users, of whom opioid-dependent persons constitute

a large proportion, decreased (63). However, as a result of high levels of needle sharing and other risky behavior in the early phases of the epidemic, the prevalence of HIV infection among heroin addicts reached as high as 50% in some areas of the United States (64). Because of the long incubation period before the development of AIDS, it is expected that future years will continue to see high levels of morbidity and mortality associated with HIV infection, although the advent of new pharmacotherapies for HIV has extended many lives.

Studies done over the last several years have identified several important interactions between methadone and drugs used to treat HIV infection. Information is not complete, however, and more studies are needed to map out the extent of these interactions completely. One important interaction is that methadone increases plasma levels of zidovudine; the associated symptoms resemble methadone withdrawal. There have been instances in which methadone doses have been increased in response to complaints of withdrawal, with increasing doses compounding the problem. Another important interaction involves decreased methadone blood levels secondary to nevirapine administration that may be associated with mild to moderate withdrawal. This interaction can be important if the patient discontinues either of these two drugs while taking methadone, because the result may be a sudden rise in methadone blood levels with signs and symptoms of overmedication (65 ,66).

Other medical complications of heroin dependence are seen in children born to opioid-dependent women. Perhaps the most serious is premature delivery and low birth weight, a problem that can be reduced if the mother is receiving methadone maintenance and prenatal care (67). Another is physiologic dependence on opioids, seen in about half the infants born to women maintained on methadone or dependent on heroin or other opioids. Effective treatments for neonatal withdrawal are available, and long-term adverse effects of opioid withdrawal have not been demonstrated. Adverse neonatal effects associated with LAAM or buprenorphine have not been observed, but few studies have been done because neither medication is approved for use in pregnancy.

The possibility that breast-feeding may cause adverse effects in infants of methadone-maintained mothers was studied. It was found that methadone was present in the breast milk of women maintained on doses as high as 180 mg, but the concentration was very low, and no adverse effects were observed in the infants (68). HIV infection is seen in about one-third of infants born to HIV-positive mothers, but this incidence can be reduced to about 10% if HIV-positive pregnant women are given zidovudine before delivery (69). HIV can also be transmitted by breast-feeding, and thus infant formula feeding is recommended for babies of HIV-positive mothers, except in some developing countries, where formula is unavailable or unaffordable. Thorough washing of infants born to HIV-infected mothers immediately after delivery also appears to reduce the incidence of HIV infection.

An important line of research resulting from the data on comorbidity has been studies on the effects of integrating psychiatric and medical care within agonist and other substance abuse treatment programs (70). Clinical experience and National Institute on Drug Abuse demonstration projects have shown that integration of these services with agonist maintenance can be done, and with very positive results, because patients are seen frequently and treatment retention is high (44). Related to this line of research are studies that have shown improved compliance with directly observed antituberculosis pharmacotherapy (71). These findings have important implications for tuberculosis control policies in methadone programs because intravenous drug users are at very high risk of tuberculosis infection and because maintenance programs provide settings in which directly observed therapy can be easily applied. Similar principles apply to administration of psychotropic medication in noncompliant patients with schizophrenia or other major axis I disorders.

Harm Reduction

Harm reduction is concerned with minimizing various negative consequences of addiction. As such, the focus is shifted away from drug use to the consequences of use and its attendant behaviors (72). Examples of harm reduction include needle exchange programs, efforts directed at reducing drug-use-associated behaviors that may result in the transmission of HIV, and making changes in policies (including increasing treatment availability) that reduce heroin use and the criminal behavior associated with drug procurement. Harm reduction refers to reducing harm not only to the individual addict, but also to family, friends, and society generally. Other terms sometimes used synonymously with harm reduction include harm minimization, risk reduction, and risk minimization (73).

Some authors have identified the limitations of harm reduction when it is used as a sole strategy to combat the adverse effects of addiction. For example, Reuter and Caulkins pointed out the benefit of integrating drug use reduction and harm reduction components into a single framework (74), because total harm may be lowered by reducing either component. Roche and colleagues proposed a model for an integrated addiction treatment strategy that incorporates harm reduction and use reduction with abstinence and nonuse (75), in addition to other critical elements such as factors related to culture and gender. Additionally, MacCoun provided a template for integrating harm reduction with prevalence reduction (discouraging the engagement in drug use) and quantity reduction (encouraging the reduction in frequency or extent of drug use) (76).

With regard to opioids, much of the health-related harm from their improper or illicit use is secondary to elements

other than the substances themselves (77). Sequelae of unhygienic methods of administration and poor injection technique are typically more serious than the constipation or other side effects of the drugs themselves, acute overdoses notwithstanding. With regard to opioid addiction treatment, medications such as methadone, LAAM, and buprenorphine, among others (including supervised heroin substitution) used for maintenance agonist treatment, may be considered harm reduction measures. All have the potential to reduce morbidity, mortality, and crime associated with the addict lifestyle. However, in this sense they are no different from other medical therapies such as those used for the treatment of hypertension, diabetes, or asthma.

Needle or syringe exchange represents one of the most controversial strategies in harm reduction. Research indicates that these types of programs may have beneficial effects in numerous areas, including a reduction in the spread of blood-borne infectious disease such as hepatitis and HIV, and acting as a conduit to more comprehensive drug-abuse treatment services (78). In one study (79), the initiation and continuation of syringe exchange program participation among high-risk injection drug users were independently associated with a cessation of syringe sharing. In another study (80), participation in a needle exchange program was associated with patients' entering detoxification treatment for both HIV-infected and noninfected groups. Not all findings have been positive, however. In a study designed to assess the association between risk behaviors and HIV seroprevalence and incidence among injection drug users, risk elevations for HIV associated with needle exchange programs were substantial and consistent despite adjustment for confounding factors (81). However, an examination of potential bias in nonrandomized comparisons (82) suggested that injection drug users participating in needle exchange programs at a given point may include a high proportion of persons whose pattern of drug use puts them at greater risk for blood-borne viral infections. Further, a prospective cohort study found no evidence of a causal association between needle exchange program participation and transmission of HIV (83).

Harm reduction related to psychoactive substance abuse has gone through numerous stages. The current phase has been described as the development of an integrated public health perspective for all drugs in which a multifaceted, strategic approach is taken (84). The direction of this approach will be guided, in part, by whether biases against a harm reduction philosophy can be overcome by those who see it as synonymous with acceptance of drug abuse or legalization, and how harm reduction objectives relate to an overall strategy to improve public health.

IMPACT OF MANAGED CARE

Part of "105 - Current and Experimental Therapeutics for the Treatment of Opioid Addiction "

Efforts to control costs by managed care have resulted in a marked reduction in use of inpatient or residential treatment programs in many locations. Funds saved from these cost reductions have often not been invested in outpatient treatment. A good example is the VA, which administers the largest network of substance abuse treatment programs in the United States. Since the application of managed care policies, the overall amount spent on substance abuse treatment declined by 41%, from $597 million in 1993 to $351 million in 1999. Measured as a percentage of overall VA health care costs, specialized substance abuse care decreased from 4.2% in 1993 to 2.3% in 1999. In contrast, overall VA health care expenditures increased 10% between 1993 and 1999 (85). Most of these reductions were achieved by reducing inpatient beds, with the funds saved allocated to other areas but not to reinvestment in other substance abuse treatment services. The result has been an overall reduction in the total number of veteran patients treated and in the amount of drug counseling provided. As a result, no new methadone programs were opened in the VA despite the recent increase in heroin addiction, evidence of waiting lists for methadone treatment, and cities (such as Portland, Oregon) with serious heroin problems but no agonist maintenance programs in spite of recent increases in heroin overdose deaths.

A focused review of substance abuse programs by the United States Senate Committee on Veterans Affairs found that changes in resource allocation have caused programs to become vulnerable to service disruptions, poor morale, burnout, and reduced motivation and quality of performance and characterized by failures to maintain service levels in accord with the mandates of law (86).

Managed care strategies have also made it very difficult to integrate medical and psychiatric services into agonist maintenance programs. Thus, both old and new pharmacotherapies for opioid addiction described earlier are underused in the VA, the largest substance abuse treatment system. There is every indication that penetration of these new treatments into the opiate treatment field at large has also been slow.

SUMMARY

Part of "105 - Current and Experimental Therapeutics for the Treatment of Opioid Addiction "

New pharmacotherapies, behavioral therapies, and treatment strategies are being developed for opioid addiction. This continued development is important, because more treatment options will encourage treatments that are more individualized and balanced across important dimensions such as patient response, adverse effects, treatment costs, comorbidity, living situations, and overall adjustment. As described earlier, various treatments can be combined to produce better patient outcomes. However, the overall effect of these developments on addiction treatment and public health is very dependent on funding support, which has become a serious problem. Parity legislation may help to

solve funding problems and result in the expansion of treatment to meet patient needs, but the details of how and when more investment in substance treatment may occur are unclear as of this writing.

Marijuana continues to garner considerable attention and is the subject of intense public debate and scientific scrutiny. It is unquestionably one of the most frequently used illicit drugs throughout the world. In Western countries, the pattern of use among age groups has not deviated significantly since the mid-1970s. The most prevalent use occurs in persons who are in their late teens and early twenties. Despite modest declines from the pinnacle of its use in the mid-1970s, there was an upsurge in use during the 1990s. Marijuana smoking is prevalent regardless of age, ethnicity, and sex. Epidemiologic data reveal that the rates of use during the year 2000 by United States students in grades 8, 10, and 12 were 17%, 32%, and 38%, respectively (1). There was a steady increase in daily marijuana use (defined as use on at least 20 occasions in the past 30 days) in all three age groups. For example, 2% of high school seniors used marijuana daily in 1991, with this figure rising to 6% in 1999. Two factors that undoubtedly contribute to the prevalence of marijuana use are the declining perception that marijuana produces harmful effects and the relative ease of acquiring marijuana.

Although marijuana has long been a subject of folklore medicine, interest as a potential therapeutic agent has intensified in recent times, likely as a result of numerous factors. The marijuana debate has increased, correlated with a period in our history marked by increased interest in nontraditional medications, increased awareness of several disease states not readily treated by current medications, and increased discourse about the public policy concerning recreational use of marijuana. Proponents cite a plethora of self-reports regarding the effectiveness of medical marijuana for a wide range of disorders, whereas opponents question its efficacy and point to potential deleterious effects of smoked marijuana. The scientific rationale for deciding the fate of marijuana as a therapeutic agent is often ignored.

As the debate concerning potential therapeutic benefits and health consequences of acute and chronic exposure to marijuana continues, considerable new scientific evidence is emerging regarding the nature of cannabinoid effects both *in vivo* and *in vitro* and the endogenous system through which marijuana acts. The emphasis of this chapter is to summarize recent discoveries of the endogenous system as they relate to both putative adverse effects and therapeutic uses of marijuana and its psychoactive constituent, Δ^9-tetrahydrocannabinol (THC). During the 1990s, numerous breakthroughs occurred that greatly increased our understanding of the cannabinoids. It is now evident that an endogenous cannabinoid system exists. A receptor has been characterized and cloned, second messenger systems identified, a putative endogenous ligand isolated and synthesized, and biochemical pathways for both synthesis and degradation of endogenous ligands described.

PHARMACOLOGY

Part of "106 - Marijuana "

Marijuana has prominent effects on the central nervous system as well as numerous peripheral effects in humans that are well recognized and were reviewed in the previous edition of this book. Acutely, cannabis produces an altered state of consciousness characterized by mild euphoria, relaxation, perceptual alterations including time distortion, and the enhancement of ordinary sensory experiences. Cognitive effects are also marked, such as impaired short-term memory. Motor skills and reaction time are also altered, so skilled activity of various kinds is frequently disrupted. Peripherally, marijuana produces prominent effects on the cardiovascular system characterized by tachycardia, and at high doses it can produce orthostatic hypotension. There are several other effects, such as antiemesis, analgesia, anticonvulsant action, and intraocular pressure lowering, discussed later. However, THC has provided most of the evidence for cannabinoid effects in laboratory animals. As for chronic marijuana use in humans, concerns arise because of potential long-term consequences on cognition and the development

of tolerance and dependence. There has been considerable interest in cannabinoid effects on performance, cognition, and the development of dependence, discussed in the following sections.

Performance

Cannabinoids affect sensory, psychomotor, and cognitive function and the ability to perform certain tasks. There is little dispute that high doses of marijuana can disrupt performance when the task is difficult. As may be expected, the effects of marijuana on performance become more variable as the complexity of the task is simplified and the dose of marijuana is reduced. In a comprehensive review, Chait and Pierri concluded that marijuana, at doses that produce moderate levels of intoxication, can affect a wide range of learned and unlearned behaviors, including simple motor tasks, and more complex psychomotor and cognitive tasks (2). Cannabinoid-induced impairment of flying and driving has been documented in numerous studies, although interpretation of the results remains controversial. THC is frequently found in the blood of drivers involved in automobile accidents, and marijuana use has been associated with impaired field sobriety test performance.

One study compared the effects of marijuana on equilibrium and simulated driving (3). Marijuana smoking that produced a “high” also increased body sway and increased brake latency to a degree comparable to that found in persons with breath alcohol concentrations near 0.05%. Marijuana smoking also acutely produces decrements in smooth-pursuit eye tracking (4). Although robust acute effects of marijuana were found on subjective and physiologic measures, and on smooth-pursuit eye tracking performance, no effects were evident the day after administration, a finding indicating that the residual effects of smoking a single marijuana cigarette are minimal. Furthermore, perceptual motor speed and accuracy, two very important parameters of driving ability, seem to be impaired immediately after marijuana use (5).

Cognition

There is lack of consensus regarding the effects of Δ^9-THC on memory and learning in that results are often inconsistent and test specific (2 ,6). Hall et al. concluded from clinical observations and cross-cultural studies that chronic marijuana use does not appear to produce severe gross impairment, but rather it may produce subtle cognitive deficits (7). The most frequently mentioned deficits were slower psychomotor performance, poorer perceptual motor coordination, and memory dysfunction. During the past few years, greater attention has been directed toward investigating specific cognitive deficits and relating these effects directly to marijuana use. Whereas THC appears to produce its greatest decrement in free recall or short-term memory, it has been proposed that chronic marijuana use in adolescents may result in long-term memory impairment (6). There are also indications that persons with learning disabilities may be more susceptible to memory deficits (6). Almost all studies have shown that marijuana has no effect on retrieval of already-learned material. THC reliably alters the perception of time, with subjects overestimating elapsed time or experiencing an increase in the subjective rate of time (2). Evidence has emerged from several studies that chronic marijuana use after many years produces subtle cognitive changes, specifically with regard to attention, as well as organization and integration of complex information (8).

These effects on memory have been supported by cannabinoid-induced deficits in several animal models. The naturally occurring cannabinoids as well as a wide range of synthetic compounds have been demonstrated to impair learning and memory in numerous laboratory animal memory tasks. Lichtman and Martin found that many synthetic cannabinoids impaired spatial memory in rats, as assessed by the eight-arm radial maze, and retarded completion time (9). Direct injection of cannabinoids into the hippocampus impaired memory, and this appeared specific to cognition because no other pharmacologic effects were produced (10).

Tolerance and Dependence

There is convincing evidence for the development of tolerance to THC in humans (11). Tolerance developed to a variety of THC’s effects, after oral administration, including cannabinoid-induced decreases in cardiovascular and autonomic functions, increases in intraocular pressure, sleep disturbances, and mood changes (11). High doses of Δ^9-THC were required for a sustained period of time to achieve behavioral tolerance. If the doses of Δ^9-THC were sufficiently small and infrequent, little behavioral tolerance seemed to develop.

Although it is well known that cessation of chronic marijuana exposure does not result in severe withdrawal symptoms, numerous case reports attest to the development of dependence (12). Several early reports came from countries where potent marijuana was used for long periods of time. On deprivation of marijuana, users experienced auditory and visual hallucinations and irritability. The development of tolerance and dependence has been studied under rigorous and controlled conditions (12 ,13). In one study, high doses of marijuana extract or Δ^9-THC were administered for up to 21 days, and the most prominent subjective symptoms were increased irritability and restlessness. Other symptoms included insomnia, anorexia, increased sweating, and mild nausea, although they were variable. Objective symptoms were increased body temperature, weight loss, and hand tremor. Readministration of a marijuana cigarette or oral Δ^9-THC alleviated the objective and subjective effects, a finding suggesting the establishment of a withdrawal symptom. Similar findings were reported by Georgotas and

Zeidenberg in abstinent subjects who had smoked high quantities of marijuana on a long-term basis (13). One study (14) found that lower doses of THC (80 and 120 mg/day, orally, each for 4 days) initially produced ratings of “high,” increased food intake over baseline by 35% to 45%, and decreased verbal interaction among participants (14). Tolerance developed to the subjective effects of THC but not to its effects on food intake or social behavior. Abstinence from THC produced anxious, depressed, and irritable symptoms, decreased the quantity and quality of sleep, and decreased food intake (14). A similar study conducted with marijuana cigarettes resulted in similar effects and led to the conclusion that abstinence symptoms may play a role in maintaining daily marijuana use, even at levels of use that do not produce tolerance (15).

Epidemiologic data support marijuana dependence as reviewed by Hall et al. (7). There are numerous cases in which persons seek treatment for dependence of which marijuana is the primary cause (16). These patients typically complained of being unable to stop or to decrease their marijuana use despite experiencing sleepiness, depression, inability to concentrate, and memorization difficulties that they directly attributed to marijuana exposure. Kandel and Davies reported similar problems in daily users of marijuana (17). Several groups of investigators have used DSM-III-R and DSM-IV criteria to diagnose marijuana dependence (18 ,19 and 20). With regard to prevalence of marijuana abuse and dependence, the strongest evidence was provided by the Epidemiological Catchment Area study involving 20,000 persons in five geographic areas of the United States (21). Approximately 4.4% of the population were diagnosed for marijuana abuse or dependence, and three-fifths of these met the criteria for dependence. After an extensive review of the literature, Hall et al. concluded that the risk of developing marijuana dependence was probably similar to that of alcohol, and daily use over a period of weeks to months results in the greatest risk of dependence development (7). Kandel and Davies estimated that the risk of dependence in near-daily marijuana users was one in three (17). Hall et al. estimated that the risk of developing dependence is 10% for those who ever used marijuana, with the risk rising to 20% to 30% for those using more than five times (7). Factors that have been associated with marijuana dependence include poor academic achievement, deviant behavior, rebelliousness, maladjustment, difficult parental relations, early initiation of drug use, and family history of drug use (7). The major complaints by marijuana-dependent persons are loss of control over drug use, cognitive and motivational impairments, lowered self-esteem, depression, and spousal discord. The risk of cannabis abuse and dependence was found to increase with the frequency of smoking occasions and slightly decreased with age (22). More severe comorbidity was associated with dependence compared with abuse, a finding suggesting that cannabis may be used to self-medicate major depression.

More recently, Budney et al. reported that most marijuana users seeking treatment for marijuana dependence had experienced symptoms consistent with either moderate or severe dependence (23). These investigators also reported that marijuana-dependent persons exhibit substantial problems (24). Comparison of marijuana- and cocaine-dependent patients revealed comparable substance-use histories and a range of impairments in both groups. However, the marijuana-dependent patients showed less severe dependence. The marijuana group was more ambivalent and less confident about stopping their marijuana use than the cocaine group was about stopping their cocaine use. The authors concluded that treatment-seeking, marijuana-dependent persons exhibit substantial problems and urged development of effective treatments for this population (24).

Some predisposing factors may contribute to marijuana dependence in some persons. Crowley et al. reported that juveniles diagnosed with both substance abuse and conduct disorders have serious problems related to cannabis, and most met standard adult criteria for cannabis dependence (25). Two-thirds of these cannabis-dependent patients reported withdrawal. The data indicate that for adolescents with conduct problems, cannabis use is not benign. Genetic risk factors may also contribute. Kendler et al. examined a large female twin population for lifetime cannabis use, heavy use, abuse, and dependence as defined by DSM-IV criteria (26). These investigators concluded that in women, genetic risk factors have a moderate impact on the probability of ever using cannabis and a strong impact on the liability to heavy use, abuse, and, probably, dependence. By contrast, the family and social environment substantially influences risk of ever using cannabis but plays little role in the probability of developing heavy cannabis use or abuse (26).

One of the difficulties in establishing the presence of cannabinoid dependence was the lack of a reliable animal model. Early attempts to demonstrate spontaneous withdrawal after cessation of chronic marijuana or THC treatment resulted in equivocal findings. However, the development of a specific cannabinoid antagonist, SR 141617A, made it possible to precipitate withdrawal in rats (27 ,28), mice (29), and dogs (30) treated chronically with THC. The physical withdrawal syndrome for cannabinoids and opioids in rodents shares many of the same characteristics. It is also clear that, in humans, THC is an essential reinforcing component in marijuana (31). Contrary to most drugs abused by humans, it has been difficult to train animals to self-administer cannabinoids. Although the physical characteristics of cannabinoids probably contribute to this difficulty, the general opinion persists that cannabinoids lack rewarding effects and therefore are devoid of dependence liability. However, Martelotta et al. demonstrated that the synthetic cannabinoid agonist WIN 55,212-2 was intravenously self-administered by mice in a concentration-dependent manner according to an inverted U-shaped curve (32).

Therefore, it appears that WIN 55,212-2 elicits both rewarding and aversive effects, depending on the concentration used. It may well be that these dual properties have hindered the development of a THC model of self-administration. Nevertheless, these studies clearly demonstrate that cannabinoid self-administration is not confined to humans.

ENDOGENOUS CANNABINOID SYSTEM

Part of "106 - Marijuana "

Cannabinoid Receptors

It is now widely recognized that most of the neurobehavioral and peripheral actions of marijuana and THC result from activation of selective receptors, two of which, named CB_1 and CB_2, have been cloned and characterized (33 ,34). The development of transgenic mice lacking the genes encoding for either of these two receptors, the CB_1 and CB_2-receptor knockout mice (35 ,36 and 37), have provided conclusive evidence that the effects of THC on motor behavior, body temperature, cardiovascular function, and nociception, on the one hand, and on some immunologic responses, on the other hand, are mediated by CB_1 and CB_2 receptors, respectively.

CB_1 receptors are widely distributed throughout mammalian tissues and have been found not only in the central and peripheral nervous systems, but also in both male and female reproductive organs, immune cells, the gastrointestinal tract, the liver, and the heart (38). In the central nervous system, CB_1 receptors are most abundant in the hippocampus (i.e., the dentate gyrus and CA pyramidal cells), the basal ganglia (namely, the substantia nigra pars reticulata, globus pallidus, caudate putamen), and the cerebellum and the olfactory bulb (39), findings in agreement with the inhibitory actions of THC on memory and cognitive functions, spontaneous activity, locomotion, motor coordination, and posture. Lower density of CB_1 receptors is present in discrete nuclei of other brain regions such as the hypothalamus, brainstem, thalamus, and limbic forebrain, thus possibly accounting for THC activity on body temperature, appetite, supraspinal mechanisms of pain perception, sensory perception, and mood or reward. CB_1 receptors are associated with nerve fibers and axon terminals, but not in the neuronal soma. This pattern is consistent with the presynaptic inhibitory effects of cannabinoids on neurotransmitter release in the brain (see ref. 40 for review). CB_1-expressing cells in mouse forebrain can be divided into distinct neuronal subpopulations. Most of the cells that highly express CB_1 are GABAergic neurons belonging mainly to the cholecystokinin-positive type of interneurons (basket cells). In the hippocampus, amygdala, and entorhinal cortex area, CB_1 mRNA is present at low but significant levels in many non-GABAergic cells that can be considered as projecting principal neurons. These data are in good agreement with the observation that cannabinoids act on principal glutamatergic circuits as well as modulate local GABAergic inhibitory circuits by inhibiting glutamate and GABA release. Virtually all striatal projection neurons contain CB_1 mRNA, which is also expressed in putative GABAergic interneurons that enable functional interactions between the direct and indirect striatal output pathways (41). CB_1 mRNA is found in striatonigral neurons that contain dynorphin and substance P and striatopallidal neurons that contain enkephalin, whereas local circuit neurons in striatum that contain somatostatin or acetylcholine do not synthesize CB_1 mRNA.

The presence of CB_1 receptors in sensory (42) and autonomic peripheral fibers (43 ,44) has been reported. CB_1 receptors seem to be mostly restricted to spinal interneurons, rather than at the axonal level (45), thus possibly accounting for spinal mechanisms of pain control ascribed to psychotropic cannabinoids. However, indirect evidence also exists for the presence of CB_1 receptors in peripheral sensory afferents (46), a finding thus supporting the concept that cannabinoids may also exert analgesia at the peripheral level. The presence of CB_1 receptors in parasympathetic and sympathetic fibers, on the other hand, may be at the basis of the vascular and smooth muscle–relaxing activity of THC through inhibition of norepinephrine and acetylcholine release, respectively (43 ,44). There is no evidence for the presence of CB_2 receptors in the central nervous system, except for their expression in microglia. Clearly, given that CB_2 receptors seem to be mostly confined to cells of the immune system (34), it would not be surprising to find these proteins only in those central nervous system cells deputed to immune defense, such as the microglia and resident mast cells. This finding may explain some of the neuroprotective activities of cannabinoids *in vivo* (see later).

Transduction Mechanisms

Studies have revealed that activation of the α subunits of G_i/G_o proteins, with subsequent inhibition of adenylate cyclase through both CB_1 and CB_2 receptors (47), blockade of voltage-activated calcium (Ca^{2+}) channels of the N- and P/Q-type through CB_1 receptors (48), and activation of inwardly rectifying potassium channels through CB_1 receptors (49), may not be the sole intracellular signaling messages delivered by psychoactive cannabinoids. There is now evidence for the coupling of CB_1, but not CB_2 receptors, to G_s proteins, with consequent activation of adenylyl cyclase. It is not clear yet whether this effect may explain the biphasic nature of cannabinoid effects on behavior in several tests. Another typical consequence of CB_1-receptor activation is the modulation of nitric oxide (NO) release. In neurons, THC and synthetic and endogenous cannabinoids can either stimulate (50) or inhibit (51) NO formation. The former effect results in inhibition of dopamine release from invertebrate ganglia, whereas the inhibition of NO release in granule cerebellar cells seems to result from inhibition of voltage-activated Ca^{2+} channels. In any case, modulation of NO levels may result in changes in cyclic guanosine

monophosphate intracellular concentrations. Finally, protein phosphorylation catalyzed by mitogen-activated protein kinase is coupled to both CB_1- and CB_2-receptor stimulation (52). This intracellular effect, together with inhibition of the cyclic adenosine monophosphate (cAMP)–dependent protein kinase A, is at the basis of cannabinoid action on the expression of several genes such as *krox-24* in HL60 cells (52) or the prolactin receptor and the high-affinity receptors *trk* for the nerve growth factor in human breast cancer cells (53). Mitogen-activated protein kinase activation by cannabinoids may occur independently from inhibition of protein kinase A (52), or it may result in part from inhibition of cAMP formation (53). Likewise, CB_1-induced activation of focal adhesion kinase in hippocampal slices, an effect suggested to lead to modulation by cannabinoids of synaptic plasticity and learning, results from inhibition of adenylate cyclase and protein kinase A.

Endogenous Ligands (Endocannabinoids)

Since the mid-1990s, several fatty acid derivatives have been isolated from mammalian tissues and have been shown to mimic the pharmacologic properties of THC. Not all these substances, however, can displace high-affinity cannabinoid ligands from selective binding sites in membrane preparations containing the CB_1 or the CB_2 receptor. Anandamide (arachidonoylethanolamide, AEA), the amide of arachidonic acid with ethanolamine, was the first of such compounds to be isolated (54). The other prominent endogenous ligand is a glycerol ester, 2-arachidonoyl glycerol (2-AG) (55). These compounds share the ability to bind to and to activate CB_1 and (particularly in the case of 2-AG) CB_2 receptors. Therefore, they induce a series of pharmacologic effects *in vitro* and *in vivo* that are, to some extent, similar to those exerted by THC. Other fatty acid derivatives, such as palmitoylethanolamide and oleamide, do not have high affinity for either CB_1 or CB_2 receptors, and yet they exhibit pharmacologic actions that in some cases resemble those of THC (56). The molecular mode of action of these latter compounds is still a subject for investigation.

Several structure-activity relationship studies have been carried out on AEA and have revealed that this compound does share with THC some of the structural prerequisites necessary for interaction with the CB_1 receptor. This relationship can be best appreciated with a successful conformational model (57), in which AEA may assume a low-energy conformation resulting in the superimposition of its *n*-pentyl chain, carbonyl amide group and ethanolamine hydroxyl group, respectively, with the *n*-pentyl chain, the phenolic hydroxyl group and the C-9 hydroxyl group in 9-*nor*-9ß-OH-hexahydrocannabinol, a potent THC analogue. Structure-activity relationship studies for the interaction with CB_2 receptors have not been performed yet, the sole exception being the article by Sugiura et al. (58) on the structural moieties necessary to 2-AG analogues to induce Ca^{2+} transients in HL60 cells through these receptors. Interestingly, in this study, AEA was shown to be a very weak and partial agonist at CB_2 receptors. Whatever its role as an endogenous agonist at CB_2 receptors, AEA, and much more so its metabolically stable analogues (*R*)-methanandamide and 2′-fluoro-2-methyl-arachidonoyl-ethanolamide, act as relatively potent (K_i between 12 and 100 nM) and selective CB_1-receptor agonists, and thus can be considered useful pharmacologic tools for studies on the bioactivity of endocannabinoids.

AEA shows, in some cases, effects qualitatively and quantitatively different from those of classic cannabinoids, possibly in part because of the rapid metabolism of this compound both *in vitro* and *in vivo* (59), and because AEA is a partial agonist in some functional assays of CB_1 activity (60). In the brain, AEA was shown to exert inhibitory actions on learning and memory (61) and to modulate the extrapyramidal control of motor behavior (62). These effects probably result from the capability of AEA to induce, by activation of CB_1 receptors, modulation of neurotransmitter (e.g., glutamate, GABA, dopamine) release, action or reuptake through intracellular signaling events similar to those described earlier for THC (40). This neuromodulatory action may also underlie AEA regulation of hormone release at the level of the hypothalamus-pituitary-adrenal axis, as well as the antinociceptive effects of the compound through both spinal and supraspinal mechanisms (63).

Endocannabinoid levels in tissues and cells can be modulated through the regulation of either their biosynthesis or inactivation. It is commonly accepted that the AEA and 2-AG are not stored as such in cells, but rather are synthesized and are directly released by cells “on demand,” after Ca^{2+} influx into the cell (such as that occurring in neurons on depolarization or in mast cells after IgE-mediated activation) and the hydrolysis of phospholipid precursors (40). For, example, AEA is produced in neurons and leukocytes together with other *N*-acyl-ethanolamines (NAEs) from the hydrolysis of the corresponding *N*-acyl-phosphatidyl-ethanolamines (NAPEs) (64). This reaction is catalyzed by a Ca^{2+}-independent phospholipase D, whereas a Ca^{2+}-dependent *trans*-acylase catalyzes the formation of NAPEs form phosphatidylethanolamine and the fatty acids on the *sn*-1 position of phosphoglycerides. Several mechanisms for the inactivation of endocannabinoids have been identified in neuronal and blood cells. A membrane-bound intracellular hydrolase catalyzes AEA hydrolysis after its diffusion into neuronal cells and leukocytes (64). A mechanism for the facilitated diffusion of AEA into cells according to its concentration gradient across the plasma membrane has been partially characterized as a saturable, temperature-sensitive, selective and sodium-independent “carrier” (64). This “carrier,” probably a protein, may be used for both the reuptake by and the release from cells of AEA. The major enzyme responsible for AEA hydrolysis is the fatty acid amide hydrolase

(FAAH), cloned so far in four different mammalian species (65).

Because the biosynthetic precursors for AEA and 2-AG, by being products of membrane phospholipid remodeling, are likely to occur in most animal tissues, the two endocannabinoids are probably to be found, at least in minute amounts, as ubiquitous metabolites. However, for these compounds to work as endogenous agonists of CB_1 and CB_2 receptors, their tissue concentrations need to be increased up to at least 50 to 100 nM after cell stimulation (e.g., neuronal depolarization, immune challenge) and subsequent activation of the proteins involved in their biosynthesis and release. Furthermore, the inactivation of endocannabinoids may be subject to regulation. In agreement with possible regulation of endocannabinoid levels under physiologic and pathologic conditions, the amounts of AEA or 2-AG have been found to vary during brain development, to be higher in some of the brain regions with the highest density of CB_1 receptors, such as the basal ganglia and the hippocampus (66), to decrease and increase in the striatum and limbic forebrain, respectively, of rats after chronic treatment with THC (67), to be inversely correlated with spontaneous activity in the globus pallidus of reserpine-treated rats (68), to vary during pregnancy in mouse uterus, levels of these agents being maximal when the uterus is least receptive to embryo implantation (69), and to be enhanced during septic or hemorrhagic shock in rat macrophages and platelets (70 ,71). Indeed, several possible regulative mechanisms have been reported for both the biosynthesis and inactivation of AEA and 2-AG in isolated, intact cells.

PHYSIOLOGIC ROLE OF ENDOGENOUS SYSTEM

Part of "106 - Marijuana "

The finding of variations in AEA and 2-AG levels during physiologic or pathologic conditions, together with observations of their pharmacological activity *in vivo* and *in vitro*, provide useful information on the possible biological role played by these compounds. Additionally, *in vivo* pharmacologic studies carried out by administering selective cannabinoid receptor antagonists may reveal a possible endocannabinoid-induced “tone” of CB_1- and CB_2-receptor activation during certain conditions, although the capability of the antagonists so far developed to behave as inverse agonists as well (72) should always be taken into account.

Pain

Extensive studies (see refs. 63 and 73 for review) have been carried out demonstrating the involvement of endocannabinoids in the control of nociception and, in particular, chronic and inflammatory pain. Electrical stimulation of the periaqueductal gray was shown to induce CB_1-mediated analgesia while leading to the release of AEA in microdialysates from this region of the brainstem (74). Moreover, the injection of formalin into the paw induced a nociceptive response concomitantly to the release of AEA from the periaqueductal gray and thereby established an correlation between supraspinal nociception and endocannabinoid release. In fact, an earlier investigation had suggested that an endocannabinoid tone may down-modulate pain perception through CB_1 receptors in another region of the brainstem, the rostral ventromedial medulla, through the same circuit previously shown to contribute to the pain-suppressing effects of morphine (75). However, other studies have shown that blockade of the action or expression of spinal CB_1 receptors by SR141716A or a CB_1-receptor antisense oligonucleotide, respectively, leads to hyperalgesia (76), a finding thus suggesting the existence of an endocannabinoid tone down-modulating nociceptive response also at the spinal level. The same group gained evidence for the presence of CB_1 receptors in peripheral sensory afferents in the skin, and for their involvement in the control of inflammatory pain (77). It may well be that an endocannabinoid and CB_1/CB_2 receptors mediate tone controlling pain at the peripheral level, because local administration of the antagonist for each receptor subtype leads to hyperalgesia and exogenous AEA blocks the painful response of mice to formalin injection. Several studies, taken together with that by Meng et al. (75) and Walker et al. (74), suggest that if endocannabinoids tonically modulate inflammatory pain perception, they may do so at sites different from those of inflammation.

There has been considerable interest in determining what role, if any, opioids play in cannabinoid-induced antinociception. In one study, marijuana produced significant dose-dependent antinociception (increased finger withdrawal latency) and behavioral effects. Naltrexone did not significantly influence marijuana dose-effect curves, a finding suggesting no role of endogenous opiates in marijuana-induced antinociception under these conditions (78). Conversely, it has been shown that cannabinoids stimulate release of endogenous opioids that contribute to cannabinoid antinociception (79). Meng et al. showed that the rostral ventromedial medulla that contributes to the pain-suppressing effects of morphine is also required for the analgesic effects of cannabinoids (75). Although cannabinoids produce analgesia by modulating rostral ventromedial medulla neuronal activity in a manner similar to morphine, their actions are not identical. They also show that endogenous cannabinoids tonically regulate pain thresholds in part through the modulation of rostral ventromedial medulla neuronal activity. These authors concluded that analgesia produced by cannabinoids and opioids involves similar brainstem circuitry and that cannabinoids are indeed centrally acting analgesics with a new mechanism of action.

Memory

The effects of cannabinoids on memory in rats are also blocked by a specific cannabinoid antagonist, SR 141716A, a finding providing strong evidence that these effects are mediated through cannabinoid receptors in the brain (9). Mallet and Beninger used a two-component instrumental discrimination task, consisting of a conditional discrimination, and a non–match-to-position to assess recent or working memory (61). These investigators found that both THC and anandamide impaired performance, an effect that could be attenuated with the administration of the CB_1-receptor antagonist SR141716A. These results suggest that anandamide-induced memory disruption is mediated by CB receptors. Studies have shown that THC produces memory deficits similar to those produced by neurochemical lesions of the hippocampus. A possible role for cannabinoid receptors and endogenous cannabinoids may be to regulate the storage and retrieval of information (80).

As discussed previously, cannabinoid receptors are highly expressed in the hippocampus, a brain region that is believed to play an important role in certain forms of learning and memory. The notion that endocannabinoids are involved in the control of learning and memory processes at the level of the hippocampus is supported by several different types of observations. First, both AEA and 2-AG inhibit hippocampal long-term potentiation (81) and modulate the release of glutamate or acetylcholine from hippocampal slices (40). Second, AEA modulates both short-term and long-term memory (61). Third, SR141716A enhances long-term potentiation, a finding thus suggesting a CB_1-receptor tone in the control of this process. Fourth, CB_1-receptor knockout mice exhibit enhancement of memory as well as of long-term potentiation (82). Finally, CB_1 receptors, AEA, and FAAH are found in high levels in the hippocampus of humans, rats, and mice (66). These findings suggest that constitutive activation of CB_1 receptors in this brain region leads to inhibition of learning and memory processes.

There is evidence that memory deficits induced by cannabinoids may be mediated through cholinergic and dopaminergic systems (83). The systemic administration of THC reduced hippocampal extracellular acetylcholine concentrations while impairing working memory in rats. Both effects were blocked by the CB_1 cannabinoid and D2 dopamine receptor antagonists and potentiated by the D2 dopamine receptor agonist quinpirole. The inhibition of hippocampal extracellular acetylcholine concentration and working memory produced by the combination of (-)- quinpirole and THC was suppressed by either CB_1 cannabinoid and D2 dopamine receptor antagonists. These researchers concluded that cannabinoid impairment of working memory and inhibition of hippocampal extracellular acetylcholine concentration are mediated by the concomitant activation of D2 and CB_1 receptors.

Movement

Central cannabinoid receptors are densely located in the output nuclei of the basal ganglia (globus pallidus, substantia nigra pars reticulata), a finding suggesting their involvement in the regulation of motor activity. However, different approaches have not managed to give a precise role of endocannabinoids in the inhibition of spontaneous activity and induction of catalepsy in rodents, typical of all CB_1-receptor agonists (84). In fact, although CB_1-receptor knockout mice seem to have different baseline locomotor activity than wild-type mice, it is not clear whether deletion of the CB_1-receptor gene in these transgenic animals leads to hypermotility (35) or hypomotility (36). However, an endogenous cannabinoid tone negatively controlling spontaneous activity and motor behavior is supported by the finding that AEA, but not 2-AG, is released in microdialysates from the dorsal striatum of freely moving rats (85), and the levels of AEA are also very high in the substantia nigra and external layer of the globus pallidus (68).

In this latter brain region, endocannabinoid levels are *inversely* correlated with spontaneous activity in the reserpine-treated rat, an animal model of Parkinson disease, in which dopamine and other catecholamines in the striatum are depleted (68). AEA levels in the striatum of normal rats are increased by selective stimulation of D2 dopamine receptors by quinpirole, whereas the CB_1 antagonist SR141716A strongly enhances quinpirole-induced movement in both normal and reserpine-treated rats (68 ,85). These data suggest that the endocannabinoid system may act as a brake on dopaminergic stimulation of movement in the basal ganglia, and an exaggerated endocannabinoid tone in this region may produce (or at least contribute to) parkinsonian symptoms in rats (68). Further evidence for such suggestions has been provided by the finding that tolerance to the motor inhibitory actions of THC in rats chronically treated with the cannabinoid is accompanied not only by down-regulation of cannabinoid receptors in the striatum, but also by a significant decrease of endocannabinoid levels in this brain area (67).

Craving, Appetite Stimulation, and Reward

The finding of CB_1 receptors in the arcuate nucleus and the medial preoptic area of the hypothalamus, the presence of endocannabinoids and their biosynthetic precursors in the hypothalamus and pituitary, and the effect of endocannabinoids on body temperature, food intake, and pituitary hormone release suggest a role for endocannabinoids in the control of hypothalamic functions, and in particular on appetite and hormone release. Indeed, the CB_1-receptor–selective antagonist, SR141716A, inhibits palatable food intake in rodents (86). It has not been established whether

this effect results from the inverse agonist properties of SR141716A (72) or from its blockade of a food-intake stimulatory tone by endocannabinoids. Another brain region possibly involved in the control of appetite and craving is the limbic forebrain and, more particularly, the nucleus accumbens. In this brain area, cannabinoids, by enhancing the release of dopamine from dopaminergic terminals originating in the ventral tegmental area, may exert reinforcing actions on the effects of other drugs of abuse or, under more physiologic conditions, may participate in the regulation of feelings of craving and reward (87). Furthermore, it was found that chronic treatment of rats with THC causes an almost fourfold increase of AEA levels (and no down-regulation of cannabinoid receptors) in the limbic forebrain (67). It is possible that dopamine released in the nucleus accumbens on chronic treatment with THC triggers AEA formation, as previously shown for the dorsal striatum (85). Conversely, dopamine may be released in this region after the activation of CB_1 receptors by AEA. Indeed, studies carried out with CB_1-receptor knockout mice showed reduced opioid dependence (35), as well as lack of morphine-induced dopamine release in the nucleus accumbens of these transgenic animals (88). Thus, contrary to the basal ganglia, endocannabinoids released in the nucleus accumbens may act to enhance the action or release of dopamine, thereby participating in reward, craving, and pleasure or in the reinforcement of drug of abuse effects. There are indications that withdrawal from chronic cannabinoid administration is associated with reduced dopaminergic transmission in the limbic system, similar to that observed with other addictive drugs, a finding consistent with a role in drug craving and relapse into drug addiction or in the reinforcing effects of drugs of abuse.

Neuroprotection

The possibility that endocannabinoids may play a role in diminishing cellular or neuronal damage is of particular relevance to neurodegenerative disorders. The suggestion that endocannabinoids may have a neuroprotective function during cell injury stems from the finding that a similar role was proposed also for other ethanolamide of fatty acids (89), as well as for both psychoactive and nonpsychoactive cannabinoids. This hypothesis is supported by the finding that stimuli leading to high intracellular Ca^{2+} concentrations (e.g., glutamate-induced excitotoxicity) and noxious agents such as ethanol and sodium azide lead to increased synthesis of AEA and related compounds in neuronal cells. Cannabinoid receptors do not appear to be involved in this elevation of Ca^{2+}. In fact AEA, via CB_1 receptors, produces the opposite effect. It inhibits Ca^{2+} influx into neurons through voltage-gated Ca^{2+} channels and counteracts membrane permeability to Ca^{2+} through *N*-methyl-D-aspartate receptor–coupled channels. Therefore, endocannabinoids should be able to inhibit glutamate-induced excitotoxicity (or other pathologic conditions arising from high intracellular Ca^{2+} concentrations) by acting at CB_1 receptors, particularly because they do not share the antioxidant effects of some synthetic cannabinoids. In conclusion, further studies are necessary to assess whether and through what mechanisms AEA and 2-AG prevent neuronal damage.

MEDICAL MARIJUANA

Part of "106 - Marijuana "

Scientific Justification

The nonmedical use of marijuana has a very long history, primarily for its mind-altering effects and the sense of well-being that it can provide. Therefore, the potential use of marijuana for diseases of the brain is a logical extension of the popularity of the use of the material in producing mood-altering effects. The initial therapeutic uses proposed for marijuana included the treatment of mental disorders and pain. As more information about the pharmacologic effects of the plant material emerged, other potential therapeutic uses became apparent. Since the 1970s, investigators have proposed many different therapeutic uses for marijuana including, but not limited to, nausea and vomiting induced by cancer chemotherapeutic agents, the wasting syndrome accompanying AIDS, mental illness, convulsions, glaucoma, cognition disorders, muscle spasticity, and neuropathic pain (90).

The consequences of the social use of marijuana, both real and as often exaggerated by opponents and proponents, have caused increased anxiety on both sides of the controversy over the medical use of marijuana. Strong proponents of the use of smoked marijuana for the treatment of various syndromes and diseases argue that smoking marijuana has produced beneficial effects in at least one disease state that could not be achieved by the oral administration THC or by any other treatment modality. Opponents are concerned with the deleterious effects of the smoked marijuana, especially the prolonged use of this plant material. The issue is further complicated by the fact that many strong proponents of the use of marijuana in medicine also advocate for its legal recreational use. Conversely, those who are opposed to its use, especially by adolescents and young adults who may be especially vulnerable to problems of abuse, effects on energy, memory, and acquisition of interpersonal skills, have not always considered the possible benefits with the same degree of objectivity as would be afforded other potential therapeutic agents. One of the major problems contributing to this dilemma is the lack of well-controlled studies attesting to the efficacy and the safety of marijuana in humans. Such studies require a reasonable hypothesis to be tested and an appropriate investigation under conditions that completely eliminate the possibility of subjectivity in the measurements. This controversy is not likely to be resolved until such studies are forthcoming.

The need for an approved medical use of marijuana itself

is questioned by some investigators because of the availability of marijuana's active constituent. THC was approved for the treatment of the nausea and vomiting associated with cancer chemotherapy in the 1980s and for the treatment of the wasting syndrome in AIDS patients in the early 1990s. It has been moved from Schedule II to Schedule III. Marijuana proponents counter that the therapeutic benefits derived from smoked marijuana are the result of many chemicals in the plant, not solely THC. There are, however, toxic pulmonary consequences to marijuana smoking. Further, the smoking route of administration used for marijuana has advantages over the oral route used for the administration of THC. The onset of action is faster while at the same time allowing the smoker to titrate blood levels better. The heightened interest in medical marijuana has not yet been translated into a satisfactory resolution of the differences. There is no doubt of the severity of the conditions and diseases for which marijuana or THC has been proposed. The availability of alternative delivery systems (e.g., aerosol) and alternative synthetics that have the desired therapeutic effect with minimal intoxicating effects are needed to resolve the controversy. Even then, however, it is likely that some will argue that it is the intoxicating effect combined with the other effects that makes marijuana particularly useful.

Medication with Plant Material

Active Constituents

Hundreds of compounds have been isolated and identified from the marijuana plant (91). Most have been shown to have minimal pharmacologic activity, and most exist in the plant in very small quantities. The major active constituent in marijuana has been shown to be THC. The pharmacologic profile of THC is essentially the same as that of smoked marijuana, and the evidence is now overwhelming that the predominant effects of marijuana on the brain result from this compound. Other cannabinoids such as Δ^8-THC, cannabidiol, and cannabinol have been studied and have been shown to have interesting pharmacologic profiles. The Δ^8-THC isomer produces many of the same effects as the Δ^9- isomer (THC), but it is generally less potent, and the quantity of Δ^8-THC in the plant material usually is less than that of THC. Cannabidiol and cannabinol are of interest because they exist in reasonable quantities in the plant and produce interesting pharmacologic effects in some systems but also are considerably devoid of activity on the central nervous system, especially in relation to mental health, memory, and cognition. The lack of effects on the central nervous system is an advantage in the potential use of one of these agents or an analogue to treat a disease or a condition with a locus of action outside the brain. The search for other cannabinoids that could have therapeutic potential has shifted almost totally to the synthetic chemistry process.

THC Content

The identification of THC as the active agent in marijuana stimulated a concentrated effort to quantitate the amount of this material in various samples of the cannabis plant. The initially reported concentrations of THC in confiscated marijuana were approximately 2% but have increased to more than 4% during the past few years (92). It was found that by altering the soil conditions and the environment, the concentration could be increased several fold. As one would expect, the pharmacologic effects of smoking marijuana are directly related to the concentration of THC. Advances in biogenetic engineering as applied to agriculture suggest that manipulations could be made to increase the concentration of THC even higher. Concentrations of more than 20% have been reported in some marijuana grown under artificial conditions in the Netherlands. How available increased-potency marijuana is in the United states remains unclear.

Consistency

As described earlier, the concentration of the active constituent in marijuana can vary over a large range. This variation clearly complicates the delivery of a consistent dose of medication. It would not be practical to quantitate the concentration of the active ingredient in each cigarette before its consumption. Most of the proposed indications for the medical use of marijuana require chronic administration, which magnifies the problem of inconsistent dosing. Administration of any drug through smoking presents an additional problem when a standard procedure does not exist for preparing cigarettes with a constant quantity of plant material in each cigarette. Further, the variability from individual to individual in the size and the rate of puffing produces another variable for the consumption of drugs by this route of administration. Even in the same patient, the volume of smoke inhaled can often differ from time to time.

Unwanted Side Products

The administration of a drug by smoking plant material causes other problems because many substances are being taken in along with the active ingredient. Each of these substances has its pharmacologic and toxicologic effects. Further, these other substances may either potentiate or interfere with the effects of the active ingredient. It is abundantly clear from the vast literature on the smoking of other products, predominantly tobacco, that numerous compounds are produced in the burning process. These pyrolysis products also have their own pharmacologic and toxicologic profile, and as with the other ingredients in the plant material, these pyrolysis products have the potential to alter the effects of the active ingredient. The major problem is the inability to control the exposure of the patient carefully to

a consistent and correct dose of the active ingredient and to establish a treatment regimen that is devoid of interference from other chemicals in the preparation or made during the administration process.

Optimal Delivery
