Treatment with typical antipsychotics may result in poorer clinical and quality of life outcomes than with atypical antipsychotics (6). The mean first-year relapse rate during continuing maintenance treatment with conventional antipsychotics is approximately 26% in schizophrenic patients with first or multiple episodes (43). Even under the best conditions, when patients are maintained on therapeutic doses of depot conventional antipsychotics, approximately 30% of discharged patients with schizophrenia will be rehospitalized within 1 year (44). Hospital readmission rates are higher for conventional antipsychotics than for atypical antipsychotics (45). The monthly relapse rate of compliant patients taking optimal doses of a depot neuroleptic is estimated to be 3.5% per month, and the rate for patients who have discontinued their medication is 11.0% per month (44).

In terms of relapse prevention, higher doses of conventional antipsychotics may help stability, yet the patient's quality of life will be reduced because of increased side effects. Often, when considering the best dose of a conventional antipsychotic, there is a trade-off between maximizing relapse prevention and optimizing comfort (46). Although there has been substantial progress in understanding maintenance dosing, for most patients with schizophrenia, this unfortunate trade-off is inevitable with conventional antipsychotic treatment (46).

Atypical Antipsychotic Drugs

A series of atypical compounds has been developed since the introduction of clozapine. These include risperidone, olanzapine, quetiapine, and ziprasidone, which were approved by the FDA in 2000, and aripiprazole and iloperidone, which are in late Phase III development.

Pharmacology

The pharmacologic properties that confer the unique therapeutic properties of atypical antipsychotic drugs are poorly understood despite intensive research efforts. Defining the role of the individual complex actions of clozapine responsible for its unique therapeutic profile (Table 56.1) is necessary for the rational design of new and improved atypical (clozapine-like) antipsychotics because this drug is the prototype atypical drug.

TABLE 56.1. AFFINITY OF ANTIPSYCHOTIC DRUGS FOR HUMAN NEUROTRANSMITTER RECEPTORS (Ki, nM)[a]

Receptor	Clozapine	Risperidone	Olanzapine	Quetiapine	Ziprasidone	Aripiprazole	Iloperidone	Haloperidol

Mechanisms of typical and atypical antipsychotic drug action in relation to dopamine and NMDA receptor hypofunction hypotheses of schizophrenia. *Mol Psychiatry* 1999;4:418–428. Lawler CP, Prioleau C, Lewis MM, et al. Interactions of the novel antipsychotic aripiprazole (OPC-14597) with dopamine and serotonin receptor subtypes. *Neuropsychopharmacology* 1999;20:612–627. Kongsamut S, Roehr JE, Cai J, et al. Iloperidone binding to human and rat dopamine and 5-HT receptors. *Eur J Pharmacol* 1996;317:417–423.

A distinguishing feature of clozapine in comparison to conventional antipsychotics is the relatively high affinity of clozapine for the 5-HT_{2A} receptor. Meltzer and associates (47) provided evidence that combined 5-HT_{2A}/D_2 antagonistic actions, with greater relative potency at the 5-HT_{2A} receptor, may be critical to atypicality, in terms of enhanced efficacy and reduced EPS liability. Based on this theoretic model, risperidone was developed to mimic the relative 5-HT_{2A}/D_2 affinities of clozapine, although risperidone has substantially higher affinity for both receptors than clozapine (Table 56.1). The reduced EPS side effects associated with low-dose risperidone treatment (4 to 6 mg per day), even at high levels of D_2 receptor occupancy, may be owing to the 5-HT_{2A} antagonistic properties of the drug (47 ,48). However, at higher doses, risperidone produces EPS, indicating that 5-HT_{2A} receptor antagonism alone cannot completely eliminate EPS associated with high D_2 receptor blockade. The potential role of 5-HT_{2A} receptor antagonism in therapeutic responses to atypical antipsychotic drugs may become more apparent when data from clinical trials are available for the selective 5-HT_{2A} antagonist M-100907. However, the results to date support the hypothesis that some degree of D_2 antagonism is still required to achieve antipsychotic effects. Moreover, at this point it is unclear what clinical effects 5-HT_{2A} antagonism confers, in addition to mitigating the adverse effect of striatal D_2 antagonism, and propensity to cause EPS (21).

Risperidone, like clozapine, has relatively high affinity for α_1- and α_2-adrenergic receptors (Table 56.1), but the potential therapeutic significance of the adrenergic receptor blocking properties of clozapine and risperidone is uncertain. Addition of the α_2-antagonist idazoxan to the regime of patients treated with the typical neuroleptic fluphenazine resulted in improved treatment responses in patients refractory

to treatment with fluphenazine alone (49). However, there has been no subsequent confirmation of the effects of α_2 antagonists as adjuncts to typical neuroleptic treatment, and it has been suggested that α_2 agonists may actually be useful for treating cognitive deficits of the disease (50).

Olanzapine is a closely related in chemical structure to clozapine, and the two drugs have many common receptor binding characteristics. Primary considerations in selection of olanzapine for development were the drug's relatively potent antagonistic effects at both D_2 and 5-HT_{2A}receptors (51 ,52). Olanzapine is more potent at 5-HT_{2A} than D_2 receptors (Table 56.1), similar to clozapine and risperidone. In addition, receptor binding characteristics of olanzapine in regard to other dopaminergic, serotonergic, cholinergic, and adrenergic receptor subtypes are similar to clozapine, but there are also some notable distinctions between the two drugs. For example, clozapine has substantially higher affinity for 5-HT_{1A} and 5-HT_7 receptors in comparison to olanzapine (Table 56.1).

Quetiapine is another drug with greater relative affinity for 5-HT_{2A} than for D_2 receptors, but also some affinity for α_1-adrenergic and H_1 receptors (53) (Table 56.1). Interestingly, quetiapine produces only transiently high striatal D_2 occupancy in schizophrenic patients, although the study has clinical and technical limitations (54). Ziprasidone has potent 5-HT_{2A} and D_2 affinities, and like clozapine, it shows 5-HT_{1A} agonist properties that could potentially act as protective effects on the development of EPS. Ziprasidone also has significant affinity for 5-HT_{1D} and 5-HT_{2C}, as well as H_1 and α_1-adrenergic receptors (55) (Table 56.1). Iloperidone has in addition to affinity for 5-HT_{2A} and $_{1A}$ and $D_{2,3}$ receptors, also affinity for the α_1- and α_{2c}-adrenergic receptors. Aripiprazole is distinct from the other atypical antipsychotic drugs because it is selective for the dopamine system and acts through partial agonism.

PET studies showing that therapeutic doses of risperidone and olanzapine produce greater than 70% occupancy of D_2 receptors suggest that D_2 receptor antagonism could be a predominant mechanism of action of these atypical drugs (56 ,57). Clozapine, however, does not exhibit high levels of D_2 receptor occupancy at therapeutically effective dose (15 ,57 ,58), suggesting that D_2 receptor antagonism alone cannot explain the greater therapeutic efficacy of clozapine (13). The low occupancy of striatal D_2 receptors by clozapine could account for its low EPS liability (20 ,58 ,59).

Clozapine, risperidone, and olanzapine occupy more than 80% of 5-HT_{2A} receptors in the therapeutic dose rage in humans (15 ,56 ,57 and 58 ,60). Although 5-HT_{2A} receptor antagonism is likely to be associated with the low EPS liability of risperidone and olanzapine, the role of this molecular action in the superior therapeutic responses to clozapine is unclear (13).

Efficacy

Although the proportion of patients who improve and the magnitude of therapeutic effects vary greatly, atypical antipsychotics

are at least as effective for psychotic symptoms as conventional drugs (3). Well-controlled double-blind studies of atypical antipsychotics suggest that clozapine, risperidone, and olanzapine may be superior to haloperidol for controlling psychotic symptoms (61). At selected doses, risperidone appears to be more effective than haloperidol in treating positive and negative symptoms (53). Olanzapine has been demonstrated to be effective for positive, negative, and depressive symptoms (62), and in some studies the drug was superior to haloperidol and risperidone in terms of negative symptoms and long-term efficacy (63 ,64). However, in a recent large double-blind study (that has only been preliminarily reported), risperidone demonstrated significantly greater efficacy than olanzapine in reducing anxiety/depression and positive symptoms (65). Quetiapine appears to be comparable to chlorpromazine and haloperidol in treating both positive and secondary negative symptoms (61). Similarly, ziprasidone appears to be as effective as haloperidol in alleviating positive and negative signs in an acute treatment study (66), whereas a 52-week placebo-controlled maintenance study found primary and secondary negative symptom efficacy for ziprasidone (67).

To date, clozapine is the only drug that has proven efficacy in treatment-refractory schizophrenia (68 ,69). The efficacy rates for clozapine in treatment-refractory patients vary from 20% to more than 70% (11 ,70 ,71). In some studies, risperidone does not appear to be as effective as clozapine in treatment-resistant schizophrenic patients (72 ,73 and 74); however, Bondolfi and associates (75) found no difference between risperidone and clozapine in treatment-resistant patients. In this latter study, certain methodologic issues may have led to an overestimation of the efficacy of both clozapine and risperidone, and there are questions as to whether the patient population studied represented “truly resistant” patients (69). Further investigation is necessary to adequately compare the relative efficacy of risperidone and clozapine in treatment-resistant patients. Olanzapine was found to be more effective than haloperidol (74 ,76), but not chlorpromazine (77), in treatment-refractory patients. In a recent randomized double-blind study of treatment-resistant schizophrenia, olanzapine and clozapine had similar antipsychotic efficacy (74). Additional studies are needed to reach definitive conclusions regarding efficacy of the newer atypical antipsychotics in treatment-resistant schizophrenia. Results of studies investigating the effects of atypical antipsychotics in treatment-resistant patients are discussed elsewhere in this chapter.

The efficacy of atypical antipsychotics in treating primary negative symptoms has not been clearly demonstrated (61). Thus, the choice of atypical drugs for patients with predominantly negative symptoms is less clear (8). In addition, the effects of atypical antipsychotics on cognitive impairment have not yet been clearly proved. A metaanalysis of 15 studies (only three of which were double-blind) of atypical antipsychotics and cognitive impairment in patients with schizophrenia suggests that they may improve attention and executive function (37). Available results, however, are relatively inconsistent and modest in effect size. Furthermore, there are statistical limitations and a lack of standard conventions in the studies of cognition (78). It appears that there could be significant differences among the atypical drugs in terms of what types of cognition they improve.

Atypical antipsychotics have been associated with a reduction in the incidence of suicidality, which may be relevant to antidepressant effects of these agents, at least in part (6). Clozapine, risperidone, and olanzapine, in particular, appear to have beneficial effects on the depressive component of schizophrenia (6 ,65) (Table 56.2).

TABLE 56.2. CLINICAL AND SIDE-EFFECT PROFILE OF ATYPICAL ANTIPSYCHOTIC DRUGS

Although atypical drugs have shown some instances of superior efficacy in comparison with conventional drugs, they are not effective in all patients and against all symptom dimensions of psychotic disorders (Table 56.2). It is clear

that the atypical drugs are unable to fully reverse already-established impairment in cognition, negative symptoms, and social disability in many patients (79). Thus, the possible use of these agents in the prodromal period of schizophrenia, before the emergence of psychosis, is an important issue to address in the next decade (79).

Safety

Although atypical antipsychotics were developed to improve on the shortcomings of conventional drugs it has already become apparent that they also have significant limitations in terms of side effects in the relatively brief period that they have been in general clinical use (3). As a class, and with some variation between the individual drugs (Table 56.2), they have a much more favorable side-effect profile, particularly in terms of EPS and TD. They do, however, produce side effects, including sedation, hypotension, dry mouth, constipation, sedation, and some types of sexual dysfunction (3). Neuroleptic malignant syndrome has also been reported with atypical antipsychotics such as clozapine, risperidone, and olanzapine (80). Weight gain is the most worrisome and potentially serious side effect that appears to be class wide, except perhaps for ziprasidone and drugs that have not yet been approved for marketing by the FDA, including aripiprazole and iloperidone (81). In particular, weight gain and sedation are common reasons for drug discontinuation for adolescent patients (78). In addition, the atypical antipsychotics have been associated with new onset type II diabetes mellitus (82). It is unclear whether these effects are secondary to weight gain, independent, or causative. Atypical drugs are also associated with increases in cholesterol and lipids, the long-term medical consequences of which are largely unknown (78). It appears prudent to monitor fasting blood sugar and lipid levels in patients treated with these agents. The new atypical drugs also have their own individual and idiosyncratic side-effect profiles (Table 56.2). Thus, each new drug should be evaluated individually in terms of side effects and safety (39).

Clozapine is associated with a very low propensity for EPS and little or no incidence of TD; thus, it is a valuable option for patients who experience EPS (11). However, clozapine can cause serious side effects that impose substantial limitations on its use. Not only must initial dose titration be quite gradual, but also there is a significant occurrence (around 0.9%) of agranulocytosis (83) and seizures, as well as sedation, hypotension, hypersalivation, and weight gain (8). The frequency of agranulocytosis with clozapine is such that regular white blood count monitoring is required (8).

Risperidone has a favorable side effect profile in comparison to haloperidol (84). Risperidone can produce dose-related EPS (≥6 mg per day), but the rate of TD is low (0.6%) for dose currently used (2 to 8 mg per day) (84 ,85). Risperidone is associated with prolactin elevation, hypotension, somnolence, insomnia, and agitation (39 ,86).

The incidence of EPS with olanzapine is not significantly different from that with placebo, and the incidence of olanzapine-related TD is low (1%) (87). There is a risk of mild sedation and mild anticholinergic side effects, and the risk of weight gain appears greater than with risperidone, but comparable to clozapine (78).

Quetiapine is associated with very low levels of EPS and its prolactin level elevation is indistinguishable from that of placebo (88). The incidence of TD with quetiapine is reportedly low or virtually nonexistent, although this remains to be demonstrated prospectively. There is a potential risk of lenticular opacities that were associated in one preclinical study in beagles (89), but have not been found in nonhuman primates or patients, yet monitoring is recommended until additional data are available. The risk of weight gain with quetiapine appears to be less than that with olanzapine and clozapine (78). Although quetiapine has virtually no cholinergic activity, tachycardia is a possible side effect, perhaps secondary to its adrenergic effects on blood pressure (39). There are several other side effects with quetiapine such as decrease in T3 and T4, orthostatic hypotension, and sedation, necessitating gradual dose titration (39).

Ziprasidone has a risk of EPS that is not significantly different from that with placebo (90). The risk of TD is not known. Ziprasidone is associated with mild dyspepsia, nausea, dizziness, and transient somnolence (90). Ziprasidone treatment has been associated with minimal weight gain, which could distinguish it among other atypical agents (80). The FDA delayed ziprasidone approval because of concern about its ability to prolong the Q-T interval (90), but an FDA Advisory Committee recommended its approval for the treatment of schizophrenia in July 2000, and the FDA issued an approval letter in September 2000.

Effectiveness

Considerable evidence indicates that relapse and rehospitalized rates are substantially better with the group of atypical antipsychotics than with conventional antipsychotics for patients who are compliant with their maintenance antipsychotic regimen (46). The decreased EPS liability of the atypical drugs will make it easier to prescribe more effective doses of antipsychotic that can maximize relapse prevention, without simultaneously interfering with the patient's quality of life or motor functioning (46). Patient-based measures of quality of life show improvement with the atypical drugs over the conventional neuroleptics (45).

In one randomized controlled trial comparing clozapine with standard neuroleptic therapy for treatment-resistant schizophrenic inpatients, the actual hospital discharge rates at 1 year were 27% for clozapine and 29% for standard care (91). The clozapine group, however, had decreased readmission rates within the first 6 months compared with the neuroleptic group (3% versus 29%) (91).

In another randomized double-blind comparative study of clozapine and haloperidol in patients with refractory schizophrenia over 1 year, clozapine-treated patients showed significant quality-of-life improvements when compared with haloperidol-treated patients (53% versus 37%) (92). The patients assigned to clozapine had significantly fewer mean days of hospitalization for psychiatric reasons than patients assigned to haloperidol (144 versus 168 days) and used more outpatient services (134 versus 98 units of service) (92).

Several studies have examined the impact of risperidone on health care utilization in the 2 years before and after risperidone treatment in small groups of schizophrenic patients. Decreases of 20% to 31% in the number of hospitalization days were reported (93 ,94), but Viale and colleagues (95) observed an increase of 12% in hospitalization days in the first year of risperidone therapy.

Extensive controlled studies have proven olanzapine to be significantly superior to haloperidol in long-term maintenance of response (62 ,96). The estimated 1-year risk of relapse was 19.7% with olanzapine and 28% with haloperidol (97). Furthermore, a significantly greater proportion of the olanzapine- than risperidone-treated responders maintained their improvement in the extended follow-up after 28 weeks of therapy (63). It is not clear whether the lower relapse rates are owing to increased prophylactic efficacy or better treatment compliance because of better tolerability. To date, there have been no definitive prospective random-assignment studies on compliance rates for atypical antipsychotics (46).

Cost-Effectiveness in Comparison with Conventional Drugs

Atypical antipsychotic drugs are approximately 10 to 40 times more expensive than conventional drugs (98). In the past few years, a number of studies comparing the cost-effectiveness of the atypical antipsychotics with that of the typical drugs have been published. However, many of these studies have frequently been criticized because of limitations in experimental design; thus, the cost-effectiveness of atypical antipsychotics has not yet been fully established (98 ,99). Most of the available cost-effectiveness evidence is from retrospective studies or economic computer models, which have considerable methodologic limitations (98).

Perhaps the best study of the cost-effectiveness of clozapine published to date in terms of its methodology is a randomized controlled trial conducted by Rosenheck and associates (92), that compared clozapine with haloperidol in patients with treatment-refractory schizophrenia over 1 year. After 1 year of treatment, the clozapine group had lower inpatient but higher outpatient costs. The total medical costs (including inpatient hospital costs, outpatient medical costs, and medication costs) of the clozapine group ($58,000) were not significantly lower than the haloperidol group ($61,000). Overall, clozapine was concluded to be cost neutral, although it demonstrated improved clinical outcomes, suggesting that it may be cost-effective (92).

The higher price of olanzapine compared with classic neuroleptics may be offset by reductions in the use of inpatient and outpatient services (45 ,100). For example, Hamilton and colleagues (100) compared the cost-effectiveness of olanzapine to those of haloperidol for the treatment of schizophrenia, in a randomized clinical trial, for 6 weeks (acute phase) and up to 1 year (maintenance phase). The medication costs for olanzapine were about 22 times larger than those for haloperidol after 6 weeks of treatment; however, patients treated with olanzapine had significantly lower inpatient and outpatient medical expenses than patients treated with haloperidol. Overall, mean total medical costs during the acute phase for the olanzapine patients were significantly lower (US$388/6 weeks) than those for the haloperidol patients. As was seen in the acute phase, these total medical cost differences were sustained (US$636 lower per patient for olanzapine over 46 weeks) during the maintenance phase (100). Glazer and Johnstone (99) also reported that the total health care costs for olanzapine treatment for 6 weeks and up to 1 year were lower than those for haloperidol treatment ($431/month lower and $345/month lower, respectively).

Palmer and associates (101) used a decision analytic model to estimate the total medical costs and effectiveness outcomes of olanzapine, haloperidol, and risperidone over 5 years for schizophrenia treatment in the United States. The estimated 5-year total medical cost of olanzapine, haloperidol, and risperidone was US$92,593, $94,132, and $94,468, respectively. The estimated disability-free years of these agents were 3.19 (olanzapine), 2.62 (haloperidol), and 3.15 (risperidone). The quality-adjusted life years (QALYs) were 3.15 (olanzapine), 2.95 (haloperidol), and 3.12 (risperidone). These data suggest a modest cost-effectiveness advantage for olanzapine over haloperidol and risperidone (101), whereas the decision-modeling approach appears to be subjective to imprecision and possible bias (45). There have been no published randomized controlled studies of the cost-effectiveness of risperidone. In addition, so far, no prospective randomized studies have been completed that compare the cost-effectiveness of the atypical antipsychotics to each other for the treatment of schizophrenia. Furthermore, the other atypical drugs are too new to have had their cost-effectiveness evaluated to any significant extent. Additional prospective randomized clinical trials with larger sample sizes and long-term assessment should be conducted in order to evaluate the cost-effectiveness of atypical antipsychotics adequately (45).

First-Episode Patients

Pharmacotherapy

First-episode patients as a group may differ from chronic patients in several aspects of pharmacologic responsiveness.

Relatively high response rates of positive and negative symptoms have been reported in first-episode samples; for example, Lieberman and colleagues (102) reported remission rates of 83% after 1 year of treatment with conventional antipsychotic agents in 70 first-episode patients. Surprisingly, remission did not occur until a median of 11 and mean of 36 weeks of treatment. Despite the apparent heightened responsiveness of first-episode patients, residual cognitive deficits and poor psychosocial adjustment are common (103 ,104). First-episode patients may also require a lower mean dose of antipsychotic medication and may be more sensitive to drug side effects compared to more chronic patients (105). Kopala and colleagues (106) treated 22 first-episode patients openly with risperidone for a mean of 7 weeks and observed a 91% response rate in patients who received risperidone 2 to 4 mg per day compared to a 27% response rate in patients who received a dose of 5 to 8 mg per day. The lower-dose group exhibited no EPS, whereas 32% of the higher-dose group developed akathisia or parkinsonism. However, because this was not a fixed-dose design, conclusions regarding dose–response relationships must be considered preliminary. In a different approach, Sanger and colleagues (107) analyzed results from the 83 first-episode patients (out of a total of 1,996 subjects) who participated in a double-blind, 6-week comparison of olanzapine and haloperidol. First-episode patients who received olanzapine had significantly better clinical response and fewer EPS than the haloperidol group. Of particular interest, first-episode patients treated with olanzapine achieved a significantly higher response rate than chronic patients treated with olanzapine. In addition, chronic patients treated with haloperidol developed significantly fewer EPS than first-episode patients treated with haloperidol. Mean doses of haloperidol and olanzapine were similar between first-episode and chronic patient groups (10.8 versus 11.0 mg per day and 11.6 versus 12.0 mg per day, respectively). Although these findings suggest that the relative benefits of olanzapine (and perhaps of other atypical agents) compared to conventionals may be greater in first-episode patients than chronic patients, issues of nonequivalent dosing between drugs may be of particular concern in light of recent work indicating that optimal D_2 receptor blockade may be achieved in first-episode patients with haloperidol 0.25 to 2 mg per day (18). Two other double-blind controlled studies have been preliminarily reported that address the question of whether first-episode patients respond better to atypical antipsychotic drugs. The first is a 52-week study of clozapine versus chlorpromazine in 164 first-episode treatment naive schizophrenia patients in China (108). The cumulative response rates of patients at 12 and 52 weeks, respectively, were 81.2% and 96.3% for clozapine (mean dose 292 mg per day), and 68.3% and 97.7% for chlorpromazine (mean dose 319 mg per day). The first-episode patients treated with clozapine had more rapid response, fewer EPS, and higher treatment retention and relapse prevention than the chlorpromazine group (108). The second is a comparison between olanzapine and haloperidol in 262 patients with first-episode psychotic disorder (109). At 12 weeks, the patients treated with olanzapine (mean dose 9.1 mg per day) demonstrated a higher response rate (55% versus 46%) and greater cognitive improvement than the patients treated with haloperidol (mean dose 4.4 mg per day).

Response of first-episode patients has also received renewed attention because of the widely held belief that early intervention may favorably affect the course of the illness. This hypothesis, which often invokes “neurotoxicity of untreated psychosis” as a mechanism, is largely based on one naturalistic study reported by Loebel and colleagues (110). Other naturalistic studies have failed to find a relationship between duration of initial untreated illness and outcome (111 ,112 and 113). Prospective controlled trials are needed to determine whether early intervention with specific antipsychotic agents improves the early course of the illness.

Psychosocial Interventions

Psychosocial interventions potentially may have the greatest impact on first-episode patients and their families. Preliminary studies have looked at stress-reduction approaches for patients identified as “premorbid” or at risk for schizophrenia, combining cognitive therapy or stress reduction interventions alone or in combination with medication (114 ,115 and 116). Preliminary studies have indicated that cognitive-behavioral therapy (CBT) approaches that have been developed for patients with treatment-resistant psychosis can be successfully modified for first-episode patients (117). Psychoeducation, family support, and interventions to enhance compliance are also expected to play important roles early in the course of the illness. However, two studies of first-episode patients in Norway failed to find benefit from the addition of behavioral family management (BFM), which emphasizes communications skills, to a basic psychoeducation program (118 ,119). The authors concluded that families of first-episode patients may be in greatest need of information and support, rather than the intensive communication skills training offered by BFM.

Maintenance Treatment

Pharmacotherapy

Maintenance treatment with conventional and atypical antipsychotic medications has consistently demonstrated prophylactic efficacy against relapse. Hogarty (120) reviewed the literature on maintenance treatment with conventional antipsychotic agents and found that the average relapse rate during the first year after hospitalization was 41% with active medication compared to 68% with placebo. Among patients who survived the first year, annual relapse rates with medication dropped to 15%, whereas relapse rates on

placebo remained constant at 65%. This pattern suggests that maintenance treatment is relatively ineffective for a substantial proportion of patients; only after this poorly responsive subgroup is removed from the sample does the benefit of medication become fully apparent. Consistent with this view are the results of a low-dose maintenance treatment trial with depot fluphenazine in which a dose–response relationship only emerged during the second year of follow-up (121 ,122). Depot preparations have significantly lowered relapse rates by an average of 15% compared to oral neuroleptics in six double-blind, randomized trials (123). The advantage of depot administration may be understated in these trials, however, because research subjects were probably poorly representative of typical clinical samples and most trials did not extend beyond 1 year. Research comparing low and standard-dose maintenance with depot neuroleptics has demonstrated a trade-off between adverse effects with higher doses, including neurologic side effects and dysphoria, versus increased relapse rates with lower doses (122 ,124). “Intermittent” maintenance treatment was associated with an unacceptable rate of hospitalizations, whereas relapses associated with low-dose depot medication generally were responsive to rescue with brief augmentation with oral neuroleptic or benzodiazepine; hospitalization rates were not elevated with low compared to standard doses (122 ,124). Carpenter and colleagues (125) reported that administration of diazepam at the earliest sign of exacerbation in medication-free patients was more effective than placebo and comparable to fluphenazine in preventing relapse. This work suggests that lower doses of depot neuroleptic may provide acceptable protection against relapse if accompanied by close monitoring and rapid psychosocial and pharmacologic intervention at the first sign of relapse. These measures presumably will also enhance maintenance treatment with atypical agents, although dose-limiting side effects are not as problematic.

Growing evidence suggests that maintenance treatment with atypical agents provides greater protection against relapse compared to conventional oral agents. In a large, open trial, Essock and colleagues (126) found that chronically hospitalized patients randomized to clozapine were not more likely to be discharged than patients receiving treatment as usual, but once discharged, relapse rates were significantly lower with clozapine. Pooled results from three double-blind extension studies revealed that relapse rates were significantly lower with olanzapine (20%) compared to haloperidol (28%) in patients with schizophrenia and related psychoses (97). Until depot preparations of atypical agents are available for study, it will be difficult to determine whether the advantage of certain atypical agents is primarily the result of enhanced compliance versus a direct modulatory effect on symptom exacerbation. It is clear from depot neuroleptic studies that large numbers of patients relapse despite adequate compliance; relapse in medication-compliant patients is often associated with depression and resolves spontaneously without change in medication (127). Whether all atypical agents are equally effective in preventing relapse is also unknown. In a naturalistic study, Conley and colleagues (128) found that relapse rates were quite similar during the first year after discharge in patients treated with clozapine versus risperidone. During the second year, no additional relapses occurred on clozapine, whereas the rate of relapse on risperidone increased from roughly 13% to 34%. In the only published comparison between risperidone and olanzapine, rates of exacerbation (increase in PANSS score by 20%) were significantly higher at 28 weeks in patients who had responded to risperidone (mean dose 7 mg per day) compared to olanzapine (mean dose 17 mg per day) (63). It will be important to determine whether specific drugs differ in prophylactic efficacy against relapse when compliance is controlled and issues of dosing equivalence are addressed. It is possible that clozapine and perhaps other atypical agents are more effective in suppressing relapse; this effect may be relatively independent of antipsychotic efficacy and mediated by different neurotransmitter systems. Continued development of psychosocial interventions to improve compliance and monitor and respond to early signs of relapse will be equally important.

Psychosocial Interventions

A diverse range of psychosocial interventions has been shown to reduce relapse rates. In over 20 controlled trials, family therapies emphasizing psychoeducation and support have reduced relapse rates for schizophrenia patients who have regular contact with family members (129 ,130). Although differences in theoretical orientations and intensity of treatment have not produced consistent differences in efficacy, recent evidence has suggested that multiple-family psychoeducation groups may be particularly effective (131). Several controlled trials have also indicated that relapse rates can be reduced by assertive community treatment programs (PACT) or similar outreach programs that provide intensive monitoring, skills training, and case management in the community, usually with continuous availability of staff (132 ,133). Social skills training improves role functioning of patients with schizophrenia, but has not substantially reduced symptoms or reduced relapse rates compared to control conditions in most studies (134). In an illuminating study, Herz and colleagues (135) found that a relatively simple, weekly monitoring of schizophrenia patients in psychoeducation groups in conjunction with the availability of rapid pharmacologic and psychosocial interventions at the first sign of decompensation substantially reduced relapse rates, by approximately fourfold, compared to treatment as usual.

Noncompliance

Pharmacotherapy

Cramer and Rosenheck (136) surveyed the literature on antipsychotic medication and found that compliance rates

averaged 42%. Similar surveys have not been conducted looking specifically at atypical agents, although it is generally believed that reduced relapse rates reported with olanzapine and clozapine may reflect, in part, improved compliance (97 ,126). Factors contributing to noncompliance are complex and probably involve the patient's perception of benefits and side effects of medication, as well as the patient's level of insight. Compliance can be compromised by psychosis, agitation, and comorbid substance abuse (137 ,138). Van Putten (139) studied compliance in 85 schizophrenia patients chronically treated with conventional neuroleptics and determined that 46% took less antipsychotic medication than prescribed. Medication refusal was associated with an early dysphoric response, which Van Putten attributed to subtle akathisia. Analysis of responses by 150 schizophrenia patients to a “Drug Attitude Inventory” revealed that, based on responses to 10 items, 89% of patients could be correctly assigned to compliant versus noncompliant categories as determined by clinician assessment of compliance (140). The strongest predictor of compliance was a positive experience with medication—this factor accounted for 60% of the total variance, whereas the factor representing a negative subjective experience accounted for 12%. Factors representing attitudes and beliefs about medication had minimal predictive power. Other studies have also found that a patient's perception of benefit from medication is the strongest predictor of compliance (141). Whereas many clinicians expect atypical agents to achieve higher levels of compliance by virtue of reduced or absent EPS, this view may seriously underestimate the impact of other side effects. Two studies have found that clinicians tend to misjudge the relative distress produced by different medication side effects (142 ,143). Side effects associated with certain atypical agents, such as sedation, patients rated weight gain, drooling, and sexual dysfunction as more distressing than EPS in these surveys (142 ,143 and 144). The advantage of atypical agents in terms of compliance may stem less from their reduced EPS and more from their improved efficacy for symptoms of anxiety, depression, and tension. Whether targeting cognitive deficits and impairment in insight will improve compliance remains to be seen.

Psychosocial Interventions

Most approaches to noncompliance involve psychoeducation, supervision, and supportive therapy in which the benefits of treatment are emphasized, whereas barriers to adherence and medication side effects are minimized (145). Family therapy and social skills training may also exert a positive impact on compliance. Cognitive behavioral approaches have recently been applied to noncompliance by Kemp and colleagues (146 ,147), who developed “compliance therapy,” a four- to six-session intervention based on motivational interviewing techniques that targets attitudes towards medication and discharge planning during acute hospitalizations. In a randomized, controlled trial, compliance therapy was found to improve insight and observer-rated adherence to treatment over an 18-month treatment period (147). Patients in the compliance therapy group also displayed significantly greater improvement in social functioning and lower relapse rates than the control group (147). In addition to educational and skills training approaches, Cramer and Rosenheck (148) demonstrated that interventions that assist patients in remembering to take medications, such as placing microchip schedulers on pill bottles, can also substantially improve compliance.

Treatment Resistance

Estimates of the incidence of treatment resistance have varied with changes in the diagnostic classification of schizophrenia and definitions of treatment response (149), which have tended to obscure potential improvements in outcome associated with advances in pharmacologic and psychosocial treatments. For example, Hegarty and colleagues (150) reviewed results of 320 clinical trials and found that, since the introduction of modern antipsychotics in the mid-twentieth century, about 50% of patients were improved at follow-up, whereas the rate of improvement dropped to 35% in the decade ending in 1994. A narrowing of the diagnostic criteria is believed to account for this decline in response rates. Rates of response have tended to be higher in first-episode psychosis, although dropout rates have been high in this population, particularly with conventional agents (102 ,107). Persistence of psychotic symptoms is more common in drug trials involving chronic patients, presumably reflecting progression of the illness as well as a possible selection bias favoring participation by more refractory patients. If the definition of treatment resistance is broadened to include persistence of negative symptoms, cognitive deficits, or failure to achieve premorbid levels of functioning, treatment resistance can be considered the rule rather than the exception.

Psychotic Symptoms

Antipsychotic Monotherapy

Response of psychotic symptoms to conventional antipsychotics, risperidone, and olanzapine has been associated with D_2 receptor occupancy in excess of 65% (18 ,57), although persistence of psychotic symptoms has been shown to occur despite adequate D_2 blockade in a subgroup of refractory patients (151). As noted, only clozapine has consistently demonstrated efficacy for psychotic symptoms in treatment of refractory patients; the mechanism responsible for this therapeutic advantage remains uncertain. In a sample of 268 patients prospectively established to be neuroleptic resistant, 30% in the clozapine group met criteria for response at 6 weeks compared to 7% treated with chlorpromazine (11). Response rates as high as 60% have been reported

after 6 months in open trials with clozapine in patients less rigorously defined as treatment refractory (152). The extent to which a prolonged trial is necessary to determine efficacy of clozapine and other atypical agents is the subject of debate (153 ,154).

The relative efficacy of atypical agents other than clozapine in patients who have failed conventional neuroleptic therapy is less clear. Marder and colleagues (155) found that schizophrenia patients presumed to be treatment-resistant on the basis of having been hospitalized for 6 months or longer at the time of study entry did not respond to haloperidol 20 mg per day but significantly improved with risperidone 6 mg per day or 16 mg per day compared to placebo. Similarly, analysis of a subgroup of 526 patients from a larger trial identified retrospectively as having had a poor response to at least one prior antipsychotic, revealed greater response of psychotic symptoms to olanzapine (mean dose 11 mg per day) than haloperidol (mean dose 10 mg per day); this difference was significant in the intent-to-treat analysis but not in a comparison of completers (76). Trials specifically designed to study treatment-resistant patients have provided less consistent support for efficacy of risperidone and olanzapine. In 67 schizophrenia patients with histories of neuroleptic resistance, risperidone 6 mg per day significantly improved total BPRS scores compared to haloperidol 15 mg per day at 4 weeks, but response did not differ between groups at 8 weeks (156). In contrast, risperidone produced significantly higher response rates than haloperidol in a large, randomized open trial involving 184 schizophrenia patients with a history of poor response (157). Relative response of psychotic symptoms to risperidone increased over time and reached a maximum improvement compared to haloperidol at the final 12-month assessment. In a 6-week trial designed to mirror the landmark Clozapine Collaborative Trial (11), only 7% of patients prospectively determined to be treatment resistant to haloperidol responded to olanzapine 25 mg per day, a response rate that did not differ from chlorpromazine (77). The same group reported that 41% of 44 patients identified as unresponsive to olanzapine in the preceding study or in an open trial subsequently exhibited a response to clozapine (158). In addition, open trials in which patients have been switched from clozapine to olanzapine or risperidone have reported a high incidence of clinical deterioration, casting doubt on claims for therapeutic equivalence between clozapine and the second-generation agents, at least at the doses tested (159 ,160). Of interest, two controlled trials have found comparable efficacy for risperidone and clozapine. However, in one 4-week trial, the 59 participants were not screened for treatment resistance at baseline and, despite equivalence in outcomes between groups using an LOCF analysis, 25% of the risperidone group dropped out owing to lack of efficacy compared to only 5% in the clozapine group (161).

The evidence is strongest in support of clozapine monotherapy as an intervention for neuroleptic-resistant patients; serum levels of 350 ng/mL or greater have been associated with maximal likelihood of response (162). Given the risk of agranulocytosis, the burden of side effects, and the requirement of white blood cell monitoring, the second-generation agents (risperidone, olanzapine, and quetiapine) are commonly tried before proceeding to clozapine. The appropriate first choice among these agents is unclear; two controlled studies that compared olanzapine and risperidone have produced divergent results, probably reflecting differences in dosing of the two agents and the use of intent-to-treat versus completer analyses (63 ,163). The focus of this research has been on comparisons of mean responses between groups; predictors of response have not been identified, nor have subgroups of patients that may exhibit preferential response to one agent of the class. Many clinicians express the impression that certain patients do respond preferentially to a single agent of this class. Sequential controlled trials of the newer agents in treatment-resistant patients will be necessary to fully examine this issue.

Combinations of Antipsychotics

The practice of combination therapy is gaining widespread popularity in the absence of controlled data in its support (164). In part based on empirical experience and the demonstration that clozapine at optimal doses achieves relatively low degrees of D_2 occupancy, European clinicians commonly add low-doses of neuroleptics to clozapine in partially responsive patients (165). Uncontrolled trials and case reports have described benefits associated with the addition of risperidone (4 mg per day) (159 ,166) and pimozide (167) to clozapine in partially responsive patients. In a small, placebo-controlled trial, addition of sulpiride 600 mg per day to clozapine significantly improved positive and negative symptoms at the end of 10 weeks in 28 subjects (168). Other combinations, most notably olanzapine plus risperidone, are also increasingly employed, often because clinicians perceive improved response during the cross-tapering phase of switching from one to the other. A theoretical rationale for this combination is less apparent, given that each agent produces maximal D_2 and 5-HT_2 occupancy when appropriately dosed (57). If combined treatment with olanzapine and risperidone is found in suitably controlled study designs to offer advantages over optimal monotherapy with either agent, such a finding would argue in favor of the existence of additional contributory receptor actions unique to each drug.

Adjunctive Treatments

A diverse range of adjunctive treatments has been proposed for antipsychotic-resistant schizophrenia, although therapeutic effects generally have been small or inconsistent in controlled trials. Very little data are available from controlled trials augmenting clozapine in partial responders (169). Lithium augmentation frequently has been cited as

the best-established intervention based on positive results from three small studies (170 ,171 and 172); however, two recent placebo-controlled studies found no benefit when well-characterized neuroleptic-resistant patients were treated with lithium (approximately 1.0 mEq/L) added to haloperidol or fluphenazine decanoate (173 ,174). Augmentation with lithium may enhance response of some patients, particularly in the presence of affective symptoms or excitement (175 ,176). Carbamazepine augmentation of conventional neuroleptics has been associated with modest reductions in persistent symptoms, including tension and paranoia, in several controlled trials (177 ,178 and 179), particularly in patients with abnormal EEGs or violence. However, induction of hepatic microsomal enzymes by carbamazepine can substantially lower blood levels of certain antipsychotic agents (180) and in one report, resulted in clinical deterioration (181). Valproate does not significantly affect serum concentrations of most antipsychotic drugs, but results from two small controlled augmentation trials have been inconsistent. Wassef and colleagues (182) reported efficacy for negative symptoms and global psychopathology associated with addition of divalproex to haloperidol in a placebo-controlled 12-week trial in 12 schizophrenia patients hospitalized for acute exacerbation. In contrast, Ko and colleagues (183) found no effect when valproic acid was added to conventional neuroleptics in six treatment-resistant patients in a placebo-controlled crossover design. Augmentation with benzodiazepines also has been advocated, in part, because of the potential role of GABAergic agents in modulating dopamine transmission, although the evidence for efficacy is not compelling (184). Short-term, acute treatment with high-dose benzodiazepines may reduce agitation and psychotic symptoms in as many as 50% of patients (185 ,186), but early reports of benefit of longer-term treatment with benzodiazepines have not been replicated consistently by controlled trials (186 ,187).

Electroconvulsant Therapy and Transcranial Magnetic Stimulation

The most consistent evidence for efficacy in neuroleptic-resistant patients can be found in the literature describing electroconvulsant therapy (ECT) (188). Response rates between 50% and 80% were observed when ECT or the convulsant, Metrozole, were administered unblinded in neuroleptic-naive patients prior to the introduction of antipsychotic medication (189 ,190 and 191). Three double-blind randomized trials comparing neuroleptic plus ECT versus neuroleptic plus sham-ECT have demonstrated a significantly greater and more rapid reduction in psychotic symptoms (delusions) with the combination treatment during 2- to 4-week trials (192 ,193 and 194). Benefits of ECT were lost, however, at follow-up 10 to 28 weeks after treatment. Predictors of a positive response to ECT include acute onset and brief duration of illness (188 ,195 ,196 ,197 and 198). Mood symptoms in schizophrenia patients have tended to be relatively unresponsive to ECT and a diagnosis of schizoaffective disorder did not predict a favorable response (192 ,193 ,194 and 195). Cases describing the successful combination of ECT with clozapine in refractory patients have also been reported, suggesting that augmentation of atypical agents with ECT warrants further investigation (199 ,200). Recently, interest has focused on the potential use of transcranial magnetic stimulation (TMS) as an alternative to ECT in schizophrenia. TMS has shown promising efficacy in depression (201 ,202 and 203). In a preliminary, sham-TMS controlled crossover study in 12 medication-resistant schizophrenia patients, the frequency and severity of auditory hallucinations were significantly reduced following 12 to 16 minutes of stimulation (204). Improvement of auditory hallucinations persisted for a mean of 14 days (range 1 to 60 days). This is an intriguing area for future research, both as a tool to explore the neural circuits underlying symptoms of schizophrenia as well as a potential treatment option in medication-resistant cases.

Psychosocial Interventions

A particularly promising psychosocial approach to medication-resistant psychotic symptoms is cognitive-behavioral therapy (CBT) (205). CBT for psychosis generally consists of alliance formation, examination, and challenge of psychotic beliefs, and the teaching of self-monitoring and coping skills. Four randomized trials, all performed in the United Kingdom, demonstrated superior efficacy for CBT compared to active control treatments on measures of global psychopathology and positive symptoms among chronic, medicated patients (206 ,207 ,208 and 209). A recent metaanalysis determined that the between-groups effect size was .65, favoring CBT over comparison treatments for the response of psychotic symptoms; delusions were generally more responsive than hallucinations (210). Improvements in ratings of psychotic symptoms have been found to persist at follow-up, 1 year after completion of CBT (209). Although therapeutic effects have been impressive, only about half of subjects have displayed improvement in controlled trials (205). Preliminary evidence suggests that patients who exhibit a capacity to entertain alternative explanations for psychotic beliefs at baseline are more likely to respond to CBT (205).

Negative Symptoms

Antipsychotic Monotherapy

Although atypical antipsychotics have generally demonstrated superior efficacy for negative symptoms compared to high-potency conventional agents, the degree of improvement is usually quite modest, leaving substantial levels of residual negative symptoms. For example, across several studies, the effect size of risperidone 6 mg per day compared to placebo on negative symptoms was small (.27) (211). Path analysis has suggested that both risperidone and olanzapine exert direct effects on negative symptoms independent of differences in psychotic, depressive, or extrapyramidal

symptoms (212 ,213). Recently, Volavka and colleagues (74) preliminarily reported a prospective double-blind randomized study, comparing the effects of clozapine, olanzapine, risperidone, and haloperidol, for 14 weeks in 157 treatment-resistant inpatients. Clozapine (mean dose 527 mg per day) and olanzapine (mean dose 30 mg per day), but not risperidone (mean dose 12 mg per day), demonstrated significantly greater efficacy than haloperidol (mean dose 26 mg per day) in reducing negative symptoms (74). However, it is debated whether clozapine's established efficacy for negative symptoms extends to the treatment of primary negative symptoms of the deficit syndrome (153 ,154 ,214). Few data are available from controlled trials to guide treatment of negative symptoms that persist despite optimal treatment with atypical agents (215). Clinicians commonly employ augmentation strategies, but evidence supporting this practice is derived mostly from an older literature describing combinations of augmenting agents added to conventional agents.

Adjunctive Agents

Following clozapine's example as an antagonist of D_2 and 5-HT_2 receptors, investigators combined haloperidol with ritanserin, a relatively selective 5-HT_{2A} and 5-HT_{1C} antagonist (216). In a 6-week, placebo-controlled trial, addition of ritanserin to haloperidol produced significant reductions in negative symptoms (primarily affective expression and social withdrawal) and depressed mood. Addition of 5-HT_2 blockade may improve negative symptoms by enhancing mesocortical dopamine release. Svensson and colleagues demonstrated that 5-HT_2 blockade increases firing of midbrain dopamine neurons and reverses the effects of *N*-methyl-D-aspartate (NMDA) antagonism (217) and hypofrontality (218) on A10 dopamine neuronal firing. Because the available atypical agents achieve maximal occupation of 5-HT_2 receptors at usual therapeutic doses (57), it is unlikely that augmentation with 5-HT_2 antagonists (e.g., nefazodone) will further improve response of negative symptoms.

Another serotonergic augmentation strategy has involved addition of selective serotonin reuptake inhibitors (SSRIs) to conventional neuroleptics, based largely on early empirical observation (219). Fluoxetine and fluvoxamine significantly improved negative symptoms when added to conventional neuroleptics in three of four controlled trials, producing generally modest effects (220). In one study, fluoxetine 20 mg per day added to depot neuroleptics decreased ratings of negative symptoms by 23% compared to a 12% reduction with placebo; this improvement occurred despite a mean 20% elevation in haloperidol serum concentrations and a 65% increase in fluphenazine levels (221). However, addition of sertraline 50 mg per day to haloperidol produced no symptomatic change in an 8-week, placebo-controlled trial in 36 chronic inpatients with schizophrenia (222). In the only reported controlled trial of SSRI augmentation of an atypical agent, fluoxetine at a mean dose of 49 mg per day produced no improvement in negative symptoms when added to clozapine in 33 patients (223).

Anticholinergic agents are commonly added to conventional antipsychotics for control of EPS (224). The atypical agents vary substantially in their muscarinic anticholinergic activity; clozapine is strongly anticholinergic, whereas quetiapine and risperidone exhibit very low affinity for muscarinic receptors (Table 56.1). Addition of anticholinergic agents to conventional agents was associated with reductions in negative symptoms in one study (225) but not others (176 ,226 ,227 and 228). Whether primary negative symptoms are improved by anticholinergics, as suggested by Tandon and colleagues (229), cannot be answered by studies in which subjects are treated with conventional agents; by attenuating psychomotor side effects of the neuroleptic, the anticholinergic may be improving secondary negative symptoms only. To address this issue, two small placebo-controlled trials have administered anticholinergic agents to medication-free patients. Negative symptoms were improved by biperiden in one study (230) and were unchanged with trihexyphenidyl in the other (231). Although the efficacy of augmentation with muscarinic anticholinergic agents for negative symptoms remains poorly established, the potential cognitive impairment that these agents can produce is well described (232 ,233).

Dopamine agonists have also been studied as augmenting agents for negative symptoms. Three of four placebo-controlled trials demonstrated improvement of negative symptoms following a single dose of amphetamine given orally or intravenously (234 ,235 ,236 and 237); in one study efficacy for negative symptoms was not affected by coadministration with pimozide (236). However, Casey and colleagues (238) found no clinical benefit in an extended, 20-week placebo-controlled trial of amphetamine augmentation of chlorpromazine. Augmentation trials of psychostimulants added to atypical agents have not been reported.

As discussed elsewhere in this chapter, augmentation strategies for negative symptoms have recently targeted glutamatergic receptors, in part based on the NMDA antagonist model for schizophrenia and the observation that clozapine differs from conventional agents in its effects on NMDA receptor activity (239). Significant improvements in negative symptoms consistently have been produced in placebo-controlled trials by the addition to conventional antipsychotics of agonists at the glycine site of the NMDA receptor. D-cycloserine, a partial agonist at the glycine site, produced a selective, 23% mean improvement of negative symptoms at 6 weeks that, compared to placebo (7% reduction), represented a large effect size (.80) (240). The full agonist, glycine, at a dose of 60 g per day produced a 30% mean reduction in negative symptoms and also improved a qualitative measure of cognitive functioning (241). Augmentation with another endogenous full agonist, D-serine 30 mg per kg per day, was associated with significant improvements

in negative, positive, and cognitive symptoms when added to conventional agents and to risperidone in an 8-week trial (242). Consistent with evidence that clozapine differs from conventional agents in its effects on NMDA receptor responsiveness, glycine, D-cycloserine, and D-serine did not improve negative symptoms when added to clozapine (242 ,243 ,244 and 245). Whether strategies that enhance NMDA receptor activation will improve response to other atypical agents remains uncertain, although both olanzapine and quetiapine resemble clozapine in certain models of NMDA receptor responsivity.

Psychosocial Treatments

Existing psychosocial approaches have not achieved notable success in the treatment of negative symptoms. Negative symptoms are substantially less responsive to CBT than are psychotic symptoms and patients with prominent negative symptoms are generally poor candidates for CBT (205). Similarly, in a pilot study, Kopelowicz and colleagues (246) found that patients meeting criteria for the deficit syndrome were relatively less likely to benefit from a program of psychoeducation and social skills training than patients without prominent negative symptoms. The presence of negative symptoms also predicts poor outcome in vocational rehabilitation programs for patients with schizophrenia (247). Although most forms of outreach and involvement of deficit syndrome patients in psychosocial programs may improve their quality of life by reducing social isolation and countering apathy, negative symptoms constitute a serious obstacle to participation in such programs and are unlikely to improve with psychosocial treatment.

Mood Symptoms

Antipsychotic Monotherapy

Depressive symptoms are common during all stages of schizophrenia and are associated with poor outcome, including relapse and suicide (248 ,249 and 250). It is not uncommon for patients to present initially with depression during the prodromal stage, prior to the appearance of psychotic symptoms (251). Approximately 25% of first-episode patients exhibit depression, although estimates of the incidence of comorbid depression vary widely according to choice of diagnostic criteria (251 ,252 and 253). The prevalence of depression as defined by moderate scores on depression rating scales ranges between 25% and 50% in chronic patients (252 ,254). Although considerable overlap exists between symptoms of depression and certain negative symptoms (e.g., anhedonia, poor concentration, psychomotor retardation), dysphoria appears to discriminate between the two (255 ,256).

Conventional antipsychotics tend to have little effect on comorbid depression, although anxiety and depression associated with acute psychotic exacerbation frequently respond to neuroleptic monotherapy (257 ,258). However, dysphoric reactions to high-potency conventional agents, although generally not meeting criteria for major depression, can closely resemble the depressive symptoms often associated with the illness (254 ,259 ,260). Clozapine, olanzapine, and risperidone have all demonstrated significantly greater efficacy for depressive symptoms compared to conventional neuroleptics in large, double-blind trials (64 ,211 ,261). Path analysis suggested that 57% of the superior response of depressive symptoms to olanzapine compared to haloperidol was a direct effect, whereas effects on negative symptoms accounted for only 21% and reductions in EPS accounted for 13% of the difference in depressive symptom response (64). Antidepressant activity of the atypical agents may have important clinical consequences because perceived improvement in anxiety and depression is a strong predictor of compliance and emergence of depressive symptoms often accompanies relapse.

Adjunctive Agents

In a placebo-controlled trial reported in 1989, Kramer (258) found that addition of desipramine or amitriptyline 5 weeks after initiating haloperidol to acutely decompensated patients with schizophrenia and depression was associated with poorer antipsychotic response and did not improve depressive symptoms. Subsequently, Siris and colleagues (262 ,263) demonstrated that imipramine added to conventional agents in stable outpatients significantly improved depression without adversely affecting psychotic symptoms. In a carefully controlled trial, imipramine 200 mg per day was associated with substantial improvement in depressive symptoms in 42% of patients compared to 12% with placebo. Hogarty and colleagues (176) found that desipramine improved symptoms of depression, anxiety, and psychosis when added to fluphenazine decanoate in a placebo-controlled trial. Benefits of desipramine were only significant in female patients and did not achieve significance until week 12. The investigators noted that improvement of psychotic symptoms might have resulted from successful prophylaxis against depressive episodes, which were associated with worsening of psychosis. Several trials of tricyclic antidepressants added to conventional agents have been reported; this literature generally supports their use for acute and maintenance treatment of depressive symptoms in stable patients (264 ,265). Augmentation with selective serotonin reuptake inhibitors has been studied primarily as a treatment for negative symptoms—use of these agents in schizophrenia patients with depression is not well studied. Similarly, addition of antidepressants to atypical agents has not been reported in schizophrenia patients with comorbid depression.

Cognitive Symptoms

Antipsychotic Monotherapy

A wide range of cognitive deficits are usually present at the time of the first psychotic episode (266) and remain stable

or only slowly progressive during the course of the illness, independent of psychotic symptoms (267 ,268 and 269). Cognitive deficits are particularly prominent in patients meeting criteria for the deficit syndrome (270) and in patients with tardive dyskinesia (271). The latter association may indicate that cognitive deficits are a risk factor for tardive dyskinesia, or alternatively, that the neurotoxic mechanism responsible for irreversible motoric deficits also compromises cognitive functioning. Targeting cognitive impairments is now a major focus of drug development because cognitive deficits are powerful determinants of vocational and social functioning and may influence quality of life (36) more than psychotic symptoms.

The conventional neuroleptics produce small and inconsistent effects on cognitive functioning; sustained attention improved in some studies, whereas motor control (finger tapping) worsened and memory and executive functioning were minimally affected (272). Recent evidence in monkeys indicates that chronic neuroleptic exposure results in decreased prefrontal cortical D_1 receptor density after 6 months (273); treatment with a D_1 agonist reversed neuroleptic-associated deficits in working memory (274). In normal subjects, clozapine administered as a single 50-mg dose worsened attention, concentration, and motor functioning (275), presumably reflecting sedative and anticholinergic properties. Studies in patients with schizophrenia have found either no effect following a switch to clozapine (276), or improvements in a wide range of cognitive functions, including verbal fluency, attention, and reaction time (37 ,277). In general, clozapine, olanzapine, and risperidone have demonstrated superior efficacy compared to conventional agents on tests of verbal fluency, digit-symbol substitution, fine motor function, and executive function (37 ,277). Atypical agents least affected measures of learning and memory (37). Enhanced performance with atypical agents could result, in part, from reduced parkinsonian side effects because these tests all measure performance during a timed trial (37). Methodologic issues limit comparisons between atypical agents, however, preliminary evidence suggests that risperidone may be more effective for visual and working memory than clozapine (277). In a 12-month, double-blind trial involving 55 schizophrenia patients randomly assigned to olanzapine (mean dose 11 mg per day), risperidone (mean dose 6 mg per day), or haloperidol (mean dose 10 mg per day), risperidone and olanzapine produced significantly greater improvement in verbal fluency compared to haloperidol, and olanzapine was superior to both haloperidol and risperidone in effects on motor skills, nonverbal fluency, and immediate recall (278). However, this finding is complicated by the high incidence of anticholinergic administration prior to the final cognitive assessment; anticholinergics were prescribed to 73% in the haloperidol group, 45% in the risperidone group, and 15% in the olanzapine group. As in efficacy studies for negative symptoms, dose equivalency is an important factor in trials comparing cognitive effects of atypical agents, particularly because excessive dosing can impair performance on time-sensitive tasks and increase anticholinergic exposure.

Adjunctive Agents

Augmentation with glutamatergic agents has shown promise for cognitive deficits in schizophrenia (279). As noted, glycine and D-serine improved ratings of cognitive functioning when added to conventional neuroleptics (241 ,280). Both agents improved the “cognitive subscale” of the PANSS compared to placebo, and D-serine was also associated with improved performance on the Wisconsin Card Sort. These findings are of interest given that NMDA antagonists produce in normal subjects deficits in attention and memory similar to those found in schizophrenia (281 ,282). The partial agonist, D-cycloserine, did not improve cognitive functioning when added to conventional agents in a study that utilized formal cognitive testing, however (240). Positive modulators of the glutamatergic AMPA receptor are also under investigation, as these agents improve performance in tests of learning and memory in animal studies (283). In a preliminary 4-week, placebo-controlled trial involving 19 schizophrenia patients, CX-516, a positive modulator of the glutamatergic AMPA receptor, improved performance on tests of memory and attention when added to clozapine (284). Effect sizes favoring CX-516 over placebo were moderate to large (.5 to 1.2) on tests of cognitive performance.

Psychosocial Treatments

Although cognitive remediation treatments have long been used for brain-injured individuals, similar treatment approaches targeting cognitive deficits in schizophrenia are relatively recent. In small studies in which schizophrenia patients practiced graduated cognitive exercises, performance on laboratory measures of attention and memory function improved, although the functional benefits of these gains are not clear (285 ,286). Brenner and colleagues (287) developed integrated psychological therapy (IPT), a cognitive remediation program in which cognitive exercises are provided in a group format stressing the integration of cognitive skills with social functioning. In a 6-month randomized trial in which patients received IPT or supportive treatment in addition to comprehensive psychiatric rehabilitation, the IPT group displayed greater improvement on the primary outcome measure of interpersonal problem solving and on a laboratory measure of attentional processing (288). This study was conducted prior to the introduction of atypical antipsychotics. Following another approach, Hogarty and Flesher (289) recently developed cognitive enhancement therapy (CET), which combines interactive software and social group exercises to improve socially and behaviorally relevant cognitive functioning. This approach is based on a neurodevelopmental model for cognitive deficits in schizophrenia (290). Preliminary results

from a controlled 1-year trial of CET have also been encouraging (289).

EXPERIMENTAL TREATMENTS AND STRATEGIES

Part of "56 - Therapeutics of Schizophrenia "

Selective Dopamine Antagonists

There are several lines of evidence suggesting that selective dopamine D_4 receptor antagonists may be potential novel antipsychotic drugs. Clozapine has a relatively higher affinity for the D_4 versus D_2 or D_3 receptors (291) (Table 56.1). Not only clozapine, but also a number of clinically efficacious antipsychotics have relatively high affinity for this receptor site (Table 56.1). In addition, an increase in D_4 receptors has been reported in the brains of patients with schizophrenia (292). Furthermore, the D_4 receptor, enriched in the prefrontal cortex and hippocampus, is located in dopamine terminal fields potentially associated with emotion and cognition, but not with movement, underscoring the potential of this receptor as a target. The selective D_4 antagonist, sonepiprazole (U-101387) increases dopamine release in the frontal cortex, but decreases dopamine release in the nucleus accumbens in rats (293). Sonepiprazole attenuates apomorphine-induced impairment of prepulse inhibition in rats (294). It also antagonized the decrease in c-fos expression in the medial prefrontal cortex and neurotensin mRNA in the nucleus accumbens produced by repetitive amphetamine administration in rats, suggesting possible antipsychotic action of the agent (295). Sonepiprazole is currently in Phase II clinical trials in patients with schizophrenia (293). An initial clinical trial with another highly selective D_4 antagonist, L-745,870, failed to demonstrate any antipsychotic activity in the treatment of schizophrenia (296 ,297). Although the single dose tested makes it difficult to draw firm conclusions regarding the potential efficacy of D_4 antagonists as antipsychotic agents (298), this drug actually caused a worsening of symptoms (297). Similarly, NGD-94-1 also did not show clinical efficacy in limited trials in schizophrenics (293). More extensive testing of D_4 antagonists in patients with schizophrenia will be necessary to adequately assess the therapeutic potential of such drugs.

Dopamine Partial Agonists

Partial dopamine agonists are agents with good affinity for one or more dopamine receptors, but with intrinsic activity less than dopamine (3). Thus, such drugs may antagonize the actions of dopamine, yet by agonistic actions, activate other dopamine-related functions (299). It has been proposed that some D_2-like dopamine agonists have a greater affinity for autoreceptors than for heteroreceptors. The action of these agonists at autoreceptors would induce a receptor-mediated inhibition of both the synthesis and release of dopamine from nerve terminals, without producing significant activation of heteroreceptors on target cells (300). Such partial dopamine agonists are therefore proposed to act as dopaminergic “buffers,” reducing dopaminergic transmission without completely blocking it when dopaminergic activity is excessive, or conversely, stimulating it when it is reduced (7 ,299).

Despite the numerous compounds that were developed as partial agonists, none has proved to be sufficiently effective to warrant its full development and introduction for clinical use. The first of this class to show consistent and robust efficacy comparable to clinically used antipsychotic drugs, both conventional and atypical, is aripiprazole (301). Aripiprazole (OPC-14597) is a dual dopamine autoreceptor partial agonist and postsynaptic D_2 receptor antagonist (302 ,303). It has a modest affinity for 5-HT_2 receptors, but no appreciable affinity for D_1 receptors (304) (Table 56.1). Aripiprazole decreased striatal dopamine release (303), and inhibited the activity of dopamine neurons when applied locally to the ventral tegmental area in rats (305). Animal behavioral studies showed that the compound exhibited weak cataleptogenic effects compared to haloperidol and chlorpromazine despite the fact it has almost identical D_2 receptor antagonistic activity (302). The potency of aripiprazole to up-regulate striatal D_2 receptors in response to chronic treatment was much smaller than that of haloperidol, suggesting lower potential for EPS, including tardive dyskinesia (31). Aripiprazole is currently going through worldwide Phase III development. Preliminary clinical studies have shown its efficacy in alleviating both positive and negative symptoms of schizophrenia. Although current dogma suggests that such a D_2-selective agent would cause profound EPS and high sustained prolactin elevation, neither side effect has been seen clinically (306 ,307 and 308). Based on available data, it would appear that aripiprazole is the first compound with partial D_2 agonist properties to be a clinically effective antipsychotic agent. It has been proposed that aripiprazole induces “functionally selective” activation of D_2 receptors coupled to diverse G proteins (and hence different functions), thereby explaining its unique clinical effects (304).

CI-1007 is a new dopamine autoreceptor agonist and partial dopamine D_2/D_3 receptor agonist that is currently under development for the treatment of schizophrenia (309 ,310). In preclinical studies, CI-1007 demonstrated that it inhibited the firing of dopamine neurons and reduced the synthesis, metabolism, utilization, and release of dopamine in the brain (310). In addition, it produced behavioral effects predictive of antipsychotic efficacy and indicated a low liability for EPS and TD (311).

5-HT Agents

The 5-HT_{2A} receptor subtype has received considerable attention because of its potential roles in the therapeutic action of atypical antipsychotic drugs (21 ,312); it is involved

in perception, mood regulation, and motor control (313). Available evidence indicates that 5-HT_{2A} receptor stimulation plays a role in promoting the synthesis and release of dopamine, either by effects on firing rates of dopamine neurons, or via heteroreceptors on dopamine nerve terminals, or both (312 ,313 ,314 and 315). 5-HT_{2A} receptor blockade may therefore contribute to "normalizing" levels of dopamine release (316) and theoretically possess antipsychotic activity.

M-100907 (formerly MDL-100,907) is a selective 5-HT_{2A} receptor antagonist devoid of affinity to dopamine receptors (21). Like the atypical antipsychotics, it decreases the firing rate of A10, but not A9, neurons after chronic treatment (317). M-100907 inhibited the behavioral response not only to amphetamine and cocaine (316 ,317 and 318), but also to NMDA receptor antagonists at doses that did not affect spontaneous activity given alone in rodents (319 ,320 and 321). M-100907, like clozapine, markedly increases dopamine release in the medial prefrontal cortex in rats (322), suggesting that the agent may have efficacy for negative symptoms. In contrast, it attenuates dopamine release in the nucleus accumbens induced by the NMDA receptor antagonist MK-801 (323). M-100907 also antagonized MK-801-induced prepulse inhibition deficit in rats (324). Further, in electrophysiologic studies, it prevented phencyclidine (PCP)-induced blockade of NMDA responses (325). These preclinical results suggest that M-100907 can attenuate variable responses to NMDA receptor antagonists *in vivo* and modulate NMDA receptor-mediated neurotransmission. M-100907, however, exhibited lower antipsychotic efficacy compared with haloperidol in Phase III clinical trials (326). Insufficient data are currently published to adequately judge the efficacy of the drug.

It has been suggested that the partial agonist activity of clozapine at 5-HT_{1A} receptors may contribute to its therapeutic action (313 ,327). Preclinical studies have suggested that serotonin 5-HT_{1A} agonists may potentiate the antipsychotic activity of dopaminergic antagonists (328). Activation of inhibitory 5-HT_{1A} autoreceptors may also counteract the induction of EPS owing to striatal D_2 receptor blockade (329). Further, in schizophrenic patients, increased 5-HT_{1A} receptor binding was seen in the prefrontal cortex (330 ,331). Based on these preclinical data, compounds that act as serotonin 5-HT_{1A} agonists are being developed as potential antipsychotic compounds.

S-16924 is a novel, potential antipsychotic agent with high affinity for dopamine $D_{2/4}$, α_1-adrenergic, and serotonin 5-HT_{2A} receptors, similar to that of clozapine, in addition to being a potent partial 5-HT_{1A} agonist (332). Reflecting its partial agonist actions at 5-HT_{1A} receptors, it attenuates cerebral serotonergic transmission, and preferentially facilitates dopaminergic transmission in mesocortical as compared to mesolimbic and nigrostriatal pathways (333 ,334). S-16924 exhibited a profile of potential antipsychotic activity and low EPS liability in animal behavioral models, similar to clozapine (332).

Muscarinic Agents

In patients with Alzheimer's disease (AD), cholinesterase inhibitors (e.g., physostigmine) have been shown to not only improve cognition, but also reduce hallucinations, delusions, suspiciousness, and other behavioral disturbances sometime associated with the illness (335 ,336 ,337 and 338). Similar positive effects on cognitive and psychotic-like symptoms in AD have been observed after treatment with the direct muscarinic agonist, xanomeline (339). In addition, high doses of some muscarinic antagonists produce psychotic-like symptoms and memory loss (340). Thus, it has been proposed that muscarinic agonists could be novel potential treatments for positive and cognitive symptoms of schizophrenia (341).

Recent findings that partial agonists of m_2/m_4 muscarinic receptors are active in animal models that predict antipsychotic activity suggest potential usefulness of muscarinic agonists in the treatment of schizophrenia (342). The drug (5R,6R) 6-(3-propylthio-1,2,5-thiadiazol-4-yl)-1-azabicyclo[3.2.1]octane (PTAC) is a muscarinic partial agonist at muscarinic m_2 and m_4 receptor subtypes (342). PTAC acts as a functional dopamine antagonist in many paradigms (consistent with known dopamine-acetylcholine interactions), although it has minimal or no affinity for central dopamine receptors. PTAC attenuates apomorphine induced climbing (341), inhibits the effects of D_1 and D_2 dopamine receptors agonists in 6-hydroxydopaminelesioned rats, and antagonizes amphetamine-induced Fos induction and hyperactivity (343). In addition, after chronic administration, PTAC reduced the number of spontaneously active dopamine cells in the ventral tegmental area, but not the substantia nigra (343). Such selective effects on the mesocorticolimbic dopamine projection neurons are similar to those observed for clozapine and olanzapine (344 ,345). The notable preclinical data of the effects of PTAC provide strong encouragement to examine the potential therapeutic effects of M_2/M_4 muscarinic agonists in schizophrenic patients. Among the agents that have been developed for the treatment of AD that are being examined in schizophrenia are donepezil, metrifonate, galantamine, and xanomeline.

Glutamatergic Agents

The NMDA Receptor Hypofunction Hypothesis of Schizophrenia

Since the late 1950s, the anesthetics phencyclidine (PCP) and ketamine have been known to induce "emergence reactions" in 40% to 50% of individuals during the recovery from anesthesia, that resembles some features of schizophrenia (346). Recent work has confirmed and extended the early clinical studies and has demonstrated that subanesthetic doses of ketamine can induce positive, negative, and cognitive schizophrenia-like symptoms in normal humans (281 ,347).

In chronic stabilized schizophrenic patients, subanesthetic doses of ketamine can also exacerbate cognitive impairment and in some cases reproduce specific hallucinations and delusional ideation remarkably similar to those experienced during active phases of the patients' illness (282 ,348 ,349). Both ketamine and PCP are potent noncompetitive NMDA receptor antagonists. These drugs bind to a site within the calcium channel of the NMDA receptor complex, and thereby interfere with calcium flux through the channel. Competitive NMDA receptor antagonists (i.e., drugs that inhibit binding to the glutamate recognition site) are also psychotomimetic (350). The ability of NMDA antagonists to induce a spectrum of schizophrenia-like symptoms has led to the hypothesis that hypofunction of NMDA receptors is involved in the pathophysiology of schizophrenia (346 ,351 ,352 and 353).

Antipsychotic Drug Actions in Relation to the NMDA Receptor Hypofunction

The well-documented psychotomimetic effects of NMDA antagonist in human suggest that effects of the drugs in experimental animals could present useful pharmacologic models of schizophrenia. In our recent studies, striking effects of subanesthetic doses of ketamine were observed on regional brain patterns of ^{14}C-2-deoxyglucose (2-DG) uptake in both rats (354 ,355) and mice (356). Ketamine induces robust and neuroanatomically selective patterns of brain metabolic activation, with especially large effects observed in the hippocampus, nucleus accumbens, and medial prefrontal cortex (354 ,355). Pretreatment of rats with clozapine or olanzapine can completely block these effects of ketamine (357 ,358). However, the typical antipsychotic haloperidol failed to antagonize the brain metabolic activation induced by ketamine (357). Similarly, clozapine and olanzapine, but not haloperidol, effectively block NMDA antagonist-induced electrophysiologic responses (325), deficits in prepulse inhibition (359 ,360), and deficits in social interactions (361). Thus, in a wide range of experimental paradigms, atypical antipsychotic drugs selectively antagonize the consequences of experimentally induced NMDA receptor hypofunction, raising the possibility that the therapeutic effects of these agents may be associated with a similar neurochemical action (362).

Therapeutic Potential of Glycine Site Agonists

If reduced NMDA receptor function is involved in the pathophysiology of schizophrenia, then drugs that enhance NMDA receptor function could be therapeutic agents and potentially improve upon, or supplement, current antipsychotic treatments (13). Direct agonists of the NMDA receptor may not be feasible candidates in this regard, because of the propensity of such drugs to produce excessive excitation and seizures.

Glycine is a positive allosteric modulator and obligatory coagonist at the NMDA receptor (363) and this allosteric regulatory site represents a potential target for drugs to augment NMDA-mediated neurotransmission. Preclinical studies have demonstrated that glycine-site agonists reverse the effects of noncompetitive NMDA receptor antagonists (364). There have been several clinical studies to test effects of different glycine site agonists in patients with schizophrenia. The earliest studies in this regard used glycine in doses of 5 to 15 g per day and obtained inconsistent results (365 ,366). In more recent work with glycine, higher doses were administered (30 to 60 g per day) and more robust and consistent effects were found, primarily in the improvement of negative symptoms (241 ,367 ,368).

D-cycloserine is a partial agonist at the glycine regulatory site on the NMDA receptor. Thus, at low dose of the amino acid, stimulatory responses are observed, but at higher doses, D-cycloserine blocks the effects of endogenous glycine. D-cycloserine has been tested in patients with schizophrenia, and in a very narrow dose range, the agent was shown to improve negative symptoms when administered alone (369), and when added to conventional antipsychotic treatment regimes (240 , 370). The “inverted U”-shaped dose response may result from the partial agonist properties of D-cycloserine, because antagonism of the actions of endogenous glycine would be predicted at higher doses of the drug. Interestingly, when D-cycloserine was administered in conjunction with clozapine, the negative symptoms of the patients worsened (244 ,371). A ready explanation for these effects is not available, but understanding the mechanisms involved in the worsening of negative symptoms after administration of D-cycloserine to clozapine-treated patients may be an important clue in understanding the actions of both of these drugs. The poor penetration of the blood–brain barrier by glycine, and the partial agonistic properties of D-cycloserine, appear to make these agents less than optimal for providing pharmacologic agonism of the glycine regulatory site on the NMDA receptor (13).

D-serine is a full agonist on the strychnine-insensitive glycine site of NMDA receptor (372) and is more permeable than glycine at the blood–brain barrier, thus requiring a lower dosage. In a recent clinical trial, D-serine (30 mg per kg per day) added to neuroleptic treatment in treatment-resistant patients with schizophrenia demonstrated significant improvements not only in negative and cognitive symptoms but also positive symptoms, which is different from glycine (280). These data, together with the results of the clinical investigations with glycine and D-cycloserine (346), offer promise for the therapeutic potential of enhancing NMDA receptor function as a strategy for the pharmacotherapy of schizophrenia. Recently, Wolosker and colleagues (373) purified an enzyme from Type II astrocytes that converts L-serine to D-serine. It may be that effectors of this enzyme (directly or through possible receptor-mediated regulation) can provide a mechanism to modulate NMDA

function. Examining the effects of synthetic compounds with greater potency and full agonistic activity at the glycine regulatory site could be an intriguing line of future research. There are, however, no such compounds available for testing at present.

Potentiation of NMDA Receptor Function by Inhibition of Glycine Uptake

Glycine transporters have been identified on both neuronal and glial cells in the central nervous system. A function of these transporters has been suggested to control the extracellular glycine concentration (374). Although there is some controversy as to whether the glycine regulatory site on the NMDA receptor is saturated under physiologic conditions, recent data demonstrate that inhibition of glycine transport by glycine transporter type 1 antagonist can potentiate electrophysiologic effects of NMDA (374 ,375). Furthermore, the glycine uptake inhibitor glycyldodecylamide attenuated PCP-induced hyperactivity more potently than glycine (364 ,376). These preclinical data suggest that inhibition of glycine uptake could represent a feasible approach to potentiate NMDA receptor-mediated neurotransmission and, possibly, treat schizophrenic patients.

Glutamate Release-Inhibiting Drugs

A number of studies have indicated that administration of relatively low (subanesthetic) doses of NMDA antagonists induces behavioral and brain metabolic activation in experimental animals and humans (362). Consistent with these data, NMDA antagonists increase glutamate release in rats (377). In contrast to the increase in glutamate release by subanesthetic doses of ketamine, anesthetic doses of the drug decreased glutamate levels (377). The effect of different doses of ketamine on glutamate levels is consistent with our observations of increased 2-DG uptake in response to a subanesthetic dose, and reduction in 2-DG uptake in response to an anesthetic dose of ketamine (354).

The stimulatory effect of NMDA receptor antagonism presumably results from disinhibitory actions, perhaps by reducing excitatory input to inhibitory interneurons (362). In hippocampal formation, GABAergic interneurons are more sensitive to the effects of NMDA antagonists than the glutamate-containing pyramidal cells (378), providing support for the hypothesis that NMDA antagonism could result in excitatory effects by disrupting recurrent inhibitory circuits (362).

If behavioral activation induced by NMDA antagonists is related to increased glutamate release, pharmacologic agents that decrease glutamate release should block the effects of the drugs. Glutamate release can be inhibited by Na^{+}-channel blockers, Ca^{2+}-channel blockers, K^{+}-decreasing agents, toxins that prevent fusion of vesicles with the presynaptic membrane, and presynaptic group II metabotropic glutamate autoreceptor agonists (379 ,380 and 381).

Administration of LY-354740, a group II metabotropic glutamate receptor agonist, blocked both behavioral activation and increased glutamate release induced by PCP in rats (382). In humans, Anand and co-workers (381) found that lamotrigine, a new anticonvulsant agent that inhibits glutamate release, can reduce the ketamine-induced neuropsychiatric effects. These data suggest the possibility that glutamate release-inhibiting drugs (e.g., LY-354740 and lamotrigine) could be useful in the treatment of schizophrenia.

AMPA/Kainate Receptor Antagonists

The increased release of glutamate observed in response to NMDA antagonist could mediate some of the behavioral actions of the drugs by activation of non-NMDA receptors, including α-amino-3-hydroxy-5-methy-isoxazole-4-propionic acid (AMPA) and kainate receptors (377). In support of the hypothesis that behavioral effects of NMDA antagonists relate to increased glutamate release, administration of an AMPA/kainate receptor antagonist, LY-293558, partially reversed impairment of working memory induced by subanesthetic doses of ketamine in rats (377). Furthermore, AMPA/kainate receptor antagonists reduce NMDA antagonist-induced hyperlocomotion (383 ,384 and 385) and neurodegeneration (386). These data suggest that AMPA/kainate receptor antagonists may have utility for treatment of cognitive deficits in which NMDA receptor hypofunction is suspect (377).

Potential of Positive Modulators of AMPA Receptors

In apparent contrast to the postulated utility of AMPA/kainate receptor antagonists as antipsychotics, ampakines, a class of compounds that allosterically enhance AMPA receptor function, have also been suggested to represent potential adjunctive treatments for schizophrenia. Ampakines enhance excitatory (glutamatergic) transmission, facilitate long-term potentiation, learning, and memory in rodents (387 ,388), and have synergistic effects with typical and atypical antipsychotics on blocking behavioral effects of methamphetamine (389). In addition, preliminary results suggest that chronic administration of an ampakine (CX-516) can improve negative and cognitive symptoms in schizophrenia patients that also receive clozapine (284). Thus, such findings are paradoxical with regard to the foregoing discussion of the hypothesis that excessive glutamate release may be involved in behavioral effects of reduced NMDA receptor function. Further clinical experience with the effects of positive and negative modulators of non-NMDA glutamate receptors will be needed to clarify the potential of these compounds for treatment of schizophrenia (3).

Protein Kinase C Inhibitors

Accumulating evidence from Manji and colleagues has identified the family of protein kinase C (PKC) isozymes as a common target in the brain for the long-term action of the two structurally highly dissimilar antimanic agents, lithium and valproate (390). Chronic treatment of rats with lithium or valproate induces a reduction in the levels of two PKC isozymes, α and ε, in the frontal cortex and hippocampus, as well as a reduction in the expression of a major PKC substrate, myristoylated alanine-rich C kinase substrate (MARCKS), which has been implicated in long-term neuroplastic events in the developing and adult brain (391). In view of the critical role of the PKC signaling pathway in the regulation of neuronal excitability, neurotransmitter release, and long-term synaptic events, Manji and associates postulated that the attenuation of PKC activity might have antimanic efficacy. In a pilot study, they found marked antimanic efficacy of a potent PKC inhibitor tamoxifen, which is also a synthetic nonsteroidal antiestrogen, in the treatment of acute mania (392). Their heuristic preliminary data suggest that PKC inhibitors may represent a novel class of antimanic agents for the treatment of bipolar disorder, and deserve further study in psychotic syndromes.

Steroidal Agents

Estrogen

The gender effect of delayed onset (by approximately 2 to 5 years) and relatively reduced symptom severity in females has been consistently observed in schizophrenia (393 ,394 and 395). Some, but not all, researchers have found an additional smaller peak of onset of schizophrenia for women at age 40 to 45 years, which is a time of decreasing levels of estrogen associated with menopause (395 ,396). The inverse relationship between estradiol levels and specific psychopathology, especially positive symptoms, was also observed over the menstrual cycle in premenopausal women with schizophrenia (397 ,398). The indirect clinical evidence suggests a potential role for estrogen in delaying the onset or attenuating the severity of psychotic symptoms associated with schizophrenia (393 ,395). In animal behavioral studies, estrogen reduces amphetamine- and apomorphine-induced stereotypy, as well as enhances neuroleptic-induced catalepsy (399). In addition, preclinical biochemical studies have shown that estrogen can alter dopamine D_2 receptor density and affinity in the brain (399), whereas the effect is dependent on the time course of the administration (395). These findings suggest a neuroleptic-like effect of estrogen, and may have important implications for the prevention and therapy of schizophrenia. To date, there have been few treatment studies examining the effect of estrogen in patients with schizophrenia. Lindamer and associates (395) presented a case report of a postmenopausal woman with schizophrenia who had an improvement in positive symptoms with estrogen augmentation of neuroleptic medication. Long-term larger double-blind trials are crucially needed to evaluate the efficacy of estrogen in conjunction with neuroleptic treatment on psychotic symptoms in women with schizophrenia.

Dehydroepiandrosterone

Dehydroepiandrosterone (DHEA) and its sulfate derivative (DHEA-S) are neuroactive neurosteroids that represent steroid hormones synthesized *de novo* in the brain and acting locally on nerve cells (400). Although DHEA and DHEA-S are the most abundant circulating steroid hormones in humans, their precise physiologic roles remain to be elucidated. In humans, DHEA levels in blood rise dramatically at puberty and sustain a monotonic decline with age, reaching very low levels in late life. *In vitro* data suggest that DHEA and DHEA-S enhance neuronal and glial survival and differentiation in mouse embryonic brain tissue cultures (401 ,402 and 403). In addition, DHEA-S shows marked neuroprotective ability against the glutamate-induced toxicity (404) and oxidative stress (405). In rodents, DHEA has been demonstrated to be a positive modulator of the NMDA receptor. In both the adult rat brain and developing mouse brain, DHEA-S was shown to potentiate substantially physiologic responses to NMDA (403 ,406 ,407). The enhancement of physiologic response to NMDA by DHEA has been suggested to result from agonistic actions at s_1 receptors in the brain (407). Consistent with a positive modulatory action of DHEA at the NMDA receptor, the neurosteroid has been demonstrated to enhance memory in mice (408 ,409 ,410 and 411). Moreover, DHEA-S attenuates NMDA receptor antagonist MK-801-induced learning impairment via an interaction with s_1-receptors in mice (412). These preclinical studies provide the neurobiological rationale for the clinical studies to explore the potential utility of DHEA to treat the NMDA receptor hypofunction postulated to occur in schizophrenia. In chronic schizophrenics, significantly lower morning levels of plasma DHEA were observed (413). Further, there are a number of earlier case reports suggesting that DHEA may be useful in the treatment of schizophrenia, especially for negative symptoms (414 ,415 and 416), although these trials were not well controlled. A recent double-blind study of patients with major depression suggests that DHEA has antidepressant effects (417). Although the mechanism of action of DHEA and DHEA-S has to be further characterized, the possibility that these compounds may have efficiency in schizophrenia should be explored.

Phospholipid Compounds

Membrane Phospholipid Hypothesis of Schizophrenia

The membrane phospholipid hypothesis of schizophrenia originated with suggestion by Horrobin (418) that schizophrenia

might be caused by a prostaglandin (PG) deficiency. The proposal was based on several clinical observations of a relationship between pyrexia and the transient dramatic remission of psychosis, the relative resistance to PG-mediated pain and inflammation and reduced rate of rheumatoid arthritis in patients with schizophrenia, and the observation that PGE_1 injected into the CSF of mammals could produce catalepsy (419). Because PGs are derived from membrane essential fatty acid (EFA), Horrobin and colleagues (420) hypothesized that schizophrenia involves a failure to produce PGE_1 from EFA precursors. Interestingly, over two decades ago, it was suggested that the structure and pharmacologic actions of clozapine are consistent with its being a PGE analogue (420). PGEs are potent stimulators of cAMP formation, and cAMP inhibits phospholipase A_2 (PLA_2). In fact, clozapine treatment induced a dramatic rise in erythrocyte membrane concentrations of the major cerebral fatty acids, arachidonic acid (AA) and docosahexaenoic acid (DHA) (421). Thus, a generally unrecognized mechanism of action of clozapine may be on membrane phospholipid composition, in addition to its receptor-blocking profile (421).

The specific EFA content of synaptic membrane plays a significant role in modifying neuronal function. The changes in membrane EFA concentrations alter the biophysical microenvironment and hence, structure and function of membrane proteins, including neurotransmitter receptors, ion channels, and enzymes (419). EFAs also contribute to cellular regulation by acting as a source of precursors for second messengers in intracellular and intercellular signal transduction (419).

In rat models, changes in brain fatty acid concentrations produced by chronic dietary omega-3 fatty acid deficiency alter dopaminergic and serotonergic neurotransmission (422) and induce a decrease in D_2 and increase in 5-HT_2 receptor density in the frontal cortex (423). Impaired behavioral performance and learning are observed in omega-3 deficient rats (424) and have been hypothesized to reflect changes in attention, motivation and reactivity consistent with a deficit in the function of prefrontal dopamine pathways (419).

The phospholipid hypothesis of schizophrenia has been supported by the accumulating consistent clinical findings in schizophrenic patients that indicate reduced levels of erythrocyte membrane EFA, elevated serum and platelet PLA_2 activity (probably owing to accelerated breakdown of membrane phospholipids), and 31-phosphorus cerebral magnetic resonance spectroscopy (MRS) evidence of decreased synthesis and increased breakdown of phospholipids in the prefrontal cortex (419). Furthermore, phospholipid hypotheses are consistent with both dysfunction of multiple neurotransmitter systems and neurodevelopmental abnormalities associated with aberrant cell remodeling, apoptosis, or migration (425).

Omega-3 Fatty Acid

The membrane EFA or PG deficiency hypotheses have provided the rationale for attempts to treat symptoms of schizophrenia with supplementation of PG precursors, including omega-6 and omega-3 fatty acids and PGE_1. Among the studies of these compounds conducted to date, omega-3 EFA treatment has consistently yielded positive results. Two small open trials and a single double-blind trial suggest supplementation with omega-3 eicosapentaenoic acid (EPA) may improve residual symptoms and tardive dyskinesia when added to standard neuroleptic treatment in schizophrenic patients (419). Surprisingly, the more recent case report by Puri and colleagues (426) demonstrates a dramatic and sustained efficacy of omega-3 EPA on both positive and negative symptoms of schizophrenia in a drug-naive patient without any adverse side effects. In addition, cerebral atrophy, observed before omega-3 EPA treatment, was reversed by 6 months of EPA treatment; however, small trials and a single case report make it difficult to draw firm conclusions regarding the potential efficacy of omega-3 EPA. A recent double-blind placebo controlled study of omega-3 EPA as an adjunctive treatment to antipsychotic drugs found no difference between placebo and omega-3 EPA (427).

Trophic Factors

There is converging evidence that an abnormal neurodevelopmental process is accountable for at least a proportion of the pathophysiology of schizophrenia (428). The neurotrophic factors such as nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), and neurotrophin (NT)-3/4/5 play a decisive role in a neurodevelopmental process, including neuronal and glial differentiation, migration, proliferation, and regeneration (429). They are not only active during embryogenesis and organogenesis, but also influence the synaptic organization and synthesis of neurotransmitters in the adult brain, and are therefore involved in the maintenance of neural plasticity (429). Thus, pathologic alterations of the neurotrophic factor system may lead to neural maldevelopment, migration deficits, and disconnections, which are proposed to be the characteristic pathogenetic features of the maldevelopmental hypothesis of schizophrenia (429). A more recent pathophysiologic theory of schizophrenia suggests that it is involved in a limited neurodegenerative process reflected by the progressive and deteriorating clinical course of the illness (430). If neurotrophic factors salvage degenerating neurons, facilitate desirable synaptic connections, and hence, halt the progression of neurodegenerative process of schizophrenia, drugs that selectively stimulate the production of neurotrophic factors could represent a new approach to forestall the progression of schizophrenia and prevent morbidity from increasing (431). However, the lack of consistent evidence supportive

of pathophysiologic progression in schizophrenia has been a weakness of this hypothesis (430). Recently, Riva and associates (432) found that acute or chronic administration of clozapine increased basic fibroblast growth factor (FGF-2) mRNA and protein in the rat striatum, suggesting neuroprotective activity of clozapine. It has been proposed that small molecules that boost the endogenous levels of BDNF or NT-3 might be useful for treating temporally protracted and severe forms of neurodegenerative disease, such as AD or Parkinson's disease (433). Although neurotrophic factors are unable to cross the blood–brain barrier, potential alterations to administration of these factors are transplantation of neurotrophic factor-producing cells, direct transfection of neurotrophic factor gene, and development of compounds that modulate endogenous neurotrophic factor homeostasis and/or the influence their signal transduction mechanisms (429). The augmentation therapy with neurotrophic factors suggests novel and innovative pharmacotherapeutic, but as yet unproved strategies for schizophrenia.

CONCLUSION

Part of "56 - Therapeutics of Schizophrenia "

The therapeutic armamentarium for the treatment of schizophrenia has become rich and varied in the half century since the inception of the pharmacologic era marked by the introduction of chlorpromazine. We now have the capacity to control many of the symptoms of the disorder and restore the lives of patients. Much remains to be done in terms of drug discovery of new and novel agents and the determination of their optimal use in conjunction with psychosocial and adjunctive therapies; however, there is reason to be optimistic that future progress will be relatively swift.

ACKNOWLEDGMENTS

ECONOMICS OF MENTAL HEALTH AND SCHIZOPHRENIA

Part of "57 - The Economics of the Treatment of Schizophrenia "

Prior to the 1980s, economists paid scant attention to schizophrenia, or indeed to mental health in general (1). Early work in the field included efforts to consider the impact of organization and financing on system efficiency and to address the supply of personnel in caring for persons with mental illness. For example, McGuire (2) reviewed the market for psychotherapy and the insurability of mental health care, and Frank (3) examined the supply of psychiatrists. Researchers at RAND analyzed the impact of cost-sharing on demand for mental health care (4). The use of diagnosis-related groupings to pay for care under prospective payment was considered by Taube and his colleagues (5). Dickey and Goldman (6) reviewed the impact of various funding mechanisms in public mental health.

During the 1990s, work on insurance, regulation, and the organization of mental health services continued. Studies of insurance mandates for mental health care, such as Frank and colleagues' (7) simulation of mandates and related costs, provided valuable information to state legislators considering such laws. Observers of systems change considered major reorganizational efforts, such as those implemented through the Robert Wood Johnson Program on Chronic Mental Illness (8) and other types of organizational reforms (9 ,10 ,11 and 12). The 1990s also brought analysis of the increasing implementation of managed care with behavioral health carve-outs (13).

These examples of the contributions of mental health economists indicate the range of activities in the field of mental health economics, including the economics of schizophrenia. This chapter focuses on two aspects of the economics of schizophrenia: cost studies and cost-effectiveness studies. Studies of the cost of mental illnesses appeared before other types of work in the economics of mental health, and they have continued throughout the past two decades. Cost studies lay the foundation for cost-effectiveness and cost-benefit studies because they identify the range of resources that are consumed as a result of an illness. Cost-effectiveness analyses of mental health programs began to appear in the early 1980s with the hallmark study by Weisbrod and colleagues (14) on the cost-benefit of assertive community treatment teams. Collectively, studies of costs and cost-effectiveness are perhaps the most important foci of the economics of schizophrenia. First, the sizable cost to society captures the attention of policy makers and taxpayers, and convinces them of the huge fiscal impact of schizophrenia. Second, decisions by clinicians, managers, and policy makers that are informed by research on costs and cost-effectiveness lead to better distribution of the resources available for mental health care.

Costs Of Schizophrenia

Early studies of the costs of mental illness (15 ,16 and 17) did not distinguish between the costs of different diagnostic categories (18). More recent studies have estimated specific costs for schizophrenia and other illnesses. Rice has estimated the cost of schizophrenia in the United States at $32.5 billion in 1990 (19) and $44.9 billion in 1994 (20). Goeree and colleagues (21) have calculated costs in Canada in 1996 to be approximately $2.35 billion, whereas Knapp (22) has estimated the costs of schizophrenia in the United Kingdom to be 2.6 billion pounds. Some schizophrenia cost studies focus only on service costs, such as Rund and Ruud's (23) study of costs in Norway and Martin and Miller's (24) study

of Georgia Medicaid recipients. In contrast, Rice's and Knapp's studies include both direct costs (treatment and other service costs) and indirect costs, such as lost income. But no study of the cost of schizophrenia can claim to capture all costs. As noted by McGuire (18), even comprehensive studies of the cost of schizophrenia often underestimate two types of costs: the costs to families and the costs of publicly owned capital.

Cost Perspective

Cost-of-illness studies like Rice's and Knapp's typically employ the perspective of society; that is, they consider economic costs. Economic, or social, costs are the costs of resources consumed because of an illness. Cost-effectiveness and cost-benefit analysis should always state the perspective from which the study is undertaken. Although a societal perspective presumably provides the balanced view of the neutral scientist, it is also helpful to examine costs from perspectives of particular stakeholders. For example, in an analysis of the impact of Assertive Community Treatment in Connecticut, Essock and colleagues (25) present costs from the perspectives of society, the state, and the Department of Mental Health. Comparison of the results from multiple perspectives may identify areas of cost-shifting that results from certain programs and policies. For example, a treatment that reduces hospital days may shift costs from state-run inpatient facilities to private nonprofit outpatient settings.

Cost Components

Costs of Treatment and other Services

The examples provided by Rice and Knapp are instructive for those conducting cost-of-illness studies and cost-effectiveness studies in the area of schizophrenia. As they show, there are many ways in which the illness is associated with greater costs. First are the costs of treatment, including medication. Treatment may be offered by public, private, or voluntary sector settings, and many persons with schizophrenia receive care in multiple places. Besides treatment, services like case management, vocational rehabilitation, and psychosocial clubhouses generate significant costs. Medical and surgical costs also may be relevant in cost-effectiveness analyses, because utilization of these services may vary depending on the adequacy of mental health care (26 ,27).

Lost Productivity and Family Burden

Mental illnesses, like other disorders, cause people to lose workdays (28) and sometimes even to forfeit aspirations of having any career at all. Although lost productivity is usually addressed in comprehensive studies of the costs of schizophrenia, many studies of interventions for persons with schizophrenia have ignored productivity losses, because of the high rates of disability in this population. However, new strategies for improving the employment outcomes for persons with serious mental illness, such as Individual Placement and Support (29), have made employment a realistic goal of rehabilitation. These new successes suggest that loss of productivity should be included when calculating the cost of interventions for persons with schizophrenia. In addition to the productivity losses of the individual, cost studies should attend to the work losses of family members, and other contributions of time and in-kind services (30).

Capital Costs

Economic cost studies appropriately study the opportunity costs of all resources, that is, the value of those resources in their best alternative use. In a cost-effectiveness study of a new residential model for persons with serious mental illness, Cannon and her colleagues (31) carefully considered the value of capital costs of a public hospital, which would have been underestimated if valued through traditional methods of depreciation. Capital costs can be large enough to change the most basic findings of a cost study, as shown by Rosenheck and colleagues (32). Public administrators may not consider the value of buildings and property to be part of a cost equation because it is not always part of the operating costs, but the value of the property in alternative use may be considerable.

Other Components

Especially where an intervention is expected to have an impact on co-occurring substance use disorders, it is important to attend to criminal justice costs (33). Another neglected aspect of cost studies is the costs of administering transfer payments (such as social security). Although disability payments themselves do not represent the use of new resources, the cost of administering these payments is a cost that should be counted, especially if the intervention could change the rate of receipt of disability payments or other public benefits (34). For example, an intervention that returns people to work will not only increase their productivity (a benefit), but also decrease disability payments (decrease a cost).

The importance of including any type of cost in a cost-effectiveness study is related to the potential impact of the cost type on the study findings. The larger the cost per unit, or the more frequently it is used, the more carefully it should be assessed (35). But should cost-effectiveness analyses always be conducted? As indicated by the range of costs and cost perspectives that might be included, these studies can be expensive to implement. This expense is further increased because, to detect meaningful differences in a highly variable outcome such as cost, significantly more study participants

may be needed than for an effectiveness study alone. The usefulness depends in large part on the likelihood that the treatment or intervention under study will have an effect on costs—either positive or negative. Cost studies are critical in the analysis of novel antipsychotic agents because of the relatively high acquisition costs of the drugs, compared to conventional antipsychotic medications, and because of the potential of these drugs to reduce the number of days that people with schizophrenia are hospitalized (36).

COST-EFFECTIVENESS

Part of "57 - The Economics of the Treatment of Schizophrenia "

The success of interventions in schizophrenia, whether medications or psychosocial rehabilitation programs, is reflected in multiple domains. An antipsychotic may have an impact on cognition, on hallucinations, on affect, on disruptiveness, on sexual functioning, on extrapyramidal side effects, on weight, on employment—the list goes on and on. These are all measures of the effectiveness of the agent, some positive and some negative. Some, such as hallucinations and delusions, may be influenced much more directly by the medication than more distal outcomes such as housing or employment. Different individuals value changes in these domains differently (elimination of hearing voices that other people don't hear may be much more important to the person who is troubled by harassing voices making a steady stream of demeaning comments than to the person whose voices are good company or connect the patient to an imagined network of internationally renowned researchers). Similarly, some people are very troubled by changes in weight or sexual functioning, whereas such changes mean little to others. Hence, much as we would like a composite measure across all effectiveness domains, this reductionistic approach is fraught with untenable compromises. Just as there is variation among different patients and different providers, patients and payers ascribe different values to the same outcome (e.g., legislators who make funding allocations to public mental health systems may be more concerned about decreases in violence and patients may be more concerned with increases in quality of life). How much is a symptom-free day worth? It depends on who is asking and who is paying.

Cost-effectiveness analyses have evolved to deal with the multiple domains touched by a single treatment. Such analyses report the change in a given effectiveness measure associated with a particular cost investment in treatment. A medication may be cost-effective with respect to certain outcomes, cost-neutral for others, and costly for yet others. Lehman (37) reminds us that the current explosion of new knowledge about effective treatments and the advent of evidence-based quality standards for treating schizophrenia come at a time when cost containment is paramount in the health policy agenda. Policy makers need to know the impact of dollars invested in treatment—but not just in a single domain like reductions in hospital care. Those who make purchasing decisions for the public systems of care under which most of the country's treatment for schizophrenia is funded need information on multiple domains of effectiveness.

An alternative to cost-effectiveness analysis is cost-utility analysis, where a comprehensive outcome indicator is calculated as a preference-weighted sum of the outcome measures. An example of a cost-utility approach is the use of quality-adjusted life years (QALYs) (38 ,39). As noted above, different stakeholder groups value different outcomes differently; hence, approaches such as QALYs create an effectiveness metric representative of at best only one stakeholder group, and at worst the resulting metric is representative of no one. Although elegant in presentation, as with sausages, observing their creation can reduce enthusiasm for their use. One must find or create weights to apply to the various effectiveness measures and then decide on a combination scheme—deciding, for example, what weight gain is the equivalent of what change in extrapyramidal side effects (EPSs) and what change in psychotic symptoms. Typically, one does this either by interviewing individuals representative of the population under study (e.g., treatment refractory patients with schizophrenia) or by adopting someone else's measures as close enough. Because “close enough” is a very subjective call, it is important for researchers to disclose the sources of the weighting estimates so that readers can make their own call. For example, Rosenheck and colleagues' (40) report of changes in QALYs among mostly male veterans with schizophrenia used weights derived as part of a doctoral dissertation by Kleinman (Johns Hopkins University, 1995) of mainly African-American women, only about half of whom (55%) were diagnosed with schizophrenia (the rest were diagnosed with major depression, bipolar, and other affective disorders). We were unwilling to take the leap of faith needed to generalize from groups this disparate when presenting cost-effectiveness results from our own work (41). Nevertheless, Rosenheck and colleagues are to be commended for providing the information necessary to follow back their methods to see what was used. This is not always the case.

Another type of utility analysis is the measure of symptom-free days (42). Under such analyses, interventions are compared with respect to the number of symptom-free days they produce. Following the methodology of Lave and colleagues (43), Simon and colleagues (42) credited a study participant with having one depression-free day if the study participant had 2 days with a depression score of 0.5. Many people with depression, as well as many researchers, would take issue with saying that someone was symptom free for half a year if they reported having 50% of full symptoms for each day of that year. Symptom-free days may be a poor measure within schizophrenia studies simply because, unlike with depression, symptoms and functioning are poorly correlated,

and the likelihood of having a completely symptom-free day is rather small.

Disability-adjusted life years (DALYs), where one DALY equals one lost year of healthy life, can also be used to express years lost, both to premature death and to disabilities associated with living with schizophrenia (44). In contrast to QALYs and estimates of symptom-free days, DALYs are proxies for negative outcomes (45) and, as such, the calculation of cost-effectiveness centers around how many DALYs are saved by using a particular intervention. In a population where individuals may live for a long period of time with a relatively debilitating illness like schizophrenia, measures of mortality alone do not adequately capture the impact of the disability. DALYs are calculated by adding together the number of years between mortality and life expectancy (years of life lost, YLL) and the number of years lived with a disability (YLDs). Calculating YLDs requires making assumptions about the relative impact of illness onset, duration, and severity on healthy living (for example, making an assumption that a first psychotic episode at age 15 is worse than a first episode at age 25). As with QALYs, these metrics can be derived by surveying individuals with schizophrenia or their proxies, with the accompanying assumptions that how one weights hypothetical events is the same as the trade-offs one would make if one could trade fewer days of healthy life for more days of life with particular disabilities. Because such ratings are inherently untestable by rigorous methods, whether reliable or not, their validity remains suspect. Further, the calculation of DALYs “presupposes that life years of disabled people are worth less than life years of people without disabilities” (46), and may even rank some individuals' lives as worse than death (47). Schizophrenia brings with it an increased risk of suicide (48), which is consistent with DALYs ranking some lives as worse than death. However, assuming that person A and person B, in reality, would make the same choices as to what fates are worse than death presumes an ecologic validity to DALY ratings that may be unwarranted.

Cost-utility measures such as QALYs, DALYs, and measures like symptom-free days, have enormous appeal because of their ability to reduce multiple effectiveness domains to a single bullet measure. By deriving a single measure, one can compare any treatment approach to any other treatment approach. Where the measure is reduced to dollars (as in QALYs), one may even compare the values of interventions between different conditions (38), for example, if dollars expended on diabetes reap more benefits than dollars spent on schizophrenia. But the assumptions built into such bullet measures may have limited usefulness for informing decisions at the level of the individual patient, prescriber, or health care payer. These individuals weigh their particular circumstances, and may be unwilling to have others' preferences serve as proxies for their own. Instead, these stakeholders are asking more specific questions. For example, the mental health commissioner asks, “If I put an extra $3 million in the pharmacy budget for medication X, what can I expect this to buy me in terms of the other domains under my purview, and what is the downside risk? What will it buy me in terms of reductions in hospital use, improvements in vocational functioning, reductions in violent episodes, and reductions in side effects?” Similarly, patients and families paying for medications ask, “If I increase/decrease my spending by changing to medication X, what changes am I likely to see in the voices I hear, in my employability, in my sexual functioning, and in my body movements?”

An alternative to composite measures are measures that contrast costs invested to a variety of outcome domains, some of which will be more important to some stakeholders than to others. An analogy is a proposal for a city park to be funded from multiple sources. Depending on one's perspective (e.g., whether you would use the park, how the park would impact the value of your property, your safety, your recreational options, what you are called on to invest), the park may or may not be a good idea. And, depending on who is paying for what, and which outcome domains are most important to you, you may stand to get a lot or a little out of the dollars going into the park. The challenge is to present the data on costs and effects in such a way that the various payers (the city, private foundations, neighborhood organizations, individual contributors) can each look from their own perspective, see what the expected gains and losses are in the outcome domains they care about most (less street noise, more open space, more dogs, more people drawn to the neighborhood), perform their own idiosyncratic weighting of these factors, and decide if they are in favor of the park or not.

In contrast to cost-utility analysis, cost-effectiveness analysis does not reduce the impact of an intervention into one measure. Some outcomes may be clearly preferential or “dominant choices” (e.g., lower costs and higher effectiveness). Other outcomes are not as clearly dominant, and in these cases it may be useful to show the likely range of cost compared to multiple domains of effectiveness. One method of examining these ranges is to create sampling distributions for costs and effectiveness measures to show the precision of estimates as well as their mean. For example, bootstrap techniques use every study participant's data to create an empirical sampling distribution of the test statistic and plot these estimates as a cost-effectiveness plane. Bootstrapping techniques offer one means of describing confidence intervals for incremental cost-effectiveness ratios (ICERs) (49 ,50). Cost data are often highly positively skewed, and ICERs provide less biased estimates of confidence intervals in highly skewed cost data (43 ,51 ,52).

Figure 57.1 shows such an approach when considering the cost-effectiveness of clozapine compared to conventional agents among long-stay state hospital patients (41). The cluster of points displays the sampling distribution of the ICER. Most of the points fall in the lower-right quadrant, indicating that clozapine is most likely to be less costly and

more effective than conventional antipsychotic agents from the cost perspective (total societal cost) and for the effectiveness measure in question (reduction in EPS). Such displays of information give the reader/policy maker a sense of the tightness of the point estimate and the risk of falling in a quadrant other than the one indicating cost-effectiveness. One can use these sampling distributions to create cost-acceptability curves from the viewpoint of particular payers for particular outcomes (e.g., the likelihood that the intervention will be cost effective for the payer who is willing to risk $1, $10, or $100 to obtain an 80% likelihood of return in sexual functioning).

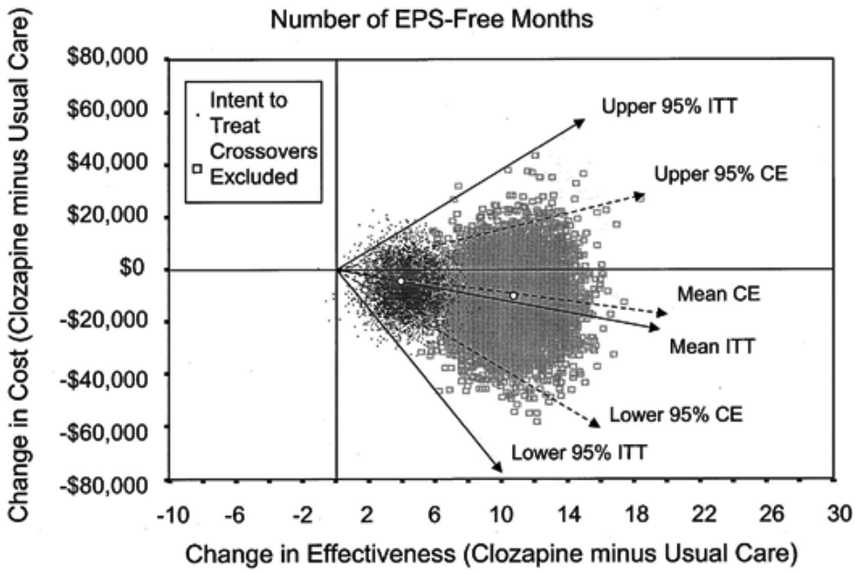

FIGURE 57.1. Ten thousand bootstrap replications plotted in the cost-effectiveness plane (intent-to-treat, *N* = 136 clozapine and *N* = 87 usual care; treatment crossovers excluded, *N* = 89 clozapine and *N* = 30 usual care). The x-axis and y-axis, respectively, show the difference between clozapine and usual-care groups in estimated number of extrapyramidal side effects (EPS)-free months and total cost during a 2-year period. The quadrant to the lower right of the origin (0,0) contains those estimates where clozapine was found to be less costly and more effective than the usual care (80% of the estimates for the intent-to-treat analyses and 81% of the estimates when treatment crossovers are excluded). (From Essock SM, Frisman LK, Covell NH, et al. Cost-effectiveness of clozapine compared with conventional antipsychotic medication for patients in state hospitals. *Arch Gen Psychiatry* 2000;57:992, with permission. Copyright 2000 American Medical Association.)

Saul Feldman (53) has held positions as the head of the National Institute of Mental Health (NIMH) Staff College and chief executive officer of one of the country's largest managed behavioral health care organizations. Thus, he has been in a position to make policy based on research, and to inform policy makers with research. He has posed the question, Is good research good if it does not inform policy and practice? It is incumbent on mental health services researchers to report their findings in ways that speak to funders and service system managers, which means providing estimates of the most likely outcome as well as the likelihood of alternative outcomes.

COST OF THE NEWER ANTIPSYCHOTIC MEDICATIONS

Part of "57 - The Economics of the Treatment of Schizophrenia "

In general, the acquisition cost of the newer antipsychotic medications is greater than that of conventional ones. These acquisition costs are reflected in formulary budgets. Once a relatively small component of treatment costs, formulary budgets in psychiatric settings have risen dramatically in the past decade, and the market share of the newer agents has risen as they have replaced the less costly conventional agents. Figure 57.2 shows the distribution of antipsychotic prescriptions paid for by Medicaid in 1998 (left) and the

dollars Medicaid paid for these prescriptions (right). These data show that the newer agents account for 58% of all antipsychotic prescriptions paid for by Medicaid but for $1.15 billion (90%) of the $1.28 billion in Medicaid costs for antipsychotic prescriptions. These charts dramatically display the disparity in medication costs associated with the newer versus the conventional agents.

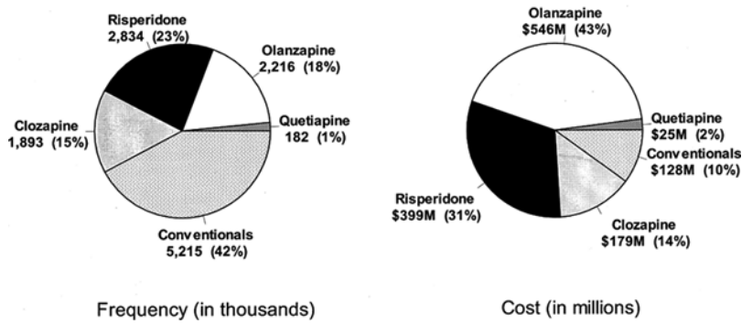

FIGURE 57.2. Distribution of (*left circle*) and total dollars paid (*right circle*) by Medicaid for antipsychotic medication prescriptions during 1998. Newer antipsychotic medications represented slightly over half of the total prescriptions, and they were responsible for 90% of the total cost.

This price difference between the older and the newer antipsychotic medications, which can be a 100-fold difference (e.g., when contrasting generic oral haloperidol with nongeneric Clozaril), prompted scores of studies asking the cost impact of using the newer medications when more than simply the cost of the medication was considered. For example, if using new and expensive medication X results in fewer days hospitalized than some alternative, then, all else being equal, using X will reduce overall costs as long as the cost savings associated with fewer days in the hospital is greater than the cost difference between medication X and the alternative.

Clozapine Cost Effectiveness Studies As Case Examples

The rub, of course, is that “all else” is rarely equal in effectiveness or cost-effectiveness studies, and the early cost projections concerning the impact of using clozapine often suffered from faulty assumptions about what was equivalent. Many of these studies were pre–post comparisons that examined changes in hospital use and lacked a comparison group (54 ,55 ,56 ,57 ,58 ,59 and 60). For example, the study by Meltzer and colleagues (59) of patients with schizophrenia who were taking clozapine collected retrospective cost data for 2 years before and after these 47 individuals began taking clozapine and concluded that clozapine was associated with a 23% drop in treatment costs. This study generated a series of letters criticizing the study's methodology (61 ,62 and 63) [see also the response by Meltzer and Cola (64)]. Critics focused on the problem of the regression toward the mean that can be expected whenever study participants are enrolled during a low point in their functioning (such as may have prompted the initiation of clozapine), and on the other potential temporal and case-mix confounds associated with mirror-image studies of individuals who were selected to begin a medication through other than a random-assignment process among all eligibles.

The results of the two randomized clinical trials of clozapine's cost-effectiveness each showed much more modest benefits associated with clozapine, both in the 2-year, open-label trial comparing clozapine to the usual care with a range of conventional antipsychotics among long-term patients in state hospitals (41 ,65 ,66), and in the 1-year masked trial comparing clozapine to haloperidol among veterans hospitalized for a year or less (67). Each trial showed clozapine to be somewhat more effective than the comparison agents, and this increase in effectiveness comes at no additional cost when costs are viewed from a societal perspective. Each trial also showed that clozapine is more effective than the usual care in minimizing days hospitalized, enough so that the reduction in hospital days more than covers the increased cost of the medication plus increased outpatient services. But, from more narrow perspectives (e.g., the hospital formulary budget, capitated outpatient service providers), clozapine would be viewed as increasing their costs. For cost-effectiveness studies to influence planning and policy making, the perspectives of these different payers need to be taken into account because it is these local incentives and disincentives that must be addressed to be sure that the fiscal incentives are lined up to promote good care. A hospital would have a great incentive to use clozapine for a heavy user of hospital services if it has a fixed budget (the case with most state hospitals), but a hospital paid a per diem would have no such incentive.

Lengthy randomized clinical trials in routine practice settings, such as the clozapine study in Connecticut state hospitals and the clozapine study in Veterans Administration (VA) hospitals, suffer from treatment crossovers. By the end of 6 months in the Connecticut study, only 11% of the usual care patients had begun a trial on clozapine, but by the end of 24 months in the study, 66% had. In the VA clozapine study, 72% of the patients assigned to masked haloperidol had ceased taking the masked medication by the end of the 1-year study period, with 49 of 157 (31%) of them switching to clozapine and the rest to conventional antipsychotics, including unmasked haloperidol (67). Because of the biases introduced by what is likely to be highly nonrandom discontinuation of the assigned treatment, the importance of intent-to-treat analyses and the unspecified biases of crossovers-excluded analyses are well documented (68). Regardless, when crossovers are common, analyses excluding crossovers offer a proxy for the best-case scenarios for each treatment condition by comparing only those who do well enough on treatment A to stay on it with only those who do well enough on treatment B to stay on it. Figure 57.1 illustrates this using data from the Connecticut clozapine study. The exclusion of treatment crossovers increases the apparent effectiveness of clozapine (the crossoversexcluded oval is shifted to the right of the intent-to-treat oval in Fig. 57.1) and decreased the estimate of the relative costliness of clozapine (the crossovers-excluded oval is shifted lower by about $5,500) (41). Clearly, individuals who leave their assigned treatment are different in terms of costs and outcomes from those who remain in their assigned treatment condition.

Another difficulty when trying to assess relative costs is the great variability in costs across patients. For example, in the VA study just cited, health care costs in the 6 months prior to randomization were approximately $27,000 with a standard deviation of about $17,000 (67). For the Connecticut clozapine study, the 95% confidence interval for patients assigned to clozapine was $96,847 to $114,308 for year 2 versus $103,665 to $121,144 for those assigned to the usual care. With such variability, cost differences are

very difficult to detect, even with the relatively large sample sizes of the VA and Connecticut trials (*N* = 423 and 227, respectively). Even for individuals who are heavy service users at study entry, mounting a trial powered to detect cost differences requires hundreds of individuals per treatment arm. If the trial were a study of outpatients who are infrequent users of expensive services like hospitals, it would require even larger samples to detect cost differences apart from medication.

From a public health perspective, an emphasis on point estimates of costs and effectiveness is misguided when the confidence intervals are so broad. Economists would call clozapine the dominant alternative in these randomized trials (because most of the range spanned by the cost confidence intervals includes the values where clozapine costs less than or the same as the usual care and the effectiveness measures favor clozapine or are neutral). The reduction of data to such a point estimate belies the broad distribution of possible outcomes that are likely to occur across patients. Planners and policy makers, as well as patients and their treating clinicians, need a sense of the range of possible outcomes and their relative likelihood to inform their decisions about what chances they want to take.

Costs Associated with Risperidone, Olanzapine, and Quetiapine

Figure 57.3 shows the frequency of prescribing by type of antipsychotic in three large states in different parts of the country among individuals whose medications are paid via

Medicaid. Because Medicaid formularies allow unrestricted access to any of these medications independent of location in the country and the same financial incentives apply, one would expect to see similar rates of prescribing these medications. Indeed, the distributions do appear quite similar to each other and to the national data (Fig. 57.2). That these distributions do not reflect what we know about the relative effectiveness of these agents suggests that other factors are strong influences on medication choice and that these influences combine to create similar patterns of antipsychotic prescribing under Medicaid nationwide. In addition to factors such as effectiveness, factors as disparate as patients' past histories of medication use, order of receiving Food and Drug Administration (FDA) approval, convenience of use, acquisition costs, relative marketing budgets, and side-effect profiles may also be at play. These figures serve as reminders that medications are started and discontinued for reasons other than effectiveness. (Data for these pie charts were extracted from the Health Care Financing Administration's (HCFA) Web site http://medicare.hcfa.gov/medicaid/drug5.htm; potential users take note that, as of March 2000, the Web site reported Medicaid expenditures in cents rather than dollars and does not label the cost units.)

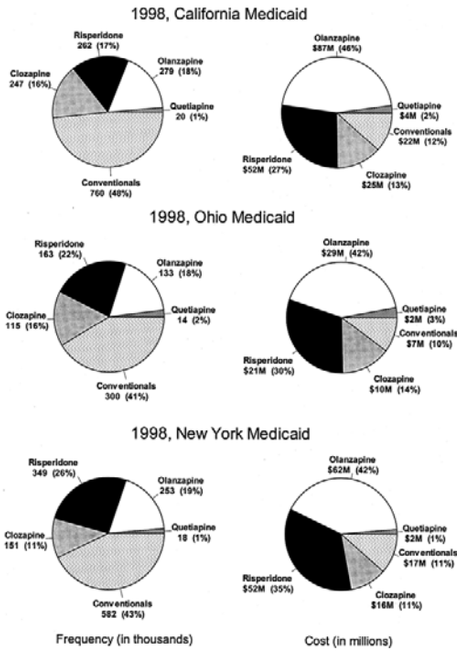

FIGURE 57.3. Distribution of (*left circles*) and total dollars paid (*right circles*) by Medicaid for antipsychotic medication prescriptions in California, Ohio, and New York during 1998.

Several studies of risperidone and olanzapine also suggest that the acquisition costs of these medications may be offset by reduction in use of more expensive health care services such as inpatient treatment. Many of these studies have methodologic shortcomings similar to those of the earlier cost studies of clozapine described above. Another concern is that industry sponsorship of many of these studies means that they do not meet the criteria for lack of an incentive for bias set forth by the *New England Journal of Medicine* (69), whose editors noted that the opportunities for introducing bias into economic studies are far greater than in studies of biological phenomena because of the unusually discretionary nature of model building and data selection in such analyses, and because drug costs in particular can be quite arbitrary as they are prices (not costs) set by the manufacturer. Hence, additional work is needed in this area.

In general, the studies by the medications' manufacturers show support for cost reductions favoring that manufacturer's medication [e.g., for risperidone (70) and for olanzapine (71 ,72)]. Although such studies form good starting points for further investigation, they need follow-up by independent investigators to assess how the agents' cost-effectiveness plays out in broader settings with representative patients, lest best-case examples be generalized to settings where they are not applicable and used to set policy there. An example of an important follow-up study is that of Conley and colleagues (73), who found that, among 84 treatment-refractory patients randomly assigned to a double-blind 8-week fixed-dose trial of either olanzapine or chlorpromazine, olanzapine appeared to have limited efficacy, showing only a 7% response. Hence, the reduction in treatment costs associated with olanzapine noted in the reviews of Palmer and colleagues (74) and Foster and Goa (75) would not be expected among treatment-refractory patients, even though these patients are heavy users of inpatient services. Under other scenarios, these patients are the very ones for whom new interventions are associated with cost savings because they have higher initial rates of utilization on which to show an impact (25 ,40). An independent study of risperidone compared to conventional antipsychotics among outpatients with schizophrenia using a matched comparison group found no difference in total treatment costs or effectiveness measures, although there was a trend for the risperidone-treated group to have higher costs, attributable to higher medication costs (76).

CONCLUSION AND ADDITIONAL RESOURCES

Part of "57 - The Economics of the Treatment of Schizophrenia "

This brief review of the economics of treating schizophrenia has emphasized some of the methodologic complexities that must be acknowledged and surmounted when addressing treatment costs. The emphasis has been on illustrating the importance of bias minimization and estimation when constructing studies and reporting results, and on the importance of reporting results from the perspective of different payers and giving estimates of the variability associated with any findings reported as point estimates. It is important to tell patients, prescribers, and payers not just the best estimate of costs and effectiveness, but the likelihood that their costs and outcomes will fall within their acceptable ranges for what they are willing to pay and/or risk to gain a given outcome.

Fortunately, this evolving literature has many active champions who publish widely and lead the way in documenting the ways in which costs and fiscal (dis)incentives have impact on access to treatment, the quality of care received, and patient outcomes. Although their work cannot be summarized here, useful source books include those by Drummond and colleagues (38), Frank and Manning (77), Gold and colleagues (39), and Hargreaves and colleagues (35). The journal *Health Affairs* continues to be a particularly valuable resource for reports on mental health economics and thoughtful analyses of the economic influences on the treatment of individuals with schizophrenia.

ACKNOWLEDGMENTS

Part of "57 - The Economics of the Treatment of Schizophrenia "

This research is the product of the collaboration of many individuals, both within and outside the Connecticut Department of Mental Health and Addiction Services (DMHAS). In particular, we would like to thank Carlos Jackson, Ph.D., of the University of Connecticut for his assistance with the data extraction and statistical analyses of the Medicaid prescription data. The research was funded

in part by U.S. Public Health Service (USPHS) grants R01 MH-48830 and R01 MH-52872 from the National Institute of Mental Health (NIMH) to Susan Essock, Ph.D., principal investigator, as well as by DMHAS. This publication does not express the views of the Department of Mental Health and Addiction Services or the State of Connecticut. The views and opinions expressed are those of the authors.

Mechanism of Action of Atypical Antipsychotic Drugs

Herbert Y. Meltzer

Herbert Y. Meltzer: Bixler Professor of Psychiatry and Pharmacology, Vanderbilt University School of Medicine, Nashville, Tennessee.

ATYPICAL ANTIPSYCHOTIC DRUGS: WHAT IS TO BE EXPLAINED

Part of "58 - Mechanism of Action of Atypical Antipsychotic Drugs "

The designation of chlorpromazine, and subsequently haloperidol, thioridazine, loxapine, thiothixene, molindone, pimozide, and related compounds as *antipsychotic drugs* (1) reflects their predominant action in humans, namely the suppression of auditory hallucinations and delusions, in some, but not all, individuals with diagnoses of schizophrenia as well as other psychoses. These drugs are also called neuroleptics because they caused catalepsy in rodents and extrapyramidal side effects (EPSs) in humans (2). Their ability to diminish psychotic symptoms was convincingly shown to be initiated by blockade of dopamine (DA) D2 receptors in mesolimbic nuclei, especially the nucleus accumbens, stria terminalis, and the extended amygdala (2 ,3 ,4 and 5). Blockade of D2 receptors in terminal regions, e.g., the striatum, nucleus accumbens, and prefrontal cortex, by these agents initially causes compensatory increases in the activity of dopaminergic neurons in the substantia nigra and ventral tegmentum, respectively, followed by a gradual decrease in the activity of DA neurons, and, ultimately, complete inactivation of DA neuron firing in both regions (6). This so-called depolarization block was suggested to be the reason for the slow onset of antipsychotic action, which is observed in some, but not all, psychotic patients. The development of depolarization block following subchronic haloperidol treatment has been challenged by Melis et al. (7) on the basis of microdialysis studies of DA release in the nigrostriatal system, but those findings have been suggested by Moore et al. (8) to be an artifact.

These first-generation antipsychotic drugs are often referred to as *typical* antipsychotic drugs because they typically produce EPSs, e.g., acute dystonic reactions, subacute parkinsonism, and akathisia, and, after chronic use, tardive dyskinesia or dystonia (see Chapter 56) as a direct or indirect result of blockade of D2 receptors in the dorsal striatum, in vulnerable individuals. The immediate cause of acute and subacute EPSs is considered to be blockade of the dopaminergic inhibition of striatal cholinergic neurons, leading to increased cholinergic activity in the basal ganglia (2). Subsequently, clozapine was found to achieve an antipsychotic effect without causing EPSs, whereas loxapine, a clozapine congener, was equipotent in producing its antipsychotic action and EPS in humans and laboratory animals (10). This led Hippius and Angst to describe clozapine as an *atypical* antipsychotic drug (11). Preclinical scientists almost invariably refer to clozapine and other drugs that have antipsychotic properties and low EPSs as atypical antipsychotics but, as will be discussed, clinical investigators do not universally accept this designation.

The atypical profile of clozapine was initially attributed to its anticholinergic properties, which, along with other unknown features, caused selective depolarization of the A9 DA neurons in the substantia nigra, which project to the dorsal striatum, sparing those of the A10 ventral tegmentum, which project to the cortex and mesolimbic systems (12). The subsequent evidence that clozapine, compared to neuroleptic drugs such as haloperidol, had at least six advantages in addition to producing significantly less EPS and tardive dyskinesia, has attracted enormous interest to clozapine and other subsequently developed atypical antipsychotic drugs. These six effects of clozapine, not all of which are fully shared with other atypical antipsychotic drugs, are (a) absence of tardive dyskinesia; (b) lack of serum prolactin elevations in humans; (c) ability to eliminate positive symptoms without exacerbating motor symptoms in patients with Parkinson's disease who become psychotic due to exogenous dopaminergic agents such as levodopa (L-DOPA); (d) ability to decrease or totally eliminate psychotic symptoms in approximately 60% of the patients with schizophrenia who fail to respond to typical neuroleptic drug; (e) ability to improve primary and secondary negative symptoms;

and (f) ability to improve some domains of cognition in patients with schizophrenia, especially secondary memory and semantic memory (verbal fluency) (9 ,11 ,13). Some of the atypical antipsychotic drugs have also been shown to be more effective than the typical neuroleptic drugs in improving depression, stabilize mood, and decrease suicidality (9 ,10). These collective advantages of clozapine led to the search for the mechanism(s) involved in these effects and to find drugs that did not have the panoply of side effects of clozapine, especially agranulocytosis (9).

The other widely available antipsychotic drugs that are classified as atypical, by consensus, are, in order of their introduction, risperidone, olanzapine, sertindole, quetiapine, and ziprasidone. Melperone, a butyrophenone, introduced at about the same time as clozapine, has also been suggested to be an atypical antipsychotic drug because of its many clinical similarities with clozapine (14). Other agents with the essential clinical characteristics of an atypical antipsychotic drug that are currently at an advanced stage of clinical testing are iloperidone, ORG-5222, and aripiprazole (9 ,10). Zotepine and amisulpride, both of which are widely used antipsychotic drugs in Europe, are also sometimes grouped with the atypical antipsychotic drugs (9 ,10). With the exception of aripiprazole, a partial DA agonist (15), and amisulpride, a selective D2/D3 antagonist (16), all of the drugs listed above cause potent serotonin (5-hydroxytryptamine, 5-HT) receptor subtype 5-HT_{2A} relative to DA D2 receptor blockade (17 ,18 and 19).

There are a very large number of drugs in development as antipsychotics that have the property of being active in various animal models that predict antipsychotic action, e.g., blockade of amphetamine-induced locomotor activity or of the conditioned avoidance response, at doses 5- to 20-fold lower than that which produce catalepsy, a predictor of EPSs. All of these drugs are routinely referred to as putative *atypical* antipsychotic drugs, at least by preclinical scientists, because of their ability to produce an antipsychotic action at doses that do not cause significant EPSs in humans and a comparable dissociation in animal models of psychosis and EPSs, e.g., blockade of conditioned avoidance response and blockade of DA-induced locomotor activity, and the induction of catalepsy, respectively. These drugs differ greatly in chemical structure and, to some extent, pharmacologic profile, and thus cannot be referred to as a group by either chemical class or pharmacologic profile. However, some clinical investigators find the term *atypical antipsychotic drug* misleading because there are important clinical differences among the compounds with regard to the six clinical features of clozapine noted above, and they prefer the term *novel* or *new generation* over *atypical* to describe these agents. However, this temporal-based nomenclature is not routed in any meaningful or enduring characteristic of these agents. Others prefer to call them *multireceptor* antipsychotics, which is clearly preferable to *5-HT/DA* antagonists, another commonly used term. It is our view that these other designations have no specific advantages and some disadvantages compared to the classic term *atypical*. Thus, this chapter continues to use the term *atypical* to designate antipsychotic drugs that have a major advantage with regard to EPSs in patients with schizophrenia or Parkinson's disease, or both, to contrast with the typical antipsychotic drugs, and to update some of the key hypotheses for explaining some of the other highly valued advantages of these agents, as well as their unique side effects.

As can be expected, there has been an intensive effort to determine the basis for the differences between the typical and atypical antipsychotic drugs. This chapter reviews the major hypotheses, which are based on the pharmacologic profiles of the numerous classes of agents with atypical properties as well as current theories of the action of drugs effective in animal models of psychosis, but not yet adequately tested in humans, e.g., AMPA antagonists and metabotropic glutamate receptor antagonists (20 ,21).

The affinities of clozapine and some of its congeners for monoamine receptors are given elsewhere in this volume (see Chapter 56) (22). The affinities reported therein are for the D1, D2, D3, D4, 5-HT_{1A}, 5-HT_{1D}, 5-HT_{2A}, 5-HT_{2C}, 5-HT_{6}, 5-HT_{7}, α_1, α_2, H_1, and muscarinic M1 receptors. Of these, the greatest interest is in the role of D2, D4, 5-HT_{1A}, 5-HT_{2A}, 5-HT_{2C}, α_1, and α_2 receptors. Clozapine does have effects on glutamate and GABA neurons and interneurons, respectively, but space considerations preclude their discussion here.

ROLE OF D2 RECEPTORS

Part of "58 - Mechanism of Action of Atypical Antipsychotic Drugs "

Most effective antipsychotics, typical as well as atypical, have affinities for the DA D2 receptor high enough to suggest that they produce effective blockade of these receptors *in vivo* (23 ,24). The model for atypical antipsychotic drug action proposed by Meltzer et al. (17) postulated that atypical antipsychotic drugs had to have some D2 receptor blockade *in vivo*, although weaker than 5-HT_{2A} receptor blockade, to achieve a low EPS profile and, possibly, some of the other advantages of clozapine. An exception to this may be amperozide, with is a potent 5-HT_{2A} antagonist and DA reuptake inhibitor with very low affinity for the D2 receptor (25). Recently, NRA0045, which has potent 5-HT_{2A}, D4, and α_1 but no D2 or D3 receptor blockade has been found to have atypical antipsychotic properties (26). Partial DA agonists, which may act as agonists at presynaptic DA receptors, and antagonists at postsynaptic DA receptors are a new class of antipsychotic drugs that has promise (15 ,27 ,28). However, clinical testing of these agents is just beginning, and current data support only the view that they are atypical in the classic sense, i.e., they are antipsychotic in preclinical or clinical testing at doses that produce weak or absent EPSs. Other evidence of the importance of α_1 antagonism for atypical antipsychotic drug activity will be discussed subsequently. The *in vitro* affinity of a drug at the DA D2 receptor

is a useful predictor of the dose that produces EPSs and control of positive symptoms for typical neuroleptic drugs (2 ,29), although it does not do so for some atypical antipsychotic drugs, e.g., ziprasidone. Furthermore, there is no agreement on how to determine the doses used in such correlations because of the differences in dosage requirements as a function of stage of illness, body mass index, and age. There is little agreement even on the best dose for haloperidol, the most widely used antipsychotic drug. A wide range of 2 to 15 mg/day has been suggested, far removed from the 20 to 40 mg/day thought to be most effective in 1966 (9 ,10). To date, no clinically proven antipsychotic with the possible exception of amperozide lacks significant D2 receptor antagonist properties. As will be discussed, the combination of D2 and 5-HT_{2A} receptor blockade, in the right ratio, produces some of the effects of clozapine and other atypical antipsychotic drugs in rodents, e.g., increases DA efflux in the cortex and striatum of rats (30) and blockade of the conditioned avoidance response, an indication of antipsychotic activity (31). There have been only limited tests of this hypothesis in humans, mainly using ritanserin, which is a mixed 5-$HT_{2A/2B/2C}$ antagonist (32). Nevertheless, various comprehensive reviews of the action of the atypical antipsychotic drugs have concluded that the combination of 5-HT_{2A}, D2, and α_1 receptor blockade is the probable basis of their antipsychotic action (10 ,18 ,19 ,22 ,33 ,34 ,35 ,36 and 37). The evidence for this hypothesis will be discussed subsequently.

Counter to the hypothesis of the importance of 5-HT_{2A} receptor antagonism to the action of clozapine and other atypical antipsychotic drugs is the proposal of Seeman and Tallerico (24) and Kapur and Seeman (38) that the basis of atypical antipsychotics may lie in their rapid dissociation from the DA D2 receptor and their relatively easily displacement by surges of endogenous DA. It has also been proposed that rapid and extensive displacement of clozapine and quetiapine from binding sites accounts for the reported low occupancy of striatal D2 receptors by these drugs (24). The authors also suggested that this might account for more rapid relapse following clozapine and quetiapine withdrawal (24). Although the evidence cited for clozapine-induced relatively rapid relapse is robust (39), the evidence with regard to quetiapine and rapid relapse has never been published and does not accord with general clinical experience. Seeman and Tallerico found that the affinity for and rate of dissociation of antipsychotics from the D2 receptor are highly correlated. Drugs with low affinity for the D2 receptor, e.g., clozapine and quetiapine, were found to have a higher dissociation rate constant than drugs with higher affinity, e.g., haloperidol. Rapid dissociation from the D2 receptor was reported to also permit easier displacement of clozapine and quetiapine by endogenous DA, thereby avoiding side effects related to DA receptor blockade such as EPSs and hyperprolactinemia (38). It was also reported that olanzapine, risperidone, and sertindole, all of which are well established as atypical antipsychotic drugs, are comparable to haloperidol in their rate of dissociation from the D2 receptor and are not displaced by raclopride or iodobenzamide, as are clozapine and quetiapine (24). Thus, this hypothesis could not explain the basis for their low EPSs. Moreover, for these agents to achieve their antipsychotic action, they would have to be less easily displaced from limbic and possibly cortical D2 receptors. There are no data to support this selectivity with regard to displacement as yet. Although there is evidence for higher occupancy of extrastriatal D2 receptors by clozapine and quetiapine in patients with schizophrenia (40 ,41), and for atypical antipsychotic drugs that show more potent 5-HT_{2A} receptor blockade in rodents (42), the same appears to be true for olanzapine, which does not show the higher off-rates of clozapine and quetiapine (R. Kessler and H. Meltzer, in preparation). Because clozapine produces a greater increase in DA release in the cortex than in the accumbens or striatum, at least in rodents and monkeys (43), clozapine might be expected to produce greater occupancy of D2 receptors in these regions than the cortex, but, as noted above, this is not the case. It is also not clear how this model could explain any of the advantages of clozapine with regard to efficacy in neuroleptic-resistant patients or for cognition.

Studies on the regulation of prefrontal cortical or limbic DA release also provide no evidence that blockade of D2 receptors alone, regardless of degree of occupancy, can mimic the effects of the multireceptor antagonists such as clozapine (31 ,44 ,45). Pharmacologic analysis of this important model for the action of atypical antipsychotic drugs on cognition and negative symptoms strongly supports the importance of combined blockade of 5-HT_{2A}, D2, and possibly α_1 receptors (36 ,37 ,44 ,45).

D3 AND D4 RECEPTOR MECHANISMS

Part of "58 - Mechanism of Action of Atypical Antipsychotic Drugs "

Ever since the cloning and characterization of the distribution of the D3 and D4 receptors, which revealed a limbic and cortical distribution, there has been considerable speculation about the role of these receptors in schizophrenia and the mechanism of action of antipsychotic drugs (19 ,46 ,47 and 48). As specific antagonists have become available, it has been possible to test their efficacy in animal models of psychosis, cognition, and motor function, as well as to carry out some clinical trials in schizophrenia. Recently, Reavill et al. (49) reported that SB-277011-A, which has high affinity and selectivity for the D3 receptor and good brain bioavailability, has an atypical antipsychotic drug profile. This compound was active in preventing isolation-induced deficits in prepulse inhibition but was not effective in blocking either amphetamine- or phencyclidine (PCP)-induced locomotor activity or, by using microdialysis, to increase prefrontal cortical DA release in rats (49). However, subchronic administration of SB-277011-A selectively decreased the firing rate of A10, but not A9, DA neurons in the rat, indicating a clozapine-like profile (50). These are the most promising

data yet that a selective antagonist of D3 receptors might be useful in the treatment of psychosis.

On the basis of the finding that the affinity of clozapine for the cloned DA D4 receptor was two to three times greater than that for the D2 receptor, Van Tol et al. (51) suggested that blockade of the D4 receptor was the basis for the superiority of clozapine over the typical neuroleptic drugs in the treatment of schizophrenia. Other investigators have found less of a difference between the affinity of clozapine for D2 and D4 receptors (48). Several typical antipsychotic drugs, including haloperidol, have nearly equivalent affinity for D2 and D4 receptors, suggesting that D4 affinity per se does not convey any special advantages for an antipsychotic drug (48). The preclinical behavioral and electrophysiologic profile of highly selective D4 antagonists provides mixed evidence with regard to antipsychotic action associated with this receptor (52 ,53 and 54). A D4/α_1 antagonist, NRA0025, appears to have promise as an antipsychotic agent based on its preclinical profile (26). A clinical trial of a selective D4 antagonist showed no sign of activity (55). A compound with potent 5-HT_{2A} and D4 antagonist properties, finanserin, was also ineffective (56). Further clinical trials of compounds that have D4 or D3 antagonism, or both, together with high affinities for 5-HT_{1A} or α_1 receptors, and without D2 affinity seems indicated.

ROLE OF SEROTONIN IN ANTIPSYCHOTIC DRUG ACTION

Part of "58 - Mechanism of Action of Atypical Antipsychotic Drugs "

Determining the biological basis for the advantages of clozapine and other atypical antipsychotic drugs cited above and described in detail by Miyamoto et al. in Chapter 56 has led to considerable interest in the role of 5-HT in antipsychotic drugs action. We now consider some of this evidence. Other reviews of this topic should also be consulted (18 ,19 ,22 ,34 ,35 ,36 and 37 ,57).

Serotonin Receptors Involved in Antipsychotic Drug Action

The hypothesis that a relatively high affinity for the 5-HT_{2A} receptor compared to an affinity for the D2 receptor was the basis for the difference between atypical and typical antipsychotic agents contributed to the development of the newer antipsychotic agents listed above, all of which support the previously mentioned hypothesis of high affinity for 5-HT_{2A} and low affinity for D2 receptors (17 ,58 ,59). However, other 5-HT receptors may be important to the action of clozapine and other recently introduced antipsychotic agents, or of potential value for developing more effective or better tolerated antipsychotic agents. These include the 5-HT_{1A}, 5-HT_{2A}, 5-HT_{2C}, 5-HT_3, 5-HT_6, and 5-HT_7 receptors (19 ,22 ,33). Although some of the atypical antipsychotic drugs developed on the basis of the 5-HT_{2A}/D2 hypothesis also have affinities for 5-HT_{2C}, 5-HT_3, 5-HT_6, or 5-HT_7 receptors that are in the same range as that for the 5-HT_{2A} receptor, this is not characteristic of all of these agents, and thus it is not likely that affinities for these receptors are primary factors contributing to the low EPS profile of the entire class of agents (19 ,22 ,60 ,61). However, this does not rule out that actions at various 5-HT receptors contribute to low EPSs of specific drugs, or other actions, e.g., cognitive improvement or improvement in negative symptoms. For example, 5-HT_{1A} receptor agonism has also been suggested to be able to contribute to an atypical antipsychotic drug profile (62), and some of the atypical antipsychotics are 5-HT_{1A} partial agonists as well as 5-HT_{2A}/5-HT_{2C} antagonists, e.g., clozapine, quetiapine, ziprasidone, and S16924 (63 ,64). The role of the 5-HT_4 receptor in cognition will be discussed subsequently. Furthermore, there is some evidence of interactions among the 5-HT_{1A}, 5-HT_{2A}, and 5-HT_{2C} receptors (19 ,35). Because of space limitations, this chapter focuses on these three 5-HT receptors and briefly considers the others.

ATYPICAL ANTIPSYCHOTICS AND THE 5-HT_{2A} RECEPTOR

Part of "58 - Mechanism of Action of Atypical Antipsychotic Drugs "

5-HT_{2A} receptors have been implicated in the genesis of, as well as the treatment of, psychosis, negative symptoms, mood disturbance, and EPSs (17 ,19 ,33 ,34 ,35 and 36 ,45). The hallucinogenic effect of indole hallucinogens has been related to stimulation of 5-HT_{2A} rather than 5-HT_{2C} receptors (65). Numerous studies have examined the density of 5-HT_{2A} receptors in various cortical regions of patients with schizophrenia with decreased (66 ,67), increased (68), or normal levels reported. It is well established that some typical and atypical antipsychotic drugs can decrease the density of 5-HT_{2A} receptors (69 ,70), so the postmortem results noted above may be related to drug treatment. Positron emission tomography (PET) studies have not found decreased 5-HT_{2A} receptors in the cortex of never-medicated or unmedicated patients with schizophrenia (71). As mentioned above, the antipsychotic effect of clozapine has been attributed, in part, to its ability to block excessive 5-HT_{2A} receptor stimulation without excessive blockade of D2 receptors (17). This conclusion is consistent with the high occupancy of 5-HT_{2A} receptors produced by clozapine at clinically effective doses and its low occupancy of D2 receptors (in the 30% to 50% range as measured with [^{3}H]raclopride), the latter being significantly below the 80% to 100% occupancy usually produced by typical neuroleptic drugs (35 ,72 ,73 ,74 and 75). The occupancy of 5-HT_{2A} and D2 receptors has been studied with other novel antipsychotic drugs such as risperidone, olanzapine, sertindole, and quetiapine with results similar to those of clozapine; all are more potent 5-HT_{2A} and D2 antagonists at appropriate doses, but less so than clozapine (72 ,73 ,74 and 75).

Some of these agents (e.g., risperidone and olanzapine) produce high D2 occupancy at high doses (76 ,77).

The bell-shaped dose–response curve of risperidone, with higher doses being less effective than lower doses (78), is consistent with the hypothesis that excessive D2 receptor antagonism may diminish some of the beneficial effects of 5-HT_{2A} receptor blockade (17 ,19 ,33 ,35 ,36). The highly selective 5-HT_{2A}agonist M100907, formerly MDL 100907, has been found in a controlled study to have some efficacy for treating positive and negative symptoms in hospitalized schizophrenic patients (79). However, because it was less effective than haloperidol, no further testing in schizophrenia has been scheduled at present. Nevertheless, the concept that 5-HT_{2A} antagonism may be useful to treat some forms of psychosis, especially when combined with weak D2 receptor blockade, warrants further study. Other 5-HT_{2A} selective agents such as SR 46349B (80) are currently being tested. Additional clinical evidence supporting the role of 5-HT_{2A} receptor blockade in the action of clozapine and possibly other drugs with potent 5-HT_{2A} affinities is available from the several reports that the His452Tyr allele of the 5-HT_{2A} receptor, which is present in 10% to 12% of the population, is associated with a higher frequency of poor response to clozapine (81 ,82). Taken together, the evidence from clinical trial data suggests that 5-HT_{2A} receptor blockade may contribute to antipsychotic drug action.

There is additional basic research that is also consistent with the relevance of 5-HT_{2A} receptor blockade for antipsychotic drug action. Thus, M100907 or other selective 5-HT_{2A} receptor antagonists, either alone or in combination with selective antagonists of other receptors, have been found to be effective in various animal models of psychosis. These include (a) blockade of amphetamine-induced locomotor activity and the slowing of ventral tegmental area (VTA) (A10) dopaminergic neurons (34); (b) blockade of PCP- and dizocilpin (MK-801)–induced locomotor activity (83 ,84); (c) blockade of MK-801–induced prepulse inhibition (85); and (d) antipsychotic-like activity in the paw test (86) among others. Of particular interest is the report of Wadenberg et al. (31) that the combination of a median effective dose (ED_{50}) of raclopride, a D2 receptor antagonist, and M100907, but not M100907 alone, was effective in blocking the conditioned avoidance response. The authors concluded that 5-HT_{2A} antagonism alone could not achieve an antipsychotic action, but that minimal blockade of D2 receptors was required to achieve such an effect. This corresponds much more closely to the apparent clinical situation than do the models where M100907 alone was effective, e.g., blockade of PCP- or MK-801–induced locomotor activity (34 ,83 ,84 ,87 ,88 and 89). As mentioned previously, administration of even a single dose of atypical antipsychotic drugs, which are relatively more potent 5-HT_{2A} than D2 blockers, has been shown to down-regulate 5-HT_{2A} receptors in rat brain (69 ,70). This has now been shown to be due to internalization of the receptors (70). Recovery from this process requires the synthesis of new receptors.

An important effect of 5-HT_{2A} (and 5-HT_{2C}) receptors that may be relevant to their contribution to psychosis is their ability to influence dopaminergic activity in the mesolimbic and mesostriatal systems (19 ,33 ,90 ,91 ,92 ,93 and 94). Increased dopaminergic activity in the nucleus accumbens and other mesolimbic and possibly cortical regions may contribute to positive symptoms, including formal thought disorder (2 ,5). Increased dopaminergic activity in the striatum would be expected to diminish EPSs (2 ,5). The 5-$HT_{2A/2C}$ agonist DOI [1-(2,5-dimethoxy-4-iodophenyl)-2-aminopropane], which itself had no effect on basal DA release, potentiated amphetamine-induced DA release and attenuated the ability of apomorphine, a direct acting D1/D2/D3 agonist, to decrease DA release in the striatum (93). Increasing serotoninergic activity, e.g., by administration of selective serotonin reuptake inhibitors (SSRIs) alone or in combination with the 5-HT_{1A} receptor antagonist WAY 100635, has no effect on basal DA output in the striatum. However, the SSRIs can significantly enhance the increase in DA outflow induced by haloperidol. These findings indicate that in the striatum, endogenous 5-HT positively modulates DA outflow when nigrostriatal DA transmission is activated (94). There is now considerable evidence from both behavioral and neurochemical studies involving *N*-methyl-D-aspartate (NMDA) antagonists such as PCP and MK-801 that 5-HT_{2A} receptors modulate activated but not basal mesolimbic DA function (84 ,95). Thus, stimulated DA release, e.g., with stress, may be increased in the forebrain terminal regions secondary to enhanced stimulation of 5-HT_{2A} receptors. Agents that block the effect of excessive, but not basal, 5-HT_{2A} receptor stimulation may be the most useful clinically. M100907 has been found to diminish the increase in DA efflux in the nucleus accumbens produced by haloperidol (30) or S-sulpiride (92). Taken together, these data suggest that 5-HT_{2A} antagonism by itself may have antipsychotic action when dopaminergic activity is slightly to moderately increased. More studies are needed to define the ability of 5-HT_{2A} receptor antagonists to potentiate the action of low doses of D2 receptor blockers in animal models as well as in humans.

Jakab and Goldman-Rakic (96) have proposed that the 5-HT_{2A} receptors on cortical pyramidal neurons may play a crucial role in psychosis by virtue of their ability to modulate intracortical and cortical-subcortical glutamatergic neurotransmission. This could contribute to the ability of 5-HT_{2A} antagonists to attenuate some of the behavioral effects of PCP and ketamine. Aghajanian and Marek (97) have proposed a link between the glutamate hypothesis of schizophrenia and the hallucinogen hypothesis. Briefly, stimulation of 5-HT_{2A} receptors on layer V pyramidal cells increases the frequency of postsynaptic potentials (PSPs). These are mostly blocked by the AMPA/kainate glutamatergic receptor antagonist LY293558, indicating that

they are mainly excitatory PSPs (EPSPs), in contrast with the piriform cortex, where 5-HT produces inhibitory PSPs (IPSPs). The selective group II metabotropic agonist LY354740, which inhibits glutamate release by stimulating inhibitory presynaptic autoreceptors on glutamatergic nerve terminals, suppresses the 5-HT–induced increase in the frequency of EPSPs. However, Aghajanian and Marek suggest that the main way in which 5-HT_{2A} receptor agonists increase glutamate release is a retrograde action from stimulation of postsynaptic 5-HT_{2A} receptors. The type of glutamate release induced by 5-HT_{2A} receptor stimulation differs from ordinary depolarization-induced neurotransmitter release, which is called synchronous release. The type of release induced by 5-HT is delayed in onset, slow, and produces small excitatory postsynaptic currents (EPSCs) and is called asynchronous release. Aghajanian and Marek propose that hallucinogens such as LSD enhance asynchronous EPSCs. They suggest that stimulation of other types of 5-HT receptors may oppose this action and that the effect of 5-HT_{2A} receptor antagonists unmasks the effect of these other types of 5-HT receptors (97). A similar proposal has been made by Martin et al. (95). Although Aghajanian and Marek do not mention the 5-HT_{1A} receptor specifically, it would be a good candidate to counter the effect of 5-HT_{2A} receptor stimulation, as will be discussed. They propose that the thalamic filter hypothesis of Carlsson (98) might be related to the effect of 5-HT_{2A} receptor stimulation on thalamocortical afferents to affect cortical function or on corticostriatal or corticothalamic efferents to affect the thalamic filter.

SEROTONIN RECEPTORS AND COGNITIVE FUNCTION

Part of "58 - Mechanism of Action of Atypical Antipsychotic Drugs "

Clozapine, risperidone, ziprasidone, quetiapine, and olanzapine have been shown to improve selected areas of cognitive function in patients with schizophrenia, with the available data suggesting differential effects on specific functions (13). The available data suggest that each of the atypical drugs has a different pattern of effects on cognitive dysfunction in schizophrenia, but more head-to-head studies are needed to confirm this impression. Whether relatively more potent 5-HT_{2A} receptor compared to D2 antagonism has a major or, indeed, any role in the cognitive effects of these agents is not known. However, this is the major characteristic that these drugs share in common. It may be that the effect of these agents on cognition is mainly dependent on their ability to increase the release of DA (99 ,100) and acetylcholine in prefrontal cortex (101), which may depend, in part, on their serotoninergic actions. The effect of the atypical agents to increase DA efflux in the medial prefrontal cortex (mPFC) of rats appears to be due mainly to actions at the terminal regions rather than cell bodies and not to be related to D2 receptor blockade because local administration of haloperidol is without effect whereas clozapine and olanzapine produce huge increases in DA efflux (102). Studies have suggested that the clozapine, olanzapine, risperidone, and ziprasidone, but not haloperidol, may enhance acetylcholine release in the rat prefrontal cortex (101 ,103). Interactions between the 5-HT and cholinergic systems have been previously reported (104). 5-HT_{1A}, 5-HT_{2C}, 5-HT_3, and 5-HT_4 receptors have also been reported to have significant effects on acetylcholine release in the rat prefrontal cortex (105 ,106 ,107 ,108 and 109).

Because cognitive enhancement is critical for functional improvement in schizophrenia, establishing the mechanism for the ability of the atypical antipsychotic drugs to increase DA efflux is of the greatest importance. The evidence concerning 5-HT receptors and cognition has been reviewed in detail elsewhere (110 ,111). 5-$HT_{2A/2C}$ antagonists have little adverse effect and no apparent beneficial effects on learning and memory (112). There is some evidence that 5-HT_4 agonists, e.g., RS 67333, can improve learning and memory in rodents (113). Impairment of working memory in humans following administration of the 5-HT_{1A}agonist flesinoxan has been reported (114). However, Sumiyoshi et al. (115) have found that tandospirone, a 5-HT_{1A} partial agonist, can improve other domains of cognition in patients with schizophrenia treated with typical neuroleptic drugs. Neurochemical differences in the patient populations, including possible abnormalities in the density of 5-HT_{1A} receptors in schizophrenia, concomitant administration of a neuroleptic to the patients with schizophrenia, and differences in the type of cognitive domain studied, may account for this discrepancy. Further study in patients with schizophrenia is clearly indicated.

5-HT_{2A} RECEPTOR BLOCKADE AND EXTRAPYRAMIDAL FUNCTION

Part of "58 - Mechanism of Action of Atypical Antipsychotic Drugs "

There have been numerous suggestions to explain the low EPSs of clozapine, namely its anticholinergic properties, lack of ability to increase acetylcholine in the striatum, D1 or D4 receptor blockade, and its effects as an α_1- or α_2-adrenoceptor antagonist (2 ,18 ,33 ,116). In addition, several lines of evidence suggest that potent 5-HT_{2A} receptor blockade is relevant to the low EPS profile of clozapine, but that 5-HT_{2A} receptor blockade by itself cannot explain the low EPS liability of these agents (17 ,58 ,59). Meltzer et al. (17) studied a group of compounds that had antipsychotic activity in humans or in animal models that are thought to be predictive of antipsychotic activity, e.g., conditioned avoidance response or blockade of amphetamine-induced locomotor activity, and which produced weak EPSs in humans or weak catalepsy in animals relative to their antipsychotic efficacy. These compounds shared in common relatively weaker D2 compared to 5-HT_{2A} receptor affinities, whereas D1 receptor affinities did not contribute to this effect.

Among the drugs studied were melperone, a butyrophenone long used in Europe and Scandinavia as an antipsychotic and reported to produce low EPSs (14). Indeed, it has been found to be tolerable to patients with Parkinson's disease (117), even more so than risperidone and olanzapine. The ∩-shaped dose–response curve of risperidone as well as the increasing incidence of EPSs as the dose increases for olanzapine and ziprasidone, together with PET studies of DA receptor occupancy previously discussed, strongly suggests that lower D2 receptor occupancy, possibly in relation to high 5-HT_{2A} receptor is necessary to avoid EPSs with these compounds.

As previously discussed, numerous compounds of diverse chemical structure that share this pharmacologic profile have been identified or deliberately synthesized and tested for antipsychotic action and EPS liability. These include risperidone, olanzapine, sertindole, quetiapine, ziprasidone, and iloperidone. All of these compounds can produce fewer EPSs than haloperidol at comparable doses. Clozapine and quetiapine have been shown to produce the least EPSs in studies of patients with Parkinson's disease. Consistent with this concept, the 5-HT_{2A} antagonist mianserin has been reported to be effective in neuroleptic-induced akathisia (118). There are also a variety of preclinical data to support the importance of relatively high 5-HT_{2A} compared to D2 receptor affinity to preserve striatal function. For example, Ishikane et al. (119) reported that M100907 is able to block haloperidol-induced catalepsy only at low doses of haloperidol. Consistent with this, Spampinato et al. (120) reported that specific 5-HT_{2A} and 5-HT_{2C} antagonists were able to modulate the ability of haloperidol at 0.01 mg/kg but not at a higher dose (1.0 mg/kg) to increase striatal DA release in freely moving rats.

THE ROLE OF THE 5-HT_{2C} RECEPTOR IN ANTIPSYCHOTIC DRUG ACTION: 5-HT_{2A} AND 5-HT_{2C} INTERACTIONS

Part of "58 - Mechanism of Action of Atypical Antipsychotic Drugs "

There has been some consideration given to the role of 5-HT_{2C} receptors in the action of atypical antipsychotic drugs. The 5-HT_{2C} receptor is found throughout the central nervous system (CNS), including the ventral tegmentum and the nucleus accumbens (121). With the availability of specific 5-HT_{2C} agonists and antagonists, evidence for a tonic inhibitory action of 5-HT_{2C} receptors on the burst firing of mesolimbic and mesocortical dopaminergic neurons has been obtained. Thus, the firing rate of VTA DA neurons is inhibited or increased by 5-HT_{2C} agonists or antagonists, respectively. This is consistent with microdialysis studies that show that 5-HT_{2C} antagonists increase extracellular concentrations of DA in the nucleus accumbens, striatum, and medial prefrontal cortex (91 ,122). Early studies found no significant differences between groups of novel antipsychotic drugs and typical neuroleptics with regard to the affinity for 5-HT_{2C} receptor or the difference between 5-HT_{2C} and D2 affinities (22 ,60). Of the approved novel antipsychotic drugs, some have equivalent affinities for the 5-HT_{2A} and 5-HT_{2C} receptors (clozapine, olanzapine, sertindole), whereas others are more selective for the 5-HT_{2A} receptor (risperidone, quetiapine, ziprasidone). This difference roughly corresponds with the potential to produce weight gain, in that clozapine and olanzapine cause the greatest weight gain and risperidone and ziprasidone the least (see Chapter 56). There is little available data for sertindole and quetiapine, but they appear to be intermediate. There is no apparent relationship between 5-HT_{2C} affinity relative to 5-HT_{2A} affinity with regard to EPSs because quetiapine and ziprasidone are comparable to olanzapine and sertindole in this regard. Similarly, there is no apparent relationship to efficacy in treatment-resistant schizophrenia. There could be a relationship to differences among the atypical antipsychotic drugs with regard to improvement in specific types of cognitive function in schizophrenia (13).

An interesting aspect of the 5-HT_{2C} receptor with regard to antipsychotic action is that 5-HT_{2C} antagonism may be functionally opposed to 5-HT_{2A} antagonism. Meltzer et al. (123) reported that atypical antipsychotic drugs were more likely to be weak 5-HT_{2C} and potent 5-HT_{2A} antagonists compared to typical neuroleptic drugs. Subsequently, neurochemical (120) and behavioral (96 ,124) data have been reported that support the notion of a functional antagonism of these two receptors that may coexist on the same neurons. Thus, Martin et al. (95) found that ritanserin, a mixed 5-$HT_{2A/2C}$ antagonist, blocked the ability of M100907 to antagonize the effect of MK-801 to increase locomotor activity in mice.

THE ROLE OF THE 5-HT_{1A} RECEPTOR IN ANTIPSYCHOTIC DRUG ACTION

Part of "58 - Mechanism of Action of Atypical Antipsychotic Drugs "

The 5-HT_{1A} receptor is located pre- and postsynaptically. The presynaptic 5-HT_{1A} receptor is an autoreceptor located on cell bodies of raphe neurons; stimulation leads to inhibition of firing of 5-HT neurons. Stimulation of postsynaptic 5-HT_{1A} receptors generally leads to hyperpolarization of neurons, which is opposite of the effect of stimulation of 5-HT_{2A} receptors. There is extensive evidence that cannot be reviewed in detail here that indicates that 5-HT_{1A} receptor agonists and 5-HT_{2A} receptor antagonists produce similar neurochemical and behavioral effects on a variety of measures (125 ,126). For example, DOI injected bilaterally into the rat medial prefrontal cortex elicits a dose-dependent head twitch response. This effect is inhibited by M100907 and ketanserin, relatively selective for 5-HT_{2A} receptors at appropriate doses, but not the selective 5-HT_{2C} antagonist SDZ SER082. Pretreatment with the 5-HT_{1A} agonist 8-OH-DPAT also inhibited the head twitch response to DOI (127). Ahlenius (128) first suggested that stimulation

of 5-HT_{1A} receptors might produce an antipsychotic like action on the basis of behavioral studies in animals using the direct 5-HT_{1A} agonist 8-OH-DPAT. Subsequent studies demonstrated that 8-OH-DPAT enhanced the antipsychotic-like effect of the D2/D3 antagonist raclopride (129) and of haloperidol (130), and antagonized the catalepsy induced by the D1 agonist SCH23390 in rats (131). The ability of clozapine to reverse olanzapine-induced catalepsy is blocked by the selective 5-HT_{1A} antagonist WAY 100635, suggesting the effect of clozapine was mediated by stimulation of 5-HT_{1A} receptors. The beneficial effect of 5-HT_{1A} agonists appears to be mediated by inhibition of median raphe serotoninergic neurons (132).

5-HT_{1A} agonists have different regional effects on DA release in the rat brain. 5-HT_{1A} receptor stimulation appears to inhibit DA release in subcortical regions. Thus, Ichikawa et al. (133) demonstrated that the 5-HT_{1A} agonist 8-OH-DPAT inhibited the ability of amphetamine to increase extracellular DA levels in the nucleus accumbens and the striatum of conscious rats. The effect of 5-HT_{1A} receptor stimulation in the nucleus accumbens would be expected to enhance the antipsychotic effect of these agents by reducing dopaminergic activity. Several atypical antipsychotic drugs, including clozapine, ziprasidone, quetiapine, and tiospirone, are partial agonist at the 5-HT_{1A} receptor. Their affinities for the 5-HT_{1A} receptor are similar to their affinities for the human D2 receptor (22). Rollema et al. (134) demonstrated that the ability of clozapine to increase DA release in the rat prefrontal cortex was due, in part, to its 5-HT_{1A} agonist properties, as it could be blocked by WAY-100635, a 5-HT_{1A} antagonist. Ichikawa et al. (92) have extended these findings in a variety of ways; e.g., the ability of risperidone and the combination of M100907 and sulpiride to increase prefrontal cortical PFC DA efflux were both blocked by WAY100635. These findings suggest that the combination of D2 antagonism and 5-HT_{1A} agonism provides some of the key features of atypical antipsychotic agents. S16924, a 5-HT_{1A} partial agonist D2 antagonist, is an example of a putative atypical antipsychotic drug based on this model. It has atypical antipsychotic properties very similar to those of clozapine in a variety of relevant animal models (64). Whether this or similar compounds will have the same spectrum of efficacy and side effect advantages as the multireceptor antagonists that are relatively more potent 5-HT_{2A} than D2 antagonists remains to be determined. Significant differences should be expected. It is noteworthy that clozapine has both relatively more potent 5-HT_{2A} antagonism than D2 antagonism as well as 5-HT_{1A} partial agonism. This may be part of the mixture that accounts for its particular advantages over other atypical antipsychotic drugs. Wedzony et al. (135) found that WAY100135, a 5-HT_{1A} antagonist, attenuated the effect of MK-801, an NMDA antagonist on locomotor activity, prepulse inhibition, and the detrimental effect of MK-801, a noncompetitive NMDA antagonist on working memory and selective attention in rats. They cite other evidence that 5-HT_{1A} antagonists may improve learning and memory in animal models and suggest this may be due to blocking the inhibitory effects of 5-HT_{1A} receptor stimulation on the firing of hippocampal neurons. This suggests that a partial agonist, acting as an antagonist, may sometimes be of benefit with regard to effects relevant to schizophrenia.

THE ROLE OF SEROTONIN RELEASE IN ANTIPSYCHOTIC DRUG ACTION

Part of "58 - Mechanism of Action of Atypical Antipsychotic Drugs "

The antagonism of multiple 5-HT receptors by clozapine would be expected to enhance the release of 5-HT by feedback mechanisms. Thus, it is surprising that Ferré and Artigas (136) reported that clozapine decreased 5-HT release in the nucleus accumbens. However, Ichikawa et al. (137) reported that clozapine (20 mg/kg) and risperidone (1 mg/kg) significantly increased extracellular 5-HT levels in the nucleus accumbens and medial prefrontal cortex, respectively, whereas amperozide (1 and 10 mg/kg) increased extracellular 5-HT levels in both regions. Hertel et al. (138) reported similar results with risperidone and suggested that this might be relevant to its ability to improve negative symptoms. If so, this is not the explanation for the effects of clozapine or olanzapine on negative symptoms because olanzapine, sulpiride, haloperidol, and M100907 had no effect on extracellular 5-HT levels in either region. The latter consideration also indicates that blockade of 5-HT_{2A} receptors is not the basis for the ability of clozapine, risperidone, or amperozide to increase 5-HT levels. The enhancement of 5-HT efflux in the prefrontal cortex may contribute to the ability of these agents to improve mood disorders and cognition.

α_2- AND α_1-ADRENERGIC MECHANISMS AND ATYPICAL ANTIPSYCHOTIC DRUGS

Part of "58 - Mechanism of Action of Atypical Antipsychotic Drugs "

Most of the atypical antipsychotic drugs are potent antagonists of the α_1 or α_2 adrenoceptors, or both. Thus, risperidone 9-hydroxyrisperidone, clozapine, olanzapine, zotepine, quetiapine, ORG-5222, sertindole and ziprasidone are potent α_1 antagonists (22). Prazosin, an α_1 adrenoceptor antagonist, has, like clozapine and other atypical antipsychotic drugs, been shown to increase DA efflux in the shell but not the core of the nucleus accumben, signifying a limbic rather than a striatal effect of α_1 antagonism (91). These authors also suggested that α_1 antagonism may explain the atypical properties of sertindole, which has been reported to achieve as high an occupancy of D2 receptors as typical antipsychotic drugs (36). All of the atypical agents mentioned above are also potent α_2 antagonists, with the exception of zotepine and sertindole (22). Kalkman et al. (116) raised the possibility that the α_{2C} subtype may be particularly relevant to the anticataleptic as well as other actions of clozapine and iloperidone. However, McAllister and Rey (139) were unable to reverse the effects of loxapine or haloperidol

on catalepsy with α_2 antagonists and showed that the effect of clozapine to reverse loxapine-induced increase in catalepsy was due to its anticholinergic rather than its adrenoceptor blocking properties. Clozapine produces massive increases in plasma norepinephrine, which may indicate that it can cause effective stimulation of α-adrenoceptors receptors in brain (140). The addition of idazozan, an α_2 antagonist, to fluphenazine, a typical neuroleptic, was reported by Littman et al. (141) to have efficacy comparable to clozapine in a small group of neuroleptic-resistant patients with schizophrenia. These results need to be replicated. Idazoxan has also been shown to improve attentional and executive dysfunction in patients with dementia of the frontal type (142), suggesting that some of the cognitive enhancing effects of the atypical antipsychotic drugs might be related to their α_2 blocking properties. Another α_2 antagonist, atipamezole, has been reported to improve cognitive performance in aged rats (143). Polymorphisms of the α_1 and α_2 receptors have been reported not to predict response to clozapine (144).

In this regard, it is of interest that idazoxan has been shown to preferentially increase DA efflux in the rat mPFC by an action at the terminal area (145). This effect appears to be independent of dopaminergic activity (146). Westerink et al. (147) demonstrated that systemic administration of clozapine, risperidone, ziprasidone, and olanzapine, as well as haloperidol, produced a dose-dependent increase in noradrenaline in the mPFC of rats. This effect was closely coupled to the increase in DA efflux. Increased levels of norepinephrine might also be related to the cognitive and antidepressant effects of the atypical antipsychotic drugs (148 ,149).

CONCLUSION

Part of "58 - Mechanism of Action of Atypical Antipsychotic Drugs "

Typical neuroleptic drugs such as haloperidol have been reliably shown to produce their antipsychotic action by blockade of D2 receptors in the mesolimbic system, suggesting that increased dopaminergic activity in these terminal areas of the ventral tegmental DA neurons are of importance to the etiology of schizophrenia. Striatal D2 receptor antagonism is the critical element in the EPSs produced by these drugs. Atypical antipsychotic drugs are those antipsychotics that achieve an antipsychotic action with quantitatively less EPSs in humans or a clear distinction between doses that affect mesolimbic and striatal dopaminergic function in rodents. Clozapine was the first atypical antipsychotic drug by the definition noted above, but more importantly it showed that antipsychotic drugs might also be effective in some patients with schizophrenia whose positive symptoms do not respond to neuroleptic-type agents and to improve negative symptoms, cognitive impairment, depression, and possibly suicidality of schizophrenia and other psychotic disorders as well (150 ,151 and 152). There is strong evidence of the role of 5-HT_{2A} receptors and suggestive evidence of the roles of the 5-HT_{1A}, 5-HT_{2C}, and α_1 receptors in various actions of clozapine, risperidone, olanzapine, quetiapine, ziprasidone, iloperidone, sertindole, and related atypical antipsychotic drugs. Atypical antipsychotic drugs that are potent 5-HT_{2A} antagonists relative to their D2 receptor blocking property appear to potentiate 5-HT_{1A}-mediated effects on dopaminergic neurons in the mesocortical, mesolimbic, and mesostriatal regions. The effects in the mesocortical regions appear to be mediated by modulation of glutamate release from pyramidal neurons. These agents have been found to preferentially increase DA efflux in the mPFC compared to limbic and striatal regions. They also increase acetylcholine release in the PFC. Effects on 5-HT_{2C}, 5-HT_3, 5-HT_4, 5-HT_6, and 5-HT_7 receptors may also be relevant to some of their actions, e.g., improvement of cognition, weight gain, etc. Other models of atypicality appear to be effective, including partial DA agonists such as aripiprazole. Selective D2/D3 antagonists such as amisulpride may also have atypical properties. At this time, multireceptor agents appear to be more promising as antipsychotic agents for the majority of psychiatric patients because of important interactions between neural circuits that employ multiple neurotransmitters.

Neurochemical and Neuropharmacological Imaging in Schizophrenia

Daniel R. Weinberger

Marc Laruelle

Daniel R. Weinberger: Clinical Brain Disorders Branch, Intramural Research Program, National Institute of Mental Health, Bethesda, Maryland.

Marc Laruelle: Division of Functional Brain Mapping, New York State Psychiatric Institute; Departments of Psychiatry and Radiology, Columbia College of Physicians and Surgeons, New York, New York.

Over the last 15 years, the ability to measure specific molecules and proteins in the living human brain underwent enormous developments, opening direct windows into neurotransmitter functions and cellular processes associated with health and disease. These techniques are based either on the injection of radioactive moieties whose distribution is recorded with positron emission tomography (PET) or single photon emission computed tomography (SPECT), or on the direct detection of molecules based on their intrinsic magnetic properties with magnetic resonance spectroscopy (MRS).

Although lacking the level of resolution of postmortem studies and limited by the relatively small number of targets that can be currently studied *in vivo*, these imaging techniques provide unique opportunities for elucidation of pathophysiology associated with neuropsychiatric conditions. *In vivo* imaging techniques enable studying patients with well-documented psychopathology, relating biochemical observations to psychiatric symptoms and cognitive processes, and clarifying abnormalities associated with the disease as opposed to its treatment. Neurochemical imaging allows longitudinal studies to investigate mechanisms of actions and consequences of treatments, as well as to characterize neurochemical abnormalities in relation to treatment response and illness outcome. Neurochemical imaging further provides insight as to the pathophysiologic bases of alterations measured with flow and metabolism imaging studies, and can provide a direct link with animal models of the illness. Moreover, these techniques enable the study of patient's relatives, in order to clarify the endophenotypes associated with illness vulnerability. These potentialities are discussed in this chapter.

This chapter also critically summarizes results obtained using neurochemical imaging techniques in schizophrenia research, and the various insights on the pathophysiology and treatment of schizophrenia gained by these results. We first consider PET and SPECT investigations, and then MRS studies.

PET AND SPECT NEUROCHEMICAL IMAGING

Part of "59 - Neurochemical and Neuropharmacological Imaging in Schizophrenia "

The principles of PET and SPECT neurochemical imaging are reviewed elsewhere in this volume. Numerous PET and SPECT radiotracers are currently available to study key proteins in the living brain, such as receptors, transporters, and enzymes. Regarding schizophrenia, the majority of clinical investigations studied various aspects of dopaminergic transmission. Dopamine (DA) D2 receptors were the first neuroreceptors visualized in the living human brain (1). Since then, several DA-related radiotracers have been developed, allowing the study of many aspects of dopaminergic transmission (DA synthesis, DA release, D1 and D2 receptors, DA transporters). Given the availability of these tools and the important role that DA transmission is believed to play in schizophrenia, it is not surprising that most of the research effort focused on this system. Despite marked limitations, these studies provide a relatively consistent picture suggesting that schizophrenia, at least during periods of clinical exacerbation, is associated with dysregulation of DA transmission.

Imaging DA Transmission Parameters In Schizophrenia

The classic DA hypothesis of schizophrenia, formulated over 30 years ago, proposed that a hyperactivity of the dopaminergic transmission is associated with this illness (2 ,3).

This hypothesis was essentially based on the observation that all antipsychotic drugs provided at least some degree of D2 receptors blockade, a proposition that is still true today (4 ,5). As D2 receptor blockade is most effective against positive symptoms, the DA hyperactivity model appeared to be most relevant to the pathophysiology of positive symptoms. The fact that sustained exposure to DA agonists such as amphetamine can induce a psychotic state characterized by some salient features of positive symptoms of schizophrenia (emergence of paranoid delusions and hallucinations in the context of a clear sensorium) also contributed to the idea that positive symptoms might be due to sustained excess dopaminergic activity (6 ,7).

These pharmacologic effects indeed suggest, but do not establish, a dysregulation of DA systems in schizophrenia. For example, these observations are also compatible with the hypotheses that DA activity per se would be normal and increased only relatively to other systems that may be deficient, such as the glutamatergic or serotoninergic system (8 ,9). Under these conditions, D2 receptor blockade would reestablish a compromised balance between dopaminergic and glutamatergic or serotoninergic tone. Thus, these pharmacologic observations do not necessarily imply a specific disturbance of DA activity per se in the brain of patients with schizophrenia. Indeed, documentation of abnormalities of DA function in postmortem studies in schizophrenia has remained elusive (10 ,11 and 12). Because positive symptoms are mostly prominent in young patients and their intensity decreases with age, the ability to detect their biochemical correlates in postmortem studies (generally performed in older subjects) may be limited.

On the other hand, negative and cognitive symptoms are generally resistant to treatment by antipsychotic drugs. Functional brain imaging studies suggested that these symptoms are associated with prefrontal cortex (PFC) dysfunction (13). Studies in nonhuman primates demonstrated that deficits in DA transmission in PFC induce cognitive impairments reminiscent of those observed in patients with schizophrenia (14), suggesting that a deficit in DA transmission in the PFC might be implicated in cognitive impairments presented by these patients (15 ,16). In addition, a recent postmortem study described abnormalities of DA terminals in the PFC associated with schizophrenia (17). Thus, a current view on DA and schizophrenia is that subcortical mesolimbic DA projections might be hyperactive (resulting in positive symptoms) and that the mesocortical DA projections to the PFC are hypoactive (resulting in negative symptoms and cognitive impairment). Furthermore, these two abnormalities might be related, as the cortical DA system generally exerts an inhibitory action on subcortical DA systems (18 ,19).

The advent in the early 1980s of techniques based on PET and SPECT to measure indices of DA activity in the living human brain held considerable promise for investigating these questions.

Striatal D2 Receptor Density

Striatal D2 receptor density in schizophrenia has been extensively studied with PET and SPECT imaging. Studies comparing parameters of D2 receptor binding in patients with schizophrenia and healthy controls (*n* = 16 studies) are listed in Table 59.1 , and included a total of 228 patients (102 were neuroleptic-naive, and 126 were neuroleptic-free for variable periods of time). These patients were compared to 213 controls, matched for age and sex. Ten studies used PET and six studies used SPECT. Radiotracers included butyrophenones ([^{11}C]N-methyl-spiperone, [^{11}C]NMSP, *n* = 3, and [^{76}Br]bromospiperone, *n* = 3), benzamides ([^{11}C]raclopride, *n* = 3, and [^{123}I]IBZM, *n* = 5) or the ergot derivative [^{76}Br]lisuride, *n* = 2). A variety of methods and outcome measures were used to estimate D2 receptors density. Six studies used empirical ratio methods, i.e., the ratio of striatal to cerebellar activities at a given time after single bolus injection of the radiotracer. Five studies used model-based methods to measure the binding potential (BP), which is equal to the product of receptor density (B_{max}) and affinity ($1/K_d$). Five studies reported both B_{max} and K_d.

TABLE 59.1. IMAGING STUDIES OF D_2 RECEPTOR PARAMETERS IN DRUG NAIVE AND DRUG FREE PATIENTS WITH SCHIZOPHRENIA

Only two out of 13 studies detected a significant elevation of D2 receptor density parameters at a level *p* <.05. However, metaanalysis of the 16 studies reveals a small (on the order of 13%) but significant elevation of D2 receptors in patients with schizophrenia. If D2 receptor density did not differ between patients and controls (null hypothesis), one would expect approximately 50% of the studies to report lower D2 receptor levels in schizophrenics compared to controls. Instead, 12 out of 16 studies reported an increase (although not significant in 10 out of 12 cases), two reported no change, and only two studies reported a decrease in patients compared to controls. This distribution is unlikely (*p* <.05, sign test) under the null hypothesis. Moreover, under the null hypothesis, the effect sizes [mean value in schizophrenic group - mean value in control group/standard deviation (SD) in control group] should be distributed around 0. The average effect size of the 16 studies was 0.57 ± 0.78 (SD), and the probability to yield such effect size under the null hypothesis is again lower than .05. The aggregate magnitude of this elevation is thus 57% of the SD of controls. Given an average control SD of 23%, the effect is about 13%. To detect an effect size of 0.50 at the .05 significance level with a power of 80%, a sample of 64 patients and 64 controls would be needed. Clearly, none of the studies included enough patients to detect this small effect with appropriate power. Another observation is that the variability in the patient sample was larger than in the control sample in 13 out of 15 studies, which was also significant (*p* <.05, sign test). The average variance ratio (SD schizophrenics/SD controls) was 1.47 ± 0.58. The larger variance in patients compared to controls further increases the sample size needed to detect this small group difference with reasonable power.

No clinical correlates of increased D2 receptor binding parameters has been reliably identified. Thus, the simplest conclusions from these studies are that patients with schizophrenia show a modest elevation in D2 receptor density parameters of undetermined clinical significance, that all studies were underpowered, and that positive results occasionally reported (20 ,21) are due to a sampling effect. These conclusions are reached under the assumptions that all studies measured parameters from the "same" D2 receptors population.

However, there is another way to look at these data. Studies performed with butyrophenones (*n* = 6) have an effect size of 1.08 ± 1.06 (*n* = 6), whereas studies performed with other ligands (benzamides and lisuride, *n* = 10) have an effect size of 0.20 ± 0.26, a difference that is significant (*p* = .022). This observation suggests that schizophrenia might be associated with an increase in butyrophenone binding and no change in benzamide or lisuride binding.

Unfortunately, no studies have been reported in which the same subjects were scanned with both ligands. Such a study is warranted to directly test this view. Nevertheless, several hypotheses have been advanced to account for the existence of a differential increase in [^{11}C]NMSP binding *in vivo* in patient with schizophrenia in the face of normal benzamide binding. Because [^{11}C]raclopride and [^{123}I]IBZM binds to D2 and D3 receptors whereas [^{11}C]NMSP binds to D2, D3, and D4 receptors, this difference could reflect a selective elevation of D4 receptors in schizophrenia (22). This hypothesis has not been substantiated. The density of D4 receptors is negligible in the striatum, and, when measured with a specific ligand, not different in postmortem striatal samples from patients with schizophrenia and controls (23). Another hypothesis derives from the observation that D2 receptors, like several G-protein–coupled receptors, exist in monomers, dimers, and other oligomeric forms (24 ,25 ,26 and 27). Photoaffinity labeling experiments suggested that butyrophenones detect only monomers, whereas benzamides detect both monomers and dimers. Thus, increased butyrophenone binding and normal benzamide binding might reflect a higher monomer/dimer ratio in schizophrenia. This interesting hypothesis warrants further exploration. A third proposition evolved around the idea that the binding of these ligands would display different vulnerability to competition by endogenous DA (28 ,29). This proposition was based on two assumptions: (a) the concentration of DA in the proximity of D2 receptors might be higher in patients compared to controls, and (b) [^{11}C]NMSP might be less affected than [^{11}C]raclopride or [^{123}I]IBZM binding by endogenous DA competition. It follows that D2 receptor density measured *in vivo* with [^{11}C]raclopride and [^{123}I]IBZM would be "underestimated" to a greater extent in patients with schizophrenia than in control subjects. This hypothesis played an important role in bringing the endogenous competition concept to the attention of the imaging field.

Striatal DA Presynaptic Function

Imaging studies of presynaptic DA function in schizophrenia included measurements of dihydroxyphenylalanine (DOPA) decarboxylase activity, DA release at baseline and following pharmacologic challenges with amphetamine, and DA transporters (DAT). These studies are summarized in Table 59.2 .

Parameter	Study	Controls (*n*)	Patients (*n*) (DN/DF)	Radiotracer (/Challenge)	Method	Outcome	Controls (*n* Mean ± SD)[a]	Patients (*n* Mean ± SD)[a]	*p*	Effect Size[b]	Ratio SD

TABLE 59.2. IMAGING STUDIES OF PRESYNAPTIC DA PARAMETERS IN DRUG NAIVE AND DRUG FREE PATIENTS WITH SCHIZOPHRENIA

DOPA Decarboxylase Activity

Five studies reported rates of DOPA decarboxylase in patients with schizophrenia, using [^{18}F]DOPA (30 ,31 ,32 and 33) or [^{11}C]DOPA (34) (Table 59.2). Four out of five studies reported increased accumulation of DOPA in the striatum of patients with schizophrenia, and the combined analysis yielded an effect size of 0.92 ± 0.45, which is significantly different from zero (*p* = .01). The variability of the DOPA accumulation was larger in the schizophrenic group compared to the control group. Several of these studies reported the observation of high DOPA accumulation in psychotic paranoid patients, and low accumulation in patients with negative or depressive symptoms and catatonia. Although the relationship between DOPA decarboxylase and DA synthesis rate is unclear (DOPA decarboxylase is not the rate-limiting step of DA synthesis), these observations are compatible with higher DA synthesis activity of DA neurons in schizophrenia, at least in subjects experiencing psychotic symptoms.

Amphetamine-Induced DA Release

As discussed above, endogenous DA competition is a source of errors for *in vivo* measurement of D2 receptors. On the other hand, the recognition of this phenomenon implies that D2 receptor imaging, combined with pharmacologic manipulation of DA release, could provide a functional evaluation of DA presynaptic activity. Indeed, over the last decade, numerous groups demonstrated that acute increase in synaptic DA concentration is associated with decreased *in vivo* binding of [^{11}C]raclopride and [^{123}I]IBZM. These interactions have been demonstrated in rodents, nonhuman primates, and humans, using a variety of methods to increase synaptic DA [amphetamine, DAT blockers, levodopa (L-DOPA), nicotine agonists, serotonin receptor subtype 2A (5-HT_{2A}) antagonists, direct electrical stimulation of DA neurons] (see ref. 35 for review of this abundant literature). It has also been consistently observed that the *in vivo* binding of spiperone and other butyrophenones is not as affected as the binding of benzamides by acute fluctuations in endogenous DA levels (35).

The decrease in [^{11}C]raclopride and [^{123}I]IBZM *in vivo*

binding following acute amphetamine challenge has been well validated as a measure of the change in D2 receptor stimulation by DA due to amphetamine-induced DA release. Manipulations that are known to inhibit amphetamine-induced DA release, such as pretreatment with the DA synthesis inhibitor α-methyl-para-tyrosine (α-MPT) or with the DAT blocker GR12909 also inhibit the amphetamine-induced decrease in [^{123}I]IBZM or [^{11}C]raclopride binding (36 ,37). These experiments support the assumption that the amphetamine effect on [^{11}C]raclopride and [^{123}I]IBZM binding is mediated by DA release. Combined microdialysis and imaging experiments in primates demonstrated that the magnitude of the decrease in ligand binding was correlated with the magnitude of the increase in extracellular DA induced by the challenge (37 ,38), suggesting that this noninvasive technique provides an appropriate measure of the changes in synaptic DA levels.

Three out of three studies demonstrated that amphetamine-induced decrease in [^{11}C]raclopride or [^{123}I]IBZM binding was elevated in untreated patients with schizophrenia compared to well-matched controls (38 ,39 and 40). A significant relationship was observed between magnitude of DA release and transient induction or worsening of positive symptoms. The increased amphetamine-induced DA release was observed in both male and female patients, and in both first-episode/drug-naive patients and patients previously treated by antipsychotic drugs (41). Combined analysis of the results of two studies revealed that patients who were experiencing an episode of illness exacerbation (or a first episode of illness) at the time of the scan showed elevated amphetamine-induced DA release, whereas patients in remission showed DA release values not different from those of controls (41). This exaggerated response of the DA system to amphetamine exposure did no appear to be a nonspecific effect of stress, as higher self-reports of anxiety before the experiments were not associated with larger effect of amphetamine. Furthermore, nonpsychotic subjects with unipolar depression, who reported levels of anxiety similar to, if not higher than, the schizophrenic patients at the time of the scan, showed normal amphetamine-induced displacement of [^{123}I]IBZM (42).

These findings were generally interpreted as reflecting a larger DA release following amphetamine in the schizophrenic group. Another interpretation of these observations would be that schizophrenia is associated with increased affinity of D2 receptors for DA. Development of D2 receptors imaging with radiolabeled agonists is needed to settle this issue (42). Another limitation of this paradigm is that it measures changes in synaptic DA transmission following a nonphysiologic challenge (i.e., amphetamine) and do not provide any information about synaptic DA levels at baseline, i.e., in the unchallenged state.

Baseline DA Release

Several laboratories reported that, in rodents, acute depletion of synaptic DA is associated with an acute increase in the *in vivo* binding of [^{11}C]raclopride or [^{123}I]IBZM to D2 receptors (see ref. 35 for review). The increased binding was observed *in vivo* but not *in vitro,* indicating that it was not due to receptor up-regulation (43), but to removal of endogenous DA and unmasking of D2 receptors previously occupied by DA. The acute DA depletion technique was developed in humans using α-MPT to assess the degree of occupancy of D2 receptors by DA (43 ,44). Using this technique, higher occupancy of D2 receptor by DA was recently reported in patients with schizophrenia experiencing an episode of illness exacerbation, compared to healthy controls (45). Again assuming normal affinity of D2 receptors for DA, the data are consistent with higher DA synaptic levels in patients with schizophrenia. This observation was present in both first-episode/drug-naive and previously treated patients.

Following DA depletion, higher D2 receptor availability was observed in patients with schizophrenia compared to controls. This observation supported the proposition that, in schizophrenia, elevated D2 receptor density might be masked by DA occupancy when imaging studies are performed with ligands vulnerable to endogenous competition (28). However, the increase in D2 receptors measured with [^{123}I]IBZM in DA-depleted patients was moderate (12%), suggesting that other factors than vulnerability to endogenous DA competition are involved in the butyrophenone-benzamides binding differences discussed above.

Interestingly, higher occupancy of D2 receptors by DA in patients with schizophrenia was not associated with the intensity of positive symptoms, but was predictive of good therapeutic response of these symptoms following 6 weeks of treatment with atypical antipsychotic medications. The fact that high levels of synaptic DA at baseline predicted better or faster response to atypical antipsychotic drugs suggested that the D2 receptor blockade induced by these drugs remains a key component of their initial mode of action.

DA Transporters

The data reviewed above are consistent with higher DA output in the striatum of patients with schizophrenia, which could be explained by increased density of DA terminals. Because striatal DATs are exclusively localized on DA terminals, this question was investigated by measuring binding of [^{123}I]-CIT (46) or [18F]CFT (48) in patients with schizophrenia. Both studies reported no differences in DAT binding between patients and controls. In addition, Laruelle et al. (46) reported no association between amphetamine-induced DA release and DAT density. Thus, the increased presynaptic output suggested by the studies reviewed above

does not appear to be due to higher terminal density, an observation consistent with postmortem studies that failed to identify alteration in striatal DAT binding in schizophrenia (47 ,48 ,49 ,50 ,51 and 52).

Subcortical DA Dysregulation as a Failure of Inhibitory Pathways

Although the studies reviewed above generally confirmed the classic DA hypothesis of schizophrenia, it is important to examine these results in light of the more recent views of schizophrenia as a neurodevelopmental illness, involving dysconnectivity of multiple cortico-subcortical and intracortical networks. Although it cannot be definitively ruled out that the DA dysregulation revealed by these studies would stem from a primary abnormality of DA neurons, it seems more likely that these abnormalities are a consequence of cortico-subcortical dysconnectivity. Moreover, given the weight of evidence implicating PFC connectivity as a central deficient node in the schizophrenic brain, it is tempting to speculate that dysregulation of DA neurons' firing activity might stem from a failure of the PFC to regulate this process. In fact, it has long been hypothesized that dysregulation of subcortical DA function in schizophrenia may be secondary to a failure of the PFC to adequately control subcortical dopaminergic function (53 ,54).

Activity of midbrain DA neurons is under dual influence of PFC via an activating pathway (the “accelerator”) and an inhibitory pathway (“the brake”), allowing fine-tuning of dopaminergic activity by the PFC (55). The activating pathway is provided by direct glutamatergic projections onto the dopaminergic cells. The inhibitory pathway is provided by glutamatergic projections to midbrain γ-aminobutyric acid (GABA)ergic interneurons or striatomesencephalic GABA neurons. The inhibition of dopaminergic cell firing following amphetamine is an important feedback mechanism by which the brain reduces the effect of amphetamine on DA release. The inhibition of dopaminergic cell firing induced by amphetamine is mediated both by stimulation of presynaptic D2 autoreceptors and by stimulation of this inhibitory pathway (56). Following administration of amphetamine (i.e., under conditions in which the inhibitory pathway should be activated), *N*-methyl-D-aspartate (NMDA) receptor blockade results in a failure of activation of the inhibitory pathway, resulting in exaggerated amphetamine-induced DA release (57). Kegeles et al. (58) recently confirmed this mechanism in humans: ketamine pretreatment significantly enhanced amphetamine-induced decrease in [^{123}I]IBZM BP, from -5.5 ± 3.5% under control conditions to -12.8 ± 8.8% under ketamine pretreatment (p = .023). The increase in amphetamine-induced DA release induced by ketamine (greater than twofold) was comparable in magnitude to the exaggerated response seen in patients with schizophrenia. These data are consistent with the hypothesis that the alteration of DA release revealed by the amphetamine challenge in schizophrenia results from a disruption of glutamatergic neuronal systems regulating dopaminergic cell activity and are consistent with the hypothesis that schizophrenia might be associated with NMDA receptor hypofunction (59 ,60 and 61).

The failure of glutamatergic control of DA release might stem from mechanisms other than NMDA hypofunction. For example, glutamatergic projections from the PFC to the ventral tegmental area (VTA) are under tonic inhibition by prefrontal GABA and DA activity (see ref. 62 and references therein). It follows that deficits in GABAergic or dopaminergic function in the PFC (both deficits also implicated in schizophrenia) are expected to have similar consequences to an NMDA deficiency on the subcortical DA response to amphetamine. Thus, in patients with schizophrenia, various or multiple mechanisms (NMDA receptor hypofunction, GABAergic or dopaminergic deficits in the PFC) may lead to the dysregulation of subcortical DA revealed by the amphetamine challenge.

As reviewed below, direct evidence has been provided that disinhibition of subcortical DA activity is associated with prefrontal pathology in schizophrenia. In patients with schizophrenia, low *N*-acetylaspartate (NAA) concentration in the dorsolateral prefrontal cortex (DLPFC), a marker of DLPFC pathology, is associated with increased amphetamine-induced DA release (63). Studies in primates have documented the consequences of neurodevelopmental alteration in PFC connectivity on subcortical DA release (64 ,65). Adult rhesus monkeys with neonatal ablation of the amygdala-hippocampal formation within 3 weeks of birth exhibit lower NAA concentration in the PFC and abnormal relationships between prefrontal and subcortical DA functions; whereas local perfusion of amphetamine into the PFC induced a decrease in striatal DA in control monkeys and in monkeys with adult lesions, PFC amphetamine perfusion increased striatal DA release in monkeys with neonatal lesions. This study documents that dysregulation of subcortical DA function might be a delayed and enduring consequence of neurodevelopmental abnormalities of PFC connectivity.

Positive Symptoms and Neuroplasticity

The fluctuating nature of the DA abnormalities documented by the imaging studies reviewed above implies that some level of neuroplasticity is involved in the emergence of this increased subcortical DA activity during episodes of illness exacerbation (66). Neurochemical sensitization of mesolimbic DA systems has been proposed by several authors as one mechanism that might underlie the progression of a “silent” vulnerability into an overt symptomatology (67 ,68 ,69 ,70 and 71). Sensitization of DA systems is a positive feedback loop, in which increased DA activity leads to more DA

activity (70 ,72). During late adolescence, the failure of cortical development associated with schizophrenia liability might limit the brain capacity to modulate stress-related increased activity of mesolimbic DA neurons. This failure of normal homeostatic and buffering mechanisms would result in an increased vulnerability of DA neurons to develop a process of endogenous sensitization, a response not observed in humans under normal circumstances. The endogenous sensitization process drives the prodromal and initial phases of the illness, characterized by increased DA activity and culminating in the expression of positive symptoms. Sustained D2 receptor blockade interrupts this positive feedback loop. Upon neuroleptic discontinuation, the brain becomes again vulnerable to the stress-induced reemergence of this endogenous sensitization process and clinical relapse.

It should be emphasized that the relationship between stimulation of D2 receptors and psychotic symptoms is complex and presumably also involves neuroplasticity. NMDA antagonists such as ketamine or 5-HT_{2A} agonists such as lysergic acid diethylamide (LSD) induce psychotic symptoms in healthy subjects immediately upon drug exposure. In contrast, sustained administration of DA agonists is required to induce psychotic symptoms in healthy subjects (7 ,73). This observation suggests that sustained overstimulation of D2 receptors leads to remodeling of prefrontal-ventrostriatal-thalamic-prefrontal loops and their modulation by hippocampal afferents projections, neuronal ensembles that are believed to underlie the psychotic experience (74 ,75). In the amphetamine studies, DA-mediated stimulation of D2 receptors explained only about 30% of the variance in the positive symptom change in untreated patients with schizophrenia (41), indicating that factors downstream from the DA synapse play a role in the exacerbation of these symptoms following amphetamine. In the α-MPT study, global severity of positive symptoms did not correlate with occupancy of striatal D2 receptors by DA (45), suggesting that, in some patients, the experience of positive symptoms is no longer (or has never been) dependent on DA overstimulation. Patients with psychotic symptoms in the presence of apparently normal DA function failed to show significant improvement in these symptoms following 6 weeks of D2 receptor blockade (45). Thus, although these imaging studies have generally confirmed the time-honored dopamine hypothesis of schizophrenia, they also contributed to pointing out the limitations of an oversimplified model linking psychosis and excess DA activity.

Prefrontal DA D1 Receptor Density

As discussed above, several lines of evidence from preclinical, clinical, and postmortem studies converge to suggest that a deficiency in DA transmission in the prefrontal cortex is involved in the pathophysiology of negative symptoms and cognitive impairment in schizophrenia (14 ,16). Furthermore, a deficient prefrontal DA function is a potential mechanism to account for the subcortical DA disinhibition discussed above, as cortical DA function has an inhibitory impact on subcortical DA function (18 ,19). *In vivo* measurement of prefrontal DA function would provide the tools to directly test these hypothesis.

The majority of DA receptors in the PFC are of the D1 subtype (76 ,77). At the ultrastructural level, they are mostly located on pyramidal spines, and are mostly abundant on the distal dendrites (78 ,79 and 80). In postmortem studies, no evidence was found of an alteration in D1 receptors in the DLPFC of patients with schizophrenia (81 ,82), and the expression of the D1 receptor gene is unaltered (83). In contrast, a PET study with [^{11}C]SCH 23390 reported decreased density of D1 receptors in younger patients with schizophrenia (84). No significant differences were found in the other regions examined (anterior cingulate, temporal, occipital, and striatum). In addition, low-PFC D1 density was associated with the severity of negative symptoms and poor performance on the Wisconsin Card Sort Test (WCST). This finding is important, because it represents the first direct evidence of an association between negative symptoms, working memory deficits, and selective alteration in prefrontal DA function. However, the camera used in this study had a limited resolution, and the low specific to nonspecific ratio of [^{11}C]SCH3390 makes the measurement of D1 receptor in PFC with this ligand quite vulnerable to noise (85). Several groups are currently attempting to replicate this finding, using better cameras and a superior D1 receptor radiotracer, [^{11}C]NNC 112 (86).

In addition, measurement of receptor availability reveals only one aspect of neurotransmission. As D1 receptors are the most abundant DA receptors in the PFC, the availability of a D1 receptor radiotracer vulnerable to competition by endogenous DA (i.e., a D1 receptor "[^{11}C]raclopride") would be invaluable to assess presynaptic DA function in the PFC. Unfortunately, such a ligand is currently lacking (87 ,88).

Studies of Nondopaminergic Receptors in Schizophrenia

Receptors related to the GABA and 5-HT systems have been studied *in vivo* in schizophrenia. Postmortem studies reported abnormalities of both systems in schizophrenia. A robust body of findings suggests deficiency of GABAergic function in the PFC in schizophrenia (see refs. 89 and 90 for reviews). *In vivo* evaluation of GABAergic systems in schizophrenia has so far been limited to evaluation of benzodiazepine receptor densities with SPECT and [^{123}I]iomazenil, and three out of three studies comparing patients with schizophrenia and controls reported no significant regional differences (91 ,92 and 93). Although some significant correlations with symptoms clusters and regional benzodiazepine densities have been observed (91 ,92 ,94 ,95), these relationships

have not been replicated by other studies. Thus, together, these studies are consistent with an absence of marked abnormalities of benzodiazepine receptor concentration in the cortex and patients with schizophrenia. Alterations of GABAergic systems in schizophrenia might not involve benzodiazepine receptors (96), or be restricted to certain cortical layers or classes of GABAergic cells that are beyond the resolution of current radionuclides based imaging techniques. Recent developments in GABA imaging with MRS (described below) are a promising new avenue to study *in vivo* GABAergic function in schizophrenia.

Abnormalities of 5-HT transporters (SERT), 5-HT_{2A} receptors and, more consistently, 5-HT_{1A} receptors have been described in postmortem studies in schizophrenia (see references in ref. 97). Given the relatively recent development of radiotracers to study 5-HT receptors, only a limited number of imaging studies have been published. The concentration of SERT in the midbrain measured by [^{123}I]β-CIT is unaltered in patients with schizophrenia (46). Studies with more specific ligands are warranted to assess the distribution of SERT in other brain areas, such as the PFC, where their density has been reported to be reduced in three out of four postmortem studies (97). Decrease in 5-HT_{2A} receptors has been reported in the PFC in four out of eight postmortem studies (97 ,98). Three PET studies in drug-naive or drug-free patients with schizophrenia reported normal cortical 5-HT_{2A} receptor binding (98 ,99 and 100), whereas one study reported a significant decrease in PFC 5-HT_{2A} binding in a small group (*n* = 6) of drug-naive schizophrenic patients (101). The most consistent abnormality of 5-HT parameters reported in postmortem studies in schizophrenia is an increase in the density of 5-HT_{1A} receptors in the PFC, reported in seven out of eight studies (97). Several groups are currently evaluating the binding of this receptor *in vivo* with PET and [^{11}C]WAY100907.

Receptor Occupancy By Antipsychotic Drugs

Maybe the most widespread use of neuroreceptor imaging in schizophrenia over the last decade has been the assessment of neuroreceptor occupancy achieved by typical and atypical antipsychotic drugs, a topic that has been the subject of recent reviews (102 ,103). Neuroreceptor studied included essentially D2 receptors, but also 5-HT_{2A} and D1 receptors. The main conclusions from this line of research are as follows: (a) Studies repeatedly confirmed the existence of a threshold of occupancy of striatal D2 receptors (about 80%) above which extrapyramidal side effects are likely to occur (104). (b) In general, studies failed to observe a relationship between degree of D2 receptor occupancy and clinical response (105 ,106). Yet, most studies were performed at doses achieving more than 50% occupancy, and the minimal level of occupancy required for therapeutic response remains undefined. Two studies performed with low doses of relatively selective D2 receptor antagonists (haloperidol and raclopride) suggested that 50% to 60% occupancy was required to observe a rapid clinical response (107 ,108). (c) Clozapine, at clinically therapeutic doses, achieved only 40% to 60% D2 receptor occupancy (104 ,106 ,109), which, in conjunction with its anticholinergic properties, accounts for its low liability for extrapyramidal symptoms (EPSs). (d) Occupancy of 5-HT_{2A} receptors by "5-HT_{2A}/D2 balanced antagonists" such as risperidone does not confer protection against EPS, because the threshold of D2 receptor occupancy associated with EPS is not markedly different between these drugs and drugs devoid of 5-HT_{2A} antagonism (110 ,111 ,112 and 113). (e) Studies with quetiapine suggested that, at least with this agent, transient high occupancy of D2 receptors might be sufficient to elicit clinical response (114 ,115).

An interesting question relates to putative differences in degree of occupancy achieved by atypical antipsychotic drugs in striatal and extrastriatal areas. Pilowsky et al. (116) reported lower occupancy of striatal D2 receptors compared to temporal cortex D2 receptors in seven patients treated with clozapine, using the high-affinity SPECT ligand [^{123}I]epidipride. In contrast, typical antipsychotics were reported to achieve similar occupancy in striatal and extrastriatal areas, as measured with [^{11}C]FLB 457 (117) or [^{123}I]epidipride (118). It should be noted, however, that these very high affinity ligands do not allow accurate determination of D2 receptor availability in the striatum. In contrast, [^{18}F]fallypride enables accurate determination of D2 receptor availability in both striatal and extrastriatal areas (119), and preliminary PET experiments in primates with [^{18}F]fallypride indicate that clozapine and risperidone achieve similar D2 receptor occupancy in striatal and extrastriatal regions (120). Finally, it is important to point out that the most robust evidence relative to the site of therapeutic effect of antipsychotic drugs in rodents points toward the nucleus accumbens (121 ,122), whereas the imaging studies reviewed above contrasted striatal versus mesotemporal D2 receptor binding. Improved resolution of PET cameras currently allows dissociating signals from ventral and dorsal striatum (123 ,124), and it is now feasible to specifically study the clinical correlates of D2 receptor occupancy in ventral striatum in humans.

Another unresolved question is the discrepant values of D2 receptor occupancy obtained with [^{11}C]raclopride versus [^{11}C]NMSP. The haloperidol plasma concentration associated with 50% inhibition of [^{11}C]NMSP binding (3 to 5 mg/mL) (125) is ten times higher than that associated with 50% inhibition of [^{11}C]raclopride binding (0.32 ng/mL) (126). Quetiapine, at a dose of 750 mg, decreased [^{11}C]raclopride-specific binding by 51%, but failed to affect [^{11}C]NMSP-specific binding (127). These observations contribute to the debate regarding differences between benzamides and butyrophenones binding to D2 receptors.

Future Developments

Despite the remarkable achievements of the last decade, imaging neurosignaling processes with PET and SPECT in schizophrenia are still limited by the relative low number of probes available. For example, despite major research efforts, direct measurement of parameters of glutamate transmission are still not available. Radiotracers enabling evaluation of second messengers and intracellular pathways are only beginning to emerge (128). A growing collaboration between academic centers and industry currently holds the promise of increasing access to molecules for evaluation as candidate radiotracers.

Studies of the DA systems in schizophrenia illustrates how dynamic measurement of neurotransmission can be more informative than simple measurement of receptor density. With the exception of the cholinergic system (129 ,130), the paradigm used with [^{11}C]raclopride and [^{123}I]IBZM has been difficult to extend to other neuroreceptor systems, maybe because the fundamental mechanisms underlying acute change in *in vivo* binding following transmitter fluctuations are still not perfectly understood (66). Additional research is warranted to better characterize the factors that confer vulnerability of radiotracers *in vivo* binding to functional status of neurotransmission.

Finally, a general limitation of these radionuclide-based techniques is the technical sophistication required as well as the high cost of these investigations. However, the growing success of PET in oncology results in a larger availability of PET cameras for neuropsychiatric clinical and basic research. This growing availability should be associated with a vigorous research effort toward the development of more F-18 based probes, since the relatively longer half-life of F-18 compared to C-11 does not require that these ligands be radiolabeled locally. For SPECT, the development of technetium-based neuroreceptor ligands (131) will further enhance the availability of these techniques to the nuclear medicine community.

MAGNETIC RESONANCE SPECTROSCOPY

Part of "59 - Neurochemical and Neuropharmacological Imaging in Schizophrenia "

Magnetic resonance spectroscopy (MRS) is a chemical assay technique. It is the only clinically available method for the direct measurement of chemical moieties in the living brain. MRS is based on the same physical principles as magnetic resonance imaging (MRI), which involves characterizing atoms and molecules based on how they interact with a magnetic field. This interaction occurs because the nuclei of atoms with an odd number of nucleons (i.e., protons and neutrons), such as ^{1}H, ^{19}F, ^{13}C, ^{7}Li, ^{23}Na, have angular momentum, so-called spin, which generates a small magnetic field around the nucleus. The spin properties of specific atoms and of the specific molecules that they compose are unique and are exploited in an MRS experiment.

When a strong external magnetic field is applied to a tissue (e.g., the main magnet of an MR scanner), nuclei with spin align themselves with the external field and assume an equilibrium state of net magnetization, which is proportional to the strength of the field and the spin properties of the nucleus. An MRS experiment involves four steps, analogous to an MRI procedure. First, specific nuclei are excited with a brief “pulse” of a radiofrequency (RF) magnetic field supplied by an RF transmitter coil. This excitation causes magnetized spins to transiently assume a higher energy state, from which they “relax” to a lower energy state of equilibrium magnetization. Because the energy states are quantitized, only specific RFs will excite the nucleus to another state and only these frequencies will be emitted during relaxation (“resonance”). These resonant frequencies are unique for each atom, and vary in proportion to the strength of the external field. The motion of spins in the process of returning to equilibrium (“relaxation”) induces a current in a receiver coil, which represents the MR signal.

The second step involves spatially encoding the signal so that its origin can be mapped to a particular locale in the field of view. This is accomplished with the application of linear magnetic gradients that add localizing characteristics to the signal. The third step involves translating the signal acquired over time into a representation of its component frequencies and amplitudes, the so-called Fourier transformation. The fourth step involves the mathematical and statistical analyses of the data.

In MRI, the signal used to reconstruct images is from hydrogen atoms (^{1}H), which are found in many molecules, but most abundantly in water and lipids. Although the signal from hydrogen contains frequencies corresponding to many different molecules, the water and lipids signals dominate and the signals from hydrogen in other molecules are ignored. MRS, however, is based on resolving these other molecular signals. These molecules are identifiable because of the phenomenon called “chemical shift.” The electron cloud that surrounds the nucleus of an atom partially shields the nucleus from the external magnetic field. This shielding effect will cause the nucleus to experience a slightly different external field, and thus to resonate at a slightly shifted frequency. Because the degree of shielding varies from one molecule to another, depending on the electron sharing of the chemical bonds in the molecule, the exact shift in the resonant frequency of a target nucleus (e.g., ^{1}H, ^{31}P) will reflect its chemical environment. In addition to electron shielding, complex interactions between neighboring spins (“j-coupling”) also may affect the resonant frequency of a nucleus in certain molecules. A Fourier transformation of the emitted signal resolves the various components of the signal into a spectrum having peaks of specific frequency and amplitude, each peak corresponding to a different chemical environment of the target nucleus. The area under the peak is directly proportional to the concentration of spins having that frequency, and thus of that specific chemical

moiety. It is customary to label peaks in the spectrum based on their relative displacement (“chemical shift”) in parts per million from a standard peak (e.g., in the proton spectra, water is assigned a value of 4.75), with higher frequencies to the left. The use of relative shift units allows for peaks to be identified regardless of the strength of the magnet. This also makes it possible to compare *in vivo* and *in vitro* data to establish the chemical identity of each peak.

In schizophrenia research, MRS has been used to approach four general topics: (a) assays of brain chemicals, (b) evidence of tissue pathology, (c) functional analysis of specific neuronal populations, and (d) drug effects. Before considering the results of these efforts, it is important to consider some general methodologic issues that are germane to the MRS literature.

MRS Methodology

MRS is a methodologically complex technique that requires many quality control steps, both at the front end in data collection and at the back end in data analysis. It is not a turnkey technique, and careful scrutiny of the raw data is essential in every experiment. There are no absolute standards for the quality of spectral data, e.g., for the sharpness of a peak, or the degree of noise in the baseline. Nevertheless, spectra derived from a particular atom (e.g., ^{1}H or ^{19}F) have a characteristic pattern, with sharp peaks at defined relative frequencies, appropriate separation of peaks, acceptable signal to noise, and a stable baseline. Because the goal of MRS is to assay the concentrations of chemicals that are in the range of three to five orders of magnitude less abundant than water, it is necessary to make compromises to maximize the signal-to-noise ratio (SNR) in the data. One of the first decisions to be made in an MRS experiment is how to sample from the brain. Most MRS studies in the schizophrenia literature have sampled from relatively large (5 to 80 mL) single volume elements (“voxels”), though so-called MRS imaging (MRSI) approaches have also been utilized. The single-voxel approach benefits from enhanced signal-to-noise (STN) and reduced scanner time (5 to 20 minutes per voxel), but it suffers from imprecise and limited anatomic localization, contamination from signal outside of the voxel, and, most importantly, partial volume averaging. Large voxels contain multiple tissue compartments, including cerebrospinal fluid (CSF), white matter, gray matter, and vascular tissue, which have different concentrations of chemical constituents. Thus, the signals from a voxel are the average of signals from all of these compartments. Although there are statistical procedures aimed at “segmenting” these compartments within a voxel, such procedures are rough approximations (132). One of the fundamental difficulties in comparing data from single-voxel studies between subject groups and across studies in the literature is uncertainty about the comparability of voxel characteristics. ^{1}H-MRSI studies generally employ smaller voxels (<1.5 mL) and have the advantage of being more anatomically precise. This means that regions based on known anatomy, rather than arbitrary voxel placement, can be compared. There also are less partial volume effects. However, because of the smaller voxels, imaging studies have reduced SNR and require longer scanner times (20 to 60 minutes for a multislice study).

Because the amplitudes and frequencies of peaks in a spectrum are critically dependent on the magnetic field surrounding a target nucleus, magnetic field uniformity within a voxel and between voxels is essential. Field homogeneity is routinely honed with “shimming” procedures. It is also possible to make additional corrections based on field mapping, which corrects for frequency shifts between voxels. Most studies in the literature have used shim procedures supplied by the manufacturer of the scanner, and it is doubtful that these procedures have been optimal and comparable across studies (133). Coil design is another important parameter in data acquisition and STN. Small surface coils have been used in many of the phosphorus spectroscopy studies, because they improve SNR. However, surface coils introduce potential variance in studies that compare signals from specific locales across individuals. This is because as transmitters, surface coils excite spins with a gradient of intensity from the surface, and again as a receiver, the sensitivity drops off across the volume of activated tissue. Clearly, differences in coil placement and in head geometry may contribute to variations in the data.

There has been much discussion in the MRS literature about absolute quantification of chemical concentrations. In practice, this is almost impossible to do. References in the schizophrenia MRS literature to studies that have employed absolute quantification are inaccurate, as all studies have employed some normalization procedure, often based on measures acquired in normal subjects. To accurately measure absolute concentration of a chemical peak, it is necessary to control for all the variables that will affect the amplitude of the peak from a given voxel. These include factors that affect field homogeneity, relaxation times of the molecule(s) responsible for the peak, transmission efficiency and reception sensitivity of the RF coil (“coil loading”), and partial volume effects. These characteristics vary across the brain within an individual and between individuals even in the same locale in the brain. Moreover, any attempt to control for these factors assumes that the voxel remains in place, i.e., that the subject does not move during the scan, which is difficult for many individuals. Thus, even with the help of absolute standards for calibration, it is very difficult to correct for differences in these parameters (134). All studies to date have employed some normalization routine, whether to noise in the baseline, to the total observed signal, to another metabolite in the spectra, or to a signal from a molecule in the spectra that is thought to be metabolically neutral (e.g., water in the ^{1}H spectra). Although each of these normalization procedures involves assumptions and trade-offs, they attempt to control for unavoidable variations

in the local field, in coil loading, in relaxation times, and, to a lesser extent, for partial volume averaging effects. A further discussion of technical issues involved in collecting and analyzing MRS data is available in several reviews of the topic (135 ,136 and 137).

^{31}P Spectroscopy: Assays Of Phospholipids And High Energy Phosphates

The first *in vivo* MRS study of schizophrenia was of ^{31}P spectra. At clinical MR field strength (1.5 to 4.0 tesla), the ^{31}P spectrum contains several peaks across a wide chemical shift range [approximately 30 parts per million (ppm)]. The major metabolite peaks represent resonances for (a) phosphomonoester (PME) compounds (at 6.5 ppm), which includes phosphocreatine, phosphorylethanolamine; (b) phosphodiesters (PDE, 2.6 ppm), which include glycerolphosphocholine, glycerolphosphoethanolamine, and various membrane phospholipids; (c) phosphate residues on adenosine triphosphate (ATP) (-16.3 ppm for beta, -7.8 for alpha, and -2.7 for gamma); (d) inorganic phosphate at 4.9 ppm; and (e) phosphocreatine, which, as the chemical shift standard, has a resonance set at 0 ppm. PME concentrations, which are thought to reflect in part membrane precursors, increase with tissue growth, including in early brain development and gliomas, but also with tissue destruction, e.g., in Alzheimer's disease and HIV. In white matter, however, PMEs are metabolites of both synthesis and breakdown of sphingomyelin. PDEs are thought to reflect in part products of membrane breakdown and have been shown to be decreased in certain brain tumors and to increase shortly after birth. However, both PME and PDE peaks include other phosphorylated proteins associated with cell organelles and with membrane phospholipids that are not clearly related to membrane turnover. This fact is underscored by studies of patients with Huntington's disease (138) and of at least some patients with Alzheimer's disease (139), which have observed no abnormalities in these metabolites. Thus, changes in PME and PDE peaks are not easily interpreted. The phosphocreatine (PCr), ATP, and Pi peaks confer information about the state of high-energy phosphate metabolism and pH in the tissue. It also should be noted that because ^{31}P spectra are acquired with large voxels (i.e., 15 to 80 cm^3), the relative contributions of various tissue components (i.e., gray matter, white matter, neurons, glia, endothelia) to the signal is uncertain.

O'Callaghan and colleagues (140) reported the first ^{31}P spectroscopy study in schizophrenia, on a sample of 18 patients and 10 control subjects. They used a surface coil to acquire data from 87-cm^3 voxels arbitrarily placed in both temporal lobes. There were no differences found in any of the peaks. Pettegrew et al. (141) reported a highly cited study of 11 first-episode patients, using a surface coil placed over the front of the head. They reported that their voxel of 20 cm^3 sampled the dorsolateral prefrontal cortex, though its exact location is unclear, as subsequent reports stated that both right and left prefrontal cortices were sampled (142). With only a single 20-cm^3 voxel, this would indicate a more midline localization. The investigators reported that patients had decreased PMEs and Pi, and increased PDEs and ATP. They interpreted their findings to reflect greater membrane turnover and less energy utilization, results that they speculated were consistent with hypotheses about excessive synaptic pruning and decreased frontal lobe metabolism.

Because of these initial reports, over fifteen ^{31}P studies of patients with schizophrenia have appeared in the literature. Although several studies have reported partial replication of the findings of Pettegrew et al. (141 ,142), particularly with respect to a reduced PME peak, the majority of the reports have failed to do so. The data with respect to high-energy phosphate peaks are especially inconsistent and generally negative. Studies that have looked outside the frontal lobe, at parietal and temporal lobes and at the basal ganglia, also have yielded most often negative or inconsistent results. Several recent reviews provide tabulated summaries of this literature (143 ,144). The reasons for the inconsistencies are unclear. The usual explanations—differences in patient sample (e.g., medicated or unmedicated, acute or chronic), differences in acquisition parameters (e.g., surface or volume coil, single voxel, or multivoxel)—seem inadequate, as both positive and negative reports have appeared regardless of the characteristics of the samples and in the context of a variety of acquisition parameters. A more likely explanation for the inconsistencies involves the low sensitivity and reproducibility of ^{31}P spectroscopy and problems in achieving a standardized placement of a region of interest (ROI) or of an acquisition plane. There are very limited data about the reliability of ^{31}P measurements in patients, with one study reporting a coefficient of variation of 30% across two scans (145). Because it is impossible to accurately register single voxels or single planes to an anatomic reference, there is unavoidable error in the localization process, which is further compounded by subject motion during the scan. Large voxel sizes also introduce error in terms of partial volume effects. The small differences that have been reported in most of the positive studies, on the order of 10% to 25%, would seem especially sensitive to such methodologic difficulties.

Two recent studies are particularly noteworthy in their efforts to control for localization variance and to improve the sensitivity of the spectral data. Volz et al. (146) acquired a plane of ^{31}P spectra, composed of 30 voxels of 19 cm^3 each, and drew ROIs on an anatomic reference scan that was acquired in a coplanar orientation, on 11 medication-free patients, including seven acute patients who were medication naive. Though the planes are not strictly registered in space, because subject motion may have tilted their relative orientations during the scans, the authors' approach to ROI

placement is more reliable than that in earlier studies. With the exception of one mesial prefrontal voxel having a decreased PDE peak and one voxel localized to the basal ganglia having a decreased PME peak, no other cerebral differences in phospholipids were found. Four prefrontal voxels having decreases in ATP and PCr also were found. The authors argued that their data suggested decreased membrane catabolism, but, given the number of voxels analyzed, chance results cannot be excluded. In an earlier study of chronic, medicated patients, they also found a decreased prefrontal PDE peak, but the high-energy phosphate data were in the opposite direction (147). Finally, Potwarka et al. (148), using signal enhancement techniques that reduce the effects of coupling between phosphorus and proton spins, were able to separate structural membrane phospholipids from other constituents of the PME and PDE peaks, with 50-cc voxels acquired as part of a plane. Although the authors found no decrease in PMEs as reported by Pettegrew et al., they did find increases in the frontal PDE peak, but not related to membrane breakdown products such as glycerophosphocholine (GPC) and glycerolphosphoethanolamine (GPE), as suggested by Pettegrew et al. and others. Rather, the difference was reflected in the membrane phospholipid components of the peak. These differences were not found in motor or occipital cortices, providing some evidence of internal validity. This study also found no differences between patients and controls in total PMEs, again in contrast to the Pettegrew et al. study, but a component of the PME peak, phosphocholine, was reduced. Potwarka et al. (148) proposed that their data implicated membrane abnormalities selectively in DLPFC, perhaps involving presynaptic vesicular phospholipids. However, to confuse the story even further, Bluml et al. (149), using a similar proton decoupled ^{31}P MRS approach, reported increases in GPC and GPE acquired with a large (97-cc) voxel in the middle of the cerebrum.

Several studies have attempted to link ^{31}P data to clinical characteristics of patients, but these also have been inconsistent. For example, Deicken et al. (150) reported a correlation between prefrontal PME signals and performance on the WCST, suggesting that prefrontal membrane abnormalities were reflected in prefrontal function. However, in the same patient sample, Deicken et al. did not find an abnormality of PME signals. Volz et al. (147) could not find a correlation between any ^{31}P signals and WCST performance. Potwarka et al. (148) found a correlation between an ATP peak in right prefrontal cortex and negative symptom ratings, but similar relationships were not found in other studies (151).

It is difficult to arrive at a synthetic analysis of the ^{31}P data in schizophrenia. Technical error is probably the critical factor in the variable results that have been reported. It is doubtful that the small differences between patients and controls could escape corruption by the many methodologic limitations of the current techniques. Future studies using higher field magnets, with better sensitivity and resolution, combined with signal enhancement and peak separation procedures may lead to more reliable methods.

Proton Spectroscopy: Assays of Cells and Cellular Metabolism

Proton spectroscopy has been a more widely applied technique in schizophrenia research and the results are much more consistent. A variety of chemicals in the proton spectrum can be assayed with clinical magnets, including several amino acids, membrane and myelin metabolites, and several high-energy substrates. Although the sensitivity of proton spectroscopy is approximately 20 times that of phosphorus, allowing for much better resolution, the metabolites of interest need to be resolved in a smaller chemical shift range (less than 10 ppm), in the presence of large concentrations of brain water (approximately 10^4 times greater concentration than the other metabolites) and mobile lipids from the skull and scalp. Until recently, most ^{1}H MRS techniques used special procedures to suppress the signal from water and lipids, procedures that can affect other signals. With the availability of analogue to digital converters having greater dynamic range, it is now possible to acquire the water signal and still resolve the other metabolites (152). In addition to preservation of neighboring signals, this approach also has the advantage of making the water signal available as an internal standard for normalization and potentially for tissue segmentation.

The proton spectrum is characterized by several relatively large and distinct peaks and several complexes of smaller overlapping peaks. The metabolite signals acquired with ^{1}H MRS vary depending on the echo time of the pulse sequence used for the acquisition. Many of the resolvable elements have short T2 (e.g., myoinositol, glutamate, glutamine, and GABA) and emit no observable signal with longer echo times. On the other hand, long echo time acquisitions produce signals from several compounds that are very distinctly resolved. The long echo time metabolite spectrum is dominated by a peak at approximately 2 ppm corresponding to the methyl group (CH_3) of several *N*-acetyl containing compounds, principally *N*-acetylaspartate (NAA) and to a small degree, *N*-acetyl aspartate glutamate (NAAG) and possibly *N*-acetylneuraminic acid (NANA) (134). NAA is an intracellular neuronal marker, found almost exclusively in mature neurons and their processes (153), with the highest concentrations in pyramidal glutamate neurons (154). NAA is the second most abundant amino acid in the brain (155). Its concentration is higher in gray matter than in white matter (156), and NAA signals increase during childhood, remaining relatively stable throughout adult life (156 ,157 and 158). The exact implications of changes in NAA signals is uncertain, as its cellular function is still unclear. It is synthesized in mitochondria from glutamate and either pyruvate or 3-hydroxybutyrate via L-aspartate-*N*-amino

transferase and also is a by-product of NAAladase catabolism of NAAG, which occurs within glia (159). Whether NAA signals are absolutely specific to neurons is unclear. Mature astroglia do not contain NAA, though small concentrations have been reported in oligodendroglial cultures (160). NAA is a nonspecific though highly sensitive marker of neuronal pathology. Virtually all neurologic conditions involving neuronal pathology that have been studied, including multiple sclerosis, motor neuron disease, Alzheimer's disease, Huntington's disease, cerebellar degenerations, multiple sclerosis, epilepsy, and various encephalopathies, show changes in NAA signals in the regions of brain pathology. Moreover, NAA changes are sensitive measures of dynamic neuropathologic processes (161 ,162 and 163), for example, correlating over time with cognitive change in Alzheimer's disease (164) and with the number of trinucleotide repeats in Huntington's disease (165). Although early studies interpreted NAA findings as indicative of cell loss, recent data have established that NAA reductions can reverse following various forms of brain damage and can change with clinical improvement and treatment (161 ,162 ,166 ,167 and 168). This has led to speculation that NAA reductions occur as a manifestation of changes in neuronal volume or in NAA concentrations within a neuron, perhaps reflecting reduced mitochondrial energy metabolism (159) or a change in the abundance and patterns of neuronal connectivity (169 ,170). It is interesting to note that in various conditions associated with tissue volume loss and reduced NAA signals (e.g., epilepsy, Alzheimer's disease, schizophrenia), these two parameters are not tightly correlated. The only condition in which NAA concentrations are increased is Canavan's disease, which involves a mutation in a gene on chromosome 17 controlling the synthesis of *N*-acetyl-L-aspartate amidohydrolase (aspartoacylase), the enzyme that breaks down NAA.

Two other prominent peaks are seen in the long echo time proton spectrum. At 3.2 ppm is a peak corresponding to the trimethylamine group of various choline (CHO)-containing compounds, mostly membrane phospholipids. This signal reflects the concentrations of several phospholipid moieties, including glycerophosphocholine, phosphocholine, and phosphatidylcholine. In pathologic conditions associated with membrane turnover or gliosis (e.g., Alzheimer's disease, gliomas, epilepsy), the CHO peak tends to be elevated. At 3.0 ppm, a peak corresponding to creatine and phosphocreatine (CRE) appears. These metabolites participate as energy buffers in many energy-consuming processes in the brain, but consistent changes in the CRE signal are generally found only in the presence of tissue loss.

At short echo time, several other peaks are observed, in addition to the peaks that persist into the long echo time spectra. The most studied of these is the myoinositol peak (3.6 ppm) and a peak complex (called tGlx) at around 2.2 to 2.4 and 3.75 ppm corresponding to overlapping signals from glutamate, glutamine, and GABA. Myoinositol is a hexol present in high concentrations in human brain, and accounts for most of the myoinositol peak, though other complex inositol phosphates also contribute to the signal. Some of these inositol phosphates may represent second-messenger signaling molecules that may vary with the state of cellular activity. The myoinositol peak, however, tends to change in conditions associated with active membrane turnover and gliosis, and is consistently increased in Alzheimer's disease. The glutamate and GABA peaks include soluble forms of these amino acids involved both in neurotransmission and in peptide synthesis. Glutamine is an intermediary in glial-based recycling of the carbon skeletons of these amino acids, and has been proposed as a more sensitive marker of turnover of the glutamate amino acid pool.

Evidence from ^{1}H MRS of Neuronal Pathology

Nasrallah et al. (171) reported the first ^{1}H MRS study of both mesial temporal lobes in schizophrenia, an investigation of 11 chronic patients and 11 controls, using a 12-cm^{3} voxel. They found decreases in NAA peaks in both voxels, with the difference on the right significant at the .05 level, and on the left at the .06 level. Since the report of Nasrallah et al., over 20 ^{1}H MRS studies of patients with schizophrenia have appeared. Most of them have addressed metabolite changes, primarily NAA, in the frontal and temporal lobes. Table 59.3 summarizes studies of frontal and temporal lobe NAA signals. Several recent reviews describe these reports in greater detail (143 ,144 ,172). Although most of these studies have involved single voxel data, with the inherent methodologic issues described above, several recent relatively high resolution (approximately 1-mL voxel) multivoxel and multislice imaging studies (MRSI) have also been reported. Reliability data for NAA are much superior to those of other metabolites in either the proton or the phosphorus spectra; for example, the coefficient of variation for repeat studies in patients using an MRSI technique is on the order of 10% (173). It is interesting in this regard that all of the MRSI studies to date that have examined cortical regions in the frontal and temporal lobes have reported reduced NAA signals in these regions (174 ,175 ,176 ,177 ,178 and 179). These studies are exemplified by a series of reports from Bertolino and colleagues (174 ,175 ,176 and 177) using a technique that acquires over 700 1.4-mL voxels in approximately 25 minutes. The technique allows for registration of spectroscopic and anatomic images, for reliable and anatomically correct ROI definition, and for relatively diminished partial volume effects. The studies of Bertolino et al. included chronic medicated patients, unmedicated and several neuroleptic-naive patients, and childhood-onset patients. In each of these samples, NAA signals were reduced selectively and bilaterally in dorsolateral prefrontal and perihippocampal cortices. Using a similar technical approach in studies of chronic patients, Deicken et al.

replicated these results (178 ,179), and also found reduced NAA signals in cingulated cortex (180) and in thalamus (181), which were not found in the Bertolino et al. studies. The only imaging study that reported no decrease in gray matter NAA did not regionally parcellate the cortex, and reported only an average measure for the entire cortex of the top half of the brain (182). Indeed, this result is consistent with the findings of Bertolino et al., in which NAA levels throughout most regions of brain were not different between patients and controls. Although most of the single voxel studies also found reductions in NAA signals in frontal and temporal lobes, the few negative studies (183 ,184 ,185 ,186 and 187) may reflect methodologic variance related to small sample sizes or to voxel placement, etc. The single voxel studies even of NAA signals also tend to have much less reliable data [e.g., a coefficient of variation (cv) in a negative study by Kegeles et al. (187) of greater than 30%]. It is clear from this literature that reduced NAA peaks are found in the frontal and temporal lobes of many patients with schizophrenia (see table for a summary).

Study	Method	Sample Size Patients/Controls	Temporal Lobe	Frontal Lobe	Other

TABLE 59.3. ^{1}H MRS STUDIES OF FRONTAL AND TEMPORAL LOBE NAA SIGNALS IN SCHIZOPHRENIA

There have been few studies of other peaks in the proton spectra, and the results have been inconclusive. Because of interest in glutamate and cortical function in schizophrenia, several groups have attempted to measure the tGlx peak, using quantitation methods based on a priori knowledge of the relative contributions of the metabolite components, but the reliability of the method is limited [e.g., cv >50% (183)]. Stanley et al. (184) found increased glutamine signals in chronically treated patients, but no differences in acute patients. Bartha et al. (183) reported increased glutamine in cingulated cortex of a group of ten patients. Rakow et al. (188) reported decreased tGlx in dorsolateral prefrontal cortex and Kegeles et al. (187) reported no changes in mesial temporal lobe. The data with choline and creatine peaks have generally been negative, and the occasional positive result has been inconsistent across studies.

There has been considerable interest in trying to understand the meaning of NAA decreases in patients with schizophrenia. The NAA changes have consistently been shown not to correlate with stage of illness, with medication status, and with length of illness. Moreover, hippocampal and prefrontal volume do not appear to correlate either. In the Bertolino et al. (175) study of unmedicated patients, several of the subjects had been chronically psychotic and untreated for over 10 years, and no relationship between NAA signals and length of untreated psychosis was found. These data suggest that NAA reductions are not the result of a linearly progressive pathologic process. They also provide evidence against the notion that chronic untreated psychosis is "neurotoxic." Because postmortem studies do not provide convincing evidence of neuronal loss or of neuronal degeneration in the areas where NAA signals are consistently reduced (i.e., hippocampal formation and prefrontal cortices) (189), the NAA changes probably reflect more subtle aspects of neuronal biology (see below). As such, they are unique *in vivo* evidence of cellular changes probably restricted to neurons in the schizophrenic brain. Although NAA reductions are found in both medicated and unmedicated patients, the assumption that NAA changes are independent of medical treatment may be incorrect. Bertolino et al. (167) recently reported that NAA signals in dorsolateral prefrontal cortex increase slightly but significantly after only several weeks of neuroleptic treatment. This slight increase is further evidence that NAA levels may reflect dynamic neuronal events, and is consistent with evidence that other pharmacologic treatments can alter NAA signals [e.g., lithium (190)]. Although NAA changes clearly occur independent of neuroleptic treatment, the neuroleptic effect illustrates that physiologic factors may contribute to the variations in NAA signals.

NAA Signals and Abnormalities of Specific Functional Systems

Because NAA signals originate perhaps exclusively in neurons, principally glutamate neurons, it is possible to probe the functional connectivity of cortical glutamate neurons with NAA as a surrogate marker of the integrity or activity of such connectivity. This has been done in animals and in human studies. In animals, optic nerve injury reduces NAA concentrations in the lateral geniculate (191), and prefrontal cortical injury reduces NAA signals in basal ganglia, suggestive of loss of afferent terminals or transynaptic cellular changes (169). Bertolino et al. (170) measured NAA signals in DLPFC of adult monkeys that had undergone mesial temporal lobe removals as neonates and in monkeys that had undergone temporal lobe removals as adults. Reduced NAA signals were found only in the animals with neonatal removals, suggesting that NAA could reflect more complex plastic neuronal modifications, perhaps at the level of local circuit architecture, than simply loss of afferent terminals. Similar results have also been observed in rodents (192).

This evidence of relationships between NAA signals and connections between neurons led to a series of studies aimed at testing hypotheses about the centrality of prefrontal connectivity in the pathophysiology of schizophrenia (193). Bertolino et al. (63 ,194 ,195) used NAA signals as a marker of glutamate projection neuronal function/integrity in predicting the activity of distributed neuronal systems implicated in positive and negative symptoms. NAA signals selectively in DLPFC were found to predict the availability of DA receptors in the striatum in patients with schizophrenia, assayed with radionuclide imaging (194). Specifically, lower DLPFC NAA predicted greater availability of DA receptors in an unstimulated, resting state, speculated to reflect less DA release and cell firing. The same measure, i.e., low NAA, also predicted the exaggerated response to amphetamine found in striatum with radioreceptor imaging (63). These data suggested that NAA in DLPFC predicted the steady-state and stimulus-induced responses of dopamine neurons in the ventral brainstem. Similar relationships were not found for any other cortical regions or in normal controls, implicating the neuronal pathology associated with the illness as instrumental in constraining these relationships. Although DA release was inferred indirectly from radioligand binding availability, the assumptions were confirmed in studies of monkeys undergoing *in vivo* microdialysis, in which NAA concentrations in DLPFC directly predicted DA release in the striatum (194).

NAA signals in DLPFC also were found in patients with schizophrenia to selectively predict the activation of the distributed working memory cortical network, studied both with PET (195) and with functional MRI (fMRI) (196). These data suggest that prefrontal glutamate neurons, by virtue of their intracortical connectivities, modulate the capacity and efficiency of distributed cortical networks involved in working memory. Working memory deficits have been consistently linked to other aspects of the negative symptoms of schizophrenia, and in fact NAA signals in DLPFC also specifically predict negative symptoms ratings in patients (197).

These various clinical studies of phenomena predicted by NAA signals in DLPFC converge on a tantalizing interpretation of these various findings—that NAA reductions reflect subtle cellular pathology of intrinsic DLPFC neurons and their local circuitry that, by virtue of intracortical and corticofugal projections, modify the activity of distributed cortical networks and of DA neurons, implicated in the negative and positive symptoms of schizophrenia, respectively. Thus, DLPFC neurons appear to be an effector neuronal population that is associated with the manifest biology of the illness. It is interesting to note that NAA signals in hippocampal formation, the other region consistently implicated in studies of patients with schizophrenia, do not show these predictable relationships. A study by Callicott et al. (177)

may shed some light on this apparent inconsistency. Callicott et al. studied 60 healthy siblings of patients with schizophrenia and found that although NAA signals were also reduced in the hippocampal formation of the healthy siblings, changes in DLPFC were not found. These data suggest that consistent with other evidence of hippocampal functional abnormalities in relatives of patients with schizophrenia (e.g., memory deficits, P-50–evoked potentials), NAA changes in the hippocampal formation may reflect biology of genetic risk. In contrast, consistent with the predictable relationships of NAA in DLPFC with other functional systems implicated in schizophrenia, NAA changes in DLPFC reflect biology of manifest illness. The lack of a difference in frontal lobe NAA in healthy relatives of patients with schizophrenia has recently been reported by another group as well (198). Therefore, these results have added hippocampal NAA measures to the list of potential phenotypic markers of genetic risk for further exploration in genetic studies of mental illness.

Future Developments

MRS is a rapidly evolving technology and its future applications in schizophrenia research should lead to important discoveries. New developments in the near future will likely emerge from methodologic advances leading to improved sensitivity and resolution, measurement of novel chemical moieties, indexing neuronal metabolism, and characterizing drug effects. The availability of high-field human magnets (3 to 7 tesla) will substantially improve the STN of MRS and allow for improved reliability and resolution. At the National Institute of Mental Health (NIMH), proton spectral images are currently acquired at 3 T with 0.7-mL voxels, and the cv of repeat NAA measurements in the hippocampus is about 3%. Various hardware upgrades have also made it possible to shim individual slices rather than slabs of tissue, and to acquire both early and late echo spectra within the same acquisition, without suppressing the water signal. Use of techniques to control for motion effects (e.g., navigator signals) may further improve reliability and make it possible to avoid lipid suppression approaches, as well. The improved STN and signal acquisition of new methods will result in more sensitive and reliable acquisition of other spectral peaks. This will improve the potential reliability of phosphorus moieties in the proton spectrum and will make calculations of the components of the tGlx peak more reliable. Preliminary results using spectral editing approaches to the GABA peak suggest that clinically meaningful data about GABA metabolism can be derived from this peak (199). Greater sensitivity and SNR also will permit spectral analyses of externally administered molecules. C13 glucose can be given as a glucose load and the fate of the C13 carbon skeleton tracked over time as changing concentrations of moieties in the C13 spectra (200). This may provide near–real-time information about glucose metabolism, and also potentially about the turnover of several neurotransmitters. Preliminary studies of fluorinated compounds, such as fluoxetine and fluphenazine, have demonstrated the feasibility of measuring the concentrations of such compounds in brain. The potential applications of such measurements will become clearer in the context of improved methodology. Finally, the demonstration that NAA changes with antipsychotic drug treatment represents the first *in vivo* evidence of an intracellular effect of these drugs. Future studies will aim to understand the basis for this change, as well as other factors that affect NAA signals.

Section VII
Anxiety and stress disorder

Dennis Charney

Dennis Charney: Mood and Anxiety Disorder Research Program, National Institute of Mental Health, Bethesda, Maryland.

Anxiety and stress disorder - Introduction

The chapters in this section reflect the advances that have been made in our understanding of the molecular neurobiology and neural circuits underlying fear and anxiety states and the potential for badly needed advances in the diagnosis, pathophysiology, and treatment of anxiety disorders.

Many readers will be surprised by the data cited in the Kessler and Greenberg chapter on the economic burden of anxiety and stress disorders. Recent surveys demonstrate that anxiety and stress disorders are the most commonly occurring of all mental disorders. Anxiety disorders are temporally the primary disorders in many people with a lifetime history of any mental disorder. Indeed the combined occurrence of high lifetime prevalence with an early age at onset and high chronicity makes anxiety disorders unique.

The chapter by Stein and Lang reviews in detail the course of anxiety and stress disorders over the lifetime. One point they make that is especially important to emphasize is the critical need for further research in childhood anxiety disorders. The presence of an anxiety disorder in childhood or adolescence is a predictor of the persistence into adulthood of not only anxiety disorders but other psychiatric disorders as well, particularly depression. It is not known if early effective treatment of childhood and adolescent anxiety disorders will prevent the development of psychiatric disorders later in life.

Important insights into the pathogenesis of anxiety disorders come from preclinical investigations reviewed by Davis in his chapter. The identification of the brain structures and neural circuits involved in the generation of fear and anxiety-related behaviors are most noteworthy. The delineation of specific neural pathways mediating conditioned and unconditioned fear can logically guide the design and conduct of clinical studies investigating the neurobiological mechanisms of anxiety disorders such as generalized anxiety disorder (unconditional fear) and phobic disorders (conditioned fear). Increased knowledge of the neural mechanisms and neurotransmitters involved in extinction may offer novel therapeutic approaches. If we can discover pharmacologic methods to enhance extinction, more effective drug treatments for conditioned fear or anxiety may be found. There is evidence of extinction being mediated by γ-aminobutyric acid (GABA) release. This suggests the possibility of augmenting extinction-based psychotherapy with GABA agonist drug treatment.

Determination of the genetic contribution to anxiety disorders is critically important to progress in understanding etiology and improving treatment.

Merikangas and Pine review the evidence that the major subtypes of the anxiety disorders aggregate in families. However, the magnitude of heritability is relatively moderate, indicating a strong environmental contribution to etiology. Unfortunately, thus far linkage and association studies in anxiety disorders have not been fruitful. Future studies should determine if components of anxiety syndromes are controlled by specific genes. The revolution occurring in genomics research as a consequence of sequencing the human genome and the identification of over 1½ million single nucleotide polymorphisms (SNPs) should make discovery of anxiety-related disease genes a reality. Strategies that are complementary to linkage analyses and utilize data from linkage studies are indicated. Such approaches couple the genotyping of candidate functional SNPs with linkage and equilibrium mapping in chromosomal regions implicated in linkage studies. In parallel with the genetic studies, enhanced efforts to identify endophenotypic biological vulnerability markers are indicated. The studies cited in the chapter on temperament, anxiety sensitivity, autonomic reactivity, psychophysiologic function, ventilatory function, neurochemical, and neuroendocrine factors are good examples of this approach.

Bakshi and Kalin point out in their chapter the advantages

of using putative animal endophenotypes of stress and anxiety to identify genetic abnormalities associated with anxiety disorders. Rodent and nonhuman primate studies of mother-infant interactions are particularly compelling, given the important clinical implications if these interactions are found to be a critical factor in future fearful disposition. Targeted mutations leading to anxiety-like endophenotypes in transgenic mice have suggested roles for serotonin receptor subtype 1A ($5\text{-}HT_{1A}$), corticotropin-releasing hormone (CRH), GABA, neuropeptide Y, cholecystokinin, and substance P neural systems in the generation on anxiety-fear behaviors. These studies provide clues for the discovery of new medications and pharmacogenomic approaches to treatment. Accelerated drug development efforts focusing on corticotropin-releasing factor 1 (CRF-1) receptor antagonists and benzodiazepine agonists with an anxioselective subunit profile are indicated. The feasibility of pharmacogenomic investigations designed to evaluate the relationships among functional polymorphisms of the $5\text{-}HT_{1A}$ receptor, benzodiazepine receptor, and GABA synthesis enzymes and therapeutic responses to specific drugs should be explored.

It is imperative that these findings from the preclinical studies of anxiety and fear states be translated into increased knowledge of the neural circuits and associated neural mechanisms that can account for the signs and symptoms in patients with anxiety disorders. Rauch and Shin reviewed the neuroimaging findings relevant to anxiety and stress disorders. Their chapter emphasizes the areas of congruence between animal studies and clinical neuroimaging investigations. For example, imaging studies in healthy subjects support a role for the amygdala in fear conditioning and the frontal cortex in extinction. In the imaging studies of patients with anxiety disorders, progress has been made in identifying specific neural circuits. Functional relationships among the amygdala, hippocampus, and medial prefrontal cortex have been reported in patients with posttraumatic stress disorder (PTSD). The imaging findings in patients with obsessive-compulsive disorder (OCD) are consistent with “pathology” in cortico-striatal-thalamo-cortical circuitry. Unfortunately, a critical gap in knowledge exists regarding the relevant neural circuits involved in panic disorder, social anxiety disorder, and generalized anxiety disorder. The neurochemical systems associated with anxiety and fear circuits are reviewed in the chapter by Charney and Drevets. As predicted from the preclinical studies, abnormalities in norepinephrine, benzodiazepine, glucocorticoid, and CRH systems have been identified in patients with anxiety disorders. However, most of the findings reviewed should be deemed preliminary, and they require replication. None of the reported neurobiological distinctions between patients and controls is robust enough to be of diagnostic relevance.

Tallman, Cassella, and Kehne review the mechanism of action of anxiolytic drugs and the status of new and novel therapeutic agents. They highlight the therapeutic potential and current status of CRH antagonist drug development. They also note the potential of developing targets for the CRF-2 receptor and other peptides, such as vasoactive intestinal peptide (VIP), involved in the regulation of stress. In regard to benzodiazepine drug development, they note an ideal drug might have limited effects on the α_1 subtype with increased responsiveness at α_2 and α_3 subunits. Glutamate receptor agonists and modulators are proposed as viable targets for anxiety disorders. For example, point mutations in the glycine-binding site of the NR1 subunit result in mice that have reduced glycine affinity and an anxiolytic profile. Group II metabotrophic glutamate agonists are in early clinical development for the treatment of anxiety disorders. Other novel drug targets include antagonists of AMPA receptors and antagonists of strychnine-sensitive glycine site, both of which show anxiolytic profiles in animal models.

Ultimately, the goal of research on the neurobiological underpinnings of anxiety disorders is to lead to more effective, more rapidly acting treatments, to achieve a more complete response, and to be able to predict responses to specific treatments. In their review, Gorman, Kent, and Coplan highlight the extremely broad spectrum of action of norepinephrine and serotonin transport inhibitors in anxiety disorders. These drugs are limited by a delayed onset and in complete response in many patients. This suggests that norepinephrine and serotonin have broad modulatory effects on other neuronal systems, which are more primarily related to the pathogenesis of anxiety disorders.

In summary, a reading of these chapters reveals that there have not been fundamental advances in our ability to diagnose anxiety disorders based on known etiology. The mainstay of medication treatment continues to be classes of medications that have existed for decades. There are major gaps in our knowledge of anxiety disorders in children. The mechanisms responsible for the occurrence of anxiety disorders in childhood and adolescence leading to increased risk for other psychiatric disorders in adulthood are unknown. However, the potential for progress is great. A multidisciplinary team approach utilizing the findings from preclinical investigations on neural circuitry, neurochemistry, and genetics to inform clinical investigations of genetic vulnerability, environmental risk factors, neuroimaging, pharmacogenomics, and novel drug design and testing will be a pathway to discovery.

Anxiety and Stress Disorders: Course Over the Lifetime

Murray B. Stein

Ariel J. Lang

Murray B. Stein and Ariel J. Lang: Department of Psychiatry, University of California–San Diego, San Diego, California.

This chapter traces the course and trajectory of anxiety disorders across the life span. The chapter discusses these disorders in three age groups: (a) childhood, (b) young adulthood to middle age, and (c) older adulthood.

ANXIETY AND STRESS DISORDERS IN CHILDHOOD

Part of "60 - Anxiety and Stress Disorders: Course Over the Lifetime "

Temperamental and Environmental Precursors

There are a number of factors that relate to the development of anxiety in general. Although this remains a controversial area, current evidence suggests that anxiety does not appear to be specifically heritable; what clusters in families is a more general predisposition to mood or anxiety disorders. Evidence of this comes from twin studies (1) as well as from studies of the incidence of disorders in the families of anxious patients (2). Specific phobia, however, may be an exception to this general heritability; family members with specific phobias tend to be associated with increased risk only for specific phobias (3).

Any biological predisposition is likely moderated by environmental factors. For example, Beidel and Turner (2) found that parental psychopathology was a risk factor for the development of disorder only among the lower socioeconomic status (STS) portion of their sample. It has been suggested that environmental factors play a significant role in the manifestation of specific psychopathology (1). Anxiety in particular is believed to be related to a combination of negative affect, a sense of lack of control over situations or environments, and attentional self-focus. Early experiences of being unable to influence or control situations, therefore, may lead to the development of anxiety (4).

Specific patterns within the family may lead to increased risk of development of childhood anxiety. Expressed emotion (EE), which is an interactional style composed of emotional overinvolvement and high levels of criticism, has been associated with an increased likelihood of childhood anxiety disorders (5) and with long-term functioning in those with anxiety disorders (6). Parents may also influence a child's anxiety by providing positive (e.g., the child gets attention) or negative (e.g., the child is allowed to avoid anxiety-provoking situations) reinforcement for expressions of anxiety, by providing inadequate affection and by excessive control/overprotection (4).

Can it be said that some people are born anxious? The answer is a qualified yes. The last decade or so of research by Jerome Kagan and colleagues has led to the identification of a temperament, “behavioral inhibition” (BI), that appears to be related to the subsequent onset of anxiety disorders. BI involves reacting to unfamiliar or novel situations with behavioral restraint and physiologic arousal (5). When confronted with an unfamiliar person or object, a BI child will withdraw, cling, be reluctant to interact, show emotional distress, and stop other activities. BI has also been associated with physiologic differences, such as high and stable heart rate, increased salivary cortisol and urinary catecholamines, pupillary dilation, and laryngeal muscle tension (7). These findings have led to the hypothesis that BI is related to a low threshold for arousal in the amygdala and hypothalamus (8). This characteristic, which appears to be present in 10% to 15% of children, has been identified in children as young as 14 months, has been shown to persist throughout childhood (9), and is more commonly found in offspring of anxious parents (8). The inhibited temperament has been associated with risk of developing an anxiety disorder, most commonly social phobia (10).

Some have suggested that childhood anxiety and depression are so closely related that they are best considered as part of the same construct, often referred to as internalizing disorder. This lack of differentiation appears to be characteristic of younger children, with increased specificity developing over time (11 ,12). At least by middle childhood, there is support for the set of anxiety-related diagnoses in the

Diagnostic and Statistical Manual of Mental Disorders, fourth edition (DSM-IV). Spence (12) conducted a confirmatory factor analysis with data from children of 8 to 12 years. The best model included six correlated factors—panic-agoraphobia, social phobia, separation anxiety, obsessive-compulsive problems, generalized anxiety, and fear of physical injury (including dogs, dentists, heights, doctors)—and a single higher-order factor reflecting overall anxiety.

There is a clear need for further research in childhood anxiety. Estimates of prevalence and recovery vary widely because of a lack of standardization of criteria, assessment instruments, and methodology (e.g., clinician rating vs. self-report, child vs. parent or teacher report). A few general conclusions can be drawn about childhood internalizing disorders. Internalizing symptoms appear to remain fairly stable over time (13 ,14). Among boys, internalizing symptoms are not only predictive of later internalizing symptoms but also of subsequent externalizing problems (15). Although there may be high rates of recovery associated with a particular anxiety disorder, children who recover are at increased risk of developing other psychiatric diagnoses, most commonly other anxiety disorders or depressive disorders (16). Similarly, the presence of an anxiety or depressive disorder [overanxious disorder (OAD)/generalized anxiety disorder (GAD), panic, major depression] in adolescence is nonspecifically predictive of anxious or depressive disorders in adulthood (17).

The remainder of this section discusses disorder-specific information, including clinical manifestations, prevalence, and course.

Generalized Anxiety Disorder (GAD)

GAD is characterized by excessive anxiety or worry, which is difficult to control and is accompanied by symptoms of tension and physiologic arousal (18). The GAD diagnosis is currently used in place of overanxious disorder (OAD), which was eliminated with the publication of the DSM-IV. Children and adolescents with GAD most frequently worry about future events, personal safety, and social evaluation, and often present with multiple somatic complaints, such as headaches and stomachaches (19).

There is little information about the prevalence of GAD in children and adolescents because the diagnosis of OAD was used previously. Prevalence estimates of OAD tended to be quite variable, 2% to 19% (19), and often very high, partially because functional impairment was not necessary for the diagnosis (20). Recent estimates of the prevalence of GAD are in the range of 2.1% to 10.8% (21). It appears to be more prevalent in older children and in girls (19). Onset typically falls between 10.8 and 13.4 years of age (4).

Information about course is not yet available for the GAD diagnosis, but some extrapolation from OAD is possible. Cohen et al. (22) looked at three different statistical measures of persistence. They found that OAD was very stable in a subset of children and younger adolescents (ages 11 to 16), but that there was a substantial amount of new onset among older adolescents (ages 17 to 19). Their conclusion was that the disorder may be trait-like for those who exhibit symptoms early and that the development of the disorder in others may be triggered in adolescence. Cantwell and Baker (23) also found considerable stability; 25% of children who had been diagnosed with OAD approximately 4 years earlier had recovered (although the group size, eight, limits the usefulness of this estimate). In contrast, Last et al. (16) reported that 80% of their OAD sample had recovered 3 to 4 years later; however, 25% had developed another anxiety disorder and 25% had developed a depressive disorder.

GAD/OAD is a frequently co-occurring disorder. Of those with a primary diagnosis of OAD, there is often an additional diagnosis of separation anxiety disorder (37% to 44%), social phobia (4% to 57%), simple phobia (9% to 43%) or a depressive disorder (1% to 69%) (24). There are a number of potential reasons for the high rates of comorbidity, including true covariation of distinct disorders, the presence of a single underlying construct, overlap of diagnostic categories, and measurement error (12 ,25).

Obsessive-Compulsive Disorder (OCD)

OCD is recognizable by the presence of obsessions and compulsions, which are distressing or cause marked interference in one's life (18). Among young children, the disorder often presents with excessive and rigid ritualized behavior. For children in general, compulsions alone are more common than obsessions alone (26). The most common compulsions include washing/cleaning, repeating/redoing, and checking, and the most common obsessions include germs/contaminants and fear of harm to the self or to another (26). OCD symptoms change over time in 90% of children (4).

OCD is relatively uncommon, with estimated prevalences of approximately 0.3% for children and 0.35% to 1.9% for adolescents (27 ,28). Mean age of onset is approximately 10 years. Information about the course of OCD is variable and may be best described as chronic but fluctuating (4). Leonard et al. (6) followed children and adolescents who had been part of National Institute of Mental Health (NIMH) treatment studies. During the 2- to 7-year follow-up period, the patients on average received two different modalities of treatment (medication, behavioral therapy, other individual therapy, and family therapy), with 96% having had additional psychopharmacologic treatment and 46% some form of behavioral therapy. In spite of ongoing treatment, at follow-up 43% met the criteria for OCD, 18% had subclinical OCD, and 28% had OC features. Of the 11% who were symptom-free, only three (of 54) patients had no symptoms and were not on current medications. However, treatment was associated with decreased functional impairment. Last et al. (16), on the other hand, found

a 75% recovery rate in their sample. Other estimates of continued OCD at follow-up (1.5 to 7 years) range from 31% to 68% (16).

Comorbidity is a frequent problem with OCD. The most common co-occurring conditions include other anxiety disorders (38%), tic disorders (24% to 30%), mood disorders (26% to 29%), and specific developmental disabilities (24%) (26). Leonard et al. (6) found that both a lifetime history of tic disorder and current affective disorder at baseline were associated with poorer outcome.

Panic Disorder (with and without Agoraphobia) (PD)

PD involves recurrent and unexpected panic attacks, which cause significant distress for the affected individual. This frequently leads to avoidance of various situations for fear of developing symptoms and being unable to escape (18). Young children tend to articulate their panic-related fears in a different way than do adolescents or adults by virtue of their developmental level; they are more likely to express concerns about sudden somatic symptoms and less likely to describe fears of dying, losing control, or going crazy (4).

PD is uncommonly reported in children, to the point that there has been some debate as to whether it exists before puberty. Evidence of the existence of PD in children comes from both retrospective reports of adults with PD and from case reports (29). There is no epidemiologic study to date, and it is likely that many cases go undetected because of the predominance of somatic symptoms in presentation. Prevalence of PD in adolescents is low, 0.7% girls and 0.4% boys (0.6 overall) according to one large high school sample (28). The rate of panic attacks is expectedly higher, 11.6% for at least one full attack and an additional 3.2% for at least one limited symptom attack (30). PD appears to be two to three times more common in females (29). Hayward et al. (31) examined the relationship between the occurrence of panic attacks and sexual development in girls and found a positive relationship. There were no reported panic attacks among the least sexually mature girls, and a rate of 8% among those who were most developed. The authors proposed a number of theories for this association, including hormonal changes, psychosocial factors, and emergence of the ability to think abstractly, but further work is necessary to draw any definitive conclusions.

In the one study of the course of early PD, 30% continued to have PD and 30% had another psychiatric disorder 3 to 4 years later, but the generalizablity of this result is questionable because of the small size of the study population (ten) (16). Retrospective reports suggest that earlier onset is associated with poorer outcomes, including greater functional impairment and increased incidence of alcohol abuse and suicidality (32). Available information suggests that there is a high rate of comorbidity in adolescents with PD, particularly with affective disorders; again, this should be interpreted with caution because it is based on a single, small (*N* = 28) study of adolescents (33).

Posttraumatic Stress Disorder (PTSD)

To meet the criteria for a diagnosis of PTSD, a person must have been exposed to a traumatic event and as a result is exhibiting symptoms of reexperiencing, numbing/avoidance, and arousal (18). A recent confirmatory factor analytic study supported the presence of these three basic clusters of symptoms in children and adolescents, although it found that arousal is often manifested as general somatic complaints (34). PTSD presentations that are specific to children include reenactment of the trauma in play, physical attempts (e.g., covering eyes or ears) to avoid memories of the trauma, reduced interest in activities, behavioral regression (e.g., thumb-sucking, enuresis), and sleep disturbance (35).

Diagnosis of PTSD depends on exposure to a traumatic stressor. Each year, 6% to 7% of Americans are exposed to traumatic events (36), but the incidence is much greater in certain subpopulations. For example, studies of urban youth report exposure rates of up to 75% (37). Not everyone who is exposed to trauma goes on to develop PTSD. Estimates vary tremendously depending on the type of trauma and the elapsed time between the event and assessment. In Saigh et al.'s (37) review of the literature, they found PTSD prevalence among exposed youth to be 0% to 70.8% for crime-related events, 8.3% to 75% for war, and 0% to 95% for disasters. Overall, it appears that exposed children may be somewhat more likely to develop PTSD than are exposed adults (36). PTSD is more common in those who have been exposed to more severe trauma (34).

The course of PTSD in children over the short- or long-term has not been well studied, but it appears that prognostically important factors are whether the trauma involves a single occurrence or is repeated, and whether it involves abuse. Although the evidence is not entirely consistent, it appears that a single exposure is less likely to lead to long-term symptomatology (36).

Comorbidity is generally high, particularly with other anxiety disorders (7.7% to 41.6%) and affective disorders (16.7% to 85%), but there is also substantial co-occurrence of attention-deficit/hyperactivity disorder (5.8% to 34.6%), conduct disorder (0% to 26.9%), and oppositional defiant disorder (25%) (37). Additional disorders may be integrally related to the trauma, such as fears about safety of the self or loved ones or grief about loss (35). Other psychopathology may also be a function of other factors, such as a disrupted or disorganized childhood or engagement in risky behaviors, which increase the risk for both psychopathology and traumatic exposure (38).

Separation Anxiety Disorder (SAD)

SAD is the only current anxiety disorder that is uniquely diagnosed in children and adolescents. The hallmark feature

of this disorder is excessive concern about separation from attachment figures. This is frequently manifested as distress at separation and excessive worry that harm will befall the attachment figure or that some negative event will lead to separation (18). These children frequently avoid going to school, fear being left alone or sleeping alone, and exhibit a panic-like physiologic response to separation (32).

Prevalence estimates for SAD are 2.0% to 5.4% for children and 1.3% to 4.6% for adolescents, with some evidence of higher rates in girls, those of lower SES, and those with less educated parents (21 ,32). The onset of SAD is usually early and associated with a major stressor (4). Of nine children with SAD followed by Cantwell and Baker (23), only one was still diagnosable 4 to 5 years later; this was the highest rate of recovery of any of the disorders that they followed. Similarly, Last et al. (16) found an approximately 96% recovery rate among their 24 children and adolescents with SAD, although 25% had developed another disorder, most commonly depressive, 3 to 4 years later. SAD frequently co-occurs with other disorders, most often other anxiety disorders (OAD, 23% to 33%; specific phobias, 12.5% to 27%; social phobia, 8%) (24) or a depressive disorder (approximately one-third) (32).

SAD has been suggested to be a childhood manifestation of PD. Evidence that has been cited in support of this idea includes the symptomatic similarity between a panic attack and the response to separation in a child with SAD; the frequency of a history of SAD in panic patients; the clustering of SAD, PD, and depressive disorders in families; and the similarities in effective pharmacologic treatments for the two conditions (39 ,40 and 41). Documented cases of panic episodes unrelated to separation, however, argue against this hypothesis (29). Nonetheless, SAD appears to be a risk factor for the later development of PD, at least among females (4).

Specific Phobia

A specific phobia is diagnosed if a child consistently displays significant and excessive fear in response to a specific object or situation (18). The most common fears among children are heights, small animals, doctors/dentists, dark, loud noises, and thunder/lightening (19). The prevalence of this disorder is in the range of 0.3% to 9.1%, with somewhat higher rates in girls and younger children (19 ,21 ,42).

Unlike the other anxiety disorders reviewed here, children with specific phobias remain a fairly distinct group. Last et al. (16) found that those with specific phobias were least likely to recover within 3 to 4 years (69.2%) but also were least likely to show onset of a different disorder within the follow-up period. Similarly, Pine et al. (17) found that simple phobias in adolescence were related only to adult simple phobias.

Social Phobia

Social phobia involves “marked and persistent fear of one or more performance or social situations in which the person is exposed to unfamiliar people or to possible scrutiny by others” (18). The anxious response in such situations is associated with cognitions involving concerns about being humiliated or embarrassed. Childhood social phobia is associated with significant impairment and distress, and frequently leads to extensive phobic avoidance and deficient social skill development (43).

Although there are few good epidemiologic studies of social phobia in childhood, data from community studies in adolescents suggest that it is quite common (1% to 2%), with a noticeable jump in prevalence rates sometime between ages 12 to 13 and ages 14 to 17 (44). One longitudinal study suggested that many cases of social phobia in childhood remit within 3 to 4 years (86.4%) (16). However, when social phobia is present in adolescence, it is a strong predictor of social phobia in adulthood (17). These data, taken together, suggest that social phobia in childhood may be a more transitory phenomenon than social phobia in adolescence. If these findings are confirmed in future studies, they may suggest critical developmental time frames during which preventative efforts may be applied.

ANXIETY AND STRESS DISORDERS IN YOUNG TO MIDDLE-AGE ADULTS

Part of "60 - Anxiety and Stress Disorders: Course Over the Lifetime "

Epidemiology

Several epidemiologic studies have documented the high rate of anxiety disorders among adults in the general population. In reports from the Epidemiologic Catchment Area (ECA) Study, anxiety disorders were found to occur as a lifetime diagnosis in 14.6% of the adult U.S. population aged 18 years or older (45). More recently, the National Comorbidity Survey (NCS) found that 24.9% of adults in the age group 15 to 54 years had a lifetime anxiety disorder diagnosis (46). The two studies used somewhat different sampling methods, and different diagnostic interviews, probably therein explaining at least some of the variance in rates between studies (47).

Comorbidity

Comorbidity among the anxiety, mood, and substance use disorders is extensive (47). For example, two-thirds of persons in the community with generalized anxiety disorder in a 12-month period also had major depressive disorder during that time frame (48). In a clinical sample of 85 patients with major depression, 29% met criteria for a current anxiety disorder and 34% had at least one anxiety disorder during their lives (49).

What is particularly noteworthy about this relationship

is the temporal sequencing of disorders. Certain anxiety disorders, social phobia in particular (which has a median onset of between 13 and 15 years of age), almost inevitably begin *prior* to the onset of the mood or substance use disorder (50 ,51). In one study of depressed patients, social phobia was the most common lifetime anxiety disorder (occurring in 15% of cases) followed closely by panic disorder with agoraphobia (in 12%) (49). Social phobia occurred on average 2 years prior to the onset of major depressive disorder in these patients. Similar findings have emerged from community studies (52), suggesting that particular anxiety disorders such as social phobia may be considered risk factors for the subsequent development of major depression. It remains to be established what the mechanisms might be for this observed relationship. Does being socially anxious lead to increased isolation or decreased self-worth, thereby leading to an increase in subsequent major depression? Is social phobia merely the earliest manifestation of an anxiety-mood disorder diathesis? These questions will only be answered with future research that focuses broadly on psychosocial and biological vulnerabilities for anxiety and mood disorders.

Another interesting aspect of the anxiety-depression link lies in the relationship between major depressive disorder (MDD) and PTSD. Extensive comorbidity between PTSD and MDD is the norm in studies of various traumatized groups, including persons exposed to combat (53 ,54), disasters (55), and intimate partner violence (56). Community studies also demonstrate strong ties between these two disorders, with approximately 35% to 50% of cases of PTSD in the general population being comorbid with MDD (57).

Studies that have examined the temporal association between major depression and PTSD have posited several causal pathways. It has been observed that preexisting major depressive disorder increases an individual's risk for PTSD following exposure to traumatic events (58 ,59). The converse has also been observed, namely that preexisting PTSD is a risk factor for the later development of MDD (58 ,60). The mechanisms for this apparent reciprocal risk have yet to be explained, but might involve a general vulnerability to stress that can result in major depression (61) or PTSD in susceptible individuals.

Functioning, Quality of Life, and Cost to Society

Data have been collected in the past several years that highlight the disability and reduced quality of life associated with anxiety disorders in young and middle-aged adults. Studies in clinical samples of patients with PD, PTSD, OCD, and social phobia all depict these as serious conditions that rob individuals of enjoyment and pleasure and impair functioning in multiple domains (62). Epidemiologic studies, where the range of severity is expected to be wider and where many milder cases are expected to be seen, also provide persuasive evidence of the seriousness of anxiety disorders (52 ,63 ,64). The annual cost of anxiety disorders in the United States was estimated at $42.3 billion in 1990, or $1,542 per sufferer (65). Other than simple phobia, all anxiety disorders analyzed were associated with impairment in workplace performance. These observations, gleaned from a variety of clinical and nonclinical perspectives, portray anxiety disorders in adults as serious mental disorders worthy (and in need) of greater societal willingness to develop and apply better interventions to prevent or mitigate their impact on the lives of individuals.

ANXIETY AND STRESS DISORDERS IN OLDER ADULTS

Part of "60 - Anxiety and Stress Disorders: Course Over the Lifetime "

Although anxiety is among the most prevalent of psychiatric disorders in the elderly, research in this area has lagged far behind that of depression and dementia (66). But in the past few years, several important studies have been conducted that provide novel information about the prevalence, features, and course of anxiety disorders in older adults.

Epidemiology

Whereas it had previously been believed that anxiety disorders decline in prevalence with age, several possible explanations for this finding have been put forward. It has been suggested that this might be an artifact of measurement error, owing to differences in the way older individuals report anxiety (67). Previous epidemiologic studies may also have underestimated the prevalence of anxiety disorders in the elderly by limiting participation to community-dwelling older adults, who may have lower rates of anxiety disorder than those living in institutions (68).

Fortunately, data have recently become available from a new community survey that provides a more accurate and detailed perspective on anxiety disorders in older adults (69). The Longitudinal Aging Study Amsterdam (LASA) is based on a random sample of 3,107 older adults (ages 55 to 85), stratified for age and sex. The overall prevalence of anxiety disorders in the community was estimated at 10.2%. GAD was most common in a 6-month time period (7.3%), followed by social phobia (3.1%), PD (1.0%), and OCD (0.6%). For comparison purposes, it is noteworthy that the 6-month prevalence of major depression in the same study was 2.0%. Thus, anxiety disorders were far more common than depressive disorders in the elderly, underscoring the point made earlier that it is surprising that the elderly have received so little attention in the clinical and research literature to date.

This study also examined vulnerability factors for anxiety disorders in older adults (69). Many of the vulnerability factors for anxiety disorders in younger adults are common to older adults (e.g., female sex, lower levels of education),

but several unique risk factors were also encountered (e.g., having suffered extreme experiences during World War II). These investigators were also able to show that current stresses commonly experienced by older people (e.g., recent losses in the family and chronic physical illness) also played a part in the onset or exacerbation of anxiety disorders. Current life stresses, then, should be evaluated as possible contributors not only to depression, but also to anxiety in the elderly.

Comorbidity

Comorbidity patterns of older adults with anxiety disorders are remarkably similar to those of younger adults. In the LASA, 48% of those with MDD also met criteria for anxiety disorders, whereas 26% of those with anxiety disorders also met criteria for MDD (70).

The entity known as “anxious depression” warrants special mention in this context. Although definitions vary, anxious depression usually refers to MDD with accompanying anxiety. Anxious depression is a particularly common presentation in the elderly (66). Although anxious depression is frequently severe and impairing, its outcome is no worse than nonanxious depression when treated appropriately (71).

Special Features of Anxiety Disorders in the Elderly

The fact that medical illness becomes more common with increasing age can put a special twist on the presentation and origins of certain anxiety disorders in the elderly. First and foremost, it must be recognized that many medical illnesses (e.g., thyroid disease, chronic obstructive pulmonary disease, and stroke, to name just a few) may be associated with *de novo* anxiety symptoms or with the exacerbation of a preexisting anxiety disorder (66). Most “new” anxiety disorders in older life are either GAD or agoraphobia, whereas most other anxiety syndromes seen in the elderly (e.g., PD and OCD) reflect recurrence or worsening of an anxiety disorder that had its onset earlier in life (72).

Agoraphobia in older adults is usually a different phenomenon, with different etiology, from agoraphobia in younger adults. In younger adults, agoraphobia is almost always a complication of PD (73)—the individual comes to avoid situations that are associated with the possible occurrence of panic or difficulty escaping should a panic attack occur. In the elderly, the new onset of agoraphobia is rarely associated with spontaneous panic attacks, but instead is a maladaptive reaction to some form of medical illness experience that renders the individual fearful of being unable to function safely away from home (66). An example is an elderly woman who breaks her hip, and even after it has satisfactorily healed, is afraid to maneuver without help and therefore avoids leaving the house alone.

SUMMARY

Part of "60 - Anxiety and Stress Disorders: Course Over the Lifetime "

Anxiety disorders span the full range of human existence from childhood to old age, though symptoms may vary considerably owing to developmental differences and related factors. Anxiety disorders in children are often transitory phenomena, with the majority showing remission by adolescence or early adulthood. Yet, in a minority, extremely shy and fearful temperament in childhood can merge almost imperceptibly into social phobic and panic disorders in adolescence. Anxiety disorders in youth appear to be a risk factor for the subsequent development of major depression (and, although less certain, possibly also substance use disorders) in late adolescence and young adulthood. By adulthood, comorbidity is the rule, with most individuals experiencing multiple anxiety disorders, or concurrent mood and anxiety disorders. For the most part, anxiety disorders are chronic, and these persist from young adulthood into old age. But even in later life, new onset of anxiety disorders can occur, often in the context of medical illness or other sources of life stress.

Genetic and other Vulnerability Factors for Anxiety and Stress Disorders

Kathleen R. Merikangas

Daniel Pine

Kathleen R. Merikangas and Daniel Pine: National Institute of Mental Health, Bethesda, Md.

Despite dramatic advances in our understanding of genetics and neurobiology, the etiology of the anxiety disorders is still relatively unknown. To date, there remain no pathognomonic markers with which a presumptive diagnosis of an anxiety disorder may be made. This highlights the importance of the empirical epidemiologic approach to investigating the definitions and risk factors for the expression of anxiety across the life course. Anxiety disorders are developmental conditions that often emerge during childhood and follow varied developmental trajectories (1 ,2). Research on early-life vulnerability factors that predict the trajectory of anxiety symptoms across development holds promise for elucidating mechanistic pathways in anxiety.

In evaluating the risk factors for the development of anxiety disorders, there are several issues requiring consideration. First, there is substantial overlap between the anxiety disorders and other psychiatric disorders both concomitantly and longitudinally. Second, manifestations of anxiety change substantially across the life course, particularly during childhood and adolescence. Therefore, a developmental perspective is essential in evaluating links between risk factors and anxiety disorders. Third, the assessment of anxiety requires evaluation of the context in which the individual experiences anxiety as well as the subjective response to anxiety-inducing situations. As such, anxiety becomes a disorder when there is a mismatch between inherent threat posed by a particular stimulus or situation and the cognitive or somatic response.

Research on vulnerability factors has undergone a relatively marked transformation in recent years, due to conceptual changes in causal theories of mental disorders. Such conceptual changes are reflected in three major themes that organize current research on vulnerability factors in anxiety. First, although studies through the early 1990s often emphasized the role of one or another particular risk factor, more recent studies emphasize the manner in which multiple risk factors might interact to cause mental syndromes, including anxiety, as part of a mechanistic pathway. For example, although dysregulation in fear conditioning has been linked to anxiety for more than two decades (3), such dysregulation is now viewed as part of a larger chain of intrinsic and extrinsic events that may ultimately culminate in an anxiety disorder (4). Second, as a corollary to this view, vulnerability markers are now conceptualized as tied to families of anxiety disorders, as opposed to specific conditions. This change in perspective follows the observation that validators of individual mental syndromes related to differential course, familial aggregation, or psychophysiology relate more closely to families of disorders than to particular disorders. Third, marked advances over the past 20 years in neuroscience have stimulated a closer integration of basic and clinical work on vulnerability markers in anxiety disorders. Progress in elucidating neural circuits related to anxiety has facilitated research on vulnerability markers for anxiety disorders that integrates data from basic and clinical science.

This chapter examines the major risk factors for the development of anxiety disorders across the life span. Particular attention is paid to the specificity of vulnerability factors and to developmental differences in expression of the disorders themselves.

MAGNITUDE AND DEMOGRAPHIC RISK FACTORS

Part of "61 - Genetic and other Vulnerability Factors for Anxiety and Stress Disorders "

Magnitude of Anxiety in General Population

The anxiety disorders are the most common psychiatric disorders both in the United States and elsewhere (2 ,5 ,6). The

results of the two large-scale community-based surveys of psychiatric disorders of adults in the United States, the Epidemiological Catchment Area study (ECA) (2) and the National Comorbidity Study (NCS) (5), reveal that the total prevalence rates of anxiety disorders are greater than those of the affective disorders, behavior disorders, and substance use disorders. Phobias tend to be the most common anxiety disorder, whereas panic disorder is fairly rare in the general population. There is substantial overlap both cross-sectionally and longitudinally between the anxiety disorders and other disorders, as well as between the subtypes of anxiety disorders themselves (6). On average, there is a threefold increased risk of having a second disorder compared to that of manifesting an anxiety disorder alone across the lifetime.

Comorbidity between anxiety disorders and other psychiatric disorders has been demonstrated in both clinical and community samples. Anxiety disorders are most strongly associated with affective disorders and with substance use disorders (6), though they are generally associated with all other major classes of disorders including depression, disruptive behaviors, eating disorders, and substance use. Comorbidity between anxiety disorders and other disorders in the *Diagnostic and Statistical Manual of Mental Disorders*, third edition revised or fourth edition (DSM-IIIR or -IV) may be even more common in adolescents than in adults (7). A review of comorbidity of anxiety and depression by Brady and Kendall (8) suggests that anxiety and depression may be part of a developmental sequence in which anxiety is expressed earlier in life than depression. Although the association between anxiety and depression is quite consistent, the evidence of links between anxiety disorders and behavior problems is inconclusive.

Sex Differences in Anxiety Disorders

Similar to the affective disorders, females tend to exhibit greater rates of anxiety disorders, though there is some variability according to specific subtypes. Table 61.1 presents the sex-specific lifetime rates of the major subtypes of anxiety disorders assessed in the ECA and NCS (5 ,6). Although the magnitude of the rates of anxiety disorders varies substantially between the two studies, the sex ratio is strikingly similar: women have an approximately twofold elevation in lifetime rates of panic, generalized anxiety disorder, agoraphobia, and simple phobia than men in both studies. In contrast, there is a nearly equal sex ratio for the lifetime prevalence of social phobia.

	Epidemiologic Catchment Area Study (5)			National Comorbidity Survey (6)		
	Males	Females	Sex Ratio (F:M)	Males	Females	Sex Ratio (F:M)
Anxiety disorders						
Anxiety disorders, total	1.8	10.3	5.7	19.2	30.5	1.6
Generalized anxiety disorder	4.3	6.8	1.6	3.6	6.6	1.8
Panic disorder	0.9	2.0	2.2	2.0	5.0	2.5
Phobic disorders						
Agoraphobia without panic	3.2	7.9	2.5	3.5	7.0	2.0
Simple phobia	7.8	14.5	1.9	6.7	15.7	2.3
Social phobia	2.5	2.9	1.2	11.1	15.5	1.4

TABLE 61.1. SEX-SPECIFIC LIFETIME PREVALENCE RATES OF ANXIETY DISORDERS IN COMMUNITY SURVEYS IN THE UNITED STATES

There is increasing evidence from community-based studies that anxiety symptoms and disorders are also the most common problems in childhood and adolescence as well. The rates of anxiety disorders in community or school-based surveys of children and adolescents as defined by contemporary diagnostic criteria range from 0.1% to 13.3% in males and 0.4% to 28.6% in females (9). Similar to the sex ratio for adults, girls tend to have more of all subtypes of anxiety disorders, irrespective of the age composition of the sample. For example, in a recent epidemiologic study, females compared to males had greater rates of current anxiety disorders (i.e., 12.2% vs. 8.5%), past anxiety disorders (5.2% vs. 2.7%), as well as anxiety symptom scores on a dimensional rating (mean = 1.9 vs. 0.9) (10). Nevertheless, Lewinsohn et al. (10) reported that despite the greater rates of anxiety in girls across all ages, there was no difference between boys and girls in the average age at onset of anxiety (mean for girls = 8.0 ± 3.9; mean for boys = 8.5 ± 3.8).

Age-Specific Patterns of Expression of Anxiety Disorders

Retrospective reports of adults with anxiety disorders suggest that the onset of anxiety disorders generally occurs in childhood or adolescence. Although there is substantial

variation across studies, the results of prospective community-based research reveal differential peak periods of onset of specific subtypes of anxiety: separation anxiety and specific phobias in middle childhood (i.e., ages 7 to 9); overanxious disorder in late childhood (i.e., 10 to 13); social phobia in middle adolescence (i.e., 15 to 16); and panic attacks, sometimes progressing to panic disorder, in late adolescence (i.e., 17 to 18) (1 ,11 ,12 ,13 and 14). Anxiety disorders, particularly the phobias, tend to persist across the life course. However, there are major differences among the anxiety subtypes in terms of specificity and chronicity. Whereas the phobic states tend to be fairly stable and nonprogressive, generalized anxiety and panic tend to be less specific and less stable over time (1 ,15 ,16).

Several follow-up studies of children and adolescents have shown that anxiety symptoms and disorders in general tend to exhibit some stability, but with substantial switching across categories of anxiety disorders over time (17 ,18). A recent 8-year follow-up study of a community sample of youth ages 9 to 18 at study entry provides compelling evidence of the stability of the subtypes of anxiety disorders (17). The stability of both social phobia and simple phobia was highly specific over time, whereas overanxious disorder was associated with major depression, social phobia, and generalized anxiety in early adulthood.

Epidemiologic surveys of adults reveal that the female preponderance of anxiety disorders is present across all stages of life but is most pronounced throughout early and mid-adulthood. The rates of anxiety disorders in males are also rather constant throughout adult life, whereas the rates in females peak in the fourth and fifth decades of life and decrease thereafter. The increased rates in females are present across all ages and do not diminish as the rates of anxiety decrease in late life. The importance of pure anxiety disorders in late life was described by Beekman et al. (19), who found different risk factors for anxiety disorders than for either depression or comorbid anxiety and depression in a community sample of adults over age 55.

Social Class and Ethnicity

Rates of anxiety disorders in general are greater among those at lower levels of socioeconomic status (20). Several community studies have yielded greater rates of anxiety disorders, particularly phobic disorders, among African-Americans (5). With respect to children, Compton et al. (14) found that Caucasian children were more likely to report symptoms of social phobia, whereas African-American children had more separation anxiety symptoms. Pine et al. (1) reported that phobias were greater among those at lower levels of social class. The reasons for ethnic and social class differences have not yet been evaluated systematically; however, both methodologic factors as well as differences in exposure to stressors have been advanced as possible explanations.

FAMILIAL AND GENETIC FACTORS

Part of "61 - Genetic and other Vulnerability Factors for Anxiety and Stress Disorders "

The familial aggregation of all of the major subtypes of anxiety disorders has been well established (21). As reviewed below, the results of more than a dozen controlled family studies of probands with specific subtypes of anxiety disorders converge in demonstrating a 3- to 5-fold increased risk of anxiety disorders among first-degree relatives of affected probands compared to controls. The importance of the role of genetic factors in the familial clustering of anxiety has been demonstrated by numerous twin studies of anxiety symptoms and disorders (22 ,23). However, the relatively moderate magnitude of heritability also strongly implicates environmental etiologic factors. Table 61.2 summarizes the results of family and twin studies of anxiety disorders.

Type of Study	Comparison	Number of Studies	Average Relative Risk	Range
Family	Rel of probands vs. rel of controls	13 panic	5.4	(4.2–17.8)
		4 social phobia	3.1	(2.5–9.7)
		3 general anxiety	4.3	(2.7–5.6)
		3 OCD	3.5	(1.0–5.1)
Twin	MZ vs. DZ	3 panic	2.4	(2.2–2.5)
		4 phobias	2.6	(1.4–9.5)
		1 OCD	4.9	—

DZ, dizygotic; MZ, monozygotic; OCD, obsessive-compulsive disorder.

TABLE 61.2. SUMMARY OF FAMILY AND TWIN STUDIES OF ANXIETY DISORDERS

Review of Family and Twin Studies of Anxiety Disorders in Adults

Panic Disorder

Of the subtypes of anxiety, panic disorder is the anxiety syndrome that has been shown to have the strongest degree of familial aggregation. A recent review of family studies of

panic disorder by Gorwood et al. (24) cited 13 studies that included 3,700 relatives of 780 probands with panic disorder compared to 3,400 relatives of 720 controls. The lifetime prevalence of panic was 10.7% among relatives of panic probands compared to 1.4% among relatives of controls, yielding a relative risk of 6.8. In addition, early-onset panic, panic associated with childhood separation anxiety, or panic associated with respiratory symptoms has each been shown to have a higher familial loading than other varieties of panic disorder (25).

Although there has been some inconsistency reported by twin studies of panic disorder (26), two studies applying modern diagnostic criteria demonstrated considerably higher rates for monozygotic compared to dizygotic twins (27 ,28). Furthermore, current estimates derived from the Virginia Twin Registry show panic disorder to have the highest heritability of all anxiety disorders at 44% (29).

Phobic Disorders

Though there are far fewer controlled family and twin studies of the other anxiety subtypes, all of the phobic states (i.e., specific phobia, agoraphobia) have also been shown to be familial (30 ,31 ,32 and 33 ; see refs 34 ,35 and 36 for reviews). The average relative risk of phobic disorders in the relatives of phobics is 3.1. Stein et al. (33) found that the familial aggregation of social phobia could be attributed to the generalized subtype of social phobia. Data from the Virginia Twin Study report the estimated total heritability for phobias to be 35% (29 ,37).

Generalized Anxiety Disorder

There is also evidence of both the familial aggregation and heritability of generalized anxiety disorder in a limited number of studies. The average familial odds ratio is approximately 5 (32 ,38), and the heritability was 0.32 among female twin pairs (37).

Obsessive-Compulsive Disorder

Likewise, there are also very few controlled family studies of obsessive-compulsive disorder. Two of the three studies (39 ,40) reported familial relative risks of 3 to 4, whereas Black et al. (41) found no evidence for familial aggregation. Nestadt et al. (40) found that both the age of onset and obsessions were associated with greater familiality. Twin studies have yielded weak evidence for heritability of obsessive compulsive disorder (42 ,43 and 44).

Linkage and Association Studies

Based on indirect evidence implicating the adrenergic system in panic disorder (45), several linkage studies have investigated the role of mutations in adrenergic receptor loci on chromosomes 4, 5, or 10 (46), but without success. Other work has similarly excluded linkage with γ-aminobutyric acid receptor A ($GABA_A$) genes (47). Reports from a genomic survey of panic disorder using 600 markers have not yielded evidence of linkage (48). Similarly, linkage studies have excluded the possibility that panic disorder was due to mutations in adrenergic receptor loci on chromosomes 4, 5, or 10 (46), and other work has similarly excluded linkage with $GABA_A$ receptor genes (47). Recent reports from a genomic survey of panic disorder using 600 markers have not yielded evidence of linkage (48).

Family Studies and Phenotypic Definitions

The lack of success in identifying specific genes for anxiety disorders is not surprising given their complexity. Similar to several other psychiatric disorders, the anxiety disorders are complicated by etiologic and phenotypic heterogeneity, a lack of valid diagnostic thresholds, unclear boundaries between discrete anxiety subtypes, and comorbidity with other forms of psychopathology. Impediments to estimating genetic influences in youth are demonstrated by dramatic differences in heritability according to the informant regarding child psychopathology. For example, Eaves et al. (49) found that the heritability of both separation anxiety and overanxious disorder was far greater for parent-reported rather than child-reported disorder.

The family study approach, particularly when employed with systematic community-based samples, is one of the most powerful strategies to minimize heterogeneity because etiologic factors for the development of a particular disorder can be assumed to be relatively homotypic within families. There is a dearth of studies that have employed within-family designs to examine either phenotypic expression or some of the putative biological factors underlying the major anxiety disorders. For example, both Perna et al. (50 ,51) and Coryell (52) have shown that healthy relatives of probands with panic disorder have increased sensitivity to CO_2 challenge, suggesting that CO_2 sensitivity may be a promising trait marker for the development of panic, as described below. Smoller and Tsuang (36) discuss the value of family and twin studies in identifying phenotypes for genetic studies.

Both family and twin studies have been used to examine sources of overlap within the anxiety disorders, and between the anxiety disorders and other syndromes including depression, eating disorders, and substance abuse. Fyer et al. (31 ,53) have demonstrated the independence of familial aggregation of panic and phobias. With respect to comorbidity, whereas panic disorder, generalized anxiety, and depression have been shown to share common familial and genetic liability (23 ,54 ,55), there is substantial evidence for the independent etiology of anxiety disorders and substance use disorders (36 ,55 ,56). Similar results have emerged from

studies of symptoms of anxiety and depression in youth in which both anxiety and depression was found to result from common genetic diathesis (57 ,58).

In a comprehensive consideration of what may be inherited, Marks (59) reviews the components of anxiety that have been investigated in both human and animal studies. Evidence from twin studies has indicated that somatic manifestations of anxiety may lie under some degree of genetic control. These studies demonstrate that physiologic responses, such as pulse, respiration rate, and galvanic skin response, are more alike in monozygotic than in dizygotic twin pairs. Furthermore, twin studies of personality factors have shown high heritability of anxiety reaction. Finally, the results of animal studies have suggested that anxiety or emotionality is under genetic control. Selective breeding experiments with mammals have demonstrated that emotional activity analogous to anxiety is controlled by multiple genes (59). These findings suggest that anxiety and fear states are highly heterogeneous and that future studies need to investigate the extent to which the components of anxiety result from common versus unique genetic factors and the role of environmental factors, either biologic or social, in either potentiating or suppressing their expression.

High-Risk Studies of Anxiety Disorders

Given the early age of onset for anxiety disorders, studies of children of parents with anxiety have become an increasingly important source of information on the premorbid risk factors and early forms of expression of anxiety. Increased rates of anxiety symptoms and disorders among offspring of parents with anxiety disorders have been demonstrated by Turner et al. (60), Biederman et al. (61), Sylvester et al. (62), Last et al. (63), Warner et al. (64), Beidel and Turner (65), Beidel (66), Capps et al. (67), Merikangas et al. (68), Unnewehr et al. (69), and Warner et al. (70). Table 61.3 presents the risk of anxiety disorders among offspring of parents with anxiety disorders compared to controls averages 3.5 (range 1.3 to 13.3), suggesting specificity of parent-child concordance within broad subtypes of anxiety disorders.

Study	Sample						
	Proband				Offspring		
Author (year)	Anxiety	Other	Other	Spouse	*N*	Age	Relative Risk
Sylvester et al., 1987 (73)	Panic	MDD	—	No Dx	91	7–17	13.3
Turner et al., 1987 (60)	Agoraphobia/OCD	Dysthymia	—	Not evaluated	43	7–12	4.8
Capps et al., 1996 (67)	Agoraphobia	Agoraphobia/Panic	—	Not evaluated	43	8–24	—
Warner et al., 1995 (64)	Panic/MDD	Panic	Early-onset MDD	Dx	145	6–29	1.3
Beidel et al., 1997 (65)	Anxiety + depression	Anxiety	MDD	No Dx	129	7–12	4.0
Merikangas et al., 1998 (68)	Panic/social phobia	Alcohol or drugs	Substance + anxiety	Dx	192	7–17	2.0
Unnewehr et al., 1998 (69)	Panic	Simple	—	Not evaluated	87	5–15	9.2

Dx, diagnosis; MDD, major depressive disorder.

TABLE 61.3. CONTROLLED HIGH-RISK STUDIES OF ANXIETY

However, similar to studies of adults that show common familial and genetic risk factors for anxiety and depression (27 ,71 ,72), studies in children have also revealed a lack of specificity with respect to depression (60 ,64 ,65 ,73). Studies that employed a comparison group of parent probands with depressive disorders have shown that rates of anxiety disorders are also increased among the offspring of these parents (60 ,62 ,65 ,70); conversely, offspring of parents with anxiety disorders and depression have elevated rates of depression when compared to those of controls (62) or to offspring of anxiety-disordered parents without depression (61). Similar findings emerged from the family study by Last et al. (63), who found an increase in rates of major depression among the adult relatives of children with anxiety. Weissman et al. (74) have even suggested that childhood anxiety represents one of the earliest manifestations of familial risk for depression. These findings are usually interpreted as providing evidence for age-specific expression of common risk factors for anxiety in childhood and depression with or without comorbid anxiety in adulthood.

The high rates of anxiety disorders among offspring of parents with anxiety suggest that there may be underlying psychological or biological vulnerability factors for anxiety disorders in general, which may already manifest in children

prior to puberty. Previous research has shown that children at risk for anxiety disorders throughout life are characterized by behavioral inhibition (75), autonomic reactivity (66 ,76), somatic symptoms (60 ,77), social fears (60 ,62), enhanced startle reflex (76), and respiratory sensitivity (160). Empirical research on each of these domains of risk is reviewed in the next section.

VULNERABILITY MARKERS

Part of "61 - Genetic and other Vulnerability Factors for Anxiety and Stress Disorders "

The current section reviews recent studies on vulnerability markers in anxiety disorders. This includes data on temperamental factors and biological profiles. The first section reviews evidence regarding individual-level vulnerability factors, whereas the subsequent section examines data linking exogenous or environmental factors with risk for anxiety. As noted above, both sets of vulnerability markers operate within complex causal chains involving multiple interacting risk factors. Moreover, in such complex chains, the boundary between intrinsic and exogenous risk factors can become blurred. For example, the effects of exogenous factors, including life events; social rearing experiences, such as trauma or parental nurturance; and factors such as the use of illicit substances may operate through effects on intrinsic factors, such as the regulation of neural systems that monitor danger.

Intrinsic, individual-oriented vulnerability markers for anxiety disorders can be conceived across a range of perspectives, focusing on increasingly more specified biological systems. At the most complex or global level, specific temperamental or personality characteristics, such as neuroticism, harm avoidance, and behavioral inhibition have been linked to risk for anxiety. At a more specified level, vulnerability can be modeled through the assessment of cognitive function, in the form of attention and memory, or peripheral physiologic function, as reflected in autonomic reactivity profiles, changes in the startle reflex, or changes in ventilatory control. These cognitive and physiologic functions, in turn, reflect functional aspects of neurochemical or neuroanatomic systems that are presumably homologous with systems linked to fear and anxiety across a range of mammalian species. Data from humans at each of these levels is reviewed within the context of research on fear and anxiety in other species.

Temperament/Personality

Behavioral Inhibition

One of the earliest indicators of vulnerability to the development of anxiety is behavioral inhibition, characterized by increased physiologic reactivity or behavioral withdrawal in the face of novel stimuli or challenging situations (79). Behavioral inhibition may be a manifestation of a biological predisposition characterized by both overt behavioral (e.g., cessation of play, latency to interact in the presence of unfamiliar objects and people) and physiologic indicators (e.g., low heart rate variability, accelerated heart rate, increased salivary cortisol level, pupillary dilation, increased cortisol level). There is an increased frequency of behavioral inhibition among children of parents with anxiety disorders compared to those of normal controls (61 ,62 ,65 ,75 ,80 ,81 and 82).

Few studies have evaluated the differences in manifest inhibition and approach/avoidance in both clinical and nonclinical samples, leaving gaps in the conceptualization of the construct of inhibition. Some studies have shown that there is more stability of behavioral inhibition across early childhood among girls than among boys (83). The expression of behavioral inhibition studied prospectively may reveal patterns of anxiety symptomatology similar to those endorsed in adult populations. In a prospective study of a large community cohort of subjects from age 3 months to 13 years, Prior et al. (84) found that maternal ratings of persistent shyness and shyness in late childhood were associated with the development of anxiety disorders in adolescence.

Anxiety Sensitivity

Anxiety sensitivity is another potential sensitive and specific trait marker for the development of anxiety disorders (85). Anxiety sensitivity is characterized by beliefs that anxiety sensations are indicative of harmful physiologic, psychological, or social consequences (e.g., fainting or an impending heart attack). The misinterpretation of bodily cues that characterizes anxiety sensitivity may lead to a self-perpetuating “fear of fear” cycle. Thus, the fear of benign arousal sensations produces anxiety, which in turn increases the frequency and intensity of physiologic sensations, and subsequently fuels apprehension regarding the significance of these sensations. This process may ultimately result in a full-blown panic attack.

Anxiety sensitivity is thought to represent a stable trait-like factor that is qualitatively different from general fear and anxiety (86). It has been proposed that anxiety sensitivity may interact with environmental experiences (e.g., hearing misinformation about the negative outcome of certain bodily sensations) to shape beliefs about the dangers of anxiety sensations. Thus, anxiety sensitivity may be involved in the development of certain anxiety disorders, particularly panic disorder (87 ,88). Of particular interest is the finding of the specificity of anxiety sensitivity with respect to development of anxiety disorders but not depression in a nonclinical sample (88). Likewise, Pollock et al. (89) reported that anxiety sensitivity appears to be specific to anxiety, as it did not contribute unique variance above self-rated anxiety symptoms in the prediction of depressive symptoms.

Anxiety sensitivity has been shown to be under genetic (90) and familial influence; anxiety sensitivity was found to

constitute a potential premorbid marker for the development of anxiety disorders in high-risk but not low-risk youth (89). Prospective studies of youth have also demonstrated the prognostic significance of anxiety sensitivity in predicting the development of anxiety disorders. Based on the results of a 5-year prospective study of adolescents, Hayward et al. (91) concluded that anxiety sensitivity appeared to be a specific risk factor for the development of panic attacks in adolescents. These findings from prospective research, particularly the specificity with respect to anxiety, together with the importance of genetic and familial liability suggest that anxiety sensitivity is an important vulnerability factor that should be examined in future studies.

Comorbid Disorders

Psychiatric

The magnitude of comorbidity in adults and adolescents with anxiety suggests that investigation of the role of other disorders in enhancing the risk of the initial development and persistence of anxiety disorders over time may be fruitful. The difficulty in dating onset of specific disorders, particularly from retrospective data, diminishes our ability to determine the temporal relations between disorders. Nevertheless, some prospective studies have examined the links between anxiety disorders and earlier expression of other forms of psychopathology. For example, whereas some studies suggest that childhood depression may presage the onset of panic attacks, the results of a fairly large prospective study suggest a bilateral temporal association between panic attacks and depression (91).

Other disorders that may enhance the risk of development of anxiety disorders include eating disorders (92), depression, and substance use and abuse. With respect to substance use disorders, Rao et al. (93) found that anxiety disorders may comprise a mediator of the link between depression and the subsequent development of substance use disorders in a clinical sample. The potential mechanisms through which anxiety may be associated with smoking in adolescents were examined by Patton et al. (94), who found that both anxiety and depression were associated with smoking initiation through increased susceptibility to peer influences. Conversely, some research suggests that substance use may trigger anxiety disorders in susceptible youth. For example, a prospective study of a community sample revealed that posttraumatic stress disorder (PTSD) may be triggered by substance abuse in about 50% of the cases (95). Similarly, Johnson et al. (96) found that adolescent smoking predicted adult onset of panic attacks, panic disorder, and agoraphobia (96). Thus, although comorbidity between anxiety and both depression and substance problems is quite common in children and adolescents, further research on the mechanisms for links between specific disorders both across and within genders is necessary.

Medical Symptoms/Disorders

Several studies have also suggested that there is an association between childhood medical conditions and the subsequent development of anxiety. Kagan et al. (97) reported an association between allergic symptoms, particularly hay fever, and inhibited temperament in young children. In a retrospective review of pre- and perinatal and early childhood risk factors for different forms of psychiatric disorders in adolescence and early adulthood, Allen et al. (98) found that anxiety disorders in adolescents were associated specifically with illness during the first year of life, particularly high fever. Likewise, Allen and Matthews (102) reported that adolescents and young adults with anxiety disorders were more likely to have suffered from infections during early childhood than others. The prevalence of high fevers in childhood along with other diseases associated with immune system were also elevated among offspring of parents with anxiety disorders in the Yale High Risk Study (76). Kagan (101) proposed that the high levels of cortisol associated with anxiety may lead to immunologic sensitivity to environmental stimuli. Taylor et al. (99) reported that immunologic diseases and infections were specifically associated with emotional disorders because children with developmental or behavioral disorders had no elevation in infections or allergic diseases. On the other hand, Cohen et al. (100) suggest that such medical problems show stronger associations with depressive as opposed to anxiety disorders during adolescence. These findings suggest that it may be fruitful to examine links between immunologic function and the development of anxiety disorders.

Prospective studies have revealed that the anxiety disorders may comprise risk factors for the development of some cardiovascular and neurologic diseases. Haines et al. (103) reported that phobic anxiety was associated with ischemic heart disease, particularly fatal ischemic events. Bovasso and Eaton (104) employed cardiac and respiratory symptoms and illness to subtype panic attacks and their association with depression in a large community-based sample. They found that “respiratory panic attacks were associated with the subsequent risk of myocardial infarction.” Likewise, phobic disorder is strongly associated with migraine, with the onset of phobias predating that of migraine (105 ,106). The results of both family studies and prospective cohort studies suggest that there may be a subtype of migraine with shared liability for anxiety and depression (105).

Autonomic Reactivity

Reactions to threatening stimuli among various organisms, including primates and lower mammals, involve changes in the autonomic nervous system. These changes can be detected through an analysis of time series for heart rate, heart period variability, blood pressure, and catecholamine levels.

There is a long history of research in this area, and much of the initial work concerned the assessment of physiologic changes associated with acute anxiety states. Hence, acute episodes of anxiety, both in the laboratory and in natural settings, are typically characterized by acute changes in heart rate, blood pressure, and heart period variability (107). These changes result from coordinated changes in the parasympathetic and sympathetic innervation of the cardiovascular system.

More recent work on physiologic changes during acute anxiety states has attempted to identify specific physiologic patterns associated with one or another emotion. The identification of such emotion-specific patterns may provide insights on emotion-specific patterns of brain activity. For example, some forms of anxiety, such as acute panic, may be characterized by marked parasympathetic withdrawal in the face of sympathetic enhancement. Other emotions, such as anger, may be characterized by a distinct physiologic “finger print,” reflecting the involvement of distinct brain systems across emotions (108 ,109 and 110). In general, consistent associations are found across development between acute anxiety states and changes in peripheral autonomic indices, including heart rate, blood pressure, or heart period variability. As a result, some suggest that perturbations in autonomic regulation may index an underlying vulnerability to develop anxiety disorders. This underlying vulnerability is thought to relate to the functioning of particular neural circuits within the brain that exert effects on both subjective internal states and physiologic activity. Potentially relevant neural circuits have been identified through basic science studies on the neural basis of fear and anxiety.

Despite consistent evidence of an association between acute anxiety states and changes in autonomic physiology, the degree to which such changes index vulnerability for anxiety, as opposed to the acute state of anxiety, remains unclear. If such changes in autonomic physiology primarily reflect downstream manifestations of relatively high degrees of acute fear, they would provide limited advantages as vulnerability markers. On the other hand, at least some of the underlying autonomic abnormalities in panic disorder persist after remission and may be independent of the current state. This suggests that changes in autonomic physiology may mirror subtle person-specific differences in brain processes related to the processing of risk or to the experience of fear. As such, autonomic indices might index vulnerability in a fashion that is more sensitive than indices derived through self-report measures. A series of recent studies provide preliminary evidence consistent with this possibility.

Autonomic physiologic profiles have been studied among individuals who face high risk for anxiety disorders. Physiologic profiles have been tied to at least three indicators of risk: temperamental factors, family history, and traumatic events. In terms of temperamental factors, Kagan (111) noted the relationship between behavioral inhibition, which predicts later anxiety, and a distinct autonomic physiology profile. Children with behavioral inhibition exhibit an autonomic physiology characteristic of the profile found during acute anxiety. Specifically, behaviorally inhibited children exhibit under conditions of novelty a shift from parasympathetic to sympathetic control of the cardiovascular system, manifest as an increase in heart rate and a reduction in high-frequency components of the heart period variability power spectrum. Such abnormalities in autonomic physiology are viewed as downstream reflections of perturbations based within the limbic system. In terms of family history, Bellodi et al. (112) found similar temperamental and physiologic abnormalities among children of parents with panic disorder. Such data are consistent with other studies finding high rates of behavioral inhibition among offspring of patients with anxiety disorders. Finally, in terms of traumatic events, physiologic reactions to an acute stress may index underlying vulnerability to develop anxiety states. Consistent with this possibility, Shalev et al. (113) found that enhanced cardiovascular activity in the emergency room immediately following a motor vehicle accident predicted the development of PTSD.

Taken together, available data clearly delineate associations between acute anxiety and autonomic physiology profiles, but the implications of this work for the study of risk remain unclear. Moreover, the underlying assumption in this work posits an effect of perturbations in brain systems on both autonomic physiology and anxiety symptoms. As such, more work is also needed relating brain function to autonomic physiology.

Psychophysiologic Function

Research on fear conditioning has facilitated an integration of basic and clinical work on vulnerability for anxiety. Fear conditioning develops following the pairing of a neutral “conditioned” stimulus (CS+), such as a tone or a light, and an aversive “unconditioned” stimulus (UCS), such as a shock, a loud noise, or an air puff. Across a range of mammalian species, including humans, fear conditioning results from changes in a relatively simple neural circuit that involves distinct amygdala nuclei, including the basolateral and central nucleus. Basic science research on the role of this circuit in learned fears has also called attention to the role played by related but relatively distinct neural circuits in the responses to other forms of danger. For example, reactions to intrinsically dangerous contexts, such as a brightly lit room for a rodent, involve a relatively extended period of vigilance. These reactions may more intimately involve the basolateral nucleus and the bed nucleus of the stria terminalis than the central nucleus of the amygdala. Such reactions in animals may model worry in humans as characteristically found in many anxiety disorders (114).

Similarly, acute reactions to intrinsically dangerous stimuli often involve rapid changes in behavior designed to facilitate escape or defense. Such reactions in animals may involve the hypothalamus and lower brainstem structures; such reactions in animals may be model acute panic in humans.

Work in neuroscience delineating circuits involved in mammal's response to danger has stimulated a series of studies on risk for anxiety in humans. Much of this work quantifies physiologic reactions to innate and learned fears with the goal of comparing physiology across high- and low-anxiety groups. Based on skin conductance data, Eysenck and Eysenck (115) suggested that abnormal habituation of conditioned fear responses confers risk for anxiety. Similarly, Raine et al. (116) suggest that deficiencies in learned fear, as modeled by skin conductance, relates to low anxiety and high risk for chronic behavior problems. However, due to methodologic advantages, more recent studies rely on startle as a physiologic index of activity in brain circuits tied to fear. Most importantly, it has been possible to map circuits that regulate startle in more precise detail, relative to circuits that regulate skin conductance or other indicators of autonomic response, such as heart rate. Cross-species parallels in startle regulation facilitate integration of basic and clinical work (76 ,114 ,117 ,118 ,119 ,120 ,121 ,122 ,123 and 124). For example, molecular genetic studies on fear conditioning in mice generate specific hypotheses on the genetics of risk human disorders (125 ,126 ,127 ,128 ,129 ,130 and 131). Fear-relevant stimuli in animals may potentiate startle through effects on genes in limbic structures, such as the amygdala, that are involved in fear conditioning. In adult humans, distinct stimuli effect startle across emotional disorders, but abnormal startle in some form is seen in many disorders, including phobias (132), PTSD (122 ,123 and 124), depression (133 ,134), and panic disorder (135). Moreover, there is some evidence that startle specifically indexes risk for anxiety. Three studies found startle abnormalities in children born to adults with an array of anxiety disorders (76 ,119), and a fourth study found startle abnormalities in inhibited children, who face high risk for anxiety disorders (111).

In a high-risk study of offspring of parents with anxiety disorders compared to psychiatric and normal controls, the startle reflex and its potentiation by aversive states was used as a possible vulnerability marker to anxiety disorders in adolescent offspring of parents with anxiety disorders (122). Startle was found to discriminate between children at high- and low-risk for anxiety disorders, as well as to discriminate between children at risk for anxiety compared to those at risk for alcoholism. However, different abnormalities in startle amplitude for high-risk males and females were observed. Startle levels were elevated among high-risk females, whereas high-risk males exhibited greater magnitude of startle potentiation during aversive anticipation. Two possible explanations for the gender differences in the high-risk groups were suggested by the authors: (a) differential sensitivity among males and females to explicit threat versus the broader contextual stimuli that are mediated by different neurobiologic pathways, and (b) different developmental levels in males and females in which the vulnerability to anxiety may be physiologically expressed earlier in females.

Nevertheless, more work in this area is needed, given inconsistencies across genders and across conditions under which startle is most discriminatory (76). These data are also consistent with the findings of Watson et al. (136). Overall, the data suggest that startle indices may provide an important window for assessing dysfunction in limbic circuits broadly related to mood and anxiety regulation.

Ventilatory Function

As in the area of autonomic physiology, a wealth of research delineates associations between respiratory perturbation and acute anxiety. This association has been most convincingly demonstrated in panic disorder, where various forms of respiratory stimulation, including lactate infusion (137) and CO_2 inhalation, consistently produce high degrees of anxiety and more pronounced perturbations in respiratory physiologic parameters. Of note, these associations extend beyond the specific diagnosis of panic disorder, because enhanced sensitivity to respiratory perturbation is also found in conditions that exhibit strong familial or phenomenologic associations with panic disorder, including limited symptom panic attacks; certain forms of situational phobias; childhood anxiety disorders, particularly separation anxiety disorder; and high ratings on anxiety sensitivity scales.

Compared to the work on autonomic physiology, a larger body of research implicates abnormalities in respiration in risk or vulnerability for anxiety. At least four sets of findings suggest that respiratory indices index risk for anxiety, independent of any association between current state and respiratory function. First, asymptomatic adult relatives of patients with panic disorder consistently exhibit enhanced subjective sensitivity to respiratory stimulation, in the form of exogenously inhaled CO_2 (51 ,138 ,139). Second, among patients with panic disorder, stronger family loading is found in panic patients with evidence of respiratory dysregulation, as opposed to those with no sign of respiratory dysregulation (51 ,140). Third, respiratory indices linked to panic disorder are strongly heritable, raising questions on the potential shared genetic vulnerability for panic attacks and respiratory dysregulation. Fourth, Pine et al. (78) reported increased carbon dioxide sensitivity in children with anxiety disorders. Such data are also consistent with work on respiratory disease (141) and smoking (96 ,142), which suggest that abnormalities in respiration predispose to later anxiety. Based on this work, abnormalities in respiration appear to provide some information on the vulnerability for anxiety states that are related to acute panic.

Despite the consistency of findings in this area, a number of questions remain. The most consistent data emerge for

subjective indices of respiratory sensitivity, manifest as a tendency to report dyspnea during stress or during respiratory stimulation. The mechanisms that contribute to such enhanced sensitivity remain poorly specified. At a cognitive level, such hypersensitivity may result from an overall sensitivity to somatic sensations, consistent with data linking high degrees of anxiety sensitivity to future panic attacks (143). On the other hand, enhanced sensitivity to respiratory sensations appears more closely tied to panic attacks than sensitivity to other somatic factors; the tie between anxiety sensitivity and respiratory sensitivity also appears relatively weak in some studies. At the physiologic level, such hypersensitivity may result from perturbations in brain systems involved in respiratory regulation or primary as opposed to learned fear states. Unfortunately, the precise role of fear systems in both respiratory regulation and human anxiety states also remains poorly specified.

Neurochemical and Neurohormonal Factors

As reviewed in other sections of this book, extensive data document associations between alterations in various neurochemical factors and ongoing anxiety disorders. This includes data on the serotoninergic, noradrenergic, and GABAergic systems. Moreover, there is some evidence to implicate neurochemical alterations in the causal chain contributing to anxiety disorders. In animal models, genetic manipulations of serotoninergic receptors, the serotonin reputake transporter gene, and components of the GABA complex each produce behavioral and physiologic effects reminiscent of clinical anxiety states. Similarly, clinical studies find that acute pharmacologic manipulations in these neurochemical systems produce concomitant change in acute anxiety. For example, the inverse GABA agonist flumazenil precipitates anxiety in patients with panic disorder, whereas GABA agonists are potent treatments for various forms of anxiety. These findings are consistent with evidence of a deficiency in GABAergic modulation among adults with anxiety disorders. Similarly, manipulations of the serotoninergic system, either through tryptophan depletion or treatment with medications, also produce both acute and more chronic changes in anxiety. Finally, manipulations of the noradrenergic system produce similar changes in both children and adults. Sallee et al. (144) found that the α_2-agonist yohimbine elevated selectively anxiety symptoms and was associated with blunting of growth hormone in children with anxiety disorders. Interestingly, as with the response of children to CO_2 inhalation (160), the response to yohimbine appeared particularly abnormal in children with separation anxiety disorder. However, evidence of perturbed noradrenergic function in children with depression or facing high familial risk for depression (145) suggest that these findings may not be specific to anxiety but rather may relate to broad risk for mood and anxiety disorders.

Despite the consistency of these findings relating neurochemical factors to anxiety, relatively few studies have examined the manner in which individual differences in neurochemical function predict vulnerability to anxiety. There is evidence from studies in adult patients that some of these neurochemical abnormalities persist after remission. For example, much like symptomatic patients, remitted patients with panic disorder exhibit abnormal secretory profiles in terms of the growth hormone and the hypothalamic-pituitary-adrenal (HPA) axis. These neurohormonal abnormalities are thought to reflect trait-related abnormalities in neurochemical systems involved in neurohormonal regulation. Finally, there have been numerous studies of patients and at-risk relatives using lactate challenge to induce anxiety (146 ,147 and 148). The limited information provided on neural pathways by this provocation test limits its value in informing the pathophysiology of anxiety disorders.

Although these studies raise the possibility that risk for anxiety may result at least partially from underlying neurochemical abnormalities, other studies are needed to confirm this possibility. For example, there are almost no studies of neurochemical function in high-risk youth, a key source of information regarding the underlying role of biological parameters in the development of anxiety disorders. One exception is the study of Reichler et al. (77), who assessed several biological factors in their high-risk study of panic disorder including lactate metabolism, mitral valve prolapse, urinary catecholamines, and monoamine oxidase. Although none of these parameters discriminated high-risk from low-risk youth, the lack of differences may have been attributable in part to low statistical power.

Likewise, very few studies have compared neurochemical function in asymptomatic relatives of patients with and without anxiety disorders. Similarly, no studies have examined family loading for anxiety disorders in patients stratified in terms of their neurochemical functioning.

Beyond this work examining monamine systems' influence on neurohormonal regulation and vulnerability for anxiety, a relatively extensive body of work examines the precise relationship between anxiety and HPA axis regulation. Corticotropin-releasing factor (CRF) represents a key neuropeptide in the regulation of this system. CRF infusions in animals produce behavioral and physiologic effects in animals that bear similarities to human anxiety states. Similarly, genetic manipulations that alter CRF produce similar effects. As such, this work suggests that an underlying dysregulation in the HPA axis, possibly centrally involving CRF, may contribute to vulnerability for anxiety. Consistent with basic science studies, clinical research notes a relationship between acute anxiety states and alterations in HPA axis function. For example, a variety of acute stressors induce consistent elevations of cortisol; patients with PTSD exhibit multiple signs of HPA axis dysregulation; multiple

other anxiety disorders exhibit other signs of HPA axis dysregulation.

Vigilance/Attention

Studies of the association between attention regulation and anxiety have revealed that adults with anxiety disorders exhibit enhanced vigilance for threat cues, as indexed by effects of fear-related words or pictures on reaction times. These effects have been attributed to amygdala influences on attention allocation (149 ,150 ,151 ,152 and 153). Enhanced attentional bias in acute anxiety represents a particularly robust finding, noted in more than 20 studies using various paradigms across virtually all anxiety disorders. These effects appear particularly robust in two paradigms, the emotional Stroop and the dot-probe tests. From a theoretical perspective, this enhanced bias is considered a vulnerability marker that antedates the developmental of anxiety disorders among adults. Consistent with this possibility, an enhanced bias for threat cues is found early in the course of anxiety disorders, particularly among children with anxiety disorders. On the other hand, this enhanced bias is generally not found in remitted patients (153), and studies have yet to document enhanced bias for threat cues in at-risk but asymptomatic individuals.

ENVIRONMENTAL EXPOSURES

Part of "61 - Genetic and other Vulnerability Factors for Anxiety and Stress Disorders "

Perinatal Exposures

There is virtually no evidence that either prenatal factors or delivery complications comprise risk factors for the development of anxiety disorders. The results of three studies that retrospectively assessed perinatal events converged in linking such exposures to behavioral outcomes, but not to subsequent anxiety. For example, Allen et al. (98) found that children who suffered from a variety of exposures ranging from prenatal substance use to postnatal injuries were more likely to develop behavior disorders, particularly attention deficit disorder and conduct problems, but not anxiety disorders. Likewise, the results of the Yale High-Risk Study yielded no association between pre- and perinatal risk factors and the subsequent development of anxiety disorders (76).

Life Events/Stressors

The role of life experiences in the etiology of anxiety states, particularly phobias and panic disorder, has been widely studied (154 ,155 ,156 and 157). Life events have often been designated a causal role in the onset of phobias, which are linked inherently to particular events or objects. More broadly, life experiences that to some extent threaten one's notion of safety and security in the world are often at least retrospectively perceived to trigger or precipitate the onset of anxiety disorders. In evaluating the evidence on the causal role of life experiences, it is critical to consider separately the subtypes of anxiety disorders. Although it is likely that life stress may exacerbate phobic and generalized anxiety states, Marks (59) concludes that phobic states resulting from exposure are far more rare than those that emerge with no apparent exposure. In contrast, posttraumatic stress disorder (PTSD) is defined as a sequela of a catastrophic life event.

The major impediment to evaluation of the causal role of life events in anxiety (or depression) is the retrospective nature of most research addressing this issue. For example, Lteif and Mavissakalian (158) found that patients with panic or agoraphobia exhibited an increased tendency to report life events in general; this suggests that studies that limit assessment of life events to those preceding onset of a disorder may be misleading because they fail to provide comparison for the time period of onset. Moreover, stressful life events may interact with other risk factors such as family history of depression in precipitating episodes of panic (159). In one of the few prospective studies, Pine et al. (160) did demonstrate a predictive relationship between life events during adolescence and both depressive as well as generalized anxiety disorder symptoms. Interestingly, the association with anxiety was limited to females, consistent with differential vulnerability to stress across genders.

In terms of specific environmental risk factors, there has been abundant literature on the role of parenting in enhancing vulnerability to anxiety disorders. Based on Bowlby's (161) theory that anxiety is a response to disruption in the mother-child relationship, it has been postulated that maternal overprotection is related to anxiety, particularly separation anxiety. Using the Parental Bonding Instrument of Parker et al. (162), several studies of clinical samples have found that adult patients with anxiety disorders recall their parents as less caring and more overprotective than did controls (163). These findings have been supported in nonclinical samples as well (164 ,165). However, all of these studies caution that a causal link cannot be established because of the lack of independent assessment of parent behaviors and offspring anxiety.

Another parental behavior that may enhance risk of anxiety in offspring is parental sensitization of anxiety through enhancing cognitive awareness of the child to specific events and situations such as bodily functions, social disapproval, the importance of routines, and necessity for personal safety (164). Bennet and Stirling (164) found that subjects with anxiety disorders and those with high trait anxiety reported greater maternal and paternal overprotection and increased maternal sensitization to anxiety stimuli than controls.

Another feature of the parental relationship that has received widespread attention in recent research has been exposure to severe childhood trauma through either separation or abuse (161 ,166). There is increasing animal research on the impact of early adverse experiences on brain systems and subsequent development (167 ,168). Pynoos et al. (169)

present a comprehensive developmental life-trajectory model for evaluating the effects of childhood traumatic stress and anxiety disorders. They propose different avenues by which dangerous circumstances, childhood traumatic experiences, and PTSD can intersect with other anxiety disorders across the life span. The developmental perspective is critical in light of different levels of neural response to experience at different stages of development (170).

SUMMARY AND FUTURE DIRECTIONS FOR RESEARCH ON ANXIETY VULNERABILITY

Part of "61 - Genetic and other Vulnerability Factors for Anxiety and Stress Disorders "

Despite the rich array of constructs associated with anxiety (Table 61.4), our ability to predict those who will suffer from anxiety disorders in adulthood is severely limited. The principles of multifinality (i.e., many outcomes of the same risk factor) and equifinality (i.e., diverse risk profiles leading to the same endpoint) apply to many of the risk pathways investigated herein (171). Although we distinguish between intrinsic and extrinsic risk factors for the development of anxiety disorders, there is increasing evidence that there is a bidirectional association between the factors subsumed under these two domains. Only a small proportion of those with known vulnerability factors truly develop anxiety disorders in adulthood, despite the vast majority of those with adulthood anxiety reporting onset in childhood and early adolescence.

TABLE 61.4. VULNERABILITY FACTORS FOR ANXIETY DISORDERS

The major impediments to identifying specific risk factors for anxiety are exclusive reliance on retrospective data, blurred boundaries between normal and pathologic anxiety, difficulty distinguishing between risk factors and early manifestations of anxiety, limited interdisciplinary conceptualization of models of risk and pathogenesis, lack of evidence of the specificity of risk factors with respect to anxiety disorders or subtypes thereof, and limited tools for direct measurement of brain function. Moreover, many of the risk factors have been shown to operate differently according to gender and age, as well as the specific subtype of anxiety. Elucidation of the different risk profiles will provide valuable information on classification, etiology, treatment, and prevention.

Future research should do the following:

- Establish more accurate and developmentally sensitive methods of assessment of anxiety, with a focus on developing objective measures of the components of anxiety.
- Apply within-family design to minimize etiologic heterogeneity and to refine diagnostic boundaries and thresholds.
- Investigate specificity of putative markers with respect to other psychiatric disorders and the longitudinal stability of specific subtypes of anxiety disorders.
- Develop research on hormonally mediated neurobiological function in order to understand gender differences predisposing women to experience decreased resiliency to fear-provoking stimuli.
- Examine mechanisms for associations between panic attacks with extrinsic exposures (i.e., substance use), developmental periods (i.e. pubertal development), and cessation in later life.

ANIMAL MODELS OF PSYCHIATRIC ILLNESS

Part of "62 - Animal Models and Endophenotypes of Anxiety and Stress Disorders "

Animal Models: Types Of Validity

An important criterion for developing animal models to study psychopathology involves establishing the validity of the model as a true representation of the process being studied. Generally, three types of validity are applied to animal models: face validity, construct validity, and predictive validity (1 ,2 and 3). Face validity refers to the outward similarity in appearance between the model and the illness. Construct validity, on the other hand, does not exclusively involve outward tangible signs of the modeled illness. Rather, it refers to the internal mechanism or state that underlies the illness. Finally, predictive validity refers to the ability of the animal model to identify therapeutic treatments for the illness. It should be noted that the different types of validity can be independent of each other; an animal model can possess predictive and construct validity without possessing face validity. Ideally, an animal model should possess both construct and predictive validity so that it may be used to understand the mechanisms and etiology of the disorder and also to identify promising treatments for the disorder.

Endophenotype Approach

Species differences in the manifestation of a particular internal state can cloud the usefulness of face validity in animal models. In addition, when considering a complex psychiatric illness, it is likely that several different symptom clusters contribute to the final pathologic condition; these different sets of symptoms may have different underlying substrates and thus may be ameliorated by different treatments. Therefore, it is difficult to come up with an animal model for an illness that meets the aforementioned criteria and also models the pathologic syndrome in its entirety. An alternative approach that has been used involves the modeling of discrete symptom clusters and physiologic alterations rather than the whole syndrome, with the assumption that what causes the symptoms contributes mechanistically to the illness. This general approach has involved the use of endophenotypes that may be related to a particular psychiatric disorder. The term *endophenotype* refers to a set of behavioral and/or physiologic characteristics that accompany a basic process that is altered in relation to the illness that is being studied (4). It is important to note that this more narrowly defined endophenotype approach does not necessarily have to capture specific symptoms that are a part of the clinical diagnosis, but rather may focus on a core process or function that is abnormal in the clinical population under study and that is thought to be related to the manifestation of the illness. For example, in the case of anxiety-related disorders, investigators have focused on studying the genetic, physiologic, and neurochemical correlates of fearful or anxious endophenotypes because a core aspect of anxiety-related disorders involves the aberrant expression of fearful responses to neutral or mildly stressful contexts (5). Thus, by identifying animals that display fearful endophenotypes, it is possible to study the neural substrates that contribute to this basic process that may underlie the development and expression of anxiety-related psychopathology.

Using endophenotypes that are based on core and basic processes rather than the entire illness offers certain advantages. Because the whole illness is not being modeled, the endophenotype approach affords greater possibility for construct and predictive validity in the model, and can incorporate species-specific manifestations of the core process being modeled. This approach may also make screening for genetic abnormalities associated with the disorder more fruitful, because the genetic factors associated with a very discrete

process (which could be mediated by a small number of genes) rather than an entire syndrome (which is likely caused by a complex set of interactions between multiple genes) is being studied (4 ,6). Moreover, heterogeneity within a diagnostic category could potentially dilute the strength of a sample population (i.e., not all patients with anxiety disorders are identical in their clinical presentation), and diminish the chances of identifying genes that contribute to the illness. Ideally, one might be able to generate several different endophenotypes for a particular disorder, and then study the genetic underpinnings of each of these separate core processes in order to identify a set of genes that might be implicated in that particular disorder. The definition and use of endophenotypes in animal models of psychiatric illness is a developing area. This chapter presents some promising candidates of animal models of fearful and anxious endophenotypes, and outlines some of the preliminary genetic factors that have been identified to contribute to the manifestation of these endophenotypes.

PUTATIVE ANIMAL ENDOPHENOTYPES OF STRESS AND ANXIETY: STUDIES OF FEARFUL TEMPERAMENT

Part of "62 - Animal Models and Endophenotypes of Anxiety and Stress Disorders "

Defensive Behaviors

In an attempt to understand the basic neural mechanisms underlying psychiatric conditions involving fear and anxiety, several groups have focused on identifying the neural substrates of defensive behaviors in animals. Defensive behaviors are exhibited by a wide array of species including rats, nonhuman primates, and humans in response to perceived threats from the environment, and are essential components of an organism's behavioral repertoire that ensure its protection and survival. Because organisms display defensive behaviors in reaction to threat, it is thought that the aberrant expression of defensive behaviors may represent a good example of a fearful endophenotype that would have relevance to stress and anxiety-related disorders. Although the specific behavioral responses that compose defensive behaviors are dependent on the environmental context and vary from species to species, a common element that unites this cross-species phenomenon is that defensive behaviors represent an organism's behavioral response to fear. Because defensive behaviors are expressed in response to an immediate threat, they characteristically supersede and interrupt the expression of other normal homeostatic behaviors such as feeding and reproduction that may be ongoing at the time of the perceived threat (7 ,8 ,9 ,10 and 11). One defensive response pattern expressed by many species is to inhibit all body movements and assume an immobile or freezing posture. This phenomenon of behavioral inhibition is effective in preventing detection and attack by predators (12 ,13), and may have special relevance for understanding psychopathology.

In nonhuman primates, defensive behaviors are composed of a constellation of responses that include vocalizations, freezing, fleeing, or defensive hostility and aggression. The particular set of responses that is emitted depends on, among other variables, the nature of the perceived threat (14 ,15). Studies of defensive behaviors in rhesus monkeys may provide valuable information that could aid in the understanding of fear and anxiety-related psychopathology in humans, because extreme fearful or defensive responses occur in dispositionally fearful humans who have an increased risk to develop psychopathology (16).

Psychiatric illnesses such as anxiety disorders and depression might involve the aberrant expression of defensive behaviors. In other words, pathologic anxiety could be conceptualized as the inappropriate expression of defensive or fear-related behaviors, consisting of either an exaggerated or overly fearful response to an appropriate context, or a fearful response to an inappropriate or neutral context. Although appropriate levels of defensive behaviors in response to environmental threats are adaptive and ensure survival, the overly intense or context-inappropriate display of fearrelated defensive behaviors may represent a liability that interferes with normal behavior and would likely contribute to certain forms of fear-related psychopathology. Thus, inappropriate or exaggerated expression of defensive behaviors may represent an important animal endophenotype of anxiety. An understanding of the specific neural substrates underlying the expression and regulation of defensive behaviors may therefore ultimately shed insight into the processes that become dysregulated in stress-related psychopathology. In defining animal endophenotypes relevant to anxiety, specific symptoms of a particular type of anxiety disorder are not being modeled, but rather the general phenomenon of hyperreactivity to mildly stressful stimuli is studied. The approach of modeling anxiety by studying defensive behaviors in animals has been described previously for rodent models (17 ,18). In the following sections, both primate and rodent analogues of stress hyperresponsiveness are described, with a particular emphasis on models of either the overly intense but context-appropriate expression of defensive behaviors or the normal but context inappropriate expression of defensive behaviors. Initially, various behavioral paradigms that have been used to measure an animal's level of defensive behavior are described, and subsequently, specific examples of fearful endophenotypes that have been identified using these tests are discussed.

Measuring Defensive Behaviors in Nonhuman Primates: Human Intruder Paradigm

One laboratory paradigm that has been developed to identify animals with fearful dispositions characterizes monkeys' fearful behavioral responses to a human intruder. In the human intruder paradigm (HIP), the monkey is placed by itself in a test cage where it remains for 30 to 40 minutes

while its behavior is recorded on videotape. A human intruder then enters the test area, representing a potential predatorial threat to the animal (14 ,15 ,19). The test session consists of three consecutive brief conditions: alone (“A,” animal left alone in cage); no eye contact (“NEC,” animal presented with the facial profile of a human standing 2.5 m away); stare (“ST,” animal presented with a human who faces it and engages it in direct eye contact). Typically, animals respond to the A condition by increasing their levels of locomotion and by emitting frequent coo vocalizations, which have been likened to the human cry and function to signal the infant's location and facilitate maternal retrieval (20 ,21). The NEC condition causes a reduction in cooing and an increase in behavioral inhibition, which functions to help the monkey remain inconspicuous in the face of a predator and is often manifested as hiding behind the food bin and freezing. The ST condition elicits aggressive (open-mouth threats, lunges, cage shaking, barking vocalizations) and submissive (lip smacking, fear-grimacing) behaviors that represent adaptive responses to the perceived threat of the staring experimenter. The different test conditions (A, NEC, ST) reliably elicit responses in young or adult laboratory-reared monkeys or in feral animals (14 ,19). Moreover, these context-specific defensive responses are not dependent on the gender of the intruder, and can also be elicited by showing the animal a videotape of the intruder (Kalin et al., unpublished data).

Behavioral Tests Used to Measure Fearful Endophenotype in Rodents

To identify fearful endophenotypes in rodents, a variety of behavioral paradigms have been employed. All of the paradigms in some manner provide an assessment of the rodent's level of defensive behavior, which is essentially thought to be an index of its level of fearfulness or anxiousness. The behavioral tests measure one of four general categories of stress-related behavior: approach-avoidance conflicts, conditioned fear, aggression, and punished responding conflicts. Detailed descriptions and protocols for these tests can be found in a recent review by File and colleagues (22).

Approach-Avoidance Conflicts

Briefly, all of the paradigms presented in this section measure the animal's ratio of approach versus avoidance behaviors by presenting a choice between an environment that is safe (usually a dark, enclosed, small space) and an environment that seems novel but risky (usually bright, wide open, large spaces). The entries into and amount of time spent in the safe environment relative to the risky environment are used as an index of the animal's stress level (an increase in exploratory behaviors toward and into the risky environment indicate a relatively low level of stress). A number of paradigms including the *elevated plus maze* (composed of safer closed, dark arms versus riskier open bright arms), the *open field* (consisting of a darker wall-bordered peripheral portion versus a brighter open center section), a *light-dark transition box* (consisting of an exploratorium divided into two halves, one that is dark and one that is bright), and a *defensive withdrawal* apparatus (composed of a small dark chamber that is inside of a brightly lit open field) have been frequently used and validated as paradigms that are sensitive to detecting shifts in an animal's approach-avoidance–based conflict (23).

Conditioned Fear

Behavioral tests that measure conditioned fear utilize basic principles of Skinnerian conditioning. Two frequently used paradigms to assess fear conditioning are conditioned freezing and fear-potentiated startle. *Conditioned freezing* is evaluated using a two-step procedure. First, during the training or conditioning phase, a stressful unconditioned stimulus (UCS, such as a foot shock) that elicits freezing is paired with a neutral stimulus that subsequently becomes a conditioned stimulus (CS). On the test day, the amount of freezing in response to the CS is assessed; animals that have not undergone the CS-UCS pairing do not normally freeze when the CS is presented, but animals that have learned to associate the CS with a foot shock show marked levels of freezing simply in response to this stimulus. The CS can either be a context (i.e., the environment in which the shock is delivered) or a discrete cue (e.g., a tone or light). The level of conditioned freezing is thought to correspond to the level of fear or anxiety that the animal is experiencing due to anticipation of a threat (24). In the case of *fear-potentiated startle*, the unconditioned startle response to a sudden stimulus (e.g., a loud noise burst) is measured in the presence and in the absence of a CS that has been paired previously with shock. The startle response is markedly increased when the startling stimulus occurs in the presence of the CS; this relative increase in startle magnitude is quantified, and serves as an index of the level of fear (thought to be elicited by a discrete cue as the CS) or anxiety (thought to be elicited by a contextual CS) that the animal may be experiencing (25).

Aggression and Social Behavior

Aggressive behaviors are emitted as part of the behavioral repertoire an animal displays when it encounters a threatening situation. The study of defensive aggressive behaviors has been summarized and reviewed by a number of investigators (26 ,27 and 28). Briefly, aggressive behaviors can be studied using a *resident intruder paradigm*, in which the offensive/agonistic responses (e.g., upright postures, attacks) of a male resident or the defensive responses (e.g., submissive posture, flight, freezing) of a male intruder are measured. Other

stress-related paradigms involve the study of affiliative behaviors and include the *social interaction* test in which approach toward and contact between two rats is measured (e.g., sniffing or grooming each other).

Punished Responding Conflict

The basic principle of punished responding tests is to present the animal with a situation in which a particular behavioral response results in both a rewarding outcome and an aversive outcome. The extent to which the animal exhibits the behavioral response during the conflict schedule is used as an index of its level of stress. For example, in the classic *Geller-Seifter* conflict test (29), rats are trained to press a lever for a food reward. Gradually, the bar press is also paired with a mild foot shock, and a stable rate of responding is established under the conflict schedule. Drugs can then be administered and evaluated for their ability to increase responding under the punished schedule. For example, benzodiazepines have been found to increase bar-pressing during the conflict schedule, putatively by decreasing the stress or anxiety induced by the aversive stimulus. Similarly, in the *Vogel punished drinking* paradigm (30), thirsty rats with access to a water bottle are periodically given mild electric shocks through the spout of the bottle; the extent to which licking is decreased is used as an index of stress.

INDIVIDUAL DIFFERENCES IN DEFENSIVE BEHAVIORS: NATURALLY OCCURRING FEARFUL ENDOPHENOTYPES

Part of "62 - Animal Models and Endophenotypes of Anxiety and Stress Disorders "

Primates

Several lines of evidence support the notion that an individual's level of defensive responding is a relatively stable trait characteristic (which in part may be derived from the nature of early postnatal maternal interactions, see below). Extreme individual differences detected early in life may be predictive of future psychopathology. For example, extremely inhibited children are at greater risk to develop anxiety and depressive disorders and are more likely to have parents that suffer from anxiety disorders (31 ,32 ,33 and 34). Moreover, behavioral inhibition in childhood (based on retrospective self-reports) is highly associated with anxiety in adulthood (35). Some of the physiologic correlates that have been observed in extremely inhibited children are elevated levels of the stress-related hormone cortisol (36) and greater sympathetic nervous system activity (37). In nonhuman primates, individual differences in defensive behaviors have been studied in an attempt to elucidate the neuroendocrine and neurobiological concomitants of extreme behavioral inhibition and to characterize a primate analogue of an anxiety-related endophenotype.

Marked individual differences among rhesus monkeys have been noted with regard to the intensity of context-specific defensive responses. These defensive responses have been characterized using the HIP (see previous section). For example, some monkeys tend to coo frequently during the A condition (in which the animal is isolated), whereas other same-aged animals engage in little or no cooing. Large individual differences have also been observed in the duration of NEC-induced freezing (in the presence of a human profile) and ST-induced hostility (in response to direct eye contact with the human intruder). Some animals freeze the entire length of the test period, whereas at the other extreme some never freeze and act relatively undisturbed by the human intruder. These individual differences in fear-related responses seen in the laboratory are similar to those that have been observed in rhesus monkeys who inhabit Cayo Santiago, a 45-acre island with approximately 1,000 free-ranging monkeys (Kalin et al., unpublished data). Importantly, it has been found that monkeys' individual differences in defensive responses are relatively stable over time, suggesting that the intensity of defensive behavior that is displayed reflects a trait rather than a state characteristic. It was initially demonstrated that the duration of NECinduced freezing behavior remained stable in 12 animals tested twice with an interval of 4 months (r = .94). Using a larger sample size, the stability of NEC-induced freezing was confirmed; ST-induced hostility was also found to be relatively stable (Kalin et al., unpublished data). Interestingly, significant correlations between the magnitude of the different types of defensive responses were not observed within an animal. Thus, monkeys that exhibited extreme levels of NEC-induced freezing did not necessarily display extreme levels of ST-induced hostility. This lack of correlation between different types of defensive responses suggests that cooing, freezing, and defensive hostility represent different and somewhat unrelated characteristics of animals' defensive styles. Pharmacologic data also support this notion. For example, manipulations of the opiate system affect A (alone condition)–induced cooing without affecting threat-induced freezing or hostility. Conversely, benzodiazepines reduce the threat-related behaviors, but have little effect on A-induced cooing (14).

Finally, to identify some of the mechanisms underlying these individual differences in defensive responding, the relationships between the stress-related hormone cortisol or asymmetric frontal EEG activity and individual differences in fearful behavior were examined. Thus, in 28 mother-infant pairs, it was found that in both mothers and infants freezing duration was significantly and positively correlated with baseline (nonstressed) cortisol levels (38). These data are consistent with findings from human studies demonstrating that extremely inhibited children have elevated levels of salivary cortisol (36 ,37), and is also consistent with findings in rodents that corticosterone (the rodent analogue of cortisol) is required for rat pups to develop the ability to freeze when threatened (39).

Extremely fearful monkeys (as identified by the HIP) also exhibit characteristic EEG patterns. In adult humans,

asymmetric right frontal brain activity has been associated with negative emotional responses (40). Our studies in rhesus monkeys have demonstrated similarities in this measure between monkeys and humans (41). Thus, it has been found that dispositionally fearful monkeys have extreme right frontal brain activity, paralleling the pattern of extreme right frontal activity in humans who suffer from anxiety-related disorders. In addition, it was found that individual differences in asymmetric frontal activity in nonhuman primates in the 4- to 8-Hz range are a stable characteristic of an animal (41 ,42). Furthermore, a significant positive correlation between relative right asymmetric frontal activity and basal cortisol levels in 50 one-year-old animals was found. As predicted, the more right frontal an animal was, the higher was its cortisol level. An extreme groups analysis revealed that extreme right compared to extreme left frontal animals had greater cortisol concentrations as well as increased defensive responses, such as freezing and hostility. The association between extreme right frontal activity and increased cortisol appeared to be long-lasting because the right frontal animals continued to demonstrate elevated cortisol levels at 3 years of age. These results are the first to link individual differences in asymmetric frontal activity with circulating levels of cortisol. This finding is important because both factors have been independently associated with fearful temperamental styles.

It has recently been found that cerebrospinal fluid (CSF) levels of corticotropin-releasing hormone (CRH), a peptide that mediates stress responses, are significantly elevated in monkeys that display exaggerated defensive responses to threatening stimuli (5). As stated before, these extreme individual differences in defensive behaviors are stable over time. Moreover, it was found that CSF CRH levels are also stable over time in rhesus monkeys. Finally, when comparing monkeys with extreme right frontal activity (that display exaggerated fearful responses) to those with extreme left frontal activity (that display low levels of fearful behaviors), the right frontal group was found to consistently have increased CSF CRH levels over a period of 4 years (5). Thus, it appears that extreme fearful behavioral responses in nonhuman primates are associated with increased levels of stress hormones such as cortisol and brain CRH, and also with extreme right frontal brain activity versus left frontal brain activity, a profile that has been found in humans suffering from stress-related psychopathology (43). Taken together, these findings suggest that in primates, a fearful endophenotype can be conceptualized as a constellation of hormonal, electrophysiologic, and behavioral characteristics. Studying species-specific defensive behaviors and their neuroendocrine and physiologic correlates offers a powerful approach for identifying animal correlates of anxiety.

Rodents

Extreme individual differences in the expression of stress-related defensive behaviors have also been noted in rodent species. The examination of naturally occurring genetic variations with regard to stress reactivity may have important implications for the elucidation of individual differences in sensitivity to stressful situations. One example of naturally occurring individual differences comes from the study of different rodent strains with regard to their level of stress-like behavioral responding to environmental stimuli. Because of the important role of the CRH system in regulating defensive behaviors induced by stressful or threatening situations, attention has been focused on identifying rat or mouse strains that display differential stress reactivity and different baseline levels of CRH gene expression. For example, it has been found that baseline levels of CRH messenger RNA (mRNA) are significantly higher in the amygdala of fawn-hooded rats compared to either Sprague-Dawleys or Wistars (44 ,45). Fawn-hooded rats have also been reported to exhibit exaggerated behavioral responses to stress such as enhanced freezing, leading to the suggestion that this strain may have utility as a model for endogenous stress-related CRH overexpression and anxiety. Strain differences, which essentially reflect differential genetic makeups, have also been found to influence the effects of acute environmental stressors on regulating CRH system gene expression. Thus, the stress of whole-body restraint produces a much larger increase in CRH mRNA levels within the hypothalamus of Fisher rats than in Wistars or Sprague-Dawleys (46 ,47). Similarly, the spontaneously hypertensive and borderline hypertensive strains of rats have increased basal and stress-induced levels of hypothalamic CRH mRNA compared to the Wistar and Sprague-Dawley strains (48 ,49 and 50).

In mice, it has been shown that the BALB/c strain is hyperresponsive to a variety of stressors compared to the C57BL/6 strain; BALB/c mice exhibit significantly higher avoidance of aversive areas in a light-dark transition test and an open field (51 ,52). These mice also show high levels of neophobia (53). Recent genetic mapping studies in these strains have revealed that these behavioral differences may be associated with differential levels of γ-aminobutyric acid receptor A ($GABA_A$) expression between the strains. For example, it has been found that BALB/c mice have significantly lower levels of benzodiazepine binding sites in the amygdala compared to C57BL/6 mice (54). As described below, alterations in the expression of $GABA_A$ receptors have been found to lead to increased anxiety-like behaviors in genetically modified mice (see CRH System Transgenic Mice).

Taken together, these findings indicate that different rodent strains, as a consequence of their distinct genetic makeups, display different baseline levels of gene expression within various systems that are known to regulate the expression of stress-induced defensive behaviors. The study of various rodent strains may thus help to identify the neurogenetic differences that contribute to individual differences in stress susceptibility, and thereby further characterize the interaction between genes and environmental

conditions in the etiology of anxiety. Although such information is useful, it remains to be determined whether or not the specific genetic differences identified above actually underlie the different behavioral effects. It is probable that a number of genes in addition to those described above are differentially expressed across different rodent strains. Which other genes differ across strains, and of these, which ones contribute to the behavioral profile? It is also unclear whether the differential gene expression patterns are the cause or the result of the different phenotypes observed in the separate strains. Future studies in which behavioral phenotypes are assessed after the application of novel gene targeting techniques to selectively disrupt or restore gene function in these rodent strains will aid in clarifying these issues.

MATERNAL DEPRIVATION: AN ENVIRONMENTAL MANIPULATION THAT CAN LEAD TO FEARFUL ENDOPHENOTYPES IN PRIMATES AND RODENTS

Part of "62 - Animal Models and Endophenotypes of Anxiety and Stress Disorders "

Converging lines of evidence from a number of species point to the importance of the early postnatal period, and in particular the bond between mother and infant, in the development of normal defensive behaviors and the putative emotional states underlying these behaviors. It has been observed that children who were placed in nurseries that lacked adequate social stimulation developed a syndrome of “protest, despair, and detachment” that may be analogous to an increase in defensive responses (55). Furthermore, recent reports suggest that children reared without appropriate nurturance can display neuroendocrinologic alterations and may develop long-term behavioral and emotional difficulties including an increased risk for stress-related psychiatric illness (56 ,57).

Perhaps the most significant environmental factor during the early development of mammals is the interaction between the infant and its mother. As described above, separation of an infant from its mother during this early developmental phase represents a significant stressor that markedly and negatively affects the subsequent emotional development of the infant (55 ,57). In fact, disruption of normal attachment behavior at critical developmental phases can, in a number of species, lead to marked and persistent disturbances in behaviors and brain systems that are thought to participate in the regulation of fear-related responses; this disruption may ultimately contribute to an individual's propensity to develop exaggerated or inappropriate defensive responses.

Altered maternal-infant interactions can lead to anxiety endophenotypes in nonhuman primates and rodents, thus identifying an environmental manipulation that can be used to create animal models of increased stress-related functioning. Indeed, a large body of work in monkeys and rats indicates that a number of deleterious and long-lasting effects are produced as a result of separating infants from their mothers prior to weaning. The notion that perturbations in the early postnatal environment might have enduring neuroendocrine, neurochemical, and behavioral effects was originally put forth several decades ago by Levine (58). It has since been demonstrated that a likely source of these alterations is a disruption of the interaction between mothers and pups (59 ,60).

Nonhuman Primates

The classic studies by Harlow and colleagues (20 ,61 ,62) of the effects of maternal separation in primates found that in addition to life-supporting nourishment, physical contact and comfort are necessary for primates' normal social and emotional development. During the first months of life, the attachment between mother and infant is intense, and as a consequence the infant remains in close proximity to its mother (61 ,63). Long-term maternal separation can result in profound alterations in stress-related behavioral responses in the separated offspring. Monkeys that have been separated from their mothers for prolonged periods during this time exhibit symptoms of enhanced defensive or fear-related behavioral responses into adulthood and appear socially withdrawn, a phenomenon that has led to the suggestion that the behavioral and neuroendocrine sequelae of maternal separation might provide a model for some of the dysfunction that is observed in anxiety disorders and depression (64 ,65 ,66 ,67 and 68).

Furthermore, neuroendocrine studies in rhesus monkeys indicate that an infant's stress hormone levels are negatively correlated with the number of offspring the mother had, suggesting that when mothers are less experienced, cortisol levels in their (early born) infants are high; elevated cortisol levels also correspond to increased fearful behavioral responses in the infants (38). Cortisol has been found to play an important role in mediating the development of defensive responses (69); thus, factors that were expected to affect infant primate cortisol concentrations were examined. It was found that maternal cortisol levels were moderately correlated with those of their infants (38). Interestingly, it was also found that maternal parity was negatively correlated with infant cortisol levels such that the current infants of mothers that previously had more offspring were likely to have lower cortisol levels. This finding indicates that a mother's past infant rearing and/or pregnancy experience may contribute to individual differences in infant baseline cortisol levels, and provides further support for the notion that the mother-infant interactions may be a critical factor in determining the future fearful disposition of the offspring (38). Although the precise mechanism for this interaction remains to be determined, it is likely that mothers with little rearing experience would interact differently with their infants than mothers with more experience.

Evidence for the notion that long-lasting dysregulation

of the CRH system may in part underlie the harmful consequences of early developmental stressors has been provided in a study of nonhuman primates that were exposed to adverse rearing conditions during infancy. Coplan and colleagues (70 ,71) found that CSF levels of CRH are basally and chronically elevated in adult bonnet macaques whose mothers were exposed for 3 months to an unpredictable variable foraging demand (VFD), in comparison to mothers confronted with either a high but predictable or low but predictable foraging demand. Infants reared by VFD-exposed mothers have been found to subsequently display abnormal affiliative social behaviors in adulthood (72). These findings are consistent with the recent results from this lab that indicate that CSF CRH levels are elevated in dispositionally fearful monkeys, and that this CRH elevation is a stable trait-like characteristic of fearful endophenotype (5).

Rats

These aforementioned findings in nonhuman primates support the notion that mother-infant interactions may be a critical factor in determining the future fearful disposition of the offspring. Maternal separation has also been found to produce long-term changes in defensive behaviors into adulthood in rats. Using the maternal separation paradigm in rats, investigators have also been able to begin to elucidate some of the alterations in gene expression that take place in response to this early life stressor.

Interestingly, the nature of the separation determines the direction of the long-term changes, as has been reviewed in detail recently (73 ,74 and 75). Thus, brief periods of separation (3 to 15 minutes per bout, once a day, for roughly 2 weeks) from the mother result in a profile indicative of diminished anxiety, whereas more protracted separations (3 hours or more) have the opposite effect, resulting in increased stress-like responses. In an elegant series of studies by Plotsky and Meaney (76), the long-term effects of these different types of maternal separation have been described, and the behavioral and neuroendocrine mechanisms underlying these long-term effects have been characterized. It was initially found that rat pups that underwent very short periods of separation (termed “handling”) from their mothers had decreased basal levels of hypothalamic CRH mRNA and median eminence CRH immunoreactivity as adults compared to undisturbed control rats. As adults, these “handled” pups also displayed significantly lower elevations of stress-induced corticosterone levels and blunted CRH release from the median eminence relative to controls. It has since been found that the mechanism underlying this reduction in stress-related functioning in handled rat pups involves the type of maternal behavior that is displayed after the pups are returned to the mother (77), confirming earlier hypotheses that maternal behavior is the critical component in the developmental milieu of the infant (58). A brief removal of rat pups from the dam results in a significant increase in the amount of licking, grooming, and arched-back nursing (LG-ABN) that the mother lavishes on the pups when they are returned; the total amount of time spent nursing and contacting the offspring is not affected, but rather the quality of the interaction between mother and pup is altered. In nonseparated pups, individual differences in LG-ABN predict hypothalamic-pituitary-adrenal (HPA) axis responsivity in adulthood such that mothers that engage in high levels of LG-ABN have offspring that, as adults, show reduced HPA axis activation in response to stress and have decreased levels of CRH mRNA in the paraventricular nucleus (PVN) of the hypothalamus (77). Pups that are born to mothers that naturally exhibit high levels of LG-ABN grow up into adults that display low-anxiety–like behaviors (increased exploration of novel environments) and compared to low–LG-ABN offspring, have decreased levels of CRH receptors in brain regions such as the locus coeruleus that are thought to mediate stress responses (78). Taken together, these findings indicate that increased nurturing physical contact from the mother can lead to a toned-down stress-responsive system in the offspring.

In contrast, longer periods of maternal separation seem to have the opposite effect on stress-related functioning later in life. Rat pups that are separated from the mother for 3 hours or longer (investigators have often used a 24-hour separation) show in adulthood increased CRH system gene expression, exaggerated HPA axis responses to stress, and increased stress-like behaviors in paradigms such as the elevated plus maze (76 ,79 ,80). Other intense stressors such as an endotoxin insult during the perinatal stage are also able to produce marked elevations in basal CRH gene expression and lead to an exaggerated stress-induced HPA axis response in adulthood (81). It has accordingly been hypothesized that the perinatal environment plays a critical role in “programming” or “setting” the animal's stress coping system (perhaps through alterations in CRH system gene expression) for the remainder of its life (73 ,74 and 75). Maternally separated rats also show alterations in other systems that are known to regulate stress-related behaviors and that are consistent with an increased fearful endophenotype. For example, maternal separation increases the release of norepinephrine into the PVN of the hypothalamus in response to restraint stress; stress-induced plasma adrenocorticotropic hormone (ACTH) levels were also elevated in maternally deprived rats (82). Early life stressors such as maternal separation may therefore play an important role in determining the eventual stress-related endophenotype that is exhibited in adulthood. Moreover, the aforementioned studies provide an example of how the animal endophenotype approach can be applied to investigating molecular correlates of anxiety-related conditions.

It should be mentioned that prenatal stress can also produce alterations in indices of stress-induced responding in adulthood. For example, in rats, disturbing the prenatal environment by stressing the mother can lead to increases in

CRH gene expression in the fetal PVN, increases in CRH content in the amygdala of adult offspring, and potentiation of stress-like behavioral responses in these rats whose mothers had undergone stress during pregnancy (83 ,84 and 85). These findings further support the notion that mother-infant interactions may be a critical factor in determining the future fearful disposition of the offspring.

TARGETED MUTATIONS LEADING TO ANXIETY-LIKE ENDOPHENOTYPES: STUDIES OF TRANSGENIC MICE

Part of "62 - Animal Models and Endophenotypes of Anxiety and Stress Disorders "

A perhaps more direct approach for studying the genetic underpinnings of a particular animal endophenotype is to characterize the change in an organism's interaction with its environment following either overexpression or underexpression of a particular gene product. Transgenic and knockout mice are thus now widely used in the ongoing effort to understand the contributions of specific genes to psychopathology. The detailed methodology for the generation of these animals and their use in neuroscience research has been reviewed (86). Briefly, genetic alterations are introduced in the embryonic stage such that the mouse develops with the mutation, thereby putatively providing a model for congenital abnormalities that may contribute to anomalous functioning and the expression of a particular endophenotype.

Using this strategy, a variety of components within the CRH, serotonin (5-hydroxytryptamine, 5-HT), and GABA systems have been successfully targeted and studied for their roles in mediating stress-related behavioral effects (87 ,88 and 89). It should be noted that in addition to the aforementioned systems, there are several other important central regulators of stress and anxiety-related processes. The norepinephrine system has long been implicated in the modulation of anxiety states. Several recent reviews detail the preclinical and clinical evidence for the involvement of norepinephrine (NE) in anxiety-related disorders such as panic and posttraumatic stress disorder (90 ,91). Indeed, ß-adrenergic receptor antagonists and α_2-receptor agonists are effective in the treatment of certain anxiety-related symptoms in humans. In addition, recent preclinical evidence indicates that a variety of central nervous system (CNS) peptides including cholecystokinin (CCK), neuropeptide Y (NPY), and substance P/neurokinins participate in the regulation of anxiety-like behaviors (92 ,93 and 94).

Although these peptide and neurotransmitter systems undoubtedly play a role in stress- and anxiety-related behaviors, the focus of the following section will be the CRH, 5-HT, and GABA systems because these three systems are perhaps the most thoroughly studied with transgenic models. Although the transgenic/knockout approach has provided valuable new information about the genetic regulation of stress-related fearful endophenotypes, it should be kept in mind that there are a number of important caveats regarding the interpretation of findings from transgenic animal studies (described at the end of this section). As outlined below, alterations of discrete genes within each of these systems results in an anxiety-like murine endophenotype, characterized by the increased expression of certain aspects of rodent defensive behaviors.

The CRH System

CRH and the related endogenous peptide agonist urocortin (95) bind to the two cloned CRH receptors, designated CRH1 and CRH2 (96 ,97 and 98), and to the CRH binding protein (CRH-BP) (99). The CRH-BP has been postulated to function as an endogenous buffer for the actions of the CRH family of ligands at their receptors (100). CRH, its receptors, and its binding-protein are expressed in key structures of the HPA axis, and thereby participate in mounting the neuroendocrine response to environmental perturbations. The various elements of the CRH system are widely and heterogeneously expressed in cortical, limbic, and brainstem structures and these regions are thought to regulate behavioral responses to stress.

CRH System Transgenic Mice

Given that central infusion of CRH results in enhanced fear-related defensive behaviors, CRH-overexpressing mice were predicted to display increased stress-like behavioral responses. Indeed, these mice have been found to have several behavioral effects associated with acute CRH administration. CRH overexpressing mice exhibit a profile that is consistent with increased levels of stress, such as reduced baseline and stress-induced exploration of a novel environment, and decreased activity and time spent in the open arms of an elevated plus maze (101 ,102). These effects are potently blocked by administration of the CRH receptor antagonist α-helical CRH. CRH transgenic mice also show a profound decrease in sexual behaviors and significant deficits in learning; higher order functions such as these are typically abolished when a situation is found threatening and defensive behaviors are recruited (103 ,104). Thus, CRH overexpressing transgenic mice may represent a genetically engineered model of a murine anxiety-like endophenotype.

Consistent with the notion that heightened CRH transmission elicits stress-like behaviors is the finding that CRH-BP knockout mice show increased stress-like behaviors. CRH-BP knockout mice displayed decreases in open arm entries and open arm time in an elevated plus maze, and showed a decrease in the number of exits from a safe box in a defensive withdrawal/open field paradigm (105). These results indicate a heightened level of neophobia in these mice. Moreover, CRH-BP knockouts have reduced body weight gain over several weeks (105 ,106), which is also syntonic

with increased basal CRH activity. The behavioral profile of CRH-BP knockouts is similar to that which is seen with exogenous CRH administration (107), and supports the notion that removal of the CRH-BP may lead to increased basal stress responses due to increased CRH tone. Thus, as with the CRH-overexpressing mice, CRH-BP knockouts may represent another rodent anxiety-like endophenotype. In terms of the predictive validity of these models, CRH receptor antagonists have been found to block the stress-like behavioral profile observed in these animals; one recent clinical study indicates that CRH1 receptor antagonists may indeed prove to be effective anxiolytics or antidepressants (108).

Interestingly, deletion of the CRH gene does not appear to decrease stress-like behaviors, as might be predicted from the aforementioned work. Although certain endocrinologic deficits are observed in CRH knockout mice, stress-related behavioral function in these animals remains relatively unaffected as assessed by multiple stress-related paradigms (109 ,110 ,111 ,112 ,113 and 114). This sparing of normal stress responsivity may be due to compensatory increases in the expression of other CRH system ligands such as urocortin. Deletion of the CRH1 receptor gene, however, does appear to consistently result in a putative reduction in anxiety (115 ,116 and 117). For example, CRH1 knockout mice show increased exploration of the open arms on an elevated plus maze and spend more time in the brightly lit compartment of a dark-light transition box than do wild-type controls. Moreover, CRH1 knockout mice appear to be immune to the anxiogenic effects of ethanol withdrawal (117). Studies of CRH2 receptor knockout mice, on the other hand, indicate that these mice display a less consistent behavioral profile than the CRH1 knockout mice (118 ,119 and 120). Part of the behavioral profile of CRH2 knockouts is suggestive of increased stress-like responding, but other aspects of the behavioral profile indicate either no alteration of stress-related responding (118 ,119), or a decrease in anxiety-like behaviors (120). The observed increases in anxiety-like behaviors in these genetically altered mice may be due to increased levels of brain CRH and/or urocortin; in two of the three studies, an elevation of baseline CRH or urocortin mRNA levels in the CNS was seen in CRH2 knockout mice (118 ,119). Thus, the endophenotype displayed by CRH2 knockout mice may actually be indirectly due to a compensatory alteration induced by the mutation rather than simply due to a lack of CRH2 receptor expression. It should be noted that acute blockade of CRH2 receptors results in a decrease in stress-induced defensive behaviors; thus the behavioral profile of these animals is opposite to that of mice that are missing the CRH2 receptor (121 ,122). Thus, the timing of the gene deletion may critically influence the nature of the behavioral phenotype that ensues. Future studies utilizing novel inducible-knockout technologies may help in clarifying the developmental versus acute role of various genes in the development of anxiety-related endophenotypes (123).

Clinically Effective CRH System Drugs for Stress-Related Disorders

A large body of preclinical literature indicates that CRH is a critical modulator of stress and anxiety-like behaviors in nonhuman primates and rodents (107 ,124). Based on the ability of CRH1 receptor-selective antagonists to block many of the behavioral effects of stress or CRH administration, these antagonists have been proposed as potentially therapeutic agents for the treatment of stress-related psychiatric conditions including anxiety and depression (125). Pharmacologic analysis of stress-induced primate defensive responses has also revealed that the CRH system is a critical modulator of this index of anxiety-related behavior. For example, administration of CRH into the cerebral ventricles of nonhuman primates results in a constellation of behavioral responses that closely resemble the defensive responses that are exhibited upon presentation of a stressor (124). Consistent with the notion that increased levels of CRH are associated with increased anxiety-like responding are the recent findings that small-molecule CRH1 receptor antagonists block the expression of some behavioral, physiologic, and neuroendocrine responses to stressors in rhesus monkeys (126 ,127). The first report of an open-label clinical trial with a CRH1 antagonist was recently published, and revealed a significant effect of this compound in ameliorating symptoms of depression and anxiety (108). Although further research is needed to firmly establish the utility of CRH1 antagonists as psychotherapeutic agents and also to determine the possible side effects associated with their use, these preliminary data support the notion that these compounds represent an important new class of drugs that may offer great promise for the treatment of illnesses associated with increased anxiety and stress.

The 5-HT System

Serotonin is a member of the monoamine family of transmitters that also include dopamine and norepinephrine. As is typical for the monoamines, cell bodies for this neurotransmitter are found in discrete nuclei within the midbrain (dorsal and medial raphe nuclei) and send widespread 5-HT–containing projections throughout the brain (128). 5-HT produces its effects through at least 15 different 5-HT receptors that are differentially distributed throughout the CNS; the principal mode of 5-HT inactivation is cellular reuptake via terminal transporter proteins (129). The 5-HT system has long been implicated in the regulation of mood states and anxiety, and selective serotonin reuptake inhibitors (SSRIs) constitute a major class of antidepressants that have anxiolytic effects. As outlined below, 5-HT transmission also plays a critical role in the regulation of anxiety-like

behaviors. Given the plethora of 5-HT receptors and the paucity of highly selective ligands for these multiple target sites, several investigators have employed murine gene targeting strategies to elucidate the roles of specific 5-HT receptors in the regulation of stress and anxiety.

5-HT System Transgenic Mice

Studies of targeted gene deletions within the 5-HT system have revealed an important role for this system in the regulation of stress and anxiety-related behaviors in mice. The behavioral sequelae of disrupting 5-HT receptor gene expression have been elegantly summarized in several review articles (89 ,130 ,131 and 132). Perhaps the best-characterized 5-HT mutant mice are the 5-HT_{1A} and 5-HT_{1B} receptor knockouts. Mice with a mutation in the 5-HT_{1A} receptor gene have been found to display increased stress-like behaviors in multiple tests of approach-avoidance conflicts. These animals show decreased entries into and time spent in the more aversive region in paradigms such as the open field, elevated plus maze, and the elevated zero maze; thus 5-HT_{1A} knockout mice avoid the center of an open field, the open arms of a plus maze, and the unenclosed regions of a zero maze (133 ,134 and 135). It is worth noting that this “increased anxiety” pattern of results was found consistently across three different research labs, indicating its robustness and reproducibility. Consistent with this profile is the finding that these mice also exhibit decreased activity in the presence of and approach toward a novel object (135). This increase in stress-like responding is not accompanied by changes in overall locomotor activity or motor and spatial coordination, as assessed in photocell cages and a RotaRod apparatus. Curiously, 5-HT_{1A} knockout mice display increased mobility in response to an acute stressor such as forced swimming or tail suspension (133 ,134 and 135). Taken together, these findings indicate that 5-HT_{1A} knockout mice may represent another animal endophenotype of increased anxiety.

The constitutive knockout of the 5-HT_{1A} receptor does not seem to lead to compensatory alterations in the expression of serotonin or its transporter, or to changes in catecholamine levels in several brain regions (135). Interestingly, a recent report indicates that this mutation alters GABA system expression and function (136). It has been found that anxiety-like behaviors in 5-HT_{1A} knockout mice are relatively unaffected by benzodiazepine treatment. Analysis of brain tissue from these animals indicates that $GABA_A$ receptor binding is reduced and that the expression of α_1 and α_2 subunits of the $GABA_A$ receptor are decreased in the amygdala. The anxiolytic actions of benzodiazepines may in part be mediated by $GABA_A$ receptors within the amygdala; the profile of results in 5-HT_{1A} knockout mice has led to the intriguing speculation that the anxiety-like endophenotype in these mice may actually in part derive from a decrease in the expression and function of the GABA*A* receptor (136). This proposed mechanism is consistent with the increase in stress-related behaviors that are seen in certain transgenic mice with mutations in the GABA*A* receptor (see below). Further work is necessary to determine the precise mechanisms through which the developmental interruption of 5-HT_{1A} gene expression results in the observed anxiety-like endophenotype.

In contrast to 5-HT_{1A} knockout mice, mice that lack the 5-HT_{1B} receptor show decreased anxiety-like behaviors in several tests of approach-avoidance conflicts. 5-HT_{1B} knockout mice spend more time in the center of an open field and more readily explore novel objects than their wild-type controls; this profile is opposite from that of 5-HT_{1A} knockout mice, and is suggestive of diminished neophobia (89 ,137). Consistent with this pattern of results is the finding that as pups, 5-HT_{1B} mice emit fewer ultrasonic vocalizations when separated from their mothers; separationinduced vocalizations are thought to provide a measure of anxiety and distress in pups (138 ,139). It is interesting to note, however, that no changes in contextual or cue-induced conditioned freezing are observed in 5-HT_{1B} mutant mice, suggesting that approach-avoidance conflicts and conditioned fear may be differentially modulated by the 5-HT system. The other main behavioral effect of constitutive 5-HT_{1B} receptor deletion is a marked increase in aggressive behavior (89 ,140 ,141). Given that aggressive behaviors represent an important part of an organism's response to threat, 5-HT_{1B} knockout mice may also provide valuable information on the neural and genetic factors associated with stress and anxiety-related functioning (89 ,142).

It should be noted that mice with null mutations of other 5-HT receptor subtypes have also been generated, but these animals have not been found to display as robust an anxiety-related behavioral profile as the 5-HT_{1A} or 5-HT_{1B} knockout mice. It has been found that 5-HT_{5A} receptor knockout mice show increased exploratory activity in the presence of novelty, but do not differ from wild-type controls with regard to avoidance behaviors from an aversive environment such as the open arms of a plus maze, or the center of an open field (143). These knockout mice also do not respond differently from control subjects in tests of startle reactivity or in burying a probe that delivered a brief electric shock. Thus, these animals appear to have yet a different behavioral profile from that of the 5-HT_{1A} or 5-HT_{1B} knockout mice. An initial report indicates that 5-HT_6 receptor deficient mice may exhibit increased avoidance of aversive environments; although these preliminary findings are interesting, further work is needed to fully characterize the phenotype of these mutant mice (144 ,145). Mice lacking either the 5-HT_{2A} or 5-HT_{2C} receptors have also been created; to the best of our knowledge, the stress-related behavioral functioning of these animals has yet to be reported (146 ,147).

Clinically Effective 5-HT System Drugs for Stress-Related Disorders

As mentioned above, one of the most commonly prescribed and effective classes of drugs that is used in the treatment of depression and anxiety is the SSRIs, which block the reuptake of 5-HT by its transporter and thereby increase serotoninergic transmission. Based on the findings of preclinical studies including those obtained from 5-HT receptor knockout mice, 5-HT_{1A} agonists have been developed for the treatment of anxiety. The clinical utility of this class of compounds, however, remains to be determined. As these transgenic approaches develop and become more refined, they will undoubtedly aid in clarifying the roles of the many other 5-HT receptor subtypes in processes related to stress and anxiety and will aid in drug development.

The GABA System

The primary inhibitory neurotransmitter in the CNS is GABA; GABA-synthesizing cells are distributed throughout the brain (128). The actions of GABA are mediated by two major classes of receptors, $GABA_A$ and $GABA_B$, both of which modulate the activity of ion channels. The principal mode of inactivation of GABA transmission is the presynaptic reuptake of GABA by its transporter protein. Although both types of GABA receptors are widely distributed through the CNS, several important differences exist between the two. Relevant to psychopharmacology is the finding that traditional anxiolytics (benzodiazepines) do not bind to $GABA_B$ receptors, but rather mediate their effects through $GABA_A$ receptors. $GABA_A$ receptors consist of a chloride channel formed by the pentameric arrangement of at least 18 different protein subunits (α_{1-6}, β_{1-4}, γ_{1-3}, δ, ε, π, ρ_{1-3}), thus allowing for considerable heterogeneity of the $GABA_A$ receptor isoforms (148). Typically, benzodiazepine-responsive $GABA_A$ receptors consist of α, ß, and γ subunits; in addition to the benzodiazepine site, these receptors also contain distinct sites for the binding of GABA, barbiturates, and ethanol. These various regions act as allosteric regulators of GABA-induced chloride channel opening. Although psychotherapeutic effects such as anxiolysis are achieved through facilitation of GABA transmission at this receptor, drugs that act as $GABA_A$ receptor agonists also produce several deleterious side effects. The extent to which differences in $GABA_A$ receptor subunit composition might contribute to possible dissociations between the beneficial and negative effects of these compounds is currently being investigated.

GABA System Transgenic Mice

The synthesis of GABA is regulated by two isoforms of the enzyme glutamate decarboxylase (GAD), GAD67, and the shorter form GAD65 (149). Whereas GAD67 is thought to maintain basal GABA levels, GAD65 is thought to regulate the synthesis of GABA at nerve terminals in response to high GABA demand (150). Given the important role of GABA in inhibitory neurotransmission associated with anxiolysis, several investigators have evaluated the behavioral profile of genetically altered mice that lack the GAD65 gene. Two separate groups have reported that $GAD65^{-/-}$ mice display an increase in stress-like behaviors in numerous behavioral paradigms (151 ,152). GAD65 knockout mice had fewer entries into and time spent in the center of an open field or the open areas of an elevated zero maze (similar to an elevated plus maze), indicating that they were more avoidant of inherently aversive areas. Similarly, these mice had lower levels of activity in the bright portion of a light-dark transition box. It should be mentioned that $GAD65^{-/-}$ mice also displayed an elevation in the occurrence of spontaneous and stress-induced seizures, and that these mice had a dramatically increased mortality rate starting at 4 to 5 weeks after birth (151). Thus, although the behavioral profile of GAD65 knockout mice is suggestive of increased anxiety-like responses, it is possible that these effects are secondary to the occurrence of seizures and to the factors leading to early lethality. The usefulness of this knockout as a model for anxiety-related deficits may therefore be limited. Given that benzodiazepines and barbiturates act as positive modulators of GABA transmission at the $GABA_A$ receptor by enhancing GABA-induced chloride channel opening, it is of interest to note that $GAD65^{-/-}$ mice were not sensitive to the effects of either benzodiazepines or barbiturates, but did respond to the direct $GABA_A$ agonist muscimol, which binds directly to the GABA site of the $GABA_A$ receptor and increases opening of the chloride channel in the absence of GABA (152). This pharmacologic profile is consistent with the finding that GABA synthesis is blocked by the GAD65 null mutation, but that $GABA_A$ receptor binding is unaffected by this change. Furthermore, this mutation does not seem to alter the functioning of GABA receptors because direct agonists stimulate the receptor but indirect modulators of GABA do not.

In an attempt to delineate the roles of the various $GABA_A$ receptor subunits in the regulation of stress- and anxiety-related behaviors, investigators have generated mutant mice with alterations in the expression of specific $GABA_A$ receptor subunits. It was initially reported that deletion of the γ_2 subunit led to a selective (94%) reduction in the expression of benzodiazepine sites in the CNS without alterations in the level of GABA sites or changes in the expression of other $GABA_A$ receptor subunits (153). Thus, γ_2 knockout mice possessed functional $GABA_A$ receptors that responded normally to GABA site ligands or barbiturates, but did not respond to benzodiazepines; these findings led to the conclusion that the γ_2 subunit is not necessary for the formation of functional $GABA_A$ receptors, but is required to create

the benzodiazepine-responsive site of those receptors. Mice that were homozygous for the mutation, however, did not live past weaning in this study. In mice carrying only one copy of the functional γ_2 gene, a 20% reduction in benzodiazepine sites was observed, but these mice did not show overt developmental deficits. In a recent study, a detailed characterization of the behavioral profile of these animals was carried out. Heterozygotes displayed a decrease in the number of entries into and amount of time spent in the open arms of an elevated plus maze and the bright compartment of a light-dark box. These animals also exhibited a decrease in the exploration of novel areas, and an increase in certain forms of fear conditioning that are thought to be mediated by the hippocampus. Finally, γ_2 heterozygotes were found to react to partially conditioned stimuli (only weakly paired with aversive consequences) as if they were full and potent predictors of threat; compared to wild-types, which showed low levels of defensive behaviors to the partially conditioned stimulus, heterozygotes displayed high levels of conditioned freezing to the partial conditioned stimulus that were identical to those displayed by all animals in response to the full conditioned stimulus. This profile has been proposed to be a model for the tendency to interpret neutral situations as threatening that is seen in anxiety patients. Taken together, the results from this extensive behavioral profile indicate that $\gamma_2^{+/-}$ mice have increased neophobia and stress-like responses and may thus provide a model for increased anxiety-like behaviors (154 ,155 and 156). Interestingly, all of the elevations in stress-like behaviors in γ_2 heterozygotes were blocked by the benzodiazepine diazepam, suggesting that this animal model may also have good predictive validity for identifying clinically effective anxiolytics.

It is also extremely important to mention the α_1 subunit transgenic mice, whose behavioral profiles have been thoroughly and insightfully reviewed in recent articles (157 ,158). In these mice, a single amino acid is altered (histidine replaced by arginine at the 101 position of the peptide) in the α_1 subunit of the $GABA_A$ receptor complex. This subtle change does not produce any overt alterations in baseline responses to stress in the genetically altered mice; these animals behave similarly to wild-type controls in tests such as the elevated plus maze and the fear-potentiated startle paradigm, a measure of conditioned fear (159 ,160). Thus, under drug-free, normal conditions, these animals do not display a behavioral pattern that is consistent with an anxiety-like endophenotype. When these mice are treated with conventional benzodiazepines, however, they react very differently to the drug than their wild-type counterparts. Mice with the mutation in the α_1 subunit display a normal reduction of stress-induced anxiety-like behaviors after benzodiazepine treatment, but fail to display some of the more deleterious side effects associated with this class of drugs such as sedation, amnesia, and ataxia. These results indicate that the anxiolytic effects of benzodiazepines can be separated from the negative side effects of these compounds, and that the α_1 subunit of the $GABA_A$ receptor is likely to mediate some of these potentially harmful properties of benzodiazepines. Interestingly, McKernan and colleagues (160) demonstrate that a novel benzodiazepine-site ligand that binds to $GABA_A$ receptors containing α_2, α_3, or α_5 subunits but avoids receptors with the α_1 subunit produces a behavioral profile that is identical to that of the α_1 subunit knockout mice; in normal mice, this compound decreases murine anxiety-like behaviors without eliciting sedation or ataxia (160).

Clinically Effective GABA System Drugs for Stress-Related Disorders

As stated above, the most widely used GABA system-based drugs for the treatment of anxiety are the benzodiazepines, which facilitate GABA transmission through the $GABA_A$ receptor. As outlined in the previous section, the search for novel compounds that may act selectively at specific $GABA_A$ subunits is ongoing, with the ultimate hope of discovering ligands that produce anxiolysis but do not cause some of the serious side effects that are commonly associated with benzodiazepines. As demonstrated by McKernan and colleagues (160), drugs that selectively target certain $GABA_A$ receptor subunits may hold great promise for the treatment of anxiety without harmful side effects. This development would represent a major breakthrough in the pharmacotherapy of anxiety-related disorders. The use of targeted genetic alterations in identifying the roles of various $GABA_A$ subunits will undoubtedly aid in this effort to create “designer drugs” for the treatment of anxiety (158).

General Issues and Caveats of Transgenic Animal Studies

As mentioned above, mice carrying certain mutations within either the CRH, the 5-HT, or the GABA system display an anxiety-like endophenotype. It appears that these genetically engineered mouse models also have some predictive validity; the stress-like endophenotype observed in at least two of the aforementioned models is normalized by administration of a clinically effective antianxiety agent that acts within the system that was genetically targeted. It remains to be determined, however, the extent to which these genetically altered models serve to identify potential antianxiety agents from different chemical classes. For example, do benzodiazepines reduce stress-like effects of CRH overexpressers? The extent to which the stress-like endophenotype in these animals is altered by compounds that act on systems that were not directly targeted by the genetic mutation will aid in determining the generalizability and utility of these models as predictors of novel anxiolytic agents. If one assumes that these animals provide a model of inherent trait-like anxiety, they can serve as a powerful tool for

screening new potential anxiolytics. These models do provide a sound approach to study the long-term effects of congenital abnormalities in these neurotransmitter and neuropeptide systems.

Several broad issues should be considered when interpreting studies utilizing genetically altered mice. Generally, the hypotheses regarding the behavioral profiles of transgenic mice are based on earlier findings from psychopharmacologic studies. For example, within the CRH field, the prediction that CRH overexpressers would display increased anxiety-like behaviors was based on the observation that CRH administration produces stress-like behaviors in rodents and primates (107 ,124). When the outcome of the transgenic studies agrees with the psychopharmacology-based prediction, the findings are taken as a confirmation of that hypothesized mechanism of action. When the outcome of the transgenic studies disagrees with the predicted phenotype, however, concerns about possible developmental confounds are raised. One of the most commonly cited drawbacks of the transgenic/knockout strategy is that the gene of interest is altered from the embryonic stage, therefore possibly influencing other genes involved in the normal development of the animal. Thus, it is difficult to tease apart the effects of under- or overexpression of that gene on the endpoints under study from effects due to compensatory or downstream developmental changes that may have occurred as a result of the mutation (86 ,87 ,161). Therefore, the transgenic/knockout approach provides an excellent method for modeling a congenital abnormality that leads to a disease state, but this approach may be less useful for identifying the discrete functions of a specific gene product because of the problems of interpretation that arise from the developmental confound. Indeed, with regard to all of the studies discussed in this section on genetically altered mice, it will be important in future studies to delineate the compensatory alterations that occur in response to the congenital mutation, and that may indirectly contribute to the adult endophenotypes that are reported for these animals. Future studies utilizing novel inducible-knockout strategies will circumvent the developmental issue; inducible knockouts may thus become a valuable tool for exploring the functions of discrete gene products for which no selective ligands are available (123).

It should also be noted that there is a large literature concerning the use of antisense oligonucleotide infusions to knock down the expression of particular gene products that may be related to fearful endophenotypes. The antisense oligonucleotide approach, however, has been plagued with a number of issues regarding toxicity, and may therefore not represent the optimal method for studying gene function *in vivo* (162).

FUTURE DIRECTIONS

Although the studies summarized in this chapter have contributed a great deal of knowledge about some of the genetic contributions to the development of stress and anxiety-like endophenotypes in animals, further information is needed to understand the precise nature of gene–environment interactions in stress regulation. It is likely that a particular stressor results in alterations of gene expression in myriad systems and that the overall response to stress involves the coordination of gene activation and/or suppression within these various systems. Novel high-throughput technologies have recently been developed that enable the expression of thousands of genes to be assayed at once. “Gene chips” and “DNA arrays” are two powerful new tools for analyzing complex multilocus genetic interactions associated with a particular environmental perturbation or disease state (163 ,164). This approach and its application to psychiatry research have been discussed comprehensively in a recent review article (165). Briefly, gene chip and DNA array technology involve the hybridization of gene transcripts from a tissue sample onto a glass slide or filter that contains up to 10,000 different nucleotide sequences. The amount and pattern of the signal hybridized to the array are then assessed; this method thus permits a rapid analysis of changes in the expression of multiple genes. This technology can also be used to identify single nucleotide polymorphisms in a particular gene by comparing the hybridization patterns of samples from different candidate populations on chips that contain multiple copies of the gene of interest, each copy differing from the previous one by just one base in the sequence. Theoretically, depending on the size of the gene, it would be possible to carry out a base-by-base examination of the entire gene on a single gene chip. However, it is important to realize that although a broad approach can be taken with this technology, it may not be sensitive enough to detect small but functionally important changes in gene expression. This technology can be applied to preclinial and clinical questions regarding the complex genetic control of stress and anxiety by examining event-related gene expression changes and also baseline differences in gene sequences (polymorphisms) that might contribute to differential stress responsivity (165). This technique, along with the recent completion of the Human Genome Project, not only raises the potential to simultaneously profile multiple gene expression systems at once, but also holds great promise for the identification of completely novel genes in stress regulation and anxiety.

A greater challenge, however, is the elucidation of the functional role of these new genes in processes related to stress and anxiety. Given this daunting task, methods for more specific and long-term gene targeting will increasingly gain importance in neuroscience research aimed at uncovering genetic dysregulation relating to psychopathology. One technique that is likely to be helpful is that of virally mediated gene transfer. In this method, a gene of interest is cloned into viral vector (with most of the viral genome removed to reduce toxicity and infection) and the modified vector is then infused into a particular brain region using

standard stereotaxic procedures (see ref. 166 for review). Depending on the gene insertion and the selection of the promoter to drive the expression of the gene, it is possible to obtain either an increase or decrease in the amount of protein resulting from the gene of interest. This method allows for highly selective gene regulation and thus provides a valuable new tool with which to study the effects of a particular gene product on stress-related functioning. The virally mediated gene transfer approach also has certain advantages over the current transgenic and antisense oligonucleotide strategies: it can be administered to the animal at any time or into any brain region, it results in a fairly robust and long-lasting up- or down-regulation of the gene, and it can be used to insert several genes at once in the same animal. Thus, the viral gene transfer approach completely avoids the issue of developmental confounds, which are perhaps the most commonly cited problems that plague current transgenic and knockout approaches. A few groups have already reported successful long-term up-regulation or down-regulation of discrete gene products related to neuroscience research applications; the behavioral effects associated with this technique appear to be quite robust and do not appear to be associated with the high level of toxicity that has been reported with antisense oligonucleotides (167 ,168 and 169). Thus, these methods may provide valuable new strategies to more rapidly uncover the neurogenetic basis for stress-related psychopathology.

On the clinical side, human genomic studies are indicating the existence of polymorphisms in the regulatory region of the gene encoding CRH (170 ,171 and 172). As careful analysis of genes for the other elements of the CRH system progresses, it will be interesting to see if particular mutations can be associated with stress-related disease states. This method has been applied successfully to study the role of the serotonin (5-HT) system in anxiety disorders; reports of polymorphisms in the gene encoding the 5-HT transporter have been made in patients with anxiety-related traits (173 ,174 ,175 and 176). Clinically, one challenge will be to develop more discrete definitions of anxiety-related dysfunction that will optimize the screening of patient populations for abnormalities in genes that are believed to be related to stress and anxiety (177). Moreover, gene chip technology applied to animal analogues of stress endophenotypes may provide a rapid and comprehensive method for identifying novel gene candidates for stress-related disorders. Using these methods, it may be possible in the near future to have even greater crosstalk between animal studies and clinical findings. These combined efforts will undoubtedly facilitate our understanding of the interactions between environmental and genetic contributions to anxiety and stress-related disorders.

Neurobiological Basis of Anxiety Disorders

Dennis S. Charney

Wayne C. Drevets

Dennis S. Charney: Mood and Anxiety Disorder Research Program, National Institute of Mental Health, Bethesda, Maryland.

W. C. Drevets: Section on Mood and Anxiety Disorders Imaging, Molecular Imaging Branch, National Institute of Mental Health, Bethesda, Maryland.

The 1990s witnessed tremendous progress in the acquisition of knowledge about the molecular, cellular, and anatomic correlates of fear and anxiety. Advances in neuropharmacology and molecular biology have enabled elucidation of multiple chemical neurotransmitter systems that play roles in fear and anxiety behavior. The anatomic circuits where these transmitters participate in mediating and modulating fear and anxiety are also being illuminated through improvements in neurotoxic techniques, which have enhanced the selectivity of lesion analyses in experimental animals, and by advances in neuroimaging technology, which have permitted mapping of the neurophysiologic correlates of emotion in humans. The findings of these investigations have informed the design and interpretation of clinical neuroscience approaches aimed at investigating how dysfunction within these neurochemical and anatomic systems may result in psychiatric conditions such as panic, posttraumatic stress, and phobic disorders. This chapter reviews the preclinical and clinical data regarding the neural mechanisms underlying normal and pathologic anxiety and discusses their implications for guiding development of novel treatments for anxiety disorders.

NEUROANATOMIC CIRCUITS SUPPORTING FEAR AND ANXIETY

Part of "63 - Neurobiological Basis of Anxiety Disorders "

Fear and anxiety normally comprise adaptive responses to threat or stress. These emotional-behavioral sets may arise in response to exteroceptive visual, auditory, olfactory, or somatosensory stimuli or to interoceptive input through the viscera and the endocrine and autonomic nervous systems. Anxiety may also be produced by cognitive processes mediating the anticipation, interpretation, or recollection of perceived stressors and threats.

Emotional processing in general can be divided into evaluative, expressive, and experiential components (1). Evaluation of the emotional salience of a stimulus involves appraisal of its valence (e.g., appetitive versus aversive), its relationship with previous conditioning and behavioral reinforcement experiences, and the context in which it arises (2 ,3). Emotional expression conveys the range of behavioral, endocrine, and autonomic manifestations of the emotional response, whereas emotional experience describes the subjective feeling accompanying the response. To optimize their capacity for guiding behavior, all these aspects of emotional processing are modulated by complex neurobiological systems that prevent them from becoming persistent, excessive, inappropriate to reinforcement contingencies, or otherwise maladaptive.

The emotional processes pertaining to fear and anxiety that have been most extensively studied (largely because of their amenability to experimental manipulation) have involved pavlovian fear conditioning and fear-potentiated startle (4 ,5). These types of “fear learning” have been shown to comprise experience-dependent forms of neural plasticity in an extended anatomic network that centers around the critical involvement of the amygdala (1 ,6). The structures that function in concert with the amygdala during fear learning include other mesiotemporal cortical structures, the sensory thalamus and cortices, the orbital and medial prefrontal cortex (mPFC), the anterior insula, the hypothalamus, and multiple brainstem nuclei (1 ,5 ,7). Much of this network appears to participate in the general process of associating a conditioned stimulus (CS) or operant behavior with an emotionally salient unconditioned stimulus (US) (see Fig. 63.1 on p. 905) (5 ,8 ,9 ,10 and 11).

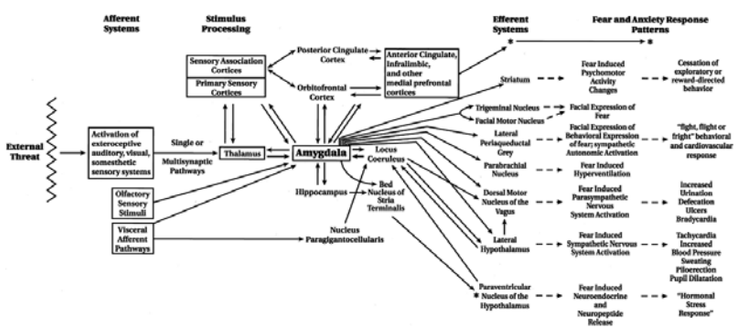

FIGURE 63.1. The innervation of the parasympathetic nervous system from limbic structures is thought to mediate visceral symptoms associated with anxiety.

Role of the Amygdala in Fear Learning and Expression

The anatomic systems supporting fear learning are organized to permit both rapid responses to simple perceptual

elements of potentially threatening stimuli and longerlatency responses to more highly processed information about complex sensory stimuli and environmental contexts. The former processes depend on monosynaptic projections from the sensory thalamus to the amygdala, whereas the latter involve projections from sensory association cortices and mesiotemporal cortical structures to the amygdala (1 ,12). These neural networks also respond to visceral input received both directly through the nucleus paragigantocellularis and the nucleus tractus solitarius (NTS) of the vagus nerve and indirectly through the locus ceruleus (LC), the anterior insula, and the infralimbic and prelimbic cortices (4 ,7 ,13). Finally, neural activity within the amygdala is modulated by cortisol, norepinephrine (NE), and other neurotransmitters and by mnemonic input related to previous conditioning and reinforcement experiences conveyed by projections from mesiotemporal and prefrontal cortical structures (14 ,15 ,16 ,17 and 18).

The lateral nucleus of the amygdala (LA) comprises the primary sensory interface of the amygdala and receives synaptic input representing sensory information from the sensory thalamus and cortex (4). Single neurons within the LA are responsive to auditory, visual, and somatic stimuli, thus enabling the LA to serve as a locus of convergence for information about CS and US (19). Olfactory input, in contrast, directly projects to the periamygdaloid cortex from the olfactory bulb through the olfactory tract (20). The olfactory tract also sends projections to the pyriform cortex and the entorhinal cortex, areas with reciprocal connections to the amygdala (20). Although the periamygdaloid cortex neurons project to deeper amygdaloid nuclei, the specific pathways conveying olfactory information through the amygdala have not been delineated.

In addition to its role in conditioning to explicit sensory stimuli, the amygdala is involved in the development of emotional responses to environmental context. The projections from the hippocampal formation to the amygdala through the fornix have been specifically implicated in spatial contextual conditioning (21 ,22). Thus, lesioning these projections specifically prevents fear conditioning to the chamber or the position within a maze in which aversive stimulation previously occurred (22 ,23 ,24 and 25). Other structures that participate in the modulation of contextual fear include the rostral perirhinal cortex and the ventrolateral PFC/ anterior (agranular) insula. Lesions of the latter regions reduce fear *reactivity* to contextual stimuli, but they do not affect CS acquisition or response extinction (26). In contrast, lesions placed in the rostral perirhinal cortex *after* fear conditioning interfere with the expression of conditioned fear responses elicited by visual and auditory stimuli when these stimuli are presented in contexts that differ from the initial conditioning context (27). Notably, genetic studies in mice identified a quantitative trait locus for contextual conditioning (28 ,29) that was associated with mouse “emotionality” in another study (30), although the molecular genetic, neurochemical, and functional anatomic correlates of this trait have not been established.

The projections from sensory thalamus to the LA are thought to support rapid conditioning to simple visual and auditory features, presumably accounting for fear responses below the level of conscious awareness (31). Thus, lesioning the *auditory cortex* before conditioning does not prevent conditioning to single auditory tones. In contrast, projections to the LA from the primary sensory and sensory association cortices appear to be essential for some aspects of conditioned responding to more complex sensory stimuli (4 ,32). These relationships are modality specific. For example, disruption of the projections from the auditory thalamus and auditory cortex to the LA specifically prevents acquisition of fear conditioning to auditory stimuli and fear-conditioned responses to previous auditory CSs (33 ,34 and 35).

After sensory input enters the LA, the neural representation of the stimulus is distributed in parallel to various amygdaloid nuclei, where it may be modulated by diverse functional systems, such as those mediating memories from past experiences or knowledge about ongoing homeostatic states (36). The most extensive extranuclear projections of the LA are composed of reciprocal projections to the basal and accessory basal nuclei and the central nucleus of the amygdala (CE) (37 ,38). Lesions of either the LA or the CE—but not of other amygdala nuclei—disrupt fear conditioning to a tone CS, a finding suggesting that this direct projection from LA to CE is sufficient to mediate conditioning to simple sensory features (4).

The projections from LA to the basal amygdaloid nuclei also participate in forming long-lasting memory traces for fear conditioning (2 ,15 ,39). Functional inactivation of the lateral and basal amygdaloid nuclei before pavlovian fear conditioning interferes with acquisition of learning, whereas inactivation immediately after conditioning has no effect on memory consolidation (40). The basal nuclei have widespread intranuclear connections and also project to other amygdalar nuclei, including the CE and the LA (41). They also share extensive, reciprocal projections with the orbital and mPFC (43). The basal nuclei are thus anatomically positioned to modulate neuronal responses in both the LA and the PFC (42 ,43).

The plasticity within the amygdala that constitutes memory for conditioning experiences has been shown to involve long-term potentiation–like associative processes (6). Plasticity related to fear learning also occurs in cortical areas, presumably making possible the establishment of explicit or declarative memories about the fear-related event through interactions with the medial temporal lobe memory system (44 ,45). The influence of the amygdala on cortically based memories has been most clearly characterized with respect to *late* plastic components of the auditory cortex neuronal responses to a CS. Single-unit recordings during fear conditioning indicate that some auditory cortex neurons, which before conditioning did not respond to the CS tone, develop

late-conditioned responses (i.e., 500 to 1,500 milliseconds after CS onset) that anticipate the US and show extinction-resistant memory storage (46). These late-conditioned auditory cortical neuronal responses take more trials to learn and respond more slowly than LA neurons within trials, and their late development is prevented by amygdala lesions. Thus, whereas rapid conditioning of fear responses to potentially dangerous stimuli depends on plasticity in the amygdala, learning involving higher cognitive (i.e., mnemonic and attentional) processing of fear experiences may depend on plasticity involving cortical neurons that is influenced by neural transmission from the amygdala to the cortex.

Other auditory cortex neurons show an early (less than 50 milliseconds of stimulus onset) plastic component during fear conditioning, in which the preexisting electrophysiologic responses of auditory cortex neurons to the CS become enhanced by conditioning (46). This short-latency plasticity within the auditory cortex appears to depend on input from the auditory thalamus and is unaffected by amygdala lesions. Nevertheless, such short-latency responses are extinguished more quickly (during repeated exposure to the CS alone) in animals with amygdala lesions, a finding implying that the amygdala is involved in preventing extinction of these responses.

In human neuroimaging studies, hemodynamic activity in the amygdala increases during initial exposures to fear-conditioned stimuli (47 ,48). However, during repeated, unreinforced exposures to the same stimulus, single-trial functional magnetic resonance imaging (fMRI) studies show that this initial elevation of hemodynamic activity attenuates and subsequently decreases to less than baseline (47). This observation suggests that synaptic input into the amygdala may be actively reduced during the extinction process (49), although the level at which this suppression of afferent synaptic activity into (or within) the amygdala is being suppressed during nonreinforced exposures to the CS has not been established.

Activation of the amygdala during an emotional event enhances the strength of long-term memory for emotional stimuli represented in other cortical memory circuits as well (16 ,50 ,51). These circuits presumably involve the medial temporal lobe memory system, which has extensive anatomic connections with the amygdala and presumably provides a neuroanatomic substrate for the interaction between storage and explicit recall of affectively salient memories (16). For example, as healthy humans read stories, the magnitude of physiologic activation in the amygdala correlates both with the negative emotional intensity and with the subsequent recall performance of the story's content (52 ,53). Physiologic activity in the amygdala and the hippocampus measured during memory encoding reportedly correlates with enhanced episodic memory for pleasant as well as aversive visual stimuli (54), and the amygdala's role in modulating emotional memory may depend more generally on the degree of arousal or the behavioral salience associated with verbally conveyed information (9 ,16).

Human neuroimaging and electrophysiologic and lesion analysis studies have also demonstrated that the amygdala is involved in the recall of emotional or arousing memories (4 ,53 ,55). In humans, bursts of electroencephalographic activity have been recorded in the amygdala during recollection of specific emotional events (56). Moreover, electrical stimulation of the amygdala can evoke emotional experiences (especially fear or anxiety) (57) and the recollection of emotionally charged life events from remote memory (58).

Role of the Amygdala in Organizing Emotional Expression

The amygdaloid output nuclei, especially the CE, receive convergent information from multiple amygdala regions and generate behavioral responses that are thought to reflect the sum of neuronal activity produced by different amygdaloid nuclei (36). The CE comprises the interface between the amygdala and the motor, autonomic, and neuroendocrine systems involved in expressing fear behavior (4 ,5). The CE projects to nuclei in the hypothalamus, midbrain, and medulla that mediate the neuroendocrine, autonomic, and behavioral responses associated with fear and anxiety. For example, the amygdala facilitates stress-related corticotropin-releasing hormone (CRH) release by both intrinsic CRH-containing neurons and bisynaptic (double γ-aminobutyric acid–ergic [GABAergic]) anatomic projections to the paraventricular nucleus (PVN) of the hypothalamus (59). Electrical stimulation of the CE produces responses similar to those elicited by fear-conditioned stimuli (60 ,61), and lesions of the CE prevent the expression of fear responses of various types (4 ,62 ,63). In contrast, lesioning of specific structures efferent to the CE, such as the lateral hypothalamus or periaqueductal gray (PAG), produces selective deficits in cardiovascular or somatomotor behavioral fear responses, respectively (1 ,64).

The amygdala also sends projections to the thalamus, the nucleus accumbens, the ventromedial caudate, and parts of the ventral putamen that participate in organizing motor responses to threatening stimuli (65). For example, activation of the amygdalar projections to the ventral striatum arrests goal-directed behavior in experimental animals (66), a finding suggesting a possible neural mechanism for the cessation of motivated or reward-directed behavior during anxiety and panic. The amygdala may also influence motor behavior by projections through the hypothalamus and PAG (1). For example, in experimental animals, stimulation of the lateral PAG produces defensive behaviors, sympathetic autonomic arousal, and hypoalgesia, whereas stimulation of the ventrolateral PAG produces social withdrawal and behavioral quiescence, as in response to deep injury or visceral pain (67).

Other Roles of the Amygdala in Fear Processing

The amygdala also appears to play important roles in mediating innate fear and in processing affective elements of social interactions (68). Amygdala lesions cause rats to lose their fear of cats and monkeys to lose their fear of snakes (reviewed in ref. 4). In monkeys, amygdala lesions reduce aggression as well as fear and cause animals to become more submissive to dominant animals (69). In humans, blood flow increases in the amygdala as subjects view faces expressing fear or sadness (70 ,71), and amygdala lesions impair the ability to recognize fear or sadness in facial expression (55 ,72) and fear and anger in spoken language (73).

Bed Nucleus of the Stria Terminalis: Hypothesized Role in Anxiety

The hypothalamic and brainstem structures that mediate the expression of emotional behavior can also be activated directly by the bed nucleus of the stria terminalis (BNST) (5). Anxiety-like responses elicited either by exposure to a threatening environment for several minutes or by intraventricular administration of CRH appear to be specifically mediated by the BNST, rather than the CE (5). This system is thus hypothesized to play a role in mediating anxiety during exposure to less explicit, or less well defined, sensory cues or to contexts that occur over a longer duration.

Other Temporal Cortical Structures

The perirhinal cortex shares reciprocal anatomic connections with the amygdala (74), and it is thought to play a role in conveying information about complex visual stimuli to the amygdala during presentation of fear-conditioned visual stimuli. Lesions of the anterior perirhinal cortex, the basolateral nucleus of the amygdala, or the CE can each completely eliminate fear-potentiated startle during exposure to some conditioned visual stimuli (75 ,76). In contrast, complete removal of the entire visual cortex, insular cortex, mPFC, and posterior perirhinal cortex produces no significant effect on the magnitude of fear-potentiated startle, and lesions of the frontal cortex only partly attenuate fear-potentiated startle. The perirhinal cortex receives input regarding conditioned visual stimuli from the lateral geniculate nucleus, and lesions of this structure can also block fear-potentiated startle (77). Finally, the anterior perirhinal cortex receives afferent projections from the visual cortices as well as from the anterior cingulate cortex (ACC), the infralimbic cortex, and the parietal cortex (74), structures implicated in modulating behavioral responses to fear-conditioned stimuli.

The temporopolar cortex has been implicated in modulating autonomic aspects of emotional responses and in processing emotionally provocative visual stimuli. Electrical stimulation of various sites within the temporopolar cortex can alter a variety of autonomic responses (reviewed in ref. 1). In humans with simple phobias or posttraumatic stress disorder (PTSD), physiologic activity increases in the anterior temporopolar cortex during experimentally induced exacerbations of anxiety involving visual exposure to phobic stimuli or word scripts describing traumatic events, respectively (78 ,79). Blood flow also increases in the anterior temporopolar cortex of healthy humans during exposure to emotionally provocative visual stimuli, whether the stimuli convey “sad,” “disgusting,” or “happy” content, relative both to conditions involving exposure to emotionally “neutral” visual stimuli and to conditions in which corresponding emotional states are elicited by recall of autobiographic information (80 ,81). Portions of the temporopolar cortex may thus function as sensory association areas that participate in evaluating the emotional salience of actual or anticipated stimuli and in modulating autonomic responses to such stimuli.

Neuroendocrine and Autonomic Responses during Fear or Stress

The peripheral hormonal and autonomic responses to threat mediated by the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic and parasympathetic autonomic nervous systems also play adaptive roles in responding to threat or stress (5). Stimulation of the lateral nucleus of the hypothalamus by afferent projections from the CE of the amygdala, the BNST, or the ventral striatum (82) activates the sympathetic system and produces increases in blood pressure and heart rate, sweating, piloerection, and pupillary dilation. Stress stimulates release of CRH from the PVN of the hypothalamus and amygdala. The CRH secretion from the PVN, in turn, increases peripheral adrenocorticotropic hormone (ACTH) levels, and this stimulates the adrenal glands to secrete cortisol. The ACC, anterior insula, and posterior orbital cortex send anatomic projections to the hypothalamus that participate in modulating or inhibiting cardiovascular and endocrine responses to threat and stress (1 ,43 ,83).

The vagus and splanchnic nerves constitute the major efferent projections of the parasympathetic nervous system to the viscera. The vagal nuclei receive afferent projections from the lateral hypothalamus, the PVN, the LC, the amygdala, the infralimbic cortex, and the prelimbic portion of the ACC (43 ,84). The splanchnic nerves receive afferent connections from the LC. The innervation of the parasympathetic nervous system from these limbic structures is thought to mediate visceral symptoms associated with anxiety, such as gastrointestinal and genitourinary disturbances (Fig. 63.1).

Role of Prefrontal Cortical Structures in Modulating Fear and Anxiety Behavior

Multiple areas of the medial and orbital PFC appear to play roles in modulating anxiety and other emotional behaviors.

These PFC structures are thought to participate in interpreting the higher-order significance of experiential stimuli, in modifying behavioral responses based on competing reward versus punishment contingencies, and in predicting social outcomes of behavioral responses to emotional events (8 ,11 ,85 ,86). These areas share extensive, reciprocal projections with the amygdala, through which the amygdala can modulate PFC neuronal activity and the PFC can modulate amygdala-mediated responses to emotionally salient stimuli (17 ,18 ,42 ,43).

Areas within the orbital and mPFC and the anterior insula also participate in modulating peripheral responses to stress, including heart rate, blood pressure, and glucocorticoid secretion (13 ,17 ,43 ,87). The neuronal activities within these areas are, in turn, modulated by various neurotransmitter systems that are activated in response to stressors and threats. For example, the noradrenergic, dopaminergic, and serotonergic systems play roles in enhancing vigilance, modulating goal-directed behavior, and facilitating decision making about probabilities of punishment versus reward by modulating neuronal activity in the PFC (86 ,88 ,89 and 90).

Medial Prefrontal Cortex

The mPFC areas implicated in anxiety and fear-related behavior in humans and experimental animals *include* the infralimbic cortex, the ACC located ventral (“subgenual”) and anterior (“pregenual”) to the genu of the corpus callosum, and a more dorsal mPFC region that extends from the rostral ACC (BA 24, 32) toward the frontal pole (91). The reciprocal projections between the amygdala and the mPFC are hypothesized to play critical roles in attenuating fear responses and extinguishing behavioral responses to fear-conditioned stimuli that are no longer reinforced (17 ,18). Lesions of the ACC in rats resulted in enhanced freezing to a fear-conditioned tone, a finding suggesting that this mPFC region may be involved in fear reduction (17). In addition, neurons in the rat prelimbic cortex (thought to be homologous to subgenual PFC) reduce their spontaneous firing activity in the presence of a conditioned, aversive tone to an extent that is inversely proportional to the magnitude of fear (42). This suppression of prelimbic cortex neuronal firing activity is inversely correlated with increases in amygdala neuronal activity. Finally, lesions of the infralimbic cortex specifically interfere with the recall of extinction processes after long delays between the acquisition of extinction learning and reexposure to the initial CS (18). Extinction does not appear to occur by erasing memory traces of the CS-US association, but rather by new learning through which the behavioral response to the CS is actively inhibited (31).

In humans, the pregenual ACC shows areas of elevated hemodynamic activity during a variety of anxiety states elicited in healthy or anxiety-disordered subjects (reviewed in ref. 49). Electrical stimulation of this region elicits fear, panic, or a sense of foreboding in humans and vocalization in experimental animals (reviewed in ref. 7). Nevertheless, physiologic activity also increases in the ACC during the generation of positive emotions in healthy humans (92 ,93) and during depressive episodes in some subtypes of major depressive disorder (MDD) (94 ,95).

The subgenual ACC has been implicated in healthy sadness, MDD, mania, and PTSD (90 ,96 ,97). In patients with familial unipolar and bipolar depression, reductions in cerebral blood flow (CBF) and metabolism were associated with left-lateralized reductions in the volume of the corresponding cortex (96 ,98 ,99). The subgenual PFC activity shows a mood state dependency in which the metabolism is higher in the depressed than the remitted phase of MDD, consistent with the findings that blood flow increases in this region in healthy, nondepressed humans during experimentally induced sadness (85 ,100 ,101) and in persons with PTSD during internally generated imagery of past trauma (97).

Both the subgenual and the pregenual ACC share reciprocal anatomic connections with areas implicated in emotional behavior such as the posterior orbital cortex, amygdala, hypothalamus, nucleus accumbens, PAG, ventral tegmental area (VTA), raphe, LC, and NTS (Fig. 63.1) (102 ,103). Humans with mPFC lesions that include the pregenual and subgenual ACC show abnormal autonomic responses to emotionally provocative stimuli, inability to experience emotion related to concepts, and inability to use information regarding the probability of aversive social consequences versus reward in guiding social behavior (104). In rats, bilateral or *right*-lateralized lesions of the ventral mPFC composed of infralimbic, prelimbic, and ACC cortices *attenuate* corticosterone secretion, sympathetic autonomic responses, and gastric stress disorders during restraint stress or exposure to fear-conditioned stimuli (17 ,83 ,105). In contrast, *left*-sided lesions of this cortical strip *increase* sympathetic arousal and corticosterone responses to restraint stress (105). Finally, the ventral ACC contains glucocorticoid receptors that, when stimulated, inhibit stress-induced corticosterone release in rats (87).

Physiologic activity also increases in more dorsal mPFC areas in healthy humans as they perform tasks that elicit emotional responses or require emotional evaluations (81 ,106 ,107). During anxious anticipation of an electrical shock, CBF increases in the rostral mPFC (vicinity of anterior BA24, BA32, and rostral BA9), and the magnitude of ΔCBF correlates inversely with changes in anxiety ratings and heart rate (107). In rats, lesions of the rostral mPFC result in exaggerated heart rate responses to fear-conditioned stimuli, and stimulation of these sites attenuates defensive behavior and cardiovascular responses evoked by amygdala stimulation (83). In primates, whereas BA24 and 32 have extensive reciprocal connections with the amygdala through which they may modulate emotional expression, the BA9 cortex has only sparse projections to the amygdala. Nevertheless, all three areas send extensive efferent projections to the PAG and the hypothalamus through which cardiovascular

responses associated with emotional behavior can be modulated (43 ,108).

In the depressed phase of MDD and bipolar disorder, metabolic activity is abnormal in the dorsomedial and dorsal anterolateral PFC (in the vicinity of rostral BA9) (91 ,109). Postmortem studies of these regions have shown abnormal reductions in the size of glia and neurons in MDD (110). Given the preclinical and neuroimaging evidence presented earlier, indicating that this area may modulate anxiety, it may be hypothesized that dysfunction of this mPFC area contributes to the development of anxiety symptoms in mood disorders.

Orbital and Anterior Insular Cortex

Other areas of the PFC that are implicated in studies of fear or anxiety in human and nonhuman primates are the posterior and lateral orbital cortex, the anterior (agranular) insula, and the ventrolateral PFC (1 ,43). Physiologic activity increases in these areas during experimentally induced anxiety states in healthy subjects and in subjects with obsessive-compulsive disorder (OCD), simple phobia, and panic disorder (PD) (49 ,111). (See Chapter 65) The baseline metabolic activity is also abnormally elevated in these regions in unmedicated study subjects with primary MDD (91) and OCD (112) scanned while resting with eyes closed. The elevated activity in these areas in both MDD and OCD appears state dependent, and effective antidepressant or antiobsessional treatment results in decreases in CBF and metabolism in the medicated-improved relative to the unmedicated-symptomatic phase (112 ,113 and 114).

A complex relationship exists between anxiety-depressive symptoms and physiologic activity in the orbital cortex and the ventrolateral PFC. In MDD, whereas CBF and metabolism increase in these areas in the depressed relative to the remitted phase, the magnitude of these measures correlates inversely with ratings of depressive ideation and severity (115 ,116). Similarly, posterior orbital cortex flow increases in OCD and animal phobic subjects during exposure to phobic stimuli and in healthy subjects during induced sadness, but this change in CBF correlates inversely with changes in obsessive thinking, anxiety, and sadness, respectively (114 ,117 ,118).

These data appear consistent with electrophysiologic and lesion analysis data showing that the orbital cortex participates in modulating behavioral and visceral responses associated with fearful, defensive, and reward-directed behavior as reinforcement contingencies change. Nearly one-half of the orbital cortex pyramidal neurons alter their firing rates during the delay period between stimulus and response, and this firing activity relates to the presence or absence of reinforcement (11). These cells are thought to play roles in extinguishing unreinforced responses to aversive or appetitive stimuli (7 ,11 ,66). The posterior and lateral orbital cortex and the amygdala send projections to each other and to overlapping portions of the striatum, hypothalamus, and PAG through which these structures modulate each other's neural transmission (Fig. 63.1) (42 ,66 ,108 ,119). For example, the defensive behaviors and cardiovascular responses evoked by electrical stimulation of the amygdala are attenuated or ablated by concomitant stimulation of orbital sites, which, when stimulated alone, exert no autonomic effects (120).

Humans with orbital cortex lesions show impaired performance on tasks requiring application of information related to punishment or reward, perseverate in behavioral strategies that are unreinforced, and exhibit difficulty in shifting intellectual strategies in response to changing task demands (11 ,121). Likewise, monkeys with surgical lesions of the lateral orbital cortex and ventrolateral PFC demonstrate “perseverative interference,” characterized by difficulty in learning to withhold prepotent responses to nonreinforced stimuli as reinforcement contingencies change (122). Activation of the orbital cortex during anxiety or obsessional states may thus reflect endogenous attempts to attenuate emotional expression or to interrupt unreinforced aversive thought and emotion (91). Conversely, dysfunction of the orbital cortex may contribute to pathologic anxiety and obsessional states by impairing the ability to inhibit nonreinforced or maladaptive emotional, cognitive, and behavioral responses to social interactions and sensory or visceral stimuli.

Posterior Cingulate Cortex

Many functional imaging studies report that exposure to aversive stimuli of various types increases physiologic activity in the retrosplenial cortex and other portions of the posterior cingulate gyrus (reviewed in ref. 123). Posterior cingulate cortical flow and metabolism have also been found abnormally elevated in some studies of depressed subjects with MDD (reviewed in ref. 91). In contrast, Mayberg et al. reported that script-driven sadness resulted in decreased posterior cingulate activity in healthy subjects, and flow was decreased in depressed relative to remitted subjects with MDD, findings raising the possibility that this large region is functionally heterogenous with respect to emotional behavior (101). The posterior cingulate cortex appears to serve as a sensory association cortex and may participate in processing the affective salience of sensory stimuli. The posterior cingulate cortex sends a major anatomic projection to the ACC, through which it may relay such information into the limbic circuitry (124).

FUNCTIONAL ANATOMIC CORRELATES OF SPECIFIC ANXIETY DISORDERS

Neuroimaging studies have assessed neurophysiologic abnormalities in anxiety-disordered samples in the baseline,

“resting” condition and during symptom provocation. These data converge with those obtained from studies of healthy subjects and of experimental animals to implicate the limbic, paralimbic, and sensory association areas reviewed earlier in the functional anatomy of emotional behavior. Nevertheless, the results of most of the imaging studies reviewed herein await replication, and the data they provide do not clearly establish whether differences between anxiety-disordered and control subjects reflect physiologic correlates of anxiety symptoms or traitlike biological abnormalities underlying the vulnerability to anxiety syndromes.

Panic Disorder

The baseline state in PD is characterized by mild to moderate levels of chronic anxiety (termed *anticipatory anxiety*). In this state, abnormalities of CBF and glucose metabolism have been reported in the vicinity of the hippocampus and parahippocampal gyrus. Reiman et al. initially reported an abnormal resting asymmetry (left less than right) of blood flow and oxygen metabolism in a region of interest placed over the parahippocampal gyrus (125). Nordahl et al. similarly found that glucose metabolism measured over the hippocampus-parahippocampal gyrus was asymmetric and concluded that this abnormality reflected an abnormal metabolic elevation on the right side (126). Bisaga et al. also found abnormal metabolism in this vicinity, but with the opposite laterality (i.e., elevated metabolism in the left hippocampal-parahippocampal area) in lactate-sensitive PD study subjects relative to healthy controls (127). In contrast, De Cristofaro et al. reported that resting perfusion, measured using single photon emission computed tomography (SPECT) and [^{99m}Tc]hexamethylpropyleneamineoxime (HMPAO), was abnormally decreased in the hippocampus, bilaterally, in lactate-sensitive PD study subjects relative to controls (128).

Each of these studies employed region-of-interest based approaches that were incapable of localizing the center of mass of the abnormality in this region. Reanalysis of some of these data using a voxel-by-voxel approach suggested that the abnormal radioactivity in the vicinity of the mesiotemporal cortex may actually reflect elevated metabolism in the adjacent midbrain (111). This midbrain region, which may reflect the lateral PAG, has been implicated in lactate-induced panic (129), other acute anxiety states (130), and animal models of panic attacks (67).

Study subjects with PD have also been imaged during panic elicited using a variety of chemical challenges. Panic attacks induced by intravenous sodium lactate infusion were associated with regional CBF increases in the anterior insula, the anteromedial cerebellum, and the midbrain (129); areas of increased CBF may also exist in the temporal polar cortex, but these findings were confounded by corresponding increases in the adjacent facial muscles during severe anxiety (115). Blood flow also increased in these regions in animal phobic subjects during exposure to phobic stimuli and in healthy subjects during the threat of a painful electrical shock, findings suggesting that these CBF changes reflect the neurophysiologic correlates of fear processing in general (111 ,130). Consistent with this hypothesis, anxiety attacks induced in healthy humans using cholecystokinin tetrapeptide (CCK-4) were also associated with CBF increases in the insular-amygdala region and the anteromedial cerebellum (131).

Indirect evidence suggests that the neurophysiologic responses in the PFC during panicogen challenge may differ between PD subjects and healthy controls. For example, panic attacks induced using CCK-4 were associated with CBF increases in the ACC in healthy humans (131), but flow did not significantly change in the ACC in subjects with PD during lactate-induced panic (129). The ACC was also a region where flow significantly increased in healthy subjects but not in subjects with PD during fenfluramine challenge in a study in which fenfluramine induced panic attacks in 56% of subjects with PD but in only 11% of control subjects (132). Finally, Cameron et al. found that normalized medial frontal CBF increased in healthy controls after yohimbine administration (i.e., after normalizing to remove effects on whole brain CBF) (133), whereas Woods et al. found that the relative prefrontal cortical flow was decreased in PD relative to control subjects following yohimbine challenge (134).

Structural MRI studies have begun to investigate whether morphometric or morphologic abnormalities may exist in PD. Ontiveros et al. reported qualitative abnormalities of temporal lobe structure in PD (135), although these findings have not been replicated. Vythilingam et al. reported that hippocampal volume did not differ between PD and healthy control subjects (136).

Phobias

In simple animal phobias, phobic anxiety was imaged by acquiring blood flow scans during exposures to the feared animal. During the initial fearful scans, flow increased in the lateral orbital-anterior insular cortex, bilaterally, the pregenual ACC, and the anteromedial cerebellum (78 ,111), areas where CBF also increases in other anxiety states (see earlier). During the development of habituation to phobic stimuli, the magnitude of the hemodynamic responses to the phobic stimulus diminished in the anterior insula and the medial cerebellum, but it increased in the left posterior orbital cortex in an area where flow had not changed during exposures that preceded habituation (117). The magnitude of the CBF increase in this latter region was inversely correlated with the corresponding changes in heart rate and anxiety

ratings. As discussed earlier, the posterior orbital cortex was a site where CBF increased in subjects with OCD during exposure to phobic stimuli, with the increase in flow inversely correlated with obsessional ratings (114).

In social anxiety disorder, an aversive conditioning paradigm (in which the US was an aversive odor and the CS was a picture of a human face) showed that hemodynamic activity decreased in the amygdala and the hippocampus during presentations of the CS in healthy controls, but it increased in social phobic subjects (137). Interpretation of these data was confounded by the problem that both human faces and aversively CSs normally activate the amygdala, so it remained unclear which of the stimuli produced abnormal responses in social phobia. Nevertheless, these data appear conceptually intriguing, given the role of hippocampal-amygdalar projections in mediating contextual fear and the possibility that deficits in the transmission of information regarding context may be involved in the pathogenesis of phobias (21).

Posttraumatic Stress Disorder

PTSD is hypothesized to involve the emotional-learning circuitry associated with the amygdala, because the traumatic event constitutes a fear-conditioning experience, and subsequent exposure to sensory, contextual, or mnemonic stimuli that recall aspects of the event elicits psychological distress and sympathetic arousal. Potentially consistent with this expectation, some studies demonstrated activation of the amygdala as patients with PTSD listened to auditory scripts describing the traumatic event (79) or to combat sounds (in combat-related PTSD) (138) or generated imagery related to the traumatic event without sensory cues (139). However, other studies found no significant changes in amygdala CBF as patients with PTSD listened to scripts describing the traumatic event or viewed trauma-related pictures, and studies comparing CBF responses with trauma-related stimuli have not shown significant differences in the amygdala between patients with PTSD and trauma-matched, non-PTSD control subjects (97 ,139 ,140 and 141). The extent to which these negative findings reflect limitations in statistical sensitivity or in positron emission tomography (PET) temporal resolution must be addressed in provocation studies involving larger subject samples and employing fMRI instead of PET. In this regard, it is noteworthy that a preliminary fMRI study found exaggerated hemodynamic changes in the amygdala in patients with PTSD relative to trauma-matched, non-PTSD control subjects during exposure to pictures of fearful faces presented using a backward-masking technique (142). If replicated, this finding may suggest that the emotional dysregulation associated with PTSD may involve amygdalar responses to emotional stimuli of various types.

Other limbic and paralimbic cortical structures have also been implicated in provocation studies of PTSD. In both patients with PTSD and trauma-matched, non-PTSD control subjects, CBF increases in the posterior orbital cortex, anterior insula, and temporopolar cortex during exposure to trauma-related stimuli, but these changes have generally not differentiated PTSD and control samples (79 ,139 ,140). In contrast, the pattern of CBF changes elicited in the mPFC by traumatic stimuli may differ between PTSD and control subjects. During exposure to trauma-related sensory stimuli, flow decreased in the left (97 ,140) but increased in the right pregenual ACC in PTSD (79 ,138), a finding potentially consistent with the evidence reviewed earlier that the role of the mPFC in emotional behavior is lateralized (105). However, CBF in the right pregenual ACC increased significantly more in non-PTSD, trauma-matched control subjects than in patients with PTSD (139). Moreover, in the infralimbic cortex, CBF *decreased* in patients with combat-related PTSD but *increased* in combat-matched, non-PTSD

control subjects during exposure to combat-related visual and auditory stimuli (141).

Given evidence that the ACC and the infralimbic cortex play roles in extinguishing fear-conditioned responses (17 ,18), the observation that patients with PTSD fail to activate these structures to a similar extent as traumatized, non-PTSD control subjects during exposure to traumatic cues (139 ,141) suggests that neural processes mediating extinction to trauma-related stimuli may be impaired in PTSD. Compatible with this hypothesis, PTSD samples have been shown to acquire *de novo* conditioned responses more readily and to extinguish them more slowly than control samples (143 ,144). Such an impairment could conceivably be related to the vulnerability to developing PTSD, because PTSD occurs in only 5% to 20% of individuals exposed to similar traumatic events.

Structural MRI studies of PTSD have identified subtle reductions in the volume of the hippocampus in PTSD samples relative to healthy or traumatized, non-PTSD control samples (145 ,146 ,147 and 148). Although limitations existed in these studies in the matching of alcohol use or abuse between PTSD and control samples, the reductions in hippocampal volume did not correlate with the extent of alcohol exposure in the PTSD samples, and no volumetric differences were found between PTSD and control samples in the amygdala, entire temporal lobe, caudate, whole brain, or lateral ventricles. Although the magnitude of the reduction in hippocampal volume only ranged from 5% to 12% in the PTSD samples relative to trauma-matched controls, these abnormalities were associated with short-term memory deficits in some studies (145 ,147). It remains unclear whether the difference in hippocampal volume may reflect a result of the chronic stress associated with PTSD (e.g., from sustained exposure to elevated glucocorticoid concentrations) or a biological antecedent that may confer risk for developing PTSD (149 ,150).

Obsessive-Compulsive Disorder

The anatomic circuits involved in the production of obsessions and compulsions have been elucidated by converging evidence from functional neuroimaging studies of OCD, analysis of lesions resulting in obsessive-compulsive symptoms, and observations regarding the neurosurgical interventions that ameliorate OCD (113 ,114 ,151). PET studies of OCD have shown that “resting” CBF and glucose metabolism are abnormally increased in the orbital cortex and the caudate nucleus bilaterally in primary OCD (reviewed in ref. 112). With symptom provocation by exposure to relevant phobic stimuli (e.g., skin contact with “contaminated” objects for patients with OCD who have germ phobias), flow increased further in the orbital cortex, ACC, caudate, putamen, and thalamus (114). During effective pharmacotherapy, orbital metabolism decreased toward normal, and both drug treatment and behavioral therapy were associated with a reduction of caudate metabolism (112). The baseline areas of hypermetabolism in the orbital cortex and the caudate may thus reflect physiologic concomitants of obsessive thoughts or chronic anxiety, and, conversely, the reduction in caudate metabolism associated with effective (but not ineffective) treatment may reflect a physiologic correlate of symptom resolution rather than a primary mechanism of treatment.

Based on the evidence reviewed earlier from electrophysiologic and lesion analysis studies indicating that the orbital cortex participates in the correction of behavioral responses that become inappropriate as reinforcement contingencies change, posterior orbital areas may be specifically activated as an endogenous attempt to interrupt patterns of nonreinforced thought and behavior in OCD (11 ,91). Compatible with this hypothesis, the posterior orbital cortex CBF increases during symptom provocation in OCD, but the magnitude of this increase correlates *inversely* with the corresponding rise in obsession ratings (r = -0.83) (114). In contrast, flow also increases in an area of the right anterior orbital cortex implicated in a variety of types of mnemonic processing, and the change in CBF in this region correlates positively with changes in obsession ratings (114 ,152).

The neurologic conditions associated with the development of secondary obsessions and compulsions also provide evidence that dysfunction within circuits formed by the basal ganglia and the PFC may be related to the pathogenesis of OCD. Such conditions involve lesions of the globus pallidus and the adjacent putamen: Sydenham chorea (a poststreptococcal autoimmune disorder associated with neuronal atrophy in the caudate and putamen), Tourette syndrome (an idiopathic syndrome characterized by motoric and phonic tics that may have a genetic relationship with OCD), chronic motor tic disorder, and lesions of the ventromedial PFC (151 ,152 ,153 and 154). Several of these conditions are associated with complex motor tics (repetitive, coordinated, involuntary movements occurring in patterned sequences in a spontaneous and transient manner). It is conceivable that complex tics and obsessive thoughts may reflect homologous, aberrant neural processes manifested within the motor and cognitive-behavioral domains, respectively, because of their origination in distinct portions of the cortical-striatal-pallidal-thalamic circuitry (113 ,155).

In contrast to the regional metabolic abnormalities found in primary OCD, imaging studies of obsessive-compulsive syndromes arising in the setting of Tourette syndrome or basal ganglia lesions have not found elevated blood flow and metabolism in the caudate and in some cases have found reduced metabolism in the orbital cortex in such subjects relative to controls (111 ,151). The differences in the functional anatomic correlates of primary versus secondary OCD are consistent with a neural model in which dysfunction arising at various points within the ventral prefrontal cortical-striatal-pallidal-thalamic circuitry may result in pathologic obsessions and compulsions. This circuitry appears

to be generally involved in organizing internally guided behavior toward a reward, switching of response strategies, habit formation, and stereotypic behavior (66 ,155).

These circuits have also been implicated in the pathophysiology of MDD, another illness in which intrusive, distressing thoughts recur to an extent that the ability to switch to goal-oriented, rewarding cognitive-behavioral sets is impaired (91). Although MDD and OCD appear distinct in their course, prognosis, genetics, and neurochemical concomitants, substantial comorbidity exists across these syndromes. Major depressive episodes occur in about one-half of patients with OCD, pathologic obsessions can arise in primary MDD, and the pharmacologic interventions that ameliorate OCD can also effectively treat MDD. Moreover, the neurosurgical procedures that are effective at reducing both obsessive-compulsive and depressive symptoms in intractable cases of OCD and MDD interrupt white matter tracts carrying neural projections between the frontal lobe, the basal ganglia, and the thalamus (155). The clinical comorbidity across these two disorders may thus reflect involvement of an overlapping neural circuitry by otherwise distinct pathophysiologic processes.

NEUROCHEMICAL BASIS OF FEAR AND ANXIETY

Part of "63 - Neurobiological Basis of Anxiety Disorders "

The neuroanatomic circuits that support fear and anxiety behavior are modulated by a variety of chemical neurotransmitter systems. These include the peptidergic neurotransmitters, CRH, neuropeptide Y (NPY), and substance P, the monoaminergic transmitters, NE, serotonin (5-hydroxytryptamine or 5-HT), and dopamine (DA), and the amino acid transmitters, GABA and glutamate. The neurotransmitter systems that have been best studied in association with responses to stress or threat involve the HPA axis and the central noradrenergic system. These neurochemical systems subserve important adaptive functions in preparing the organism for responding to threat or stress, by increasing vigilance, modulating memory, mobilizing energy stores, and elevating cardiovascular function. Nevertheless, these biological responses to threat and stress can become maladaptive if they are chronically or inappropriately activated. Additional neurochemical systems that play important roles in modulating stress responses and emotional behavior include the central GABAergic, serotonergic, dopaminergic, opiate, and NPY systems. The preclinical and clinical literature regarding these neurochemical concomitants of stress and fear and their potential relevance to the pathophysiology of anxiety disorders are reviewed in the following sections.

Role of the Central Noradrenergic System in Fear and Anxiety

Exposure to stressful stimuli of various types increases central noradrenergic function. Thus, exposure to fear-conditioned stimuli, immobilization stress, foot shock, or tail pinch increases NE turnover in the LC, the hypothalamus, the hippocampus, the amygdala, and the cerebral cortex (156). The firing activity of LC neurons also increases during exposure to fear-conditioned stimuli and other stressors or threats (157 ,158 and 159). For example, the firing activity of NE neurons in the cat LC increases two- to threefold during confrontation with a dog or an aggressive cat, but it remains unchanged during exposure to other novel stimuli or to nonaggressive cats (160). However, repeated exposure to severe stressors from which the animal cannot escape results in the behavioral pattern termed *learned helplessness*, which is associated with depletion of NE, possibly reflecting a point at which NE synthesis cannot keep pace with NE release (161 ,162).

Acquisition of fear-conditioned responses requires an intact central noradrenergic system, a finding suggesting that NE release plays a critical role in fear learning (157 ,163 ,164). For at least some types of emotional learning, memory consolidation depends on noradrenergic stimulation of ß- and α_1-adrenoreceptors in the basolateral nucleus of the amygdala (15). The activation of NE release in such models may, in turn, depend on effects of stress hormones on noradrenergic neurons (15).

The responsiveness of LC neurons to future novel stressors can be enhanced by chronic exposure to some stressful experiences. In rats, the amount of NE synthesized and released in the hippocampus and the mPFC in response to a novel stressor or to local depolarization is increased after repeated exposure to chronic cold stress (165 ,166 and 167). This effect may result from a stress-mediated alteration in the sensitivity of presynaptic α_2-adrenoreceptors, which inhibit NE synthesis and release. In the native state, administration of the α_2-adrenoreceptor antagonists, idazoxan or yohimbine, increases the electrophysiologic response of LC neurons to stressful stimuli (without altering their basal firing rates) and increases NE release and synthesis, whereas administration of the α_2-adrenoreceptor agonist, clonidine, decreases NE release and synthesis (167 ,168). In chronically cold-stressed rats, idazoxan administration produces a greater increase in NE release and synthesis, and clonidine administration produces a blunted attenuation of NE release and synthesis relative to naive rats (167). Consistent with these observations, Torda et al. found that cold immobilization stress decreases the α_2-adrenoreceptor density in the hippocampus and the amygdala (169).

The effect of chronic stress on noradrenergic responses to subsequent, novel stressors may constitute a form of “behavioral sensitization,” a process by which single or repeated exposures to aversive stimuli or pharmacologic agents can

increase the behavioral sensitivity to subsequent stressors (reviewed in ref. 170). Such phenomena are hypothesized to account for clinical observations that patients with anxiety disorders report experiencing exaggerated sensitivity to psychosocial stress. Neural models for the pathogenesis of anxiety disorders built on sensitization phenomena thus hold that *repeated* exposure to traumatic stress comprises a risk factor for the subsequent development of anxiety disorders, particularly PTSD.

Noradrenergic Function in Anxiety Disorders

The recurrent symptoms of anxiety disorders, such as panic attacks, insomnia, exaggerated startle, and chronic sympathetic autonomic arousal, may conceivably reflect elevated noradrenergic function (171 ,172 and 173). Patients with PTSD and PD show evidence of heightened peripheral sympathetic nervous system arousal that, because of the correlation between peripheral sympathetic activity and central noradrenergic function, is compatible with the hypothesis of increased central NE activity in these disorders (174 ,175). Moreover, patients with PD, PTSD, and phobic disorders report that their hyperarousal symptoms and intrusive memories are attenuated by alcohol, benzodiazepines (BZDs), and opiates, agents known to decrease LC neuronal firing activity, but are exacerbated by cocaine, which increases LC neuronal firing. The risk of abuse of these substances appears increased in patients with anxiety disorders, a finding raising the possibility that such patients are "self-medicating" anxiety symptoms with these agents. It remains unclear, however, whether alterations in noradrenergic function play a primary, etiologic role in the pathogenesis of anxiety disorders, or instead reflect secondary, compensatory changes in response to disorders in other systems.

PD has been specifically associated with elevations of α_2-adrenoreceptor sensitivity and nocturnal urinary NE excretion (176), although ß-adrenoreceptor function, baseline heart rate and blood pressure, and other measures reflecting central NE secretion have not been consistently altered in PD (see Table 63.1) (177). Altered α_2-adrenoreceptor sensitivity is evidenced by findings that administration of the α_2-adrenoreceptor agonist, clonidine, results in greater hypotension and larger reductions in plasma 3-methoxy-4-hydroxyphenylethylene glycol (MHPG) in PD relative to control subjects (178 ,179 ,180 and 181). In addition, administration of the α_2-adrenoreceptor antagonist, yohimbine (which stimulates NE release by antagonizing presynaptic α_2-adrenoreceptors) produces exaggerated anxiogenic and cardiovascular responses and enhanced plasma MHPG and cortisol increases in PD relative to control subjects (133 ,172 ,173 ,182 ,183 ,184 ,185 and 186). Finally, yohimbine administration resulted in reduced relative frontal cortex flow in patients with PD that did not occur in control subjects, as measured with SPECT and [^{99m}Tc]HMPAO (134); it remains unclear, however, whether this difference reflected a differential physiologic sensitivity to yohimbine or an effect of greater anxiety in the patients with PD, because all the patients with PD but only one control subject developed increased anxiety in response to yohimbine. The sensitivity of α_2-adrenoreceptors also appears increased in PTSD. Patients with combat-related PTSD show increased behavioral, chemical, and cardiovascular responses to yohimbine, relative to healthy controls (187 ,188 and 189).

TABLE 63.1. EVIDENCE OF ALTERED CATECHOLAMINERGIC FUNCTION IN ANXIETY DISORDERS

	PTSD	Panic Disorder
Increased resting heart rate and blood pressure	+/–	+/–
Increased heart rate and blood pressure response to traumatic reminders/panic attacks	+++	++

Considerable evidence also indicates that noradrenergic function is abnormal in PTSD (see Table 63.1). Women with PTSD secondary to childhood sexual abuse showed elevated 24-hour urinary excretion of catecholamines and cortisol (190). In addition, men—but not women—with PTSD resulting from a motor vehicle accident exhibited elevated urinary levels of epinephrine, NE, and cortisol 1 month after the accident and still had higher epinephrine levels 5 months later (191). Similarly, maltreated children with PTSD excreted greater amounts of urinary DA, NE, and cortisol over 24 hours than controls, with the urinary catecholamine and cortisol output positively correlated with the duration of PTSD trauma and the severity of PTSD symptoms (192). Exposure to traumatic reminders (e.g., combat films or sounds) produced greater increases in plasma, epinephrine, NE, and cortisol in patients with PTSD than in control subjects (191 ,193 ,194), although baseline concentrations of catecholamines are not consistently altered in combat-related PTSD (188 ,189). Geracioti et al. found that cerebrospinal fluid (CSF) NE concentrations are abnormally elevated in PTSD (195). Finally, platelet α_2-adrenoreceptor density (196), platelet basal adenosine, isoproterenol, forskolin-stimulated cyclic adenosine monophosphate signal transduction (197), and basal platelet monoamine oxidase activity (198) were decreased in PTSD, findings hypothesized to reflect compensatory responses to chronically elevated NE release.

In study subjects with specific phobias, plasma NE and epinephrine concentrations, heart rate, blood pressure, and subjective anxiety ratings increase in response to exposure to phobic stimuli (199). Subjects with social anxiety disorder show greater increases in plasma NE during orthostatic challenge than healthy subjects or those with PD (200).The growth hormone response to intravenous clonidine (a marker of central α_2-adrenoreceptor function) is blunted in social anxiety disorder (201), although the density of lymphocyte ß-adrenoreceptors has not differed between social anxiety–disordered and control samples (202) (Table 63.1).

Finally, Gerra et al. reported that, plasma NE concentrations increased to a greater extent in male peripubertal patients with generalized anxiety disorder than in controls in response to a psychological stress test (203). However, the

pretest baseline NE concentrations did not differ between the anxious and control subjects.

Hypothalamic-Pituitary-Adrenal Axis and Corticotropin-Releasing Hormone

Exposure to acute stress of various types results in release of CRH, ACTH, and cortisol. This HPA-axis activation during acute stress can produce a transient elevation of the plasma cortisol concentration and partial resistance to feedback inhibition of cortisol release that persists during and shortly after the duration of the stressful stimulus. This phenomenon may involve a rapid down-regulation of glucocorticoid receptors, because elevated glucocorticoid levels such as those elicited by acute stress decrease the number of hippocampal glucocorticoid receptors, with a resulting increase in corticosterone secretion and feedback resistance (204). After stress termination, as glucocorticoid levels decrease (presumably because the limbic drive on CRH release diminishes), glucocorticoid-receptor density increases, and feedback sensitivity normalizes (204).

During some types of *chronic* stress, adaptive changes in ACTH and corticosterone secretion occur such that the plasma ACTH and corticosterone concentrations achieved are lower than those seen in response to acute stress (205). In contrast, other types of chronic stress are associated with enhanced corticosterone secretion in rats (206). Moreover, Dallman and Jones showed that the experience of prior stress can result in augmented corticosterone responses to subsequent stress exposure (207). The factors that determine whether adaptation or sensitization of glucocorticoid activity occurs after chronic stress remain poorly understood.

Some stressors experienced within critical periods of neurodevelopment exert long-term effects on HPA-axis function. In rats exposed to either severe prenatal *(in utero)* stress or early maternal deprivation stress (208 ,209), the plasma concentrations of corticosterone achieved in response to subsequent stressors are increased, and this tendency to show exaggerated glucocorticoid responses to stress persists into adulthood. Early postnatal adverse experiences such as maternal separation are associated with long-lasting alterations in the basal concentrations of hypothalamic CRH mRNA, hippocampal glucocorticoid-receptor mRNA, median eminence CRH, and in the magnitude of stress-induced CRH, corticosterone, and ACTH release (210 ,211 and 212). In nonhuman primates, adverse early experiences induced by variable maternal foraging requirements reportedly result in alterations in juvenile and adult social behavior, such that animals are more timid, less socially interactive, and more subordinate (213). Adult monkeys who were raised in such a maternal environment are also hyperresponsive to yohimbine and have elevated CRH concentrations and decreased cortisol levels in the CSF, findings that parallel those in humans with PTSD (213).

Conversely, positive early-life experiences during critical developmental periods may have beneficial long-term consequences on the ability to mount adaptive responses to stress or threat. For example, daily postnatal handling of rat pups by human experimenters within the first few weeks of life has been shown to produce persistent (throughout life) increases in the density of type II glucocorticoid receptors. This increase was associated with enhanced feedback sensitivity to glucocorticoid exposure and reduced glucocorticoid-mediated hippocampal damage in later life (214 ,215). These effects are hypothesized to comprise a type of “stress inoculation” induced by the mothers' repeated licking of the pups after they were handled by humans. Taken together with the data reviewed in the preceding paragraph, these data indicate that a high degree of plasticity exists in stress-responsive neural systems during the prenatal and early postnatal periods that “programs” future biological responses to stressful stimuli (210).

Regional differences in the regulation of CRH function by glucocorticoid-receptor stimulation and stress may play major roles in the mediation of fear and anxiety (216). The feedback inhibition of CRH function by glucocorticoids (to suppress HPA-axis activity) occurs at the level of the PVN of the hypothalamus, where systemically administered glucocorticoids reduce CRH expression, and the anterior pituitary, where glucocorticoids decrease CRH *receptor* expression (217 ,218 ,219 and 220). The regulation of CRH *receptor* mRNA expression shows a regional specificity that becomes altered when stress occurs concomitantly with elevated glucocorticoid concentrations. After both short-term and long-term corticosterone (CORT) administration, the CRH *receptor* RNA expression decreases in the PVN and the anterior pituitary (219). However, after acute or repeated immobilization stress sufficient to produce a large increase in plasma CORT levels, the CRH mRNA expression decreases in the anterior pituitary, but *increases* in the PVN. In contrast, neither CORT administration nor restraint stress alters the CRH *receptor* expression in the CE of the amygdala or the BNST. Furthermore, CRH secretion is not constrained by glucocorticoids in the CE or the lateral BNST, and CRH mRNA expression *increases* in these areas during systemic CORT administration (217 ,218 ,220). It is thus conceivable that the positive feedback of glucocorticoids on extrahypothalamic CRH function in the amygdala or the BNST may contribute to the production of anxiety symptoms (216 ,221).

Another level through which the CRH-glucocorticoid system maintains homeostasis and provides mechanisms for modulating mechanism over stress or anxiety responses involves functional differences between CRH-receptor subtypes. The CRH_1 and CRH_2 receptors appear to play reciprocal roles in mediating stress responsiveness and anxiety-like behaviors (221). Mice genetically deficient in CRH_1-receptor expression exhibit diminished anxiety and

stress responses to threat or stress (222 ,223). In contrast, mice deficient in CRH_2 receptors display heightened anxiety in response to stress (224 ,225). The affinity of CRH is higher for CRH_1 than CRH_2 receptors, a finding consistent with evidence that CRH elicits anxiogenic effects either when exogenously administered to native animals or when endogenously released in mice genetically altered to overexpress CRH (221). Also consistent with the hypothesis that CRH_1-receptor stimulation facilitates anxiety responses, oral administration of the CRH_1-receptor antagonist, antalarmin, inhibits the behavioral, sympathetic autonomic, and neuroendocrine responses (i.e., attenuating increases in the CSF CRH concentration and in the pituitary-adrenal and adrenal-medullary activity) to acute social stress in monkeys (226).

Regional differences in the anatomic distribution of CRH_1 and CRH_2 receptors likely play a role in balancing facilitatory versus modulatory effects of CRH-receptor stimulation on stress responses. In monkeys, the CRH_1-receptor density is high in most amygdaloid nuclei, the cingulate cortex, the PFC, the insular cortex, the parietal cortex, the dentate gyrus, and the entorhinal cortex, and it is moderate in the CE and the LC. The CRH_2-receptor density is high in the cingulate cortex, the mPFC, the CE, the CA-1 region of the hippocampus, and the PVN and supraoptic nucleus of the hypothalamus. An important avenue of future research will involve assessments of the homeostatic balance between CRH_1- and CRH_2-receptor systems in anxiety disorders.

HPA-Axis Function and CRH Release in Anxiety Disorders

The anxiety disorder for which abnormalities of CRH or HPA-axis function has been most commonly reported is PTSD. Nevertheless, the nature of such abnormalities has been inconsistent across studies, because basal plasma or 24-hour urine cortisol concentrations have been reported to be abnormally decreased (227 ,228 and 229), not different (230 ,231), or abnormally increased (190 ,192 ,232 ,233) in PTSD samples relative to healthy or trauma-matched control samples. Differences across these studies may reflect effects of gender, age of illness onset (i.e., childhood versus adult), trauma type or duration, or physiologic variation relative to illness phase. For example, Hawk et al. showed that 24-hour urine cortisol concentrations were elevated in males but not females with PTSD, and that this abnormality in males was evident at 1 month but not 6 months after the traumatic event (191).

The HPA-axis responses to behavioral or pharmacologic challenge have also been assessed in PTSD. During provocation of PTSD symptoms by exposure to combat sounds, the *changes* in plasma cortisol and ACTH concentrations did not differ between patients with combat-related PTSD and either healthy or combat-matched, non-PTSD control subjects (232). In response to dexamethasone administration, cortisol suppression was found to be normal (234) or enhanced (228 ,235 ,236) in PTSD, with the latter result particularly found in response to low-dose (0.25 and 0.5 mg) dexamethasone. Yehuda et al. also observed that patients with PTSD have an increased density of glucocorticoid receptors on peripheral lymphocytes (228). This finding, together with the observations that patients with PTSD show hypersensitivity to low-dose dexamethasone, led Yehuda et al. to hypothesize that an increase in hypothalamic glucocorticoid-receptor function results in enhanced feedback sensitivity to cortisol, leading to decreased peripheral cortisol levels (237). Preliminary data suggest that a reduced cortisol response after trauma exposure may predict PTSD development, a finding raising the possibility that enhanced feedback sensitivity to cortisol may arise acutely or may even antedate illness onset in some patients with PTSD (229 ,238).

The central release of CRH in PTSD was examined in two studies of CSF concentrations, both of which found abnormally *increased* in chronic, combat-related PTSD (239 ,240). Potentially consistent with this observation, PTSD samples show a blunted ACTH response to CRH relative to control samples (241 ,242). Although these observations would appear most consistent with findings that basal cortisol secretion and excretion are abnormally increased in PTSD (190 ,192 ,232 ,233), they do not clearly contradict the findings of normal or reduced peripheral cortisol concentrations in PTSD because hypothalamic and extrahypothalamic CRH secretion are independently regulated (216).

Nevertheless, the studies that either identified reductions or were unable to identify elevations in peripheral cortisol concentrations in PTSD present a challenge to the hypothesis that the reduced hippocampal volume found in MRI studies of PTSD (reviewed earlier) are accounted for by cortisol hypersecretion (150). This hypothesis may still be reconciled with the peripheral cortisol measures associated with chronic PTSD if the cortisol secretion was elevated near the time of the stressor (191 ,243). Longitudinal studies in male patients who developed PTSD after motor vehicle accidents suggest that cortisol secretion is elevated 1 month after the trauma, but it is normal when measured 6 months after the trauma (191). In rats, the atrophy of pyramidal cell apical dendrites that occurs in response to stress-induced corticosterone secretion is reversible when the exposure to elevated glucocorticoid concentrations is terminated early, but it can become irreversible if the elevated corticosterone concentration persists beyond a critical time period (149). Hippocampal damage may thus conceivably occur in PTSD during a period of excessive cortisol secretion that follows the traumatic event and is prolonged enough so that hippocampal neuronal atrophy becomes irreversible. An alternative hypothesis for the reduction of hippocampal volume in PTSD, however, is that this abnormality antedates the

development of PTSD and may comprise a risk factor for developing PTSD in response to traumatic stress.

In PD, the results of studies examining CRH-receptor and HPA-axis function have been less consistent (Table 63.2). Elevated plasma cortisol levels were reported in one study (244), but not in another (245), and the results of studies assessing urinary free cortisol have been similarly inconsistent (177 ,246). In a study of 24-hour secretion of ACTH and cortisol, PD subjects had subtle elevations of nocturnal cortisol secretion and greater amplitude of ultraradian secretory episodes relative to control subjects (247), but these findings await replication. Both normal and elevated rates of cortisol nonsuppression after dexamethasone administration have been reported in PD (248). After combined dexamethasone-CRH challenge, the HPA-axis response was higher in PD subjects than in healthy controls, but the magnitude of this abnormality was less than that seen in depressed samples (249 ,250). The ACTH response to CRH was blunted in some studies (249 ,250), but not in others (250), in PD relative to control samples, although CSF levels of CRH did not differ between PD and control samples (251). The extent to which pathophysiologic heterogeneity within PD samples may account for the inconsistency of these findings remains unclear.

TABLE 63.2. EVIDENCE OF ALTERATIONS IN CRF-HPA AXIS FUNCTION IN ANXIETY DISORDERS[a]

	PTSD	Panic Disorder
Alteration in urinary cortisol	+/–[a]	+/–

Functional Interactions among Noradrenergic, HPA, and CRH Systems

Coordinated functional interactions between the HPA axis and the noradrenergic systems play major roles in producing adaptive responses to stress, anxiety, or fear. The secretion of CRH increases LC neuronal firing activity and results in enhanced NE release in a variety of cortical and subcortical regions (252 ,253). Conversely, NE release stimulates CRH secretion in the PVN (the nucleus containing most of the CRH-synthesizing neurons in the hypothalamus). During chronic stress in particular, the LC is the brainstem noradrenergic nucleus that appears preferentially to mediate NE release in the PVN (254). Conversely, as CRH release in the PVN stimulates ACTH secretion from the pituitary and thereby increases cortisol secretion from the adrenal glands, the rise in plasma cortisol concentrations acts through a negative feedback pathway to decrease both CRH and NE synthesis at the level of the PVN. Glucocorticoid-mediated inhibition of NE-induced CRH stimulation may be evident primarily during stress, rather than under resting conditions, as an adaptive response that restrains stress-induced neuroendocrine and cardiovascular effects mediated by the PVN (254). NE, cortisol, and CRH thus appear tightly linked as a functional system that offers a homeostatic mechanism for responding to stress.

A clinical phenomenon of anxiety disorders that may be specifically regulated by interactions between NE and glucocorticoid secretion involves the acquisition and consolidation of traumatic memories. A characteristic feature of PTSD and PD is that memories of the traumatic experience or the original panic attack, respectively, persist for decades and are recalled in response to multiple stimuli or stressors. In experimental animals, alterations of both brain catecholamine and glucocorticoid levels affect the consolidation and retrieval of emotional memories (50 ,51). Glucocorticoids influence memory storage by activation of glucocorticoid receptors in the hippocampus, whereas NE effects are mediated in part through ß-adrenoreceptor stimulation in the amygdala (255). In humans, adrenocortical suppression blocks the memory-enhancing effects of amphetamine and epinephrine (256), and propranolol impairs memory for an emotionally provocative story, but not for an emotionally “neutral” story (257). These data suggest that the acute release of glucocorticoids and NE in response to trauma may modulate the encoding of traumatic memories. It is conceivable that long-term alterations in these systems may account for memory distortions seen in PTSD, such as the memory fragmentation, hypermnesia, and deficits in declarative memory.

Central Benzodiazepine-GABA–Receptor System

Several lines of preclinical and clinical evidence have established that BZD-receptor agonists exert anxiolytic effects

and have suggested that BZD-receptor function may be altered in anxiety disorders. Central BZD receptors are expressed are present throughout the brain, but they are most densely concentrated in the cortical gray matter. The BZD and $GABA_A$ receptors form parts of the same macromolecular complex, and although they constitute distinct binding sites, they are functionally coupled and regulate each other in an allosteric manner (258). Central BZD-receptor agonists potentiate and prolong the synaptic actions of the inhibitory neurotransmitter, GABA, by increasing the frequency of GABA-mediated chloride channel openings (258 ,259). Microinjection of BZD-receptor agonists in limbic and brainstem regions such as the amygdala and the PAG exert antianxiety effects in animal models of anxiety and fear (260). Conversely, administration of BZD-receptor *inverse* agonists, such as ß-carboline-3-carboxylic acid ethylester, produces behaviors and increases in heart rate, blood pressure, plasma cortisol, and catecholamines similar to those seen in anxiety and stress (261 ,262), effects that can be blocked by administration of BZD-receptor agonists (263).

Transgenic mouse studies have identified behavioral roles for specific $GABA_A$-receptor subunits. The anxiolytic action of diazepam appears absent in mice with α_2 subunit point mutations, but it is present in mice with α_1 or α_3 subunit point mutations (264 ,265). These data suggest that the anxiolytic effect of BZD agonists is at least partly mediated by the $GABA_A$-receptor α_2 subunit, which is largely expressed in the limbic system, but not by the α_3 subunit, which is predominately expressed in the reticular activating system, or the α_1 subunit, which is implicated in mediating the sedative, amnestic, and anticonvulsive effects of BZDs (265 ,266). These findings hold clear implications for investigations of the pathophysiology of anxiety disorders and for the development of anxioselective BZD-receptor agonists.

Some other agents with anxiolytic effects appear to modulate the function of the $GABA_A$/BZD-receptor–chloride ionophore complex by mechanisms distinct from those of the BZD agonists. The neurosteroid, allopregnenolone, exerts antianxiety effects in conflict paradigms that serve as putative animal models of anxiety. The anticonflict effects of allopregnenolone are reversed by either isopropylbicyclophosphate, which binds at the picrotoxinin site on the $GABA_A$ receptors, or RO15-4513 (ethyl-8-azido-5,6-dihydro-5-methyl-6-oxo-4H-imidazo[1,5-α]-[1,4]benzodiazepine-3-carboxylate), a BZD-receptor inverse agonist that inhibits $GABA_A$-activated chloride flux in neuronal membranes. In contrast, administration of the BZD-receptor antagonist flumazenil (ethyl-8-fluoro-5,6-dihydro-5-methyl-6-oxo-4H-imidazo[1,5-α]-[1,4]benzodiazepine-3-carboxylate) does not block allopregnenolone's anxiolytic-like effects, a finding indicating that allopregnenolone does not bind at the BZD site. Allopregnenolone may thus exert anxiolytic-like effects by stimulating the chloride channel in $GABA_A$ receptors by binding at the picrotoxinin site or at a site specific for RO15-4513.

The antianxiety effects of antidepressant drugs with primary effects on monoamine reuptake may also be partly mediated through a GABAergic mechanism. These agents are effective for the treatment of a spectrum of anxiety disorders including social anxiety disorder, generalized anxiety disorder, PD, and PTSD. One of the multiple secondary effects of these agents involves potentiation of GABAergic function. For example, in rats, the effective dose of phenelzine (15 mg/kg) on the elevated plus maze administered produces a more than twofold increase in whole-brain level GABA concentrations, whereas an ineffective dose of phenelzine (5.1 mg/kg) does not significantly alter GABA levels (267). Moreover, the *N*-acetylated metabolite of phenelzine, *N*-2-acetylphenelzine, which potently inhibits monoamine oxidase but does not change whole-brain GABA concentrations, does not produce anxiolytic effects in the elevated plus-maze test (267). Phenelzine's anxiolytic effects in the plus-maze model may thus depend on elevating brain GABA concentrations, in contrast to the mechanism of the classic BZDs, which instead increase the affinity of $GABA_A$ receptors for GABA.

Effects of Stress on Benzodiazepine-$GABA_A$ Receptors

BZD- and GABA-receptor function can be altered by exposure to stress in some brain regions. In experimental animals exposed to inescapable stress in the form of cold swim or foot shock, the BZD-receptor binding decreases in the frontal cortex, with less consistent reductions occurring in the hippocampus and hypothalamus, but no changes in the occipital cortex, striatum, midbrain, thalamus, cerebellum, or pons (268). Chronic stress in the form of repeated foot shock or cold water swim resulted in decreased BZD-receptor binding in the frontal cortex and hippocampus, and possibly in the cerebellum, midbrain, and striatum, but not in the occipital cortex or pons (268 ,269 and 270). These reductions in BZD-receptor binding were associated with deficits in maze escape behaviors that may have reflected alterations in mnemonic processing (269 ,270). Some of these stress effects may be mediated by glucocorticoids, because chronic exposure to stress levels of CORT alters mRNA levels of multiple $GABA_A$-receptor subunits (271). Consistent with the effects of chronic stress on BZD-receptor expression, the *Maudsley "genetically fearful" rat strain* shows decreased BZD-receptor density relative to other rats in several brain structures including the hippocampus (272).

Stressors arising early in life may also influence the development of the GABAergic system. In rats, early-life adverse experiences such as maternal separation result in decreased $GABA_A$-receptor concentrations in the LC and the NTS, reduced BZD-receptor sites in the LC, the NTS, the frontal cortex, and the CE and the LA of the amygdala, and reduced mRNA levels for the γ2 subunit of the $GABA_A$-receptor complex in the LC, the NTS, and the amygdala (273). The extent to which these developmental responses to early-life

stress may alter the expression of fear and anxiety in adulthood remains unclear.

Benzodiazepine-GABA–Receptor Function in Anxiety Disorders

The central BZD receptor has been implicated in anxiety disorders on the basis of the anxiolytic and anxiogenic properties of BZD agonists and inverse agonists, respectively, and by the evidence that the BZD-receptor sensitivity to BZD agonists is reduced in some anxiety-disordered subjects (21 ,274 ,275). Hypotheses advanced regarding the role of $GABA_A$-BZD–receptor function in anxiety disorders have proposed either that changes in the $GABA_A$-BZD macromolecular complex conformation or that alterations in the concentration or properties of an endogenous ligand account for the pathologic anxiety symptoms seen in anxiety disorders. However, these hypotheses have not been conclusively tested by *in vivo* or postmortem studies of anxiety-disordered humans.

In PD, oral (276) and intravenous (274) administration of the BZD-receptor antagonist, flumazenil, produces panic attacks and increases anticipatory anxiety in some subjects with PD, but not in healthy controls. In addition, the sensitivity to the effects of diazepam on saccadic eye movement velocity is abnormally reduced in PD, a finding implying that the functional sensitivity of the $GABA_A$-BZD supramolecular complex is attenuated in brainstem regions controlling saccadic eye movements (275). Subjects with PD also show abnormally reduced sensitivity to the suppressant effects of diazepam on plasma NE, epinephrine, and heart rate (see Table 63.3 on p. 920) (277).

TABLE 63.3. EVIDENCE OF ALTERATION IN OTHER NEUROTRANSMITTER SYSTEMS IN ANXIETY DISORDERS

Receptor imaging studies using PET and SPECT have assessed central BZD-receptor binding in anxiety disorders. SPECT studies have reported reduced uptake of the selective BZD-receptor radioligand, [^{123}I]iomazenil, in the frontal (278 ,279 and 280), temporal (278 ,279), and occipital (278) cortices in subjects with PD relative to control subjects. However, interpretation of these results was limited by the absence of medication-free PD study subjects and of healthy controls (278 ,279) or by the dependence on nonquantitative methods for estimating BZD-receptor binding. A SPECT-iomazenil study that quantitated BZD-receptor binding by derivation of distribution volumes found reduced binding in the left hippocampus and precuneus in unmedicated PD relative to healthy control samples and reported an inverse correlation between panic anxiety ratings and frontal cortex iomazenil binding (281). Another SPECT-iomazenil study reported lower distribution volumes for BZD receptors in the dorsomedial PFC in PTSD relative to control samples (281a). These findings appeared consistent with the evidence cited earlier that stress down-regulates BZD-receptor binding in the frontal cortex and the hippocampus of experimental animals.

Central BZD-receptor binding has also been assessed in PD using PET and [^{11}C]flumazenil. Malizia et al. reported a global reduction in BZD site binding in seven study subjects with PD relative to eight healthy controls, with the most prominent decreases evident in the right orbitofrontal cortex and the right insula (areas consistently activated during normal anxiety processing) (282). In contrast, Abadie et al. found no differences in the B_{max}, K_d or bound/free values for [^{11}C]flumazenil in any brain region in ten *unmedicated* PD study subjects relative to healthy controls (283).

Dopaminergic System

Acute stress increases DA release and turnover in multiple brain areas. The dopaminergic projections to the mPFC appear particularly sensitive to stress, because brief or low-intensity stressors (e.g., exposure to fear-conditioned stimuli) increase DA release and turnover in the mPFC in the absence of corresponding changes in other mesotelencephalic dopaminergic projections (284). For example, in rats, low-intensity electric foot shock increases tyrosine hydroxylase activity and DA turnover in the mPFC, but not in the nucleus accumbens or the caudate-putamen (285). In contrast, stress of greater intensity or longer duration additionally enhances DA release and metabolism in other areas as well (285). The regional sensitivity to stress appears to follow a pattern in which dopaminergic projections to the mPFC are more sensitive to stress than the mesoaccumbens and nigrostriatal projections, and the mesoaccumbens dopaminergic projections are more sensitive to stress than the nigrostriatal projections (284).

Thus far, there is little evidence that dopaminergic dysfunction plays a primary role in the pathophysiology of human anxiety disorders. In PD, Roy-Byrne et al. found a higher plasma concentration of the DA metabolite, homovanillic acid (HVA), in patients with high levels of anxiety and frequent panic attacks relative to controls (286). Patients with PD were also shown to have a greater growth hormone response to the DA-receptor agonist, apomorphine, than depressed controls (287). However, Eriksson et al. found no evidence of alterations in the CSF HVA concentrations in patients with PD or for correlations between CSF HVA and anxiety severity or panic attack frequency (288). In addition, genetic studies examining associations between PD and gene polymorphisms for the DA D4 receptor and the DA transporter have produced negative results (289).

In social phobia, two preliminary SPECT imaging studies involving small subject samples reported abnormal reductions in DA-receptor binding. Tiihonen et al. found a significant reduction in ß-CIT binding in the striatum in social phobic relative to healthy control samples (290), presumably reflecting a reduction in DA-transporter binding. Schneier et al. reported reduced uptake of the DA D2/D3-receptor radioligand, [^{123}I]IBZM, in social phobic subjects relative to healthy control subjects (291). Both findings await replication.

Serotonergic System

Exposure to various stressors including restraint stress, tail shock, tail pinch, and high-level (but not low-level) foot shock results in increased 5-HT turnover in the mPFC, nucleus accumbens, amygdala, and lateral hypothalamus in experimental animals (285). During exposure to fear-conditioned stimuli, the 5-HT turnover in the mPFC appears particularly sensitive to the severity of stress, increasing as the aversiveness of the US and the magnitude of the conditioned fear behavioral response increases (285). However, exposure to repeated electric shocks sufficient to produce learned helplessness is associated with reduced *in vivo* release of 5-HT in the frontal cortex (292), a finding possibly reflecting a state in which 5-HT synthesis is outpaced by release. Preadministration of BZD-receptor agonists or tricyclic antidepressant drugs prevents stress-induced reductions in 5-HT release and interferes with the acquisition of learned helplessness, whereas infusion of 5-HT into the frontal cortex after stress exposure *reverses* learned-helplessness behavior (292 ,293). Finally, administration of 5-HT–receptor antagonists produces behavioral deficits resembling those of the learned helplessness seen after inescapable shock during animal stress models that do not ordinarily result in learned helplessness (293).

The effect of stress in activating 5-HT turnover may stimulate both anxiogenic and anxiolytic pathways within the forebrain, depending on the region involved and the 5-HT–receptor subtype that is predominantly stimulated. For example, microinjection of 5-HT into the amygdala appears to enhance conditioned fear, whereas 5-HT injection into the PAG inhibits unconditioned fear (260). Graeff et al. hypothesized that the serotonergic innervation of the amygdala and the hippocampus mediates anxiogenic effects by 5-HT_{2A}–receptor stimulation (260), whereas serotonergic innervation of hippocampal 5-HT_{1A} receptors suppresses formation of new CS-US associations and provides resilience to aversive events. Potentially compatible with this hypothesis, 5-HT_{1A}-receptor knockout mice exhibit behaviors consistent with increased anxiety and fear, and long-term administration of 5-HT_{1A}–receptor partial agonists exerts anxiolytic effects in generalized anxiety disorder (295).

Notably, stress and glucocorticoids exert major effects on the genetic expression of 5-HT_{1A} and 5-HT_{2A} receptors. Postsynaptic 5-HT_{1A}–receptor gene expression is under tonic inhibition by adrenal steroids in the hippocampus and possibly other regions where mineralocorticoid receptors are expressed (reviewed in ref. 296). Thus, 5-HT_{1A}–receptor density and mRNA levels decrease in response to chronic stress or CORT administration and increase after adrenalectomy (296 ,297 ,298 and 299). The stress-induced down-regulation of 5-HT_{1A}–receptor expression is prevented by adrenalectomy, a finding showing the importance of circulating adrenal steroids in mediating this effect (296). Although both mineralocorticoid-receptor stimulation and glucocorticoid-receptor stimulation are involved in mediating this effect, the former is most potent, and 5-HT_{1A} mRNA levels markedly decrease within hours of mineralocorticoid-receptor stimulation (296). Conversely, 5-HT_{2A}–receptor expression is up-regulated during chronic stress and CORT administration, and it is down-regulated in response to adrenalectomy (298 ,300). In view of evidence that 5-HT_{1A} and 5-HT_{2A} receptors may play reciprocal roles in mediating anxiety, it is conceivable that these corticosteroid mediated effects on 5-HT_{1A} and 5-HT_{2A} expression may be relevant to the pathophysiology of anxiety.

Serotonergic Function in Anxiety Disorders

The literature regarding serotonergic function in anxiety disorders is in disagreement (see Table 63.3). In PD, platelet 5-HT uptake has been reported to be abnormally elevated (301), normal (302), or abnormally reduced (303). Platelet imipramine binding (to a site related to the 5-HT transporter site), did not differ in PD relative to control samples (304 ,305). Another study reported reduced concentrations of circulating 5-HT in PD relative to control samples (306), although this finding has not been replicated.

Pharmacologic challenge studies involving 5-HT have been similarly unable to establish a primary role for 5-HT in the pathophysiology in PD. Neuroendocrine responses to challenge with the 5-HT precursors, L-tryptophan and 5-hydroxytryptophan (5-HTP), did not differentiate PD study subjects from healthy controls (307 ,308). Moreover, tryptophan depletion did not prove anxiogenic in unmedicated PD study subjects (309). Nevertheless, challenge with the 5-HT releasing agent, fenfluramine, produced greater increases in anxiety, plasma prolactin, and cortisol in PD compared with control subjects (131 ,310). Fenfluramine challenge also resulted in reduced CBF in the left posterior parietal-superior temporal cortex in PD study subjects relative to healthy controls (131), although it was unclear whether this abnormality reflected an abnormality of serotonergic function or a physiologic correlate of fenfluramine-induced anxiety, because more PD study subjects (56%) developed panic attacks than did control subjects (11%).

Preliminary data regarding the sensitivity of specific 5-HT–receptor subtypes appear more promising, particularly because the elevation of plasma ACTH and cortisol and the hypothermic responses to the 5-HT_{1A} partial agonist, ipsapirone, were blunted in PD relative to healthy control samples (311). Finally, increases in anxiety and plasma cortisol in PD relative to control samples have been reported after oral (312), but not intravenous, administration of the 5-HT_2–receptor agonist, m-chloromethylpiperazine (mCPP) (313).

Samples with combat-related PTSD have been shown to have decreased paroxetine binding in platelets relative to controls, a finding suggesting alterations in the 5-HT transporter (314).

Southwick et al. observed that a subgroup (five of 14 subjects) with PTSD experienced panic anxiety and “flashbacks” after mCPP challenge (189). Thus, a subgroup of patients with PTSD may have abnormal sensitivity to serotonergic provocation.

Cholecystokinin

CCK is an anxiogenic neuropeptide present in both the brain and the gastrointestinal tract. CCK-containing neurons are found in high density in the cerebral cortex, amygdala, hippocampus, midbrain PAG, substantia nigra, and raphe. Iontophoretic administration of CCK has depolarizing effects on pyramidal neurons and stimulates action potential formation in the dentate gyrus of the hippocampus (reviewed in ref. 315).

The CCK-receptor agonist, CCK-4, is anxiogenic in a variety of animal models of anxiety, whereas CCK-receptor antagonists exert anxiolytic effects in the same models (315). CCK has important functional interactions with other systems implicated in anxiety and fear (noradrenergic, dopaminergic, BZD). For example, the panicogenic effect of CCK-4 in PD is attenuated by administration of the ß-adrenoreceptor antagonist, propranolol, and by long-term imipramine treatment, which down-regulates ß-adrenoreceptors (316).

Study subjects with PD or PTSD are more sensitive to the anxiogenic effects of CCK-4 than are control subjects (317 ,318). For example, Strohle et al. found that of 24 PD study subjects tested, 15 experienced a panic attack after CCK-4 administration (319). Although the mechanism underlying the enhanced sensitivity to CCK-4 has not been elucidated, it is noteworthy that CSF concentrations of CCK are lower in PD study subjects than in healthy controls (320).

The neuroendocrine effects associated with CCK-4 induced panic appear to differ between PD and PTSD. In PTSD, CCK-4–induced panic was associated with a *lower* ACTH response in the PTSD study subjects than in healthy controls, and cortisol concentrations increased in both the PTSD and control groups (318). The elevation in the cortisol concentrations attenuated more rapidly in the PTSD group than in the control group.

In contrast to the findings in PTSD, ACTH secretion was higher in subjects with PD who developed panic attacks in response to CCK-4 than in those who did not, although even the latter subjects showed brief, less pronounced increases in ACTH concentrations (319). Neither PD subgroup showed significant changes in the plasma cortisol concentration after CCK-4 administration. The elevation of ACTH concentrations suggested that CRH secretion increases in CCK-4–induced panic in PD (consistent with preclinical evidence regarding the role of CRH in stress and anxiety and the interaction of CRH and CCK in modulating anxiety) (221).

The CCK receptors are classified into CCK-A and CCK-B subtypes. Kennedy et al. reported a significant association between PD and a single nucleotide polymorphism found in the coding region of the CCK-B–receptor gene (321). In contrast, genetic polymorphisms for the CCK-A–receptor gene and the CCK-pre-pro hormone genes showed no association with PD (321). If confirmed by replication, these data would suggest that a CCK-B–receptor gene variation may be involved in the pathogenesis of PD.

Pande et al. assessed the efficacy of the selective CCK-B–receptor antagonist, CI-988, for preventing panic attacks in PD (322). No differences in the rate of panic attacks were seen between the active drug and placebo treatment groups. Nevertheless, because of the limited bioavailability of oral CI-988, studies involving this drug may not have sufficiently tested the hypothesis that CCK-B–receptor antagonism produces antipanic effects in PD.

Other Neuropeptides

Opioid Peptides

Acute, uncontrollable shock increases secretion of opiate peptides and decreases µ-opiate–receptor density (323 ,324). The elevation of opioid peptide secretion may contribute to the analgesia observed after uncontrollable stress and exposure to fear-conditioned stimuli (325). This analgesic effect shows evidence of sensitization, because subsequent exposure to less intense shock in rats previously exposed to uncontrollable shock also results in analgesia (326).

Potentially consistent with these data, Pitman et al. found that patients with PTSD showed reduced pain sensitivity compared with veterans without PTSD after exposure to a combat film (327), an effect that was reversed by the opiate antagonist naloxone (a finding suggesting mediation by endogenous opiate release during symptom provocation). In the baseline state, the CSF ß-endorphin levels were abnormally elevated in PTSD relative to control samples (328). However, Hoffman et al. found *lower* morning and evening *plasma* ß-endorphin levels in a PTSD group versus healthy control samples (329). Another study found no differences in plasma methionine-enkephalin concentrations between PTSD subjects and control subjects, although this compound's degradation half-life was higher in the PTSD group (330).

During opiate administration, Bremner et al. reported that some patients with combat-related PTSD experience an attenuation of their hyperarousal symptoms (331). Because preclinical studies in experimental animals have shown that opiates potently suppress central and peripheral noradrenergic activity, these data appear compatible with the hypothesis that some PTSD symptoms are mediated by noradrenergic hyperactivity (discussed earlier). Conversely, during opiate withdrawal noradrenergic activity increases, and it

has been noted that some symptoms of PTSD resemble those of opiate withdrawal (170).

Neuropeptide Y

NPY administered in low doses intraventricularly attenuates experimentally induced anxiety in a variety of animal models (332). Consistent with these data, transgenic rats that overexpress hippocampal NPY show behavioral insensitivity to restraint stress and absent fear suppression of behavior in a punished drinking task (333). In healthy humans subjected to uncontrollable stress during military training exercises, plasma NPY levels increased to a greater extent in persons rated as having greater stress resilience (334). During stress exposure, the NPY plasma levels were positively correlated with plasma cortisol concentrations and behavioral performance, and they were negatively correlated with dissociative symptoms (334).

In humans with PD, plasma NPY concentrations were abnormally elevated, and this finding, given NPY's putative anxiolytic effects, may reflect an adaptive response to anxiety symptoms (335). In contrast, patients with combat-related PTSD had *lower* plasma NPY concentrations both at baseline and in response to yohimbine challenge than healthy controls (336). In the PTSD group, the baseline NPY levels were inversely correlated with PTSD and panic symptoms and with yohimbine-induced increases in MHPG and systolic blood pressure (336). If this finding proves reproducible, it suggests that a deficit in endogenous NPY secretion may be involved in the generation of anxiety and sympathetic autonomic symptoms in PTSD.

Thyrotropin-Releasing Hormone and the Thyroid Axis

In the early twentieth century, Graves described cases in which thyroid hormone hypersecretion was associated with anxiety, palpitations, breathing difficulties, and rapid heart rate in persons recently exposed to traumatic stress. Nevertheless, systematic epidemiologic studies of the relationship between stress and thyroid disease have not been conducted. Although few studies have looked at thyroid function in anxiety disorders, Mason et al. found elevated levels of triiodothyronine in patients with combat-related PTSD (337) (Table 63.3), a finding consistent with evidence that stress results in long-lasting elevations of thyroid hormone secretion (338).

Respiratory System Dysfunction in Panic Disorder

Associations between respiratory perturbation and acute anxiety have been demonstrated in PD, in which various forms of respiratory stimulation consistently produce panic anxiety and alterations in parameters of respiratory physiology (339 ,340 ,341 and 342). The most straightforward forms of respiratory stimulation that produce panic anxiety produce elevations of carbon dioxide pressure (hypercapnia). Thus, panic attacks can be consistently induced in patients with PD by rebreathing air, inhaling 5% to 7% carbon dioxide in air (343 ,344), or inhaling a single deep breath of 35% carbon dioxide (345 ,346). Other panicogenic chemical challenges have also been hypothesized to induce anxiogenic effects

through respiratory stimulation (340 ,341 ,347). Although the panicogenic mechanism of intravenous administration of sodium lactate remains unclear, it may also involve respiratory stimulation (339 ,340).

The evidence that respiratory parameters index risk for panic anxiety includes data showing the following: (a) asymptomatic adult relatives of patients with PD have abnormally increased sensitivity to respiratory stimulation by carbon dioxide inhalation; (b) among PD samples, stronger family loading for PD is found among persons with evidence of respiratory dysregulation; and (c) the respiratory indices associated with PD are heritable, a finding suggesting a shared genetic vulnerability for panic attacks and respiratory dysregulation (reviewed in Chapter 61). Nevertheless, these data partly depend on subjective ratings of dyspnea during stress or respiratory stimulation, and the mechanisms underlying this sensitivity remain unclear. One possibility is that this hypersensitivity reflects an overall sensitivity to somatic sensations, because high degrees of anxiety sensitivity are linked to future panic attacks (348).

The associations between respiratory perturbation and acute anxiety are not specific to PD. Exaggerated sensitivity to respiratory perturbation has also been reported in anxiety-disordered patients with some simple phobias, limited symptom panic attacks, childhood separation anxiety disorder, or limited-symptom anxiety attacks and in nonpsychiatrically ill subjects with high ratings on anxiety sensitivity scales. (See Chapter 61) For example, children with separation anxiety disorder exhibit greater changes in somatic symptoms during carbon dioxide inhalation that positively correlate with increases in respiratory rate, tidal volume, minute ventilation, end-tidal carbon dioxide pressure, and irregularity in respiratory rate during room-air breathing (349).

CONCLUDING REMARKS

Part of "63 - Neurobiological Basis of Anxiety Disorders "

The inconsistency in the results of biological investigations of anxiety disorders highlights the importance of addressing the neurobiological heterogeneity inherent within criteria-based, psychiatric diagnoses. Understanding this heterogeneity will be facilitated by the continued development and application of genetic, neuroimaging, and neurochemical approaches that can refine anxiety disorder phenotypes and can elucidate the genotypes associated with these disorders. Application of these experimental approaches will also facilitate research aimed at elucidating the mechanisms of antianxiety therapies.

The knowledge reviewed herein regarding the neurobiology of fear and anxiety already suggests themes along which the development of new therapeutic approaches can be organized. In general, anxiolytic treatments appear to inhibit neuronal activity in the structures mediating fear expression and behavioral sensitization and facilitate endogenous mechanisms for modulating the neural transmission of information about aversive stimuli and responses to such stimuli. Novel treatments being developed to exploit the former type of mechanisms include pharmacologic agents that selectively target subcortical and brainstem pathways supporting specific components of emotional expression (e.g., CRH-receptor antagonists). In contrast, nonpharmacologic treatments for anxiety may augment the brain's systems for modulating anxiety responses, by facilitating the extinction of putative fear-conditioned responses or directing the reinterpretation of anxiety-related thoughts and somatic sensations (so they produce less subjective distress). Informed by increasingly detailed knowledge about the pathophysiology of specific anxiety disorders and the neural pathways involved in anxiety and fear processing, the development of therapeutic strategies that combine both types of approaches may ultimately provide the optimal means for reducing the morbidity of anxiety disorders.

Neural Circuitry of Anxiety and Stress Disorders

Michael Davis

Michael Davis: Department of Psychiatry, Emory University School of Medicine, Atlanta, Georgia.

BRAIN SYSTEMS IN THE GENERATION OF FEAR AND ANXIETY

Part of "64 - Neural Circuitry of Anxiety and Stress Disorders "

Role of the Amygdala

Many data now indicate that the amygdala, along with its many efferent connections, is critically involved in emotion. Although the amygdala complex is generally defined by several distinct groups of cells, including the lateral, basal, accessory basal central, medial, and cortical nuclei, new data indicate that it is more useful to think of the amygdala as the *basolateral amygdala* (Bla) and to think of its several target areas as parts of a broader network that subserve more specialized functions (Fig. 64.1). The Bla receives sensory information from the thalamus, cortex (169), and ventral hippocampus (54) and then activates or modulates synaptic transmission in target areas appropriate for the reinforcement signal with which the sensory information has been associated. This involves both positive and negative associations. However, because most of the literature on the amygdala has analyzed the role of the Bla and its adjacent target, the central nucleus of the amygdala (CeA), in aversive conditioning, this work serves as the main focus of this chapter. Brief summaries of the role of Bla outputs to other targets shown in Fig. 64.1 follow. Because the periaqueductal gray (PAG) has received considerable attention in the study of defensive behavior and the hippocampus in the study of contextual fear conditioning, these data are reviewed next. Finally, brain systems and neurotransmitters involved in the inhibition of fear are reviewed, given the clinical significance of this information.

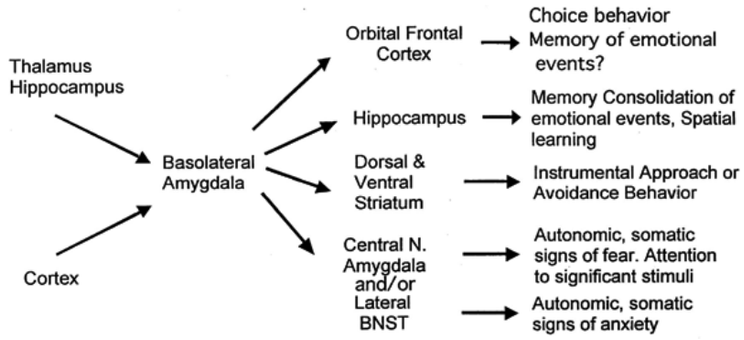

FIGURE 64.1. Schematic diagram of the outputs of the basolateral amygdala to various target areas and how these connections may be involved in fear and anxiety.

Basolateral Nucleus of the Amygdala to CeA or BNST Pathway as It Relates to Conditioned and Unconditioned Fear

Figure 64.1 shows that the Bla projects directly to the CeA, as well as to a related structure, the lateral division of the bed nucleus of the stria terminalis (BNST), to form part of the *lateral extended amygdala* (6). Figure 64.2 summarizes work done in many different laboratories indicating that the CeA and BNST have direct projections to various anatomic areas that may be expected to be involved in many of the symptoms of fear or anxiety (65). The CeA and BNST have been grouped together because fibers from the Bla that project to the BNST pass through the CeA and cells in the lateral division of the CeA project to the BNST. Thus, many effects previously attributed to the CeA may really depend on the BNST.

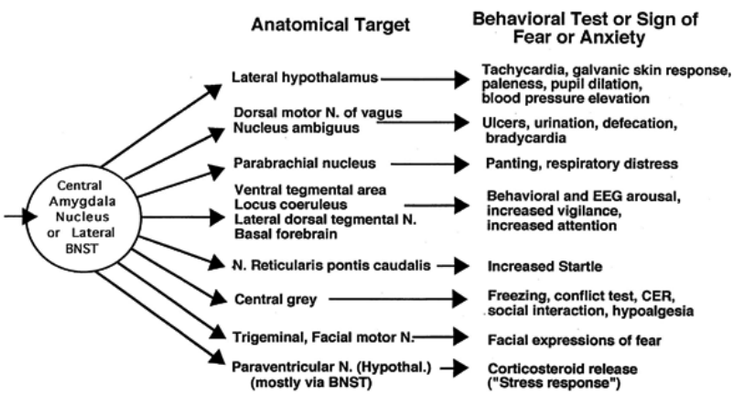

FIGURE 64.2. Schematic diagram of the outputs of the central nucleus of the amygdala and the lateral division of the bed nucleus of the stria terminalis to various target areas and how these connections may be related to specific aspects of fear and anxiety. BNST, bed nucleus of the stria terminalis; CER, conditioned emotional response; EEG, electroencephlographic; N, nucleus.

Autonomic and Hormonal Measures

Anatomically, the CeA and the BNST are well situated to mediate the various components of the fear response. Both structures send prominent projections to areas such as the lateral hypothalamus, which is involved in activation of the sympathetic autonomic nervous system seen during fear and anxiety (155). Direct projections to the dorsal motor nucleus of the vagus, nucleus of the solitary tract, and ventrolateral medulla may be involved in lateral extended amygdala modulation of heart rate and blood pressure, which are known to be regulated by these brainstem nuclei (222). Projections to the parabrachial nucleus may be involved in respiratory (as well as cardiovascular changes) during fear, because electrical stimulation and lesions of this nucleus are known to alter various measures of respiration. Indirect projections of the CeA to the paraventricular nucleus through the BNST and preoptic area may mediate the prominent neuroendocrine responses to fearful or stressful stimuli.

Attention and Vigilance

Projections from the lateral extended amygdala to the ventral tegmental area may mediate stress-induced increases in dopamine metabolites in the prefrontal cortex (101). Direct projections to the dendritic field of the locus ceruleus or indirect projections through the paragigantocellularis nucleus may mediate the increase in firing rates of cells in the locus ceruleus in the presence of a fearful stimulus. Direct

projections to the lateral dorsal tegmental nucleus and parabrachial nuclei, which have cholinergic neurons that project to the thalamus, may mediate increases in synaptic transmission in thalamic sensory relay neurons during states of fear. This cholinergic activation, along with increases in thalamic transmission accompanying activation of the locus ceruleus, may thus lead to increased vigilance and superior signal detection in a state of fear or anxiety.

As emphasized by Kapp et al. (141), in addition to its direct connections to the hypothalamus and brainstem, the CeA has the potential for indirect widespread effects on the cortex through its projections to cholinergic neurons that project to the cortex. The rapid development of conditioned bradycardia during pavlovian aversive conditioning, critically dependent on the amygdala, may reflect a general increase in attention.

Motor Behavior

Release of norepinephrine onto motor neurons by lateral extended amygdala activation of the locus ceruleus, or through projections to serotonin containing raphe neurons, could lead to enhanced motor performance during a state of fear, because both norepinephrine and serotonin facilitate excitation of motor neurons. Direct projections to the nucleus reticularis pontis caudalis, as well as indirect projections to this nucleus through the central gray, probably are involved in fear potentiation of the startle reflex. Direct projections to the lateral tegmental field, including parts of the trigeminal and facial motor nuclei, may mediate some of the facial expressions of fear as well as potentiation of the eyeblink reflex. The lateral extended amygdala also projects to regions of the central gray that appear to be a critical part of a general defense system and that have been implicated in conditioned fear in certain behavioral tests including freezing, sonic and ultrasonic vocalization, and stress-induced hypalgesia (20 ,33 ,78 ,103 ,121 ,155).

Elicitation of Fear Responses by Electrical or Chemical Stimulation of the Extended Amygdala

Electrical stimulation or abnormal electrical activation of the amygdala (i.e., by temporal lobe seizures) can produce a complex pattern of behavioral and autonomic changes that, taken together, highly resembles a state of fear.

Autonomic and Hormonal Measures

As outlined by Gloor: “The most common affect produced by temporal lobe epileptic discharge is fear…. It arises ‘out

of the blue.' Ictal fear may range from mild anxiety to intense terror. It is frequently, but not invariably, associated with a rising epigastric sensation, palpitation, mydriasis, and pallor and may be associated with a fearful hallucination, a frightful memory flashback, or both" (98). In humans, electrical stimulation of the amygdala elicits feelings of fear or anxiety as well as autonomic reactions indicative of fear (57 ,99). Although other emotional reactions occasionally are produced, the major reaction is one of fear or apprehension.

Electrical stimulation of the CeA or chemical activation by the cholinergic agonist carbachol or the neurotransmitter glutamate produces prominent cardiovascular effects that depend on the species, site of stimulation, and state of the animal. CeA stimulation can also produce gastric ulceration and can increase gastric acid, and these features can be associated with chronic fear or anxiety. It can also alter respiration, a prominent symptom of fear, especially in panic disorder.

Using very small infusion cannulas and very low doses, Sanders and Shekhar found increases in blood pressure and heart rate when the γ-aminobutyric $acid_A$ ($GABA_A$) antagonist bicuculline was infused into the Bla but not the CeA (215). Local infusion of *N*-methyl-D-aspartate (NMDA) or AMPA into the basolateral nucleus also increased blood pressure and heart rate (230). Repeated infusion of initially subthreshold doses of bicuculline into the anterior basolateral nucleus led to a "priming" effect in which increases in heart rate and blood pressure were observed after three to five infusions (216). This change in threshold lasted at least 6 weeks and could not be ascribed to mechanical damage or generalized seizure activity based on EEG measurements. Similar changes in excitability were produced by repetitive infusion of very low doses of corticotropin-releasing hormone (CRH) or the related peptide, urocortin (210). Once primed, these animals exhibited behavioral and cardiovascular responses to intravenous sodium lactate, a panic-inducing treatment in certain types of psychiatric patients.

In general, electrical stimulation of the amygdala causes an increase in plasma levels of corticosterone. The effect of electrical stimulation appears to depend on both norepinephrine and serotonin in the paraventricular nucleus. Depletion of these transmitters through local infusions of 6-hydroxydopamine or 5,7-DHT, or local infusion of the norepinephrine or serotonin antagonists prazosin or ketanserin, into the paraventricular nucleus attenuated the effects of electrical stimulation (80).

Attention and Vigilance

Studies in several species indicate that electrical stimulation of the CeA increases attention or processes associated with increased attention. For example, stimulation of sites in the CeA that produce bradycardia (142) also produce low-voltage fast EEG activity (140). In fact, an attention or orienting reflex was the most common response elicited by electrical stimulation of the amygdala (16 ,241). These and other observations led Kapp et al. to hypothesize that the "central nucleus and its associated structures function, at least in part, in the acquisition of an increased state of nonspecific attention or arousal manifested in a variety of CRs which function to enhance sensory processing. This mechanism is rapidly acquired, perhaps via an inherent plasticity within the nucleus and associated structures in situations of uncertainty but of potential import; for example, when a neutral stimulus (CS) precedes either a positive or negative reinforcing, unexpected event (US)" (141). Electrical stimulation of the amygdala can also activate cholinergic cells that are involved in arousal-like effects depending on the state of sleep and perhaps the species.

Motor Behavior

Electrical or chemical stimulation of the CeA produces a reduction of prepotent, ongoing behavior, a critical component in several animal models such as freezing, the operant conflict test, the conditioned emotional response, and the social interaction test. Electrical stimulation of the amygdala also elicits jaw movements and activation of facial motoneurons, which may mimic components of the facial expressions seen during the fear reaction. These motor effects may be indicative of a more general effect of amygdala stimulation, namely, that of modulating brainstem reflexes such as the massenteric, baroreceptor nictitating membrane, eyeblink, and the startle reflex.

Summary of the Effects of Stimulation of the Amygdala

Viewed in this way, the pattern of behaviors seen during fear may result from activation of a single area of the brain (the extended amygdala), which then projects to various target areas that themselves are critical for each of the specific symptoms of fear (the expression of fear), as well as the experience of fear. Moreover, it must be assumed that all these connections are already formed in an adult organism, because electrical stimulation produces these effects in the absence of prior explicit fear conditioning. Thus, much of the complex behavioral pattern seen during a state of "conditioned fear" has already been "hard wired" during evolution.

For a formerly neutral stimulus to produce the constellation of behavioral effects used to define a state of fear or anxiety, it is only necessary for that stimulus to activate the amygdala, which, in turn, will produce the complex pattern of behavioral changes by virtue of its innate connections to different brain target sites. Viewed in this way, plasticity during fear conditioning probably results from a change in synaptic inputs before or in the Bla (173 ,192 ,204), rather than from a change in its efferent target areas. The ability to produce long-term potentiation (LTP) in the Bla (55 ,56 ,58 ,91 ,129 ,226) that can lead to an increase in responsiveness to a physiologic stimulus (203) and the finding

that local infusion of NMDA antagonists into the amygdala block the acquisition of fear conditioning (65) are consistent with this hypothesis.

Effects of Lesions of the Amygdala on Conditioned and Unconditioned Fear in Rodents and Other Species

Many studies in rodents and other species indicate that lesions of the Bla or CeA block many different measures of conditioned fear, as well as unconditioned fear. Table 64.1 and Table 64.2 show selected examples of such studies in animals, which have been extensively reviewed elsewhere (64 ,65). More recent studies in humans also point to the amygdala in fear and anxiety.

Method	Species	Site	Effect of Lesion	Reference
Aspiration (pre)	Human	AC	Decrease galvanic skin response during classic fear conditioning unilateral lesions	153
Aspiration (pre)	Human	AC	Decrease galvanic skin response during classic fear conditioning	26
Electrolytic	Rabbit	Ce	Decrease bradycardia to cue paired with shock	139
Ibotenic acid (pre)	Rabbit	Ce	Decrease bradycardia to cue paired with shock	168
Ibotenic acid (Ce)	Rat	Ce	Decrease blood pressure rise to cue paired with shock	137
Electrolytic (MG)		MG	(Ce, unilateral, MG, contralateral)	
Cooling (pre)	Cat	Ce	Decrease bradycardia, respiratory increases and blood pressure changes to cue paired with shock	259
Electrolytic (pre)	Rat	L	Decrease blood pressure rise during classic conditioning	154,206
NMDA (pre or post)	Rat	C	Decrease secretion of corticosterone and defecation to cue paired with shock; decrease rise in dopamine, serotonin, or norepinephrine metabolites in prefrontal cortex to cue paired with shock	101
Electrolytic (pre)	Rat	Ce	Decrease freezing to cue paired with shock	157
Ibotenic acid (pre)	Rat	Ce and Bla	Decrease freezing to context paired with shock	118
Electrolytic (pre)	Rat	L	Decrease freezing to cue paired with shock	154
Radiofrequency (pre)	Rat	AC	Decrease freezing to cues paired with shock; decrease shock probe avoidance	30
Ibotenic acid (amygdala) M (medial geniculate) (pre)	Rat	Ce, MG	Decrease freezing to cue paired with shock (Ce, unilateral; MG, contralateral), some damage to L and Bla	137
NMDA (pre or post)	Rat	Bla	Decrease acquisition of freezing to odor or context or expression of both when lesions made 1 or 15 days after conditioning	61
NMDA (pre and post)	Rat	Bla	Decrease acquisition or expression of freezing to context or cue paired with shock even when lesions made 1 month after training	166
Lidocaine (pre or pretesting or both)	Rat	Ce and Bla	Decrease expression of freezing to context paired with shock; weaker effect when inactivation given before training	119
Muscimol (pre or post)	Rat	Bla	Decrease freezing when given either before testing or training but not immediately after training	183
NMDA (pre or post)	Rat	Bla	Decrease freezing or high-frequency vocalizations to shock or cues paired with shock	101
Ibotenic acid (pre)	Rat	Ce not Bla	Anticonflict (licking), decrease effects of restraint stress on plus maze	175
Electrolytic (pre)	Rat	Ce not Bla	Anticonflict effect	225,256
Quinolinic acid or 6-OHDA (pre)	Rat	Bla	Decrease reduction in licking during conditioned emotional response test	224
NMDA (pre)	Rat	AC	Decrease avoidance of water spout paired with shock but not with quinine	48
Ibotenic acid (pre)	Rat	Ce, not Bla	Decrease disruption of bar pressing to cue paired with shock; could still avoid shock bar	146
Quinolinic acid (pre)	Rat	Bla not Ce	Decrease avoidance of shocked bar, no reduction of disruption of bar pressing to cue paired with shock	146
NMDA (pre or post)	Rat	Bla	Decrease expression or acquisition of fear-potentiated startle to visual conditioned stimulus	214
NMDA (post)	Rat	Bla	Decrease expression of fear-potentiated startle even when lesions made 1 month after training	159
Ibotenic acid (post)	Rat	Ce	Decrease expression of fear-potentiated startle to visual or auditory conditioned stimulus	52
Ibotenic acid (pre)	Rat	Ce and Bla	Decrease expression of hypoalgesia to context paired with shock (formalin test)	118

AC, amygdala complex; Bla, basolateral complex; central nucleus; MG, medial geniculate; post, posttraining; pre, pretraining.

TABLE 64.1. EFFECTS OF LESIONS OF THE AMYGDALA ON CONDITIONED FEAR

Method	Species	Site	Effect of Lesion	Reference
Electrolytic	Rat	Ce	Decrease secretion of ACTH to immobilization stress	23,24
Ibotenic acid	Rat	Ce	Decrease rise corticosterone to immobilization stress	242
Radiofrequency	Rat	**	Decrease the compensatory hypersecretion of ACTH that normally occurs following adrenalectomy	7,8
Electrolytic (pretraining but not posttraining)	Rat	Ce	Decrease secretion of corticosterone and prolactin to shock; no effect on epinephrine, norepinephrine	207
Radiofrequency	Rat	Ce	Decrease ulceration produced by restraint	122,123
Radiofrequency	Rat	Ce	Decrease ulceration produced by shock stress	124
Electrolytic	Rat	Ce	Decrease gastric ulcers to water restraint	59
Ibotenic acid	Rat	Ce	No effect on ulcers to water restraint	59
Electrolytic	Rat	Ce	Decrease noise-elicited hypertension	88
Electrolytic	Wild Rat	CO, Ce	Decrease emotionality in measured in terms of flight and defensive behaviors	144,145
Electrolytic	Rat	CO, Me Ce	Increase the number of contacts a rat will make with a sedated cat	30
Electrolytic	Many species	AC	General taming effect	For review, see 100
Electrolytic	Wild Rat	CO, Ce	Decrease emotionality in measured in terms of flight and defensive behaviors	144,145
Electrolytic	Rat	CO, Me Ce	Increase the number of contacts a rat will make with a sedated cat	30
Radiofrequency	Rat	Ce	Decrease jump withdrawal sign in morphine dependent rats after intraperitoned naloxone	51
Radiofrequency	Rat	Ce, L and Bla	Decrease analgesia produced by exposure to cat or shock (tail flick test)	85
Electrolytic	Rat	L or Ce	Decrease loud noise-induced hypoalgesia (tail fick test)	28
Electrolytic	Rat	Ce, not Bla	Decrease analgesic effects of systemic flumazenil (hot plate test)	106
NMDA	Rat	Ce not Bla or Me	Decrease morphine (low dose) induced antinociception (formalin or tail flick tests)	164,165
Lidocaine	Rat	Ce	Decrease morphine induced antinociception (tail flick test)	165

AC, amygdala complex; Bla, basolateral complex; Ce, central nucleus; Me, medial nucleus.

TABLE 64.2. EFFECTS OF LESIONS OF THE AMYGDALA ON UNCONDITIONED FEAR OR STRESS

Effects of Lesions of the Amygdala in Humans and Nonhuman Primates

In nonhuman primates (160 ,184 ,205) and in humans (9 ,117), cells have been found in the amygdala that respond selectively to faces or direction of gaze (42). In humans, removal of the amygdala has been associated with an impairment of memory for faces (4 ,138 ,240 ,257) and deficits in recognition of emotion in people's faces and interpretation of gaze angle (41 ,50 ,257). In a very rare case involving bilateral calcification confined to the amygdala (Urbach-Wiethe disease), patient SM046 could not identify the emotion of fear in pictures of human faces and could not draw a fearful face, even though other emotions such as happy, sad, angry, and disgusted were identified and drawn within the normal range. The deficit in recognizing facial expressions of fear

only seemed to occur after bilateral amygdala damage (3). This patient and two others also tended to view even the most threatening faces as trustworthy and approachable (2). A more detailed evaluation of patient SM046 showed that she correctly identified valence (e.g., pleasant versus unpleasant) in faces displaying happy, surprised, afraid, angry, disgusted, or sad emotion, but she was highly abnormal in rating the level of arousal to the afraid, angry, disgusted, and sad faces (1). Another patient (SP) with extensive bilateral amygdala damage also showed a major deficit in her ability to rate levels of fear in human faces, yet was perfectly normal in generating a fearful facial expression in comparison with neurologically normal subjects, based on the ratings of three judges (13).

Patients with unilateral (153) or bilateral (26) lesions of the amygdala also have been reported to have deficits in classic fear conditioning using the galvanic skin response as a measure of fear. In monkeys, removal of the amygdala decreases reactivity to sensory stimuli measured with the galvanic skin response (17 ,18).

Effects of Local Infusion of Drugs into the Amygdala on Measures of Fear and Anxiety

If the amygdala is critically involved in fear and anxiety, then drugs that reduce fear or anxiety clinically may well act within the amygdala. It is also probable that certain neurotransmitters within the amygdala may be involved in fear and anxiety. In fact, many studies indicate that local infusions of GABA or GABA agonists, benzodiazepines, CRH antagonists, opiate agonists, neuropeptide Y, dopamine antagonists, or glutamate antagonists decrease measures of fear and anxiety in several animal species. Table 64.3 gives selected examples of some of these studies, which have been extensively reviewed (65). Conversely, local infusions of GABA antagonists, CRH or CRH analogues, vasopressin, thyrotropin-releasing hormone, opiate antagonists, cholecystokinin (CCK) or CCK analogues tend to have anxiogenic effects. Table 64.4 shows selected examples of such studies that also have been reviewed (65).

Substance	Species	Site	Effect of Substance Infused	Reference
GABA or chlordiazepoxide	Rat	Ce	Decrease stress-induced gastric ulcers	232
GABA or benzodiazepines	Rat	Bla	Increase punished responding in operant conflict test (anticonflict effect)	105,126,189, 218,239
Benzodiazepines	Rat	Ce	Increase punished responding in operant conflict test (anticonflict effect)	225,234
Midazolam	Rat	Bla	More time on open arms in plus-maze, no effect on shock probe avoidance	188
Diazepam	Rat	Ce or Bla	Decrease freezing to footshock	120,258
Diazepam	Mice	AC	More time in light side in light-dark box test (anxiolytic effect)	60
Muscimol	Rat	Bla	Anxiolytic effect in the social interaction test; no effect in Ce	216
Muscimol	Rat	Bla	Increase punished responding in operant conflict test (anticonflict effect); no effect in Ce	218
a-CRH	Rat	Ce	Block noise-elicited increase in tryptophan hydroxylase in cortex	35
a-CRH	Rat	Ce	Anxiolytic effect (plus maze) in socially defeated rat	116
a-CRH	Rat	Ce	Anxiolytic effect in plus maze during ethanol withdrawal in ethanol-dependent rats; no effect in plus maze in nondependent rats	194
a-CRH	Rat	Ce	Decrease behavioral effects of opiate withdrawal	115
CRH receptor antisense	Rat	Ce	Anxiolytic effect in the plus maze in rats that previously experienced defeat stress	161
a-CRH	Rat	Ce	Decrease duration of freezing to an initial shock treatment or to re-exposure to shock box 24 h later	233
a-CRH	Rat	Ce	No effect on grooming and exploration activity under stress-free conditions	247
Enkephalin analogue	Rat	Ce	Decrease stress-induced gastric ulcers, prevented by 6-OHDA or clozapine	195,196,198
Opiate agonists	Rb	Ce	Block acquisition of conditioned bradycardia	89,90
Morphine	Rat	Ce	Anxiolytic effect in social interaction test	83
Neuropeptide Y	Rat	Bla, not Ce	Anxiolytic effect in social interaction test, blocked by Y-1 antagonist	213
Neuropeptide Y1 agonist	Rat	Ce	Anxiolytic effects in conflict test; NPY-Y2 agonist much less potent	114
Oxytocin	Rat	Ce	Decrease stress-induced bradycardia and immobility responses	209
SCH 23390	Rat	AC	Decrease expression of fear-potentiated startle	151
SCH 23390	Rat	AC	Decrease acquisition and expression of freezing to tone or context; not due to state-dependent learning	107
CNQX	Rat	Bla	Blocks expression of fear-potentiated startle (visual, auditory CS)	149
NBQX	Rat	Bla or Ce	Blocks expression of fear-potentiated startle (visual CS)	243
AP5	Rat	Bla	Block facilitation of eyeblink conditioning by prior stress when given prior to stressor session	227
AP5 or CNQX	Rat	Bla	Anxiolytic effect in social interaction test	212
CNQX	Rat	Ce	Decrease naloxone precipitated withdrawal signs in morphine-dependent rats	235

AC, amygdala complex; Bla, basolateral complex; Ce, central nucleus.

TABLE 64.3. EFFECTS OF NEUROTRANSMITTER AGONISTS INFUSED INTO THE AMYGDALA ON FEAR AND ANXIETY

Substance	Species	Site	Effect of Substance Infused	Reference
Bicuculline, picrotoxin	Rat	Bla	Anxiogenic effects in the social interaction test; repeated infusion led to sensitization	216
Bicuculline	Rat	Bla	Anxiogenic effects in social interaction, blocked by either NMDA or non-NMDA antagonists into the amygdala	211
Bicuculline (un)	Rat	Bla not Ce	Increases in blood pressure, heart rate, and locomotor activity; bigger effect with repeated infusions	215,216
Bicuculline (un)	Rat	Bla	Increases in blood pressure, heart rate; blocked by infusion of either NMDA or non-NMDA antagonists into the amygdala	211
Bicuculline NMDA, AMPA (un)	Rat	Bla	Increases in blood pressure, heart rate blocked by either NMDA or non-NMDA antagonists infused into Bla or the dorsomedial hypothalamus	229,230
CRH	Rat	Ce	Increase heart rate; effect blocked by a-CRH into Ce	248
CRH, TRH, or CGRP	Rat	Ce	Increase in blood pressure, heart rate, and plasma catecholamines	43
Urocortin or CRH	Rat	Bla	After repeated subthreshold doses get increase in blood pressure to systemic lactate	210
CRH	Rat	Ce, not Bla	Increased grooming and exploration in animals tested under stress-free conditions (i.e., in the home cage)	247,250
CRH	Rat	Ce	Increase defensive burying	249
CRH or Urocortin	Rat	Bla	Anxiogenic effect in plus maze, sensitization with repeated subthreshold doses; now get behavioral and cardiovascular effects to systemic lactate	210
Vasopressin	Rat	Ce	Increased stress-induced bradycardia and immobility responses in rats bred for low rates of avoidance behavior but not the more aggressive rats that show high avoidance rates	209
Vasopressin	Rat	Ce	Bradycardia (low doses) or tachycardia and release of corticosterone (high dose); tachycardia blocked by oxytocin antagonist	208
Vasopressin	Rat	Ce	Immobility, seizures second infusion	251
Vasopressin	Rat	Ce	Immobility in rats bred for low rates of avoidance but not bred for high avoidance rates	209
TRH	Rat	Ce	Increase stress-induced gastric ulcers	196,198
TRH or physostigmine	Rat	Ce	Increase stress-induced gastric ulcers, blocked by muscarinic or benzodiazepine agonists	197
TRH analogue	Rat	Ce	Increase gastric contractility, blocked by vagotomy	182
TRH	Rat	Ce	Produce gastric lesions and stimulated acid secretion	125
TRH analogue	Rat	AC	No effect on gastric secretion, whereas large effect after infusion into dorsal vagal complex or nucleus ambiguus	136
Naloxone	Rat	Ce	Increase stress-induced gastric ulcers	196,198
Naloxone	Rat	AC	Elicit certain signs of withdrawal (depending on site) in morphine-dependent rats (unilateral)	51
Methyl naloxonium	Rat	AC	Place aversion to context where injections given to morphine-dependent rats	231
Methyl naloxonium	Rat	AC	Weak withdrawal signs in morphine-dependent rats	163
Yohimbine	Rat	Ce	Facilitation of the startle reflex	82
CCK analogues	Rat	AC	Anxiogenic effect in plus maze but not clear because significant decrease in overall activity	27
Pentagastrin	Rat	AC	Increase acoustic startle, blocked by CCK B antagonist that also blocked effect of pentagastrin (ICV)	86

AC, amygdala complex; Bla, basolateral complex; Ce, central nucleus; un, unanesthetized.

TABLE 64.4. EFFECTS OF NEUROTRANSMITTER ANTAGONISTS INFUSED INTO THE AMYGDALA ON FEAR AND ANXIETY

In summary, connections between the Bla and the CeA or BNST are critically involved in various autonomic and motor responses seen during a state of fear or anxiety. However, it is also the case that connections between the basolateral nucleus and other target areas are involved in emotional behavior.

Basolateral Nucleus of the Amygdala to Dorsal Striatum Pathway as It Relates to Avoidance or Escape from Aversive Events

As emphasized by McGaugh, Packard, and others, the amygdala modulates memory in various tasks such as inhibitory avoidance and motor or spatial learning (49 ,170 ,171 ,185 ,186). For example, posttraining intracaudate injections of amphetamine enhanced memory in a visible platform water maze task but had no effect in the hidden platform, spatially guided task (185 ,186). Conversely, posttraining intrahippocampal infusion of amphetamine enhanced memory in the hidden platform water maze task but not in the visible platform task. However, posttraining intraamygdala injections of amphetamine enhanced memory in both water maze tasks (185 ,186).

Moreover, preretention intrahippocampal lidocaine injections blocked expression of the memory-enhancing effects of posttraining intrahippocampal amphetamine injections in the hidden platform task, and preretention intracaudate lidocaine injections blocked expression of the memory-enhancing effects of posttraining intracaudate amphetamine injections in the visible platform task. However, preretention intraamygdala lidocaine injections did not block the memory-enhancing effect of posttraining intraamygdala amphetamine injections on either task. Finally, in the hidden platform task, posttraining intrahippocampal, but not intracaudate, lidocaine injections blocked the memory-enhancing effects of posttraining intraamygdala the visible platform task, posttraining intracaudate, but not intrahippocampal, lidocaine injections blocked the memory-enhancing effects of posttraining intraamygdala amphetamine. The findings indicate a double dissociation between the roles of the hippocampus and caudate-putamen in memory and suggest that the amygdala exerts a modulatory influence on both the hippocampal and caudate-putamen memory systems.

Perhaps similarly, lesions of the CeA block freezing but not escape to a tone previously paired with shock, whereas lesions of the basal nucleus of the Bla have just the opposite effect (10). However, lesions of the lateral nucleus, which receive sensory information required by both measures, block both freezing and escape. Lesions of the Bla, but not the CeA, also block avoidance of a bar associated with shock (146). It is possible that basolateral outputs to the dorsal or the ventral striatum mediate the escape behavior, given the importance of the striatum in several measures of escape or avoidance learning. However, combined, unilateral lesions of each structure on opposite sides of the brain would be required to evaluate whether this results from serial transmission from the basolateral nucleus to the striatum.

Basolateral Nucleus of the Amygdala to Hippocampus Pathway as It Relates to Avoidance or Escape from Aversive Events

As mentioned earlier, posttraining intrahippocampal as well as intraamygdala injections of amphetamine selectively enhance memory in a hidden platform water maze task (185 ,186). Posttraining infusion of norepinephrine into the basolateral nucleus enhanced retention in the hidden platform water maze task, whereas posttraining infusion of propranolol had the opposite effect (113). These results suggest that

the amygdala exerts a modulatory influence on hippocampal-dependent memory systems, presumably by direct projections from the basolateral nucleus of the amygdala, perhaps by modulation of LTP in the hippocampus. Lesions (131), NMDA antagonists (132), or local anesthetics (134) infused into the Bla decrease LTP in the dentate gyrus of the hippocampus. Conversely, high-frequency stimulation of the amygdala facilitates induction of LTP in the dentate gyrus (130 ,133). However, combined, unilateral lesions of each structure on opposite sides of the brain would be required to evaluate whether this results from serial transmission from the basolateral nucleus to the hippocampus.

Basolateral Nucleus of the Amygdala to Frontal Cortex Pathway as It Relates to Emotion

Importance of the Bla in US Representation

After pavlovian conditioning, presentation of a conditioned stimulus (CS) elicits some neural representation of the unconditioned stimulus (US) with which it was paired. For example, the sound of a refrigerator door opening or an electric can opener may bring the family cat into the kitchen in expectation of dinner. Several studies suggest that the Bla, perhaps by connections with cortical areas such as the perirhinal cortex (93), is critical for these US representations based on studies using a procedure called *US devaluation*. In these experiments, a neutral stimulus (e.g., a light) is first paired with food so a conditioned response can be measured. Some animals then have the food paired with something that makes them sick (US devaluation). After such treatment, these animals show a reduction in the conditioned response to the light compared with animals that did not experience US devaluation. This result suggests that, after conditioning, animals have a representation of the value of a reinforcement that is elicited by the cue paired with that US. When that representation is changed, then the behavior elicited by the cue also is changed in the same direction. Lesions of the basolateral, but not the CeA, block US devaluation (112). In a related paradigm, rats are trained to be fearful of a weak shock in the presence of a tone. When this is followed by presentation of a stronger shock, without further tone-shock pairing, more freezing occurs to the tone. Temporary inactivation of the Bla during this *inflation* procedure blocks this effect when testing subsequently occurs with a normal, unlesioned, amygdala (5).

Second-order conditioning also depends on a US representation elicited by a CS. In this procedure, cue 1 is paired with a particular US (e.g., shock or food), and cue 2 is paired with cue 1. After such training, cue 2 elicits a similar behavior as that elicited by cue 1, depending on the US with which cue 1 was paired. Thus, it may elicit approach behavior if cue 1 was formerly paired with food and avoidance if cue 1 was paired with shock. This indicates that cue 1 elicits a representation of the US that then becomes associated with cue 2. Lesions of the Bla, but not the CeA, block second-order conditioning (72 ,73 ,112), as do local infusions of NMDA antagonists into the Bla (92).

Importance of the Bla Projection to the Frontal Cortex in Using US Representations to Guide Behavior

Converging evidence now suggests that the connection between the Bla and the prefrontal cortex is critically involved in the way in which a US representation (e.g., very good, pretty good, very bad, pretty bad) guides approach or avoidance behavior. Patients with late- or early-onset lesions of the orbital regions of the prefrontal cortex fail to use important information to guide their actions and decision making (14 ,25 ,63). For example, on a gambling task, they choose high, immediate reward associated with long-term loss rather than low, immediate reward associated with positive long-term gains. They also show severe deficits in social behavior and make poor life decisions.

Studies using single-unit recording techniques in rats indicate that cells in both the Bla and the orbitofrontal cortex fire differentially to an odor, depending on whether the odor predicts a positive (e.g., sucrose) or negative (e.g., quinine) US. These differential responses emerge before the development of consistent approach or avoidance behavior elicited by that odor (220). Many cells in the Bla reverse their firing pattern during reversal training (i.e., the cue that used to predict sucrose now predicts quinine and vice versa) (221), although this has not always been observed (217). In contrast, many fewer cells in the orbitofrontal cortex showed selectivity before the behavioral criterion was reached, and many fewer reversed their selectivity during reversal training (221). These investigators suggest that cells in the Bla encode the associative significance of cues, whereas cells in the orbitofrontal cortex are active when that information, relayed from the Bla, is required to guide choice behavior.

Taken together, these data suggest that the connection between the Bla and the frontal cortex may be involved in determining choice behavior based on how an expected US is represented in memory. The necessity for communication between the amygdala and the frontal cortex was shown in monkeys using a “disconnection approach” in which the amygdala on one side of the brain and the frontal cortex on the other side were lesioned together (22). Because the reciprocal connections between the two structures are ipsilateral, this procedure completely eliminated activity of the network connections while preserving partial function of each structure. Using this approach in rhesus monkeys, Baxter et al. found a decrease in US devaluation after unilateral neurotoxic lesions of the basolateral nucleus in combination with unilateral aspiration of orbital prefrontal cortex (22). These monkeys continued to approach a food on which they had recently been satiated, whereas control monkeys consistently switched to the other food.

Neuroimaging Studies of the Amygdala in Humans

As reviewed by Whalen (244), neuroimaging studies in normal human subjects have shown activation of the amygdala by presentation of biologically relevant sensory stimuli that probably induce strong negative emotional states. For example, the functional magnetic resonance imaging (fMRI) signal intensity within the amygdala is greater when subjects view graphic photographs of negative material (e.g., mutilated human bodies) compared with when they view neutral pictures (135). Positron emission tomography metabolic activity within the amygdala increased to negative material presented by film clips (199), and the amount of amygdala activity during film clips predicted later recall (47). In addition, fMRI signal intensities in humans during classic fear conditioning increased in response to stimuli that predicted an aversive event (45 ,150 ,179).

Amygdala activation also seems to be greater during presentations of fearful faces compared with neutral facial expressions (40 ,180), happy facial expressions (180 ,246), or when subjects looked at a fixation point on an otherwise blank screen (246). Whalen et al. used a backward masking technique in which very brief presentations of fearful and happy facial expressions (33 milliseconds) were followed immediately by presentations (167 milliseconds) of neutral faces (245). Most study subjects reported seeing neutral “expressionless” faces, but not any afraid or smiling faces. Nonetheless, the amygdala demonstrated greater fMRI signal intensity to masked fearful faces compared with masked happy faces. In addition, subjects reported that these masked stimuli did not induce any noticeable changes in their state of emotional arousal. As suggested by Whalen (244), “this study offers preliminary support for the notion that the amygdala constantly monitors the environment for such signals. More than functioning primarily for the production of strong emotional states, the amygdala would be poised to modulate the moment-to-moment vigilance level of an organism.”

Role of the Periaqueductal (Central) Gray

Outputs from the CeA to the ventral central gray appear to mediate several components of the fear response including freezing, conditioned analgesia, and fear-related vocalizations, but, surprisingly, maybe not cessation of operant behavior (11). More dorsal regions of the PAG play a role in active defensive responses (33), depending on whether the threat is distal or proximal (31 ,71). Fanselow (79), for example, showed that dorsal, but not ventral, PAG lesions eliminate activity bursts elicited by foot shock, whereas ventral, but not dorsal, PAG lesions diminish freezing responses elicited by cues previously paired with foot shock. Fanselow suggested that these stimuli (i.e., foot shock versus stimuli predicting foot shock) access different points on a “predatory imminence” continuum in which proximal threats activate the dorsal PAG to generate active defensive behaviors. More distal threats activate the ventral PAG and generate passive or preparatory defensive behaviors such as freezing and analgesia. From a similar perspective, Deakin and Graeff et al. proposed that moderately threatening stimuli inhibit the dorsal PAG (66 ,104), but this inhibition is overcome with more extreme danger, thus allowing active defense or panic behaviors to emerge.

Results from stimulation studies have suggested an anatomic division of function within PAG. In particular, Depaulis and colleagues showed that chemical or electrical stimulation of PAG regions lateral to the aqueduct produces active behaviors such as forward avoidance, defensive aggression, and cardiovascular activation (67 ,68), whereas stimulation of more ventral regions of the PAG elicits passive responses such as behavioral arrest and decreased cardiovascular output (21 ,69). Electrical stimulation of the dorsal PAG in humans produces a pattern of cardiovascular effects that resemble those seen during a natural panic attack, and patients often experience fear, anxiety, and the desire to terminate stimulation (162). Exposure of rats to a cat or high-frequency vocalizations of conspecifics that often signal a predator in the environment increases neuronal firing in the dorsal PAG inferred from an increase in the immediate early gene c-*fos* (162).

Based on these and other data, several investigators have suggested that the dorsal PAG may be involved in panic attacks in humans, perhaps resulting from a dysregulation of various transmitters systems within this structure (162). The dorsal PAG has heavy innervation of the panicogenic peptide CCK, which has been shown to excite the majority of cells in this region. CCK antagonists functionally decrease the effects of electrical stimulation of the dorsal PAG, as does elevating serotonin, perhaps relevant to the use of serotonin reuptake inhibitors in the treatment of panic disorder. Whether these effects depend on connections between the amygdala and the PAG or whether they represent examples where the PAG can function autonomously remains to be determined.

Role of the Hippocampus in Contextual Fear Conditioning

Rats given cue-shock pairings learn to be afraid of the cue as well as the place where cue-shock pairings occurred *(context conditioning)*. In 1992, two seminal articles reported that the hippocampus was necessary for context but not explicit cue conditioning (148 ,190). Both studies found that electrolytic lesions of the dorsal hippocampus blocked freezing in the presence of a fearful context but not in the presence of a cue paired with shock in that context. Kim and Fanselow found such effects when lesions were made shortly after training (1 or 7 days) but not 28 days later (148), whereas Phillips and LeDoux used pretraining lesions (190).

Although the role of the hippocampus in contextual fear conditioning had been discovered earlier using a place aversion measure (223), these articles were more influential because they integrated the well-known role of the hippocampus in spatial learning with a simple, yet powerful measure of classic fear conditioning. Contextual freezing was quickly adopted by investigators interested in the role of hippocampal LTP in learning because contextual fear conditioning was rapid and long lasting, like LTP, and it was easy to measure without complex or expensive equipment. The idea was that the hippocampus was required to form a representation of the context and that this representation was then associated with shock, perhaps in the amygdala. The hippocampus was not needed when an explicit cue, such as a tone, was used because this could be relayed directly to the amygdala without having to be processed by the hippocampus.

As attractive as this hypothesis is, there are problems with concluding that the hippocampus is involved in all forms of contextual conditioning (96 ,97 ,202). Hippocampal lesions often produce substantial behavioral activation, which may interact with the expression of freezing and lead to a disruption of the freezing response itself, rather than of contextual fear. In fact, hippocampal lesions disrupt not only conditioned freezing responses, but also *unconditioned* freezing responses, such as the response elicited by a rat when confronted by a cat (32 ,34 ,147). The finding that hippocampus lesions did not block freezing to an explicit cue makes this competing response interpretation more difficult to accept, but some studies have found that hippocampal lesions disrupt freezing to an explicit cue (167). However, increases in activity cannot account for disruption of contextual freezing by hippocampal lesions in all instances. In an elegantly designed study, Anagnostaras et al. showed that hippocampal lesions disrupted freezing to a context that had been paired with shock shortly before surgery (12). In the same subjects, however, freezing to a second context, that had been paired with shock 28 days preoperatively, was not impaired. Thus, the freezing deficit to the recently conditioned context could not have resulted from an inability to freeze.

Although pretraining electrolytic lesions of the dorsal hippocampus (167) block contextual fear conditioning, neurotoxic lesions fail to do so (97 ,167 ,202), as does local infusion of muscimol (128). To explain this difference, Maren et al. suggested that rats with damage to cells in the hippocampus pick out salient explicit cues in the context and use these as elemental cues for fear conditioning (167). However, these investigators suggested that rats with electrolytic lesions do not do this because the lesion disrupts fibers that connect the ventral subiculum to the nucleus accumbens, which decreases exploration and thus sampling of the context to pick out salient explicit cues to associate with shock. In fact, experiments found a blockade of the acquisition but not the expression of contextual fear conditioning measured by freezing using infusion into the nucleus accumbens of a local anesthetic (108). This effect did not occur using tone-shock pairings, even using a weaker trace conditioning procedure that produced relatively low levels of freezing to the tone.

Another possibility is that fibers from the dorsal to the ventral hippocampus are important in these anterograde amnestic effects of electrolytic lesions of the dorsal hippocampus because neurotoxic lesions of either the entire hippocampus (102 ,202) or just the ventral hippocampus blocked contextual freezing, whereas neurotoxic lesions of the dorsal hippocampus again failed to block contextual conditioning (202). However, in contrast to the hypothesis that contextual fear conditioning involves processes similar to spatial learning, lesions of the ventral hippocampus did not block but instead actually facilitated spatial learning in a water maze task (202). As these investigators concluded, these data directly contradict the “widely held notion that spatial and contextual forms of learning are essentially different manifestations of the same basic underlying process” (202). Because these lesions also impaired freezing to a tone, these authors suggested that the ventral lesions disrupted freezing by increasing activity.

Because all these studies have relied on freezing as the measure of conditioned fear, it is important to assess the effects of hippocampal lesions on other behavioral or autonomic responses associated with fear. If hippocampal lesions disrupted multiple measures of contextual fear, it would provide further support for the hippocampal theory of context conditioning. However, posttraining hippocampal lesions were found not to disrupt context-specific potentiated startle, even though context-elicited freezing was disrupted in the same animals (174). This could not be explained by an excitatory effect of hippocampal lesions on startle amplitude itself (96). In contrast, lesions of the CeA completely blocked both freezing and startle.

In another experimental design (95), lesions of the dorsal hippocampus failed to block a phenomenon called *contextual blocking*, whereby prior contextual fear conditioning retards subsequent cue conditioning. However, as in other studies, freezing to the fearful context was blocked by hippocampal lesions. These data, along with several other reports in the literature (96 ,97 ,202), severely limit the general impression that the hippocampus is required for contextual fear conditioning. However, it does seem to be involved in certain situations, so further work is needed to predict those occasions in which it is and is not involved.

BRAIN SYSTEMS IN THE INHIBITION OR SUPPRESSION OF FEAR AND ANXIETY

Part of "64 - Neural Circuitry of Anxiety and Stress Disorders "

Extinction

The inability to suppress unwanted fear memories or irrational worry is a major problem in many psychiatric disorders, yet very little is known about brain systems involved

in the inhibition of fear. One way to study this important problem is to analyze brain systems involved in *extinction*, defined as a reduction in conditioned fear when the CS is presented many times in the absence of the US. Although such a procedure can decrease the conditioned response, this does not result from an erasure of the original fear memory. Instead, something new is learned that overcomes or competes with the original fear memory. For example, an extinguished conditioned response can return with the passage of time (spontaneous recovery, 187), after a subsequent stressor (reinstatement, 201), or when testing occurs in a different context (renewal, 36). Such results indicate that extinction (but see discussion in ref. 74) may involve a form of active inhibition that is fragile compared with conditioned fear itself.

Conditioned Inhibition

In a conditioned inhibition procedure, cue 1 predicts food or shock, and a compound stimulus (cue 1 plus cue 2) predicts the absence of these USs. There is general agreement that conditioned inhibition, closely related to extinction, does involve active inhibition. In fact, it has been argued that extinction is a special case of conditioned inhibition (38). The *summation test* is the basic method for observing conditioned inhibition (200). In this procedure, the putative conditioned inhibitor (e.g., a light) is presented in compound with an excitatory CS (e.g., a tone). If the combination produces a decrease in the conditioned response below the level observed when the CS is presented alone, then that stimulus is said to act as a conditioned inhibitor. When the conditioned inhibitor is removed, excitation returns to its original level. Various control procedures indicate that a stimulus trained in this way is in fact acting by inhibition.

Because psychotherapy often involves procedures to rid patients of unwanted fear memories, a behavioral analysis of extinction or conditioned inhibition has certain clinical implications, as suggested by Bouton and Swartzentruber (39). As they pointed out, “performance after extinction is inherently unstable” (39). Phenomena such as spontaneous recovery and reinstatement may explain why conditioned fears and phobias in humans sometimes seem to return spontaneously without any obvious cause. The renewal effect may explain why fears reduced successfully in the therapist's office reappear when the patient returns home or to work. If a drug is used as an adjunct to therapy, renewal of fear could occur when the fearful stimulus is encountered in the absence of the drug. In fact, animal experiments show that when benzodiazepines are given during extinction, fear of the CS returns when testing occurs in the absence of the drug (37).

Brain Areas in Extinction or Conditioned Inhibition

Sensory Cortex

Assuming that extinction results from active inhibition (see earlier), one could expect that lesions of various brain areas would disrupt either the development or expression of extinction. LeDoux, Romanski, and Xagoraris reported that rats given ablations of visual cortex before light–foot shock pairings failed to show extinction of lick suppression relative to sham controls over days (156). In a similar study employing heart rate conditioning in the rabbit, Teich et al. showed that although bilateral lesions of either auditory or visual cortex did not disrupt acquisition of fear conditioning to a tone CS, auditory cortex lesions, but not visual cortex lesions, blocked extinction of conditioned heart rate responses to the tone (237). Based on known anatomic connections between sensory cortex and thalamic structures, the authors of both experiments concluded that, during extinction, sensory cortices exert a modality specific inhibition of the thalamic structures important for the performance of conditioned responses.

However, my colleague and I found no effect of complete visual cortex lesions on extinction of fear-potentiated startle using a visual CS when the lesions were made either before light-shock pairings or after light-shock pairings and extinction (77). Although there were procedural differences between these reports, the conclusion that sensory cortex is universally involved in extinction of conditioned fear is not supported.

Frontal Cortex

Rats with lesions of the ventral medial prefrontal cortex made before fear conditioning required more days to reach an extinction criterion using an auditory CS and freezing as the measure of fear (178). However, in these same animals, extinction of conditioned fear to contextual cues was not impaired. In an extensive series of experiments, my colleagues and I found normal rates of extinction to both explicit and contextual cues after total removal of the ventral medial prefrontal cortex using both freezing and fear-potentiated startle as measures of conditioned fear (94). Because the lesions in the study by Morgan et al. were performed before fear conditioning (178), the apparent blockade of extinction after ventral medial prefrontal cortex lesions may have resulted from an increase in the strength of original fear conditioning, rather than from interfering with the process of extinction. Although the lesions and shams groups did not differ significantly in their level of freezing before the extinction sessions, freezing to explicit cues often becomes maximal after a very few training trials, so “ceiling effects” may well have been operating. Because extinction rate can be a more sensitive index of the strength of original

conditioning than the terminal level of performance before the initiation of extinction (15), the slower rate of extinction in the lesioned animals may have reflected a stronger degree of original learning. Although these authors do not believe their effects can be explained in this way (177), the finding that the lesions had no effect on the rate of extinction of context conditioning, which clearly was not at the ceiling of the freezing scale, is consistent with this interpretation. Similarly, we did not find any effect of pretraining ventral prefrontal cortex lesions on extinction of contextual fear-potentiated startle or freezing (94). In addition, we did not find any effect of ventral medial prefrontal cortex lesions on extinction when lesions were made after fear conditioning but before extinction (94). Morgan and LeDoux also found no effect on the rate of extinction when ventral prefrontal cortex lesions were made after fear conditioning, but before extinction (176). If the frontal cortex is required for the development of extinction or for the inhibition of fear after extinction, one would expect lesions to block the development of extinction, irrespective of whether the lesions were made before or after the initial phase of fear conditioning.

Similarly complex effects on extinction have been reported regarding depletion of dopamine in the prefrontal cortex (181). Preconditioning lesions of dopamine terminals in the medial prefrontal cortex retarded the rate of extinction when a 0.8-mA shock was used but not when a 0.4-mA shock was used. Inspection of the results strongly suggests that the 0.8-mA group was at the ceiling of the measurement scale at the beginning of the extinction session, whereas the 0.4-mA group was not. Conversely, 6-hydroxydopamine lesions of the frontal cortex substantially retarded extinction after 0.8-mA tone-shock pairings, even when the lesions were made after training (181). Thus, it is possible that dopamine levels in the prefrontal cortex are important for extinction when conditioning has produced high, but not more moderate, levels of fear, although further studies using posttraining lesions are required to verify this.

Quirk et al. found that pretraining lesions of the ventral medial prefrontal cortex did not block the development of conditioned freezing or the rate of within session extinction (191). However, the lesioned rats showed much more spontaneous recovery measured 24 hours later. Similar results were found in rats given systemic administration of an NMDA antagonist (193). In contrast, we found no change in the rate or final level of extinction, measured with fear-potentiated startle and freezing, when extinction was assessed over 18 daily sessions using a small number of CS presentations each day (94). There also were no differences in the degree of spontaneous recovery measured 5 days later or in shock-induced reinstatement measured 24 hours after a single foot shock. Hence, the findings of Quirk et al. may depend critically on the use of a relatively small amount extinction training (191 ,193). Moreover, their lesions were generally more ventral than ours, and this may have contributed to the differences. Clearly, more work needs to be done to examine the limits of the role of the prefrontal cortex in extinction of conditioned fear, given the clinical importance of these data.

Hippocampus

Although a complete review of the hippocampal literature on extinction is beyond the scope of this chapter, this brain area has received a great deal of experimental attention and was once widely believed to be involved in extinction. Theories of extinction confront the problem of designing a mechanism capable of discriminating occasions of reinforcement from nonreinforcement. Douglas suggested that the hippocampus is a nonreinforcement detector providing the organism with the means to “tune out” information that is of no motivational consequence (70). It is possible that the hippocampus recognizes that the CS is no longer followed by the US and inhibits relevant sensory or conditioned response production centers.

Various conditioning paradigms have been used to assess the role of the hippocampus in extinction, including the rabbit nictitating membrane response (29 ,219 ,228), conditioned heart rate (44), and conditioned suppression (152). Although some of these experiments have found that hippocampal lesions attenuate extinction (219), others have found no effect (228), and still another has shown facilitated extinction (152).

Because extinction is context specific (see earlier), one could expect that lesions of the hippocampus would disrupt this contextual control of extinction. However, direct tests of this hypothesis have not found a disruption of context specific extinction using pretraining lesions. Hence, neither fimbria-fornix lesions (252) nor excitotoxic lesions of the entire hippocampus (87) had any effect on the rate of extinction or on renewal of conditioned fear, although both types of lesions disrupted reinstatement. In contrast, large hippocampal lesions were not found to disrupt reinstatement of appetitively conditioned behavior (84). Overall, therefore, the role of the hippocampus in extinction remains uncertain.

Neurotransmitters in Extinction

Role of NMDA Receptors in Extinction

Local infusion of NMDA antagonists into the amygdala blocked the development of extinction measured with fear-potentiated startle (76). Intraamygdala infusion of AP5 also blocked extinction using an auditory CS and freezing as a measure of conditioned fear (158). Perhaps similarly, systemic administration of the NMDA antagonist MK-801 fully blocked extinction of conditioned analgesia, a reliable

measure of conditioned fear (62), and this effect could not be explained by state-dependent context extinction. A similar blockade of extinction was reported using a lick-suppression paradigm (19), as well as extinction of the rabbit nictitating membrane preparation (143). Taken together, these data indicate that NMDA antagonists can block the development of extinction measured on subsequent test sessions. This may even occur under conditions in which the antagonist does not block the development of short-term extinction. Thus, systemic injection of the NMDA antagonist CPP before extinction blocked the expression of conditioned freezing by about 40% but did not block the development of extinction. However, the CPP group showed substantial recovery of conditioned freezing measured 24 hours later, a finding suggesting that CPP blocked the long-term development of extinction. (193). Interestingly, these investigators found a similar effect with preconditioning lesions of the ventral prefrontal cortex (191), although the connection between these two sets of data remains to be made.

Role of GABA in Extinction

Several studies have suggested that GABA agonists given before nonreinforced CS presentations interfere with the development of extinction (37 ,74). However, many of these effects may be attributable to state-dependent learning rather than to a blockade of learning during nonreinforced CS exposure. For example, Bouton, using lick suppression as a measure of fear, showed a blockade of extinction when rats were given chordiazepoxide during nonreinforced CS presentations and were then tested in the absence of the drug (37). However, when chordiazepoxide also was given before testing, extinction was still evident. This finding suggests that the benzodiazepine did not actually block the learning that was occurring during extinction, but, instead, the change in drug state between extinction and testing was the factor that produced renewal (36).

Interestingly, a series of experiments by Harris and Westbrook found similar effects on excitatory conditioning. For example, rats given fear conditioning after injection with benzodiazepines showed an impairment in conditioned freezing measured 24 hours later in the same context compared with rats trained under the drug but tested in a different context (111) or rats given a stressor before testing (109). Thus, the benzodiazepines did not actually prevent original learning, but instead produced a state during conditioning that interfered with retrieval during testing.

Hence, it would seem that GABA agonists do not directly interfere with either excitatory or inhibitory learning, but, instead, act on processes that are important for retrieval of prior learning. However, if extinction is a form of active inhibition, it is possible that GABA may be one of the neurotransmitters necessary for the expression of extinction. In fact, in an elegant set of experiments, Harris and Westbrook provided evidence that extinction is mediated by GABA release (110). Pretraining or pretesting administration of the inverse agonist FG 7142, which decreases GABA transmission, blocked both development and expression of extinction to an auditory CS paired with foot shock, using freezing as a measure. This effect could not be ascribed to state dependency or to a ceiling effect. Pretest administration of FG 7142 reinstated freezing when assessed in the context where extinction took place, but not in a novel context, which itself reinstated freezing, and the two effects were not additive statistically. However, the disruption of extinction by FG 7142 was not complete, a finding leaving open the possibility that other mechanisms and neurotransmitters also may be involved.

Role of Adrenocorticotropic Hormone and Vasopressin in Extinction

Work by DeWied, Van Wiersima, Izquierdo, and Richardson and their co-workers indicated that administration of various peptides such as adrenocorticotropic hormone or vasopressin either before or after extinction training attenuates subsequent extinction performance (for review see ref. 74).

Neural Systems in Conditioned Inhibition

Using fluorodeoxyglucose autoradiography to measure neural activity, Mcintosh and Gonzalez-Lima compared region-specific activity in parallel auditory pathways in two groups presented with a tone-light compound (172). In both groups, the tone was a fear-eliciting CS. The groups differed with respect to the significance of the light, which had been trained as a conditioned inhibitor in one group and as a neutral stimulus in the other. Thus, the experiment allowed for an analysis of whether a conditioned inhibitor modulates activity in sensory areas normally activated by an auditory fear-eliciting CS. Interestingly, in only one area, the ventral medial geniculate nucleus, was there a significant difference in activation between the two groups. This structure showed less activation in the conditioned inhibition group, a finding suggesting that a conditioned inhibitor may act at this locus in the auditory pathway to inhibit conditioned fear normally produced by an auditory CS.

We found normal conditioned inhibition of fear-potentiated startle, using a visual excitatory stimulus and an auditory conditioned inhibitor after lesions of either the medial prefrontal cortex (94) or the nucleus accumbens (75). In addition, local infusion into the nucleus accumbens of either amphetamine or glutamate antagonists did not alter the magnitude of conditioned inhibition, as they alter responding to conditioned reinforcers trained in an operant situation (46 ,236).

In an appetitive learning situation, Holland et al. reported that lesions of the hippocampus appeared to block

feature negative conditional discrimination (127), a phenomenon closely related to conditioned inhibition.

Several studies suggested that the lateral septum may play an important role in conditioned inhibition. Using pavlovian discriminative fear conditioning, single-unit firing rates in the dorsal lateral septal nucleus increased in the presence of a conditioned inhibitor and decreased in the presence of a conditioned excitor (238 ,254). This finding was not seen when recordings were made in the medial septal nucleus (253). More recently, Yadin and Thomas reported that stimulation of the same area of dorsolateral septal nucleus inhibited restraint stress-induced ulcers (255). Using c-*fos* mRNA as a measured of neuronal activation, we found a unique increase in c-*fos* in a ventral part of the lateral septum, the so-called septohypothalamic nucleus, when a conditioned inhibitor of fear was presented (53). Curiously, however, lesions of the lateral septal nucleus did not block the expression of conditioned inhibition in preliminary pilot studies, although further work certainly is required to evaluate the role of the lateral septum, perhaps using acute inactivation techniques rather than lesions.

One study suggests that the dorsal central gray may play an important role in conditioned inhibition of fear. Fendt reported that posttest infusions of 5 ng of picrotoxin (a GABA chloride channel blocker) into the dorsal central gray, but not the lateral or ventrolateral central gray, reduced the expression of conditioned inhibition without affecting the expression of conditioned fear (81). Although this result is complicated by the finding that neither 2.5-ng doses nor 10-ng doses affected conditioned inhibition, it raises the intriguing possibility that a conditioned inhibitor of fear releases GABA into the dorsal central gray. Alternatively, because low doses of picrotoxin would be expected to activate the dorsal central gray by removing tonic inhibition, these results could be interpreted as indicating that the dorsal central gray is involved in inhibiting an unknown brain structure mediating conditioned inhibition (81). Given the prominent role of the central gray in the expression of fear (162), more work is needed to investigate the role of the dorsal central gray in conditioned inhibition of fear.

GENERAL PRINCIPLES

Part of "65 - Structural and Functional Imaging of Anxiety and Stress Disorders "

Neuroimaging research has emerged as a powerful force in shaping neurobiological models of psychiatric disorders. In this chapter, neuroimaging findings pertaining to anxiety and stress disorders are reviewed. This review necessarily extends previous ones that we have written, together with our colleagues, on this same and related topics (97 ,98 ,103).

Anxiety and Stress Disorders

Whereas anxiety disorders comprise a discrete category within the current version of the *Diagnostic and Statistical Manual* (2), the concept of stress disorders is less well defined. Although growing evidence suggests that stress may play a role across a variety of psychiatric disorders (such as major depression), posttraumatic stress disorder (PTSD) and acute stress disorder remain the only conditions for which exposure to traumatic stress is explicitly acknowledged as an etiologic factor and a criterion for diagnosis. In this chapter, we survey the imaging data pertinent to models of PTSD and other anxiety disorders, including obsessive-compulsive disorder (OCD), specific phobias (SpP), social phobia (SoP; also called social anxiety disorder) and panic disorder (PD).

In general, patients with anxiety disorders suffer either exaggerated fear responses to relatively innocuous stimuli (e.g., phobias) or spontaneous fear responses in the absence of true threat (e.g., PD). Thus, it is important to consider the mediating neuroanatomy of normal threat assessment and the fear response. In fact, contemporary models focus on these systems as candidate neural substrates for the anxiety disorders.

Relevant Neuroanatomy

The limbic system plays an important role in mediating human emotional states, including anxiety. Anterior paralimbic cortex (i.e., posterior medial orbitofrontal, anterior temporal, anterior cingulate, and insular cortex) links cortical regions subserving higher level cognition and sensory processing with deep limbic structures, such as the amygdala and the hippocampus (81).

Modern models of threat assessment and the normal fear response have focused on the role of the amygdala (1 ,75). The amygdala is positioned to receive input regarding the environment both directly and, thus, rapidly from the thalamus as well as from sensory cortex. The amygdala appears to serve several related functions, including preliminary threat assessment; facilitation of fight-or-flight responses; facilitation of additional information acquisition; and enhancement of arousal and plasticity, so the organism can learn from the current experience to guide responses optimally in future similar situations.

Conversely, several brain areas provide important feedback to the amygdala (1 ,75): medial frontal cortex (e.g., anterior cingulate and orbitofrontal cortex) may provide critical “top-down” governance over the amygdala, thus enabling attenuation of the fear response once danger has passed or when the meaning of a potentially threatening stimulus has changed; the hippocampus provides information about the context of a situation (based on information retrieved from explicit memory stores); and corticostriatothalamic circuits mediate “gating” at the level of the thalamus and thereby regulate the flow of incoming information that reaches the amygdala.

Finally, neuromodulators influence the activity within each of these various brain areas, as well as the interactions

among the nodes of the entire system outlined earlier. Ascending projections from the raphe nuclei (serotonin) and the locus ceruleus (norepinephrine), as well as widespread local γ-aminobutyric acid–ergic (GABAergic) neurons, are perhaps most relevant to the physiology of anxiety (30 ,65 ,114). These transmitter systems likely serve as the principal substrates for contemporary anxiolytic medications, including serotonergic reuptake inhibitors, monoamine oxidase inhibitors, other antidepressant medications, and benzodiazepines.

Neuroimaging Methods

Morphometric magnetic resonance imaging (mMRI) methods can be used to test hypotheses regarding abnormalities in the size or shape of particular brain structures. Functional imaging methods include positron emission tomography (PET) with tracers that measure blood flow (e.g., oxygen-15–labeled carbon dioxide) or glucose metabolism (i.e., fluorine-18–labeled fluorodeoxyglucose [FDG]), single photon emission tomography (SPECT) with tracers that measure correlates of blood flow (e.g., technetium-99– labeled hexamethylpropylene amine oxime [TcHMPAO]), and functional MRI (fMRI) to measure blood oxygenation level–dependent (BOLD) signal changes. Each of these techniques yields maps that reflect regional brain activity.

Functional imaging methods can be applied in the context of various experimental paradigms. In *neutral state paradigms*, subjects are studied during a nominal “resting” state or while they perform a nonspecific continuous task. Thus, between-group comparisons are made to test hypotheses regarding group differences in regional brain activity, without particular attention to state variables. In *treatment paradigms*, subjects are scanned in the context of a treatment protocol. In pre/posttreatment studies, subjects are scanned both before and after a trial. Then, within-group comparisons are made to test hypotheses regarding changes in brain activity profiles associated with symptomatic improvement. Alternatively, correlational analyses can be performed to identify pretreatment brain activity characteristics that predict good or poor treatment response. In *symptom provocation paradigms*, subjects are scanned during a symptomatic state (after having their symptoms intentionally induced) as well as during control conditions. Within-group comparisons can be made to test hypotheses regarding the mediating anatomy of the symptomatic state; group-by-condition interactions can be sought to distinguish responses in patient versus control groups. Behavioral and pharmacologic challenges can be used to induce symptoms. In some cases, when symptomatic states occur spontaneously, experiments are designed to capture these events without the need for provocation or induction *per se*. In *cognitive activation paradigms*, subjects are studied while they perform specially designed cognitive-behavioral tasks. This approach is intended to increase sensitivity by employing tasks that specifically activate brain systems of interest. Again, group-by-condition interactions are sought to test the functional responsivity or integrity of specific brain systems in patients versus control subjects.

Imaging studies of neurochemistry have employed PET and SPECT methods in conjunction with radiolabeled high-affinity ligands. In this way, regional receptor number and or affinity can be characterized *in vivo* (i.e., receptor-characterization studies). Other approaches include the use of magnetic resonance spectroscopy (MRS) to measure the regional relative concentration of select “MRS-visible” compounds. For instance, MRS can be used to measure the compound *N*-acetylaspartate (NAA), which is a purported marker of healthy neuronal density.

These various neuroimaging techniques should be viewed as complementary. Convergent findings across paradigms and laboratories yield the most cohesive and compelling models of pathophysiology.

RELEVANT NEUROIMAGING FINDINGS IN HEALTHY SUBJECTS

Part of "65 - Structural and Functional Imaging of Anxiety and Stress Disorders "

Anxiety and Other Negative Emotional States

Behaviorally Induced Fear and Anxiety

Fischer and colleagues used PET to study regional cerebral blood flow (rCBF) in bank officials while they viewed security camera videotape of a robbery that they had experienced previously (46). Watching the robbery video was associated with rCBF increases in orbitofrontal cortex, visual cortex, and posterior cingulate gyrus; rCBF decreases occurred in Broca's area, left angular gyrus, operculum, and secondary somatosensory cortex. Paradiso et al. studied rCBF in healthy elderly subjects who viewed emotionally evocative film clips; a fear/disgust versus neutral comparison revealed activation in orbitofrontal cortex, among other areas (93). Similarly, Kimbrell et al. studied induced emotional states in healthy adults (67); relative to a neutral condition, an anxiety condition was associated with rCBF increases in left anterior cingulate and left temporal pole, whereas rCBF decreases were found in nonparalimbic frontal cortical regions. Liotti et al. used PET and autobiographic memory scripts to examine the neural correlates of anxiety and sadness in healthy women (77); relative to a neutral condition, an anxiety condition was associated with rCBF increases in insular, orbitofrontal, and anterior temporal cortex and rCBF decreases in parahippocampal gyri.

Pharmacologically Induced Fear and Anxiety

Benkelfat et al. examined rCBF changes associated with the administration of cholecystokinin tetrapeptide versus saline in healthy persons (10). Administration of cholecystokinin

tetrapeptide was accompanied by increased heart rate and panic symptoms and rCBF increases in right cerebellar vermis, left anterior cingulate gyrus, bilateral claustrum-insula-amygdala, and bilateral temporal poles. However, further analyses suggested that the apparent temporal pole activations were attributable to extracranial artifacts of jaw muscle contraction. Ketter et al. used PET to study rCBF changes during procaine versus saline administration in healthy persons (66). In the procaine versus saline contrast, rCBF increases occurred in amygdala and anterior paralimbic structures, including anterior cingulate gyrus, insular cortex, and orbitofrontal cortex. Blood flow in left amygdala was positively correlated with fear intensity and was negatively correlated with euphoria intensity. Similar results were reported by Servan-Schreiber et al. (126).

Other Negative Emotions

Several studies examining rCBF associated with behaviorally induced sadness in healthy subjects have implicated both anterior paralimbic and nonparalimbic frontal cortical areas (4 ,54 ,55 ,77 ,94). Some studies of behaviorally induced sadness have also found rCBF changes within the amygdala (71 ,120 ,121). Of note, studies of other behaviorally induced negative emotions, including anger (39 ,67) and guilt (127), have likewise found activation of anterior paralimbic cortical territories.

Processing Unpleasant, Arousing, or Threat-Related Stimuli

In functional imaging studies of responses to unpleasant pictures (73), several studies have found amygdala activation when contrasted with a neutral (63 ,72) or pleasant picture (92) comparison condition. In a separate study, Lane et al. reported that anterior paralimbic regions were activated when study subjects attended to the emotions evoked by the pictures rather than when subjects attended to physical attributes of the depicted scenes (70). Functional imaging studies have also demonstrated a correlation between amygdala activity during encoding of emotionally arousing pictures or film clips and subjects' subsequent memory of them (29 ,59).

Several functional imaging studies have shown greater amygdala responses to overtly presented fearful human facial expressions in comparison with neutral or happy faces (14 ,86). Whalen et al. used fMRI and a technique called “backward masking” to study amygdala responses to emotional faces in the absence of explicit knowledge (142). Although subjects were unaware of seeing the “masked” emotional faces, a comparison of the masked fear and masked happy conditions yielded activation in the amygdala bilaterally.

Habituation

The term *habituation* refers to a decrement in responses over repeated presentations of a stimulus. Measures of habituation can be obtained peripherally (e.g., skin conductance) or more centrally (e.g., rCBF or fMRI BOLD signal). For example, declining fMRI BOLD signal within the amygdala has been observed in response to repeated presentations of fearful faces, regardless of whether subjects are aware the stimuli are present (14 ,142).

A few studies have directly examined the neural correlates of habituation. Fischer et al. used PET to study rCBF changes over repeated presentation of videotaped scenes in healthy women (45). In separate scanning conditions, subjects watched two repeated videotaped presentations of neutral park scenes and snakes. From the first to the second presentation of the videotapes, rCBF decreased in bilateral secondary visual cortex and right medial temporal cortex, including amygdala and hippocampus. In an fMRI study, Fischer et al. also found response decrements over repeated presentations of human face stimuli in amygdala and hippocampus, as well as thalamus, and prefrontal, inferior temporal, and posterior cingulate cortex (47). Similar results have also been reported by Wright et al. (146).

Conditioning and Extinction

Fear conditioning involves the presentation of a neutral stimulus (i.e., a conditioned stimulus [CS]), such as a tone, that is temporally paired with an aversive stimulus (i.e., the unconditioned stimulus [US]), such as a shock. After repeated presentations of the CS and US, the CS alone begins to elicit fear-related autonomic changes, such as skin conductance responses. Subsequently, over repeated presentations of the CS without the US, fear responses decline, and this process is referred to as *extinction*. Existing research suggests that the amygdala plays a critical role in fear conditioning (27 ,35 ,74 ,75 ,141), and the medial prefrontal cortex may play a critical role in the process of extinction (56 ,83 ,84).

Fredrikson and Furmark and their colleagues used PET to study healthy subjects who viewed a videotape of snakes (CS) both before and after the video was paired with shock (US) (49 ,52). The findings revealed a significant correlation between rCBF changes in right amygdala and electrodermal activity changes. Hugdahl et al. used PET to compare patterns of blood flow before and after classic conditioning in healthy male study subjects, by employing a paradigm in which a tone (CS) was paired with brief shock (US) (62). Extinction was associated with widespread activations in right prefrontal, including orbitofrontal, cortex, as well as left occipital and superior frontal cortex.

In a different conditioning paradigm, Morris et al. showed study subjects pictures of faces that were previously paired with an aversive burst of white noise (CS+) and faces that were never paired with the noise (CS-) (85). A comparison of the CS+ versus CS- conditions yielded activation in right thalamus, orbitofrontal cortex, and superior frontal gyrus. There was a positive correlation between

activation in thalamus and in right amygdala, orbitofrontal cortex, and basal forebrain. Morris and colleagues subsequently used PET and backward masking techniques to study rCBF responses to conditioned face stimuli with and without awareness in healthy male subjects (87). When all CS+ conditions were compared with all CS- conditions, bilateral activation in amygdala was observed. Right amygdala activation was found in the condition in which subjects were aware; left amygdala activation was found in the condition in which subjects were unaware of the emotionally expressive face stimuli.

In a single-trial fMRI study, LaBar et al. examined amygdala activation during both acquisition and extinction in a mixed-gender cohort (69). In the acquisition condition, a colored shape (CS+) was paired with a shock (US), whereas a different colored shape (CS-) was never paired with shock. No shocks were delivered during the extinction condition. Comparing CS+ with CS- trials revealed activation in periamygdaloid cortex and amygdala during early acquisition and early extinction trials, respectively. Activation in both these regions declined over time. Büchel and colleagues also used a single-trial fMRI to study the neural correlates of fear conditioning in healthy subjects (26). Study subjects were scanned during an acquisition phase in which two neutral faces (CS+) were presented with a loud tone (US) and two other neutral faces were presented alone (CS-). To disambiguate the effects of the CS+ and US, the US was not presented on half of the CS+ trials (i.e., $CS+_{unpaired}$). The critical comparison, $CS+_{unpaired}$ versus CS-, revealed activation in anterior cingulate, bilateral insular, parietal, supplementary motor, and premotor cortex. A time by event type interaction revealed that fMRI signal in amygdala decreased over time in the $CS+_{unpaired}$ condition relative to the CS- condition. Similar results were reported by Büchel et al. in a trace conditioning study, in which a temporal gap occurs between the offset of the CS and onset of the US (28). These researchers also found conditioning-related hippocampal activation that declined over time.

Summary

Taken together, functional imaging studies in healthy human subjects extend findings from animal research. Normal anxiety and fear reactions are associated with increased activity in limbic and paralimbic regions, whereas other territories of heteromodal association cortex exhibit decreased activity. However, similar patterns of limbic and paralimbic activation may be observed in association with other emotional states, and hence this general profile should not be taken as specific to anxiety or fear. Exposures to unpleasant, arousing, or threat-related stimuli often produce detectable amygdala responses, which can be associated with enhanced memory. Additional paralimbic recruitment may be related to a person's attention to his or her emotional state. Habituation can be observed in widely distributed brain regions, including limbic, paralimbic, and sensory areas. Consistent with animal data, human imaging results point to a role for the amygdala in fear conditioning and for the frontal cortex in extinction. The accessory role of the hippocampus in these processes remains less well defined.

POSTTRAUMATIC STRESS DISORDER

Part of "65 - Structural and Functional Imaging of Anxiety and Stress Disorders "

Amygdalocentric Neurocircuitry Model

We previously presented a neurocircuitry model of PTSD that emphasizes the central role of the amygdala and its interactions with the hippocampus, medial prefrontal cortex, and other heteromodal cortical areas purported to mediate higher cognitive functions (103). Briefly, this model hypothesizes hyperresponsivity within the amygdala to threat-related stimuli, with inadequate top-down governance over the amygdala by medial prefrontal cortex, specifically, the affective division of anterior cingulate cortex (142), and the hippocampus. Amygdala hyperresponsivity mediates symptoms of hyperarousal and explains the indelible quality of the emotional memory for the traumatic event; inadequate influence by the anterior cingulate cortex underlies deficits of habituation, and decreased hippocampal function underlies deficits in identifying safe contexts, as well as accompanying explicit memory difficulties (21). Further, we propose that in threatening situations, patients with PTSD exhibit an exaggerated reallocation of resources to regions that mediate fight-or-flight responses and away from widespread heteromodal cortical areas, as a neural substrate for dissociation.

Structural Imaging Findings

mMRI studies have reported smaller hippocampal volumes in veterans with PTSD than in comparison subjects. Bremner and colleagues (21) found that right hippocampal volumes were 8% smaller in 26 veterans with PTSD than in 22 civilians without PTSD. In addition, the PTSD group exhibited poorer performance on a standard measure of verbal memory, and their percent retention scores on this test were directly correlated with right hippocampal volume (i.e., lower scores were associated with smaller right hippocampal volumes). Gurvits and colleagues (58) used mMRI to study seven Vietnam combat veterans with PTSD, seven Vietnam combat veterans without PTSD, and eight nonveterans without PTSD. These investigators found significantly smaller hippocampal volumes bilaterally for the PTSD group in comparison with both control groups. Across the 14 veterans, hippocampal volume was inversely correlated with extent of combat exposure and PTSD symptom severity.

Similar hippocampal volumetric differences also have been reported in mMRI studies of PTSD resulting from childhood abuse. Bremner and colleagues (22) found 12%

smaller left hippocampal volumes in 17 adult survivors of childhood abuse with PTSD than in 21 nonabused comparison subjects. Stein and colleagues (134) found 5% smaller left hippocampal volumes in 21 adult survivors of childhood sexual abuse (most of whom had PTSD) than in 21 nonabused comparison subjects. Furthermore, total hippocampal volume was smaller in abused subjects with high PTSD symptom severity than in those with low PTSD symptom severity. In contrast to these results, DeBellis et al. (36) failed to find decreased hippocampal volumes in 44 maltreated children and adolescents with PTSD, compared with 61 nonabused healthy subjects. However, the PTSD group had smaller intracranial and cerebral volumes than did the comparison group.

Taken together, the results of structural neuroimaging studies of adult samples suggest that PTSD is associated with reduced hippocampal volume, which, in turn, may be associated with cognitive deficits and PTSD symptom severity. Although the extent of traumatic exposure may be correlated with hippocampal volume, it appears that differences between PTSD and control groups cannot be explained by traumatic exposure alone (58). The results of DeBellis et al. (36) suggest that hippocampal volumetric differences between groups may not be evident in samples of children and adolescents or in samples of persons with relatively recent traumatic exposures.

Stress, Glucocorticoids, and the Hippocampus

In this review about neuroimaging of anxiety and stress disorders, it is worth elaborating on the potential relationship between stress and hippocampal findings in PTSD. Animal research has provided evidence that stress is associated with damage to the hippocampus (16). For example, sustained, fatal social stress in vervet monkeys was associated with degeneration of neurons in the CA3 region of the hippocampus (139); chronic restraint stress in rats was associated with atrophy of apical dendrites of hippocampal CA3 pyramidal neurons (140); and exposure to cold water immersion stress in rats was related to structural damage to hippocampus (CA3 and CA2 fields) and deceased local CBF in hippocampus (42).

The effect of stress on hippocampus appears to be mediated by glucocorticoid hormones. Exposure to glucocorticoids is associated with hippocampal damage in both rats and primates. For example, Sapolsky et al. reported that chronic exposure to corticosterone in rats led to a loss of neurons in the CA3 region of the hippocampus (115). Woolley and colleagues found that daily corticosterone injections decreased dendritic branching and length in the CA3 region of the rat hippocampus (145). In a study of primates, Sapolsky et al. reported that chronic exposure to cortisol (through steroid-secreting pellets stereotactically implanted in hippocampus) was related to neuronal shrinkage and dendritic atrophy in the CA3 region (117). Moreover, chronic stress during development is capable of inhibiting normal cellular proliferation within the hippocampus, a process mediated by glucocorticoids and glutamatergic transmission by an *N*-methyl-D-aspartate receptor–dependent excitatory pathway (57).

Clinical research has also revealed decreased hippocampal volumes in humans with elevated cortisol levels resulting from Cushing's syndrome (130); furthermore, in these patients, a treatment-related reduction of cortisol levels is associated with increased hippocampal volumes (131). High cortisol levels and decreased hippocampal volumes have also been found in patients with major depressive disorder (25). The hippocampus is also involved in the modulation of the hypothalamic-pituitary-adrenal (HPA) axis, and lesions to hippocampus appear to increase the release of glucocorticoids during stress (43 ,60); this, in turn, may further damage the hippocampus (116).

Although these findings may have great relevance to anxiety and stress disorders, the picture is complicated by the finding that cortisol levels are characteristically reduced, rather than elevated, in PTSD (147). One parsimonious theory suggests that patients with PTSD suffer hypersensitivity to glucocorticoids, resulting in both reduced levels of cortisol (because of accentuated feedback inhibition) and reduced hippocampal volume (147).

Functional Imaging Findings

Semple and colleagues used PET to study six patients with combat-related PTSD and comorbid substance abuse versus seven normal control subjects (125). rCBF was measured in three conditions: resting state, an auditory continuous performance task, and a word generation task. Compared with the control group, the PTSD group exhibited greater rCBF during both task conditions within orbitofrontal cortex.

Rauch and colleagues studied a mixed-gender cohort of eight subjects with PTSD, using PET and a script-driven imagery method for inducing symptoms (104). In the provoked versus control condition, patients exhibited increased rCBF within anterior cingulate cortex, right orbitofrontal, insular, anterior temporal and visual cortex, and right amygdala. rCBF decreases occurred within left inferior frontal (Broca's area) and left middle temporal cortex. Interpretations of this initial study, with regard to the pathophysiology of PTSD, were limited by the absence of a comparison group.

Using a similar paradigm and a comparison group, Shin and colleagues studied eight women with childhood sexual abuse–related PTSD and eight matched trauma-exposed control subjects without PTSD (129). In the traumatic versus neutral comparison, both groups exhibited anterior paralimbic activation. However, a group-by-condition interaction revealed that the control group manifested a

significantly greater rCBF increase within anterior cingulate cortex than did the PTSD group, whereas the PTSD group showed significantly greater rCBF increases within anterior temporal and orbitofrontal cortex. Bremner and colleagues (20) also used script-driven imagery and PET to study rCBF in ten female survivors of childhood sexual abuse with PTSD and 12 without PTSD. Consistent with the findings of Shin et al. (129), Bremner and colleagues (20) reported relatively attenuated recruitment of anterior cingulate cortex in the PTSD group.

Bremner and colleagues (23) studied rCBF responses to trauma-related pictures and sounds in ten Vietnam veterans with PTSD and in ten veterans without PTSD. In the combat versus neutral comparison, the PTSD group exhibited rCBF decreases in medial prefrontal cortex (subcallosal gyrus) and anterior cingulate cortex. Liberzon and colleagues (76) used SPECT to study rCBF in 14 Vietnam veterans with PTSD, 11 veteran control subjects, and 14 healthy nonveterans. In separate scanning sessions, subjects listened to combat sounds and white noise. In the combat sounds versus white noise comparison, all three groups showed activation in anterior cingulate/medial prefrontal cortex, but only the PTSD group exhibited activation in the left amygdaloid region.

Bremner et al. (17) used PET to examine the effect of yohimbine challenge on glucose metabolic rates in ten combat veterans with PTSD and in ten nonveteran subjects without PTSD. Yohimbine administration was associated with increased anxiety and panic symptoms, as well as widespread decreases in cerebral glucose metabolism in the PTSD group.

Shin and colleagues studied seven patients with combat-related PTSD and seven matched trauma-exposed control subjects without PTSD in the context of a PET cognitive activation paradigm (128). Subjects were required to make judgments about pictures from three categories: neutral, general negative, and combat-related. Subjects performed two types of tasks: one involved responding while actually seeing the pictures (perception), and another involved responding while recalling the pictures (imagery). In the combat imagery versus control conditions, the PTSD group exhibited rCBF increases in right amygdala and ventral anterior cingulate gyrus and rCBF decreases in left inferior frontal gyrus (Broca's area).

Using another cognitive activation paradigm, Rauch et al. studied the functional integrity of the amygdala in eight combat veterans with PTSD and eight healthy combat veterans (108). During fMRI, subjects viewed fearful and happy faces temporally masked by neutral faces. Healthy persons are typically aware of seeing only the neutral faces, although they show amygdala activation to the masked fearful faces (142). Rauch and colleagues found greater amygdala activation to masked fearful faces in persons with PTSD than in control subjects (108). Furthermore, the magnitude of amygdala activation was correlated with PTSD severity. These results suggest that PTSD may be characterized by amygdala hyperresponsivity to general threat-related stimuli, consistent with our neurocircuitry model of PTSD.

Imaging Studies of Neurochemistry

Schuff and colleagues used mMRI and MRS to study seven veterans with PTSD and seven nonveteran control subjects (123). Although these investigators found a nonsignificantly smaller (6%) right hippocampus in the PTSD group by mMRI, they found an 18% reduction in right hippocampal NAA by MRS, a finding suggestive of reduced density or viability of neurons in this region.

DeBellis and colleagues used MRS to study NAA/creatine ratios in 11 maltreated children and adolescents with PTSD and 11 healthy comparison subjects without histories of maltreatment (37). The PTSD group had lower NAA/creatine ratios in pregenual anterior cingulate gyrus. This result is consistent with those of symptom provocation PET studies (20 ,23 ,129), which have reported failure to activate anterior cingulate in PTSD.

Bremner et al. (18) used SPECT and [^{123}I]iomazenil to study benzodiazepine-receptor binding in 13 veterans with PTSD and 13 nonveterans without PTSD. These investigators found decreased benzodiazepine-receptor binding in prefrontal cortex in the PTSD group, relative to the control group.

Summary

Taken together, data from neuroimaging studies are consistent with the current neurocircuitry model of PTSD that emphasizes the functional relationship among the amygdala, hippocampus, and medial prefrontal cortex. Hippocampal volumes and NAA levels appear to be decreased in persons with PTSD. These findings dovetail with animal research that points to a relationship among stress, HPA axis function, and cell viability within the hippocampus. Functionally, in comparison with control subjects, patients with PTSD exhibit the following: (a) greater activation within orbitofrontal cortex, anterior temporal poles, and the amygdala; (b) diminished activation in anterior cingulate and medial prefrontal cortex, as well as reduced NAA/creatine ratios in pregenual anterior cingulate; and (c) decreased activation within widespread areas that are associated with higher cognitive functions, such as Broca's area and dorsolateral prefrontal cortex.

OBSESSIVE-COMPULSIVE DISORDER

Part of "65 - Structural and Functional Imaging of Anxiety and Stress Disorders "

Corticostriatal Model

One current neuroanatomic model of OCD focuses on corticostriatothalamocortical circuitry (98 ,106). According to

this model, the primary disorder lies within the striatum (specifically, the caudate nucleus). This leads to inefficient gating at the level of the thalamus, which results in hyperactivity within orbitofrontal cortex (corresponding to the intrusive thoughts) and hyperactivity within anterior cingulate cortex (corresponding to anxiety, in a nonspecific manner). Compulsions are conceptualized as repetitive behaviors that are performed to recruit the inefficient striatum ultimately to achieve thalamic gating and hence to neutralize the unwanted thoughts and anxiety.

Structural Imaging Findings

The results of several mMRI investigations of OCD have suggested volumetric abnormalities involving the caudate nucleus, although the nature of the observed abnormalities has been somewhat inconsistent. Scarone et al. (119) studied a mixed-gender cohort of 20 patients with OCD versus 16 matched controls and found increased right caudate volume in the OCD group. Robinson et al. (111) studied a mixed-gender cohort of 26 patients with OCD versus 26 matched controls and found bilaterally decreased caudate volumes in the OCD group. Jenike et al. (64) studied an all-female cohort of ten patients with OCD versus matched controls and found trends toward a rightward shift in caudate volume (p = .06) as well as overall reduced caudate volume (p = .10) in the OCD group. Aylward et al. (3) studied a mixed-gender cohort of 24 patients with OCD versus 21 matched controls and found no significant differences in striatal volumes. Rosenberg et al. (112) studied 19 treatment-naive pediatric subjects with OCD and 19 case-matched psychiatrically healthy comparison subjects. These investigators found reduced striatal volumes in the OCD group and an inverse correlation between striatal volume and OCD symptom severity.

Functional Imaging Findings

Neutral state paradigms employing PET and SPECT have most consistently indicated that patients with OCD exhibit increased regional brain activity within orbitofrontal and anterior cingulate cortex, in comparison with neurologically normal control subjects (6 ,7 ,78 ,89 ,113 ,136). Observed differences in regional activity within the caudate nucleus have been less consistent (6 ,113).

Pre/posttreatment studies have reported treatment-related attenuation of abnormal regional brain activity within orbitofrontal cortex, anterior cingulate cortex, and caudate nucleus (8 ,9 ,61 ,95 ,124 ,137). In addition, both pharmacologic and behavioral therapies appear to be associated with similar brain activity changes (8 ,124). Some treatment studies have also reported that lower pretreatment glucose metabolic rates in orbitofrontal cortex predict a better response to serotonergic reuptake inhibitors (24 ,118 ,136).

Symptom provocation studies employing PET (80 ,99) as well as functional MRI (15) have also most consistently shown increased brain activity within anterior-lateral orbitofrontal cortex, anterior cingulate cortex, and caudate nucleus during the OCD symptomatic state.

Cognitive activation studies using PET and fMRI have probed the functional integrity of the striatum in OCD (102 ,105). In these studies, patients with OCD perform an implicit (i.e., nonconscious) learning paradigm shown reliably to recruit striatum in healthy individuals (101 ,107). In both studies, patients with OCD failed to recruit striatum normally and instead activated medial temporal regions typically associated with conscious information processing.

Imaging Studies of Neurochemistry

Several MRS studies have been performed to measure NAA concentrations in patients with OCD versus healthy comparison subjects. Ebert and colleagues (41) found reduced relative NAA levels in right striatum and anterior cingulate cortex in 12 patients with OCD in comparison with six healthy control subjects. Bartha and colleagues (5) found lower left striatal NAA concentrations in 13 patients with OCD than in 13 matched control subjects.

MRS has also been used to demonstrate elevated glutamatergic concentrations within the striatum of a child with OCD (82). Glutamate is the principal transmitter mediating frontostriatal communication. Interestingly, elevated striatal glutamate levels were attenuated toward normal after successful pharmacotherapy. These findings suggest that orbitofrontal hyperactivity in OCD may be mirrored by elevated glutamate at the site of orbitofrontal ramifications in striatum, and treatment-related attenuation of orbitofrontal activity may be accompanied by decreased glutamate concentration within the striatum.

Summary

Taken together, these neuroimaging findings are consistent with disorders in corticostriatothalamocortical circuitry. Consistent with the hypothesis of a primary abnormality in the striatum, MRI and MRS studies of OCD have shown reduced striatal volumes and reduced striatal NAA, respectively. PET studies have revealed hyperactivity within orbitofrontal cortex, and the magnitude of this hyperactivity predicts response to treatment. In addition, in neurologically normal persons, the performance of repetitive motor routines does facilitate striatal recruitment in the service of thalamic gating, whereas this pattern is not readily demonstrated in patients with OCD. These imaging data further support the working model of striatal pathology and striatothalamic inefficiency, together with orbitofrontal hyperactivity.

SOCIAL AND SPECIFIC PHOBIAS

Part of "65 - Structural and Functional Imaging of Anxiety and Stress Disorders "

Neuroanatomic Models

Currently, there are no cohesive neuroanatomically based models for the phobias (53 ,132). One possibility is that phobias are learned and hence reflect another example of fear conditioning to specific stimuli or situations. Alternatively, phobias may represent the product of dysregulated systems for detecting potentially threatening stimuli or situations. For instance, if humans have evolved a neural network specifically designed to assess social cues for threatening content, and another to assess threat from small animals, these may represent the neural substrates for the pathophysiology underlying phobias.

Structural Imaging Findings

Given the high prevalence of phobias and the relative ease with which medication-free phobic subjects without significant comorbidities can be recruited, it is striking how few imaging studies have been conducted in this arena. Potts et al. used mMRI to examine volumetric measures of total cerebrum, caudate, putamen, and thalamus in 22 patients with SoP and in 22 matched healthy control subjects (96). The groups did not significantly differ on any of these measures.

Functional Imaging Findings

Studies of SpP to date have principally employed PET symptom provocation paradigms and have reported somewhat inconsistent results. Mountz and colleagues found that persons with small-animal phobia exhibited increased heart rates, respiratory rates, and subjective reports of anxiety during exposure to phobic stimuli; however, no changes in rCBF measurements were observed (88).

Wik and colleagues studied six patients with snake phobias during exposure to videotapes of neutral, generally aversive, and snake-related scenes (143). During the phobic condition, they found significant rCBF increases in secondary visual cortex and rCBF decreases in prefrontal cortex, posterior cingulate cortex, anterior temporopolar cortex, and hippocampus. These findings were similar to those of two other studies of phobia from the same laboratory (50 ,51).

Using *in vivo* exposure and PET, Rauch and colleagues studied rCBF in seven persons with a variety of small animal phobias (100). In the provoked versus control condition, patients with phobias exhibited rCBF increases within multiple anterior paralimbic territories (i.e., right anterior cingulate, right anterior temporal pole, left posterior orbitofrontal cortex, and left insular cortex), left somatosensory cortex, and left thalamus.

Whereas one neutral-state SPECT study of patients with SoP and healthy control subjects found no significant between-group differences in rCBF (133), more recent cognitive activation studies performed in conjunction with fMRI have yielded more informative results. Birbaumer et al. (11) used fMRI to study seven patients with SoP and five healthy control subjects during exposure to slides of neutral human faces or aversive odors. In comparison with the control group, the SoP group exhibited hyperresponsivity within the amygdala that was specific to the human face stimuli. In a follow-up study, Schneider et al. used fMRI to study 12 patients with SoP and 12 healthy control subjects (122). The researchers used a classic conditioning paradigm in which neutral face stimuli were the conditioned stimuli and odors (negative odor and odorless air) served as the unconditioned stimuli. In response to conditioned stimuli associated with the negative odor, the SoP group displayed signal increases within amygdala and hippocampus, whereas healthy comparison subjects displayed signal decreases in these regions.

Imaging Studies of Neurochemistry

Davidson et al. (34) used MRS to study NAA in 20 patients with SoP and in 20 healthy control subjects. Relative to the control group, the SoP group exhibited decreased NAA in white matter and cortical and subcortical gray matter (e.g., caudate and thalamus).

Tiihonen et al. used SPECT and I-123–labeled ß-CIT to measure the density of dopamine reuptake sites in 11 patients with SoP and in 28 healthy comparison subjects (138). They found significantly reduced striatal dopamine reuptake binding site density in the SoP versus control group.

Summary

Although relatively few neuroimaging studies of SpP have been conducted, findings from existing research suggest activation of anterior paralimbic regions and sensory cortex corresponding to stimulus inflow associated with a symptomatic state. Although such results are consistent with a hypersensitive system for assessment of or response to specific threat-related cues, they do not provide clear anatomic substrates for the pathophysiology of SpP. Cognitive activation neuroimaging studies of SoP reveal exaggerated responsivity of medial temporal lobe structures to human face stimuli; this hyperresponsivity may reflect a neural substrate for social anxiety in SoP.

PANIC DISORDER

Part of "65 - Structural and Functional Imaging of Anxiety and Stress Disorders "

Neuroanatomic Models

Neurobiological models of PD have emphasized a wide range of disparate elements (31). Satisfactory models of PD must account for spontaneous panic attacks, which are a

defining feature of PD. It is possible that spontaneous panic corresponds to a normal physiologic anxiety response that is mediated by intact fear-anxiety circuits but, owing to homeostatic deficits, occurs in inappropriate, threat-free situations. This is consistent with theories of hypersensitivity to carbon dioxide at the level of the brainstem (i.e., the suffocation false alarm model), as well as theories regarding fundamental monoaminergic dysregulation. Another possibility is that panic attacks emerge in the context of what should be minor anxiety episodes because of failures in the systems responsible for limiting such normal responses; hippocampal deficits may underlie such a failure to inhibit anxiety responses. Finally, panic episodes described as spontaneous (i.e., without identifiable precipitants) could reflect anxiety responses to stimuli that are not processed at the conscious (i.e., explicit) level, but instead, recruit anxiety circuitry without awareness (i.e., implicitly). There is strong evidence that the amygdala can be recruited into action in the absence of awareness that a threat-related stimulus has been presented (142). By this model, PD may be characterized by fundamental amygdala hyperresponsivity to subtle environmental cues, triggering full-scale threat-related responses in the absence of conscious awareness.

Structural Imaging Findings

Fontaine et al. (48) published a qualitative MRI study involving 31 patients with PD and 20 matched healthy control subjects. The frequency of gross structural abnormalities was higher in the PD group (40%) than in the control group (10%); the most striking focal findings in the PD group involved abnormal signal or asymmetric atrophy of the right temporal lobe.

Functional Imaging Findings

In an initial PET neutral-state study, Reiman and colleagues studied 16 patients with PD and 25 normal control subjects (109). In the subset of patients who were vulnerable to lactate-induced panic (n = 8), the investigators found abnormally low left/right ratios of parahippocampal blood flow. DeCristofaro et al. used SPECT to measure rCBF at rest in seven treatment-naive patients with PD and in five age-matched healthy control subjects (38). Relative to the control group, the PD group exhibited elevated rCBF in left occipital cortex and reduced rCBF in the hippocampal area bilaterally. Nordahl et al. used PET and FDG to measure regional cerebral metabolic rate glucose (rCMRglc) in 12 patients with PD and 30 normal control subjects during an auditory continuous performance task (90). The investigators found that the PD group exhibited a lower left/right hippocampal ratio. In a follow-up experiment (91), these investigators used PET-FDG methods to study imipramine-treated subjects with PD and found a rightward shift in symmetry of rCMRglc within hippocampus and posterior inferior frontal cortex. In comparison with the untreated group, the imipramine-treated group exhibited rCMRglc decreases in posterior orbital frontal cortex. Bisaga et al. (12) used PET and FDG to study a cohort of six women with PD and six matched control subjects. In contrast to previous studies, the PD subjects displayed elevated rCMRglc in the left hippocampus and parahippocampal area.

The literature contains three symptom provocation studies of PD, all of which have employed pharmacologic challenges. Stewart et al. used SPECT and the xenon inhalation method to measure CBF during lactate infusion in ten patients with PD and in five healthy control subjects (135). The patients with PD who experienced lactate-induced panic attacks (n = 6) displayed global cortical CBF decreases. Woods et al. used SPECT and yohimbine infusions to study six patients with PD and six normal control subjects (144). In the PD group, yohimbine administration increased anxiety and decreased rCBF in bilateral frontal cortex. In a PET study, Reiman et al. measured rCBF during lactate infusions in 17 patients with PD and in 15 normal control subjects (110). The eight patients who suffered lactate-induced panic episodes exhibited rCBF increases in bilateral temporopolar cortex and bilateral insular cortex/claustrum/putamen. Healthy control subjects and patients with PD who did not experience lactate-induced panic attacks did not exhibit such rCBF changes. Of note, the temporopolar findings were subsequently questioned as possibly reflecting extracranial artifacts from muscular contractions (40 ,10). In a symptom capture case report, Fischer and colleagues (44) found that a spontaneous panic attack was associated with rCBF decreases in right orbitofrontal, prelimbic (area 25), anterior cingulate, and anterior temporal cortex.

Imaging Studies of Neurochemistry

Dager and colleagues used MRS to measure brain lactate levels during hyperventilation in seven treatment-responsive patients with PD and in seven healthy comparison subjects (32). The PD group showed a significantly greater rise in brain lactate in response to the same level of hyperventilation. Dager et al. also used MRS to measure brain lactate levels during lactate infusions in 15 patients with PD and in ten healthy comparison subjects (33). The PD group exhibited a significantly greater brain lactate level during lactate infusion, a finding consistent with the interpretation of reduced clearance, rather than higher production, of lactate in PD.

Three studies have used SPECT and [^{123}I]iomazenil to measure benzodiazepine-receptor binding in PD. Kuikka et al. (68) studied 17 subjects with PD and 17 matched healthy comparison subjects and found that the PD group exhibited a greater left/right ratio in benzodiazepine-receptor uptake that was most prominent in prefrontal cortex. Brandt et al. (13) studied 12 medication-naive patients with PD and nine

matched healthy control subjects and found that the PD group exhibited significantly elevated benzodiazepine-receptor binding within right supraorbital frontal cortex, as well as a trend toward elevated binding in the right temporal cortex. Bremner et al. (19) included 13 patients with PD and 16 healthy comparison subjects and found that the PD group showed decreased benzodiazepine-receptor binding in left hippocampus and precuneus.

Using PET and carbon-11–labeled flumazenil, Malizia et al. studied seven patients with PD and eight healthy comparison subjects (79). These investigators found that the PD group exhibited a global reduction in benzodiazepine binding that was most pronounced in right orbitofrontal and right insular cortex.

Summary

Resting state neuroimaging studies have suggested abnormal hippocampal activity in PD. Symptom provocation studies have revealed reduced activity in widespread cortical regions, including prefrontal cortex, during symptomatic states. MRS studies have reported greater brain lactate levels in response to hyperventilation and lactate infusions. Finally, receptor-binding studies of PD suggest widespread abnormalities in the GABAergic/benzodiazepine system. Consistent with prevailing neurobiological models of PD, it is possible that fundamental abnormalities in monoaminergic neurotransmitter systems, originating in the brainstem, underlie the abnormalities of metabolism, hemodynamics, and chemistry found in widespread territories of cortex. Further, regional abnormalities within the medial temporal lobes provide some support for theories regarding hippocampal or amygdala dysfunction in PD.

CONCLUSIONS AND FUTURE DIRECTIONS

Part of "65 - Structural and Functional Imaging of Anxiety and Stress Disorders "

Neuroimaging research is helping to advance neurobiological models of anxiety and stress disorders. At the current early stage of this scientific enterprise, there are hints of commonalities across anxiety disorders as well as leads regarding disorder-specific features. Beyond the need for a general expansion of the existing database, it will be critical to explore the specificity of initial findings by conducting studies with psychiatric comparison groups in addition to healthy control subjects. This is of particular relevance to the concept of stress disorders, in which common etiologic factors or vulnerability factors may have corresponding pathophysiologic profiles that are independent of our current diagnostic scheme. For instance, the relationship between early or chronic life stress and hippocampal structure and function may well span anxiety, mood, and even psychotic disorders. In this light, longitudinal and developmental studies may be of particular importance in elucidating the neural correlates and consequences of stress. Similarly, genetic studies in animals and humans will benefit from neuroimaging methods that can illuminate the bidirectional link from behavior to brain structure, function, and chemistry. For instance, research regarding the heritability of anxious temperament may be enhanced by using extended phenotypes of conditionability or distributed brain function within amygdala, hippocampus, and medial frontal cortex. In fact, the gamut of existing animal and human experimental paradigms with relevance to anxiety and stress disorders provides a promising context for advancing integrated models across scales and neuroscientific modes of inquiry. As such integrated models evolve, targets for new and improved neuropsychopharmacotherapies are destined to emerge. Indeed, neuroimaging is likely to play a role not only in conceptually motivating but also in discovering and testing such new therapies as part of the next generation of progress in this domain.

Current and Emerging Therapeutics of Anxiety and Stress Disorders

Jack M. Gorman

Justine M. Kent

Jeremy D. Coplan

Jack M. Gorman, Justine M. Kent, and Jeremy D. Coplan: Columbia University, New York State Psychiatric Institute, New York, New York.

During the 1960s and 1970s the concept of “pharmacologic dissection” became popular as a putative method for differentiating among different categories of psychiatric illness. At the time, it was widely held that anxiety disorders, but not depression, respond to benzodiazepines, whereas depression, but not anxiety disorders, responds to antidepressants. Panic disorder was held to be the one exception, responding only to antidepressants. Alprazolam, selective serotonin reuptake inhibitors (SSRIs), and buspirone had not yet been tested. On the basis of these observations, it was asserted that anxiety and depression are clearly distinct categories of illness.

Thirty years later we find that the situation has changed dramatically. The first inconsistency with the notion of pharmacologic dissection was the clear finding that panic disorder does indeed respond to benzodiazepines. For a while, alprazolam and then clonazepam were regarded by some authorities and clinicians as first-line therapies for panic disorder, replacing tricyclics and monoamine oxidase inhibitors.

An even more potent challenge, however, has come from the evidence not only that anxiety disorders respond to antidepressants but also that antidepressants work better than benzodiazepines for most of them. As this chapter discusses, antidepressants are now considered the appropriate pharmacologic intervention for panic disorder, social anxiety disorder, posttraumatic stress disorder (PTSD), and generalized anxiety disorder (GAD). The latter case is particularly interesting. Once considered the sole domain of benzodiazepines, GAD was then shown to be responsive to a drug in an entirely new category, with no relationship whatsoever to the benzodiazepine receptor or γ-aminobutyric acid (GABA)—buspirone. At about the same time evidence began to accumulate from just a few studies that GAD might also respond to antidepressants. This evidence was largely ignored, and pharmaceutical companies were advised to stay away from GAD, a condition supposedly so placebo-responsive that no drug would ever be shown effective in large clinical trials. To the contrary, venlafaxine is now approved by the Food and Drug Administration (FDA) for the treatment of GAD, and there is also evidence for the efficacy of paroxetine.

At this point, rather than “dissecting” among the anxiety disorders or between anxiety disorders and depression, pharmacologic grounds might lead one to assume that these conditions are variants of each other. This also would probably be an oversimplification. Anxiety and depression are different and we can make distinctions among the anxiety disorders. Nevertheless, the finding that antidepressants are so ubiquitously effective across categories raises interesting questions and challenges. We review here the evidence for responsiveness of four anxiety disorders to medication.

PANIC DISORDER

Part of "66 - Current and Emerging Therapeutics of Anxiety and Stress Disorders "

Panic disorder (PD) has a reported lifetime prevalence of between 1.5% and 3.5% (1 ,2), is highly comorbid with major depression, and is associated in its own right with significant impairment in psychosocial functioning independent of depressive symptomatology. In the Epidemiologic Catchment Area study, subjective reports of patients with PD indicate that approximately one-third experience poor physical and emotional health, rates comparable with major depression (2).

Historical Notes

Recognized as a distinct disorder that could be distinguished from the general diagnosis of “anxious neurosis,” in part

through the pharmacologic dissection work of Klein and Fink (3 ,4) in the 1960s, PD was first categorized as a discrete diagnostic entity in the *Diagnostic and Statistical Manual of Mental Disorders*, third edition (DSM-III), in 1980. Despite some minor changes in diagnostic criteria in the third edition revised (DSM-III-R) and the fourth edition (DSM-IV), primarily involving the number and frequency of attacks required, the major criteria remain essentially the same. The key triad of symptoms are (a) the occurrence of spontaneous panic attacks; (b) the presence of anticipatory anxiety; and (c) the presence of phobic avoidance, resulting in some degree of functional impairment. The pharmacologic treatment of PD has evolved dramatically since the heterocyclic antidepressants were first established as possessing powerful antipanic properties in the early 1960s (4). Throughout the 1970s and 1980s, the heterocyclic antidepressants continued to be the mainstay of pharmacologic treatment of PD, with the monoamine oxidase inhibitors (MAOIs) used primarily in patients who failed trials of heterocyclic antidepressants. The high potency benzodiazepines were increasingly prescribed as both primary and adjunct treatments throughout this same time period. With the introduction of the SSRIs in the United States in the late 1980s and early 1990s for the treatment of depression, this class of drug began being used in the treatment of PD with promising results. In the late 1990s, several large-scale, controlled trials established the SSRIs to be effective and safe treatments for PD, thus supplanting the heterocyclic antidepressants and benzodiazepines as first-line treatment. Although the serotonin, norepinephrine, and GABA systems remain the traditional targets for the majority of antipanic medications, widely different classes of drugs targeting an array of neurochemical systems are now being explored as potential treatments for PD.

Heterocyclic Antidepressants

Numerous controlled trials have confirmed the efficacy of the heterocyclic antidepressants, since the initial observations of Klein (4), in both the acute and long-term treatment of PD. In general, heterocyclics with greatest serotoninergic reuptake inhibition effect, such as imipramine and clomipramine, appear to be most effective in the treatment of PD (5 ,6 and 7). By far the best studied of this class of antidepressants is imipramine, which due to its well-established efficacy has been generally accepted as the gold standard of PD treatment (8). In the Cross-National Collaborative Panic Study, more than 1,000 patients in 14 countries were randomized into a study comparing imipramine, alprazolam, and placebo (9). At the study's end, imipramine and alprazolam were found to have comparable efficacy, and both were significantly superior to placebo on most outcome measures. A positive dose–response relationship between imipramine levels and clinical improvement has been reported, with plasma levels of 140 mg/mL associated with the greatest improvement in panic symptoms (10). Although several other of the heterocyclic antidepressants have been used in the treatment of PD (amitryptyline, desipramine, nortriptyline, clomipramine), far less controlled data are available supporting their efficacy (11 ,12). Although effective, side effects often limit the use of this class of medication in the treatment of PD. This is particularly true in the case of clomipramine, which due to its anticholinergic and antihistaminergic effects can be difficult for patients to tolerate (13). The use of the heterocyclic antidepressants is often limited by the presence of comorbid medical conditions such as cardiac disease and glaucoma. Lethality in overdose is another concern given the reported high rates of suicide in this population when depression is comorbid (14 ,15 and 16). Although the SSRIs are often touted as offering a more tolerable side-effect profile than the heterocyclics, the side-effect burden of imipramine has recently been shown to be comparable to, although different in nature from, that of the SSRIs, with most side effects (with the exception of dry mouth, sweating, and constipation) not persisting beyond the first few weeks of treatment (17).

Monoamine Oxidase Inhibitors

Like the heterocyclic antidepressants, the MAOIs, are clearly established to be effective in the treatment of PD, yet have yielded to newer antidepressants with similar antipanic efficacies but less drug–drug and dietary interactions. Among the MAOIs, phenelzine is the best studied in PD, and its efficacy in the acute treatment of PD is supported by several studies (18 ,19 and 20). Dietary restrictions, lethality in overdose, and drug interaction concerns limit the widespread use of the traditional MAOIs. Stemming from these concerns, the reversible inhibitors of MAOI (RIMAs) were developed and have demonstrably fewer drug–drug and dietary interactions. These include moclobemide and brofaromine, neither of which is currently marketed in the United States, but are used extensively throughout Europe and other parts of the world. The efficacy of moclobemide has been shown in the treatment of PD in placebo-controlled studies (21), and moclobemide has been found to be comparable in efficacy to clomipramine (21) and fluoxetine (22). Moclobemide has also been shown to be as effective as fluoxetine in maintenance treatment of PD (23). Brofaromine was shown to be comparable to fluvoxamine (24) and clomipramine (25) in small randomized, double-blind studies lacking a placebo. In a placebo-controlled study of the efficacy of brofaromine, 30 patients with PD (DSM-III-R definition) were treated for 12 weeks. Although there was no significant reduction in the number of panic attacks for those patients treated with brofaromine, patients demonstrated clinical improvement on several other measures, including agoraphobic avoidance (26).

Benzodiazepines

The high-potency benzodiazepines, another mainstay of treatment for PD, have been shown to be effective, well tolerated, and safe. In the absence of comorbid substance abuse, concerns about abuse potential have proven largely unfounded in this population (27 ,28 ,29 and 30). Among the benzodiazepines, alprazolam and clonazepam are labeled for the treatment of panic disorder and have been shown in numerous, controlled trials to be effective treatments (31 ,32 ,33 ,34 ,35 and 36). Clonazepam, with a long half-life of 20 to 50 hours, allows fewer doses per day than the short-acting alprazolam, and may reduce the likelihood of rebound symptoms between doses. The benzodiazepines have repeatedly been shown to offer an early advantage in the treatment of anxiety by providing almost immediate relief of anxiety-related somatic symptoms such as muscle tension and insomnia (27 ,37 ,38). However, in the long term, antidepressants may offer the advantage of better targeting and relief of psychic symptoms of anxiety (37), and provide the added benefit of treating associated depressive symptoms. Discontinuing long-term pharmacotherapy with benzodiazepines can be difficult, with as many as a third of patients with PD being unable to discontinue use due to dependence/withdrawal (27). Thus, despite their efficacy and safety, many clinicians remain concerned about the risk of dependence (39).

Selective Serotonin Reuptake Inhibitors (SSRIs)

Among the antidepressants currently used in the treatment of PD, the SSRIs have become first-line treatments (40 ,41). Following in the wake of numerous promising open and controlled trials, several large, multicenter, placebo-controlled studies involving hundreds of subjects each have demonstrated the efficacy of the SSRIs in the treatment of PD (Table 66.1) (42 ,43 ,44 ,45 ,46 ,47 ,48 ,49 and 50). Both sertraline and paroxetine are labeled in the United States for the treatment of PD, and citalopram is approved in several European countries for this indication. Although fluvoxamine has not been studied in clinical trials on the scale of the other SSRIs, it has been shown to be efficacious in smaller (<100 subjects), randomized, placebo-controlled studies (25 ,44). Despite their established efficacy in the treatment of PD, there are certain problems inherent in prescribing the SSRIs in patients with PD. Of primary concern on the initiation of treatment is the commonly observed anxiogenic effect, which, despite being dose-dependent, can nonetheless make the initial several days of treatment a challenge for patients. Initiating treatment with a dose of one-fourth to one-half that of the normal starting dose may greatly reduce the patient's feelings of restlessness and increased anxiety. The delayed onset of anxiolytic action contributes to making the period of SSRI initiation difficult for patients with PD. Other effects such as sexual dysfunction and weight gain with long-term use can make these drugs as problematic as earlier classes for some patients. Overall, though, the side-effect burden associated with SSRI treatment has been shown to be more tolerable for most patients than the heterocyclics and benzodiazepines (51). Because the SSRIs have been associated with a discontinuation syndrome characterized by anxiety, tremor, dizziness, paresthesias, nausea, and other symptoms when abruptly stopped, these medications should be tapered over a few weeks, if possible, to minimize discontinuation symptoms (38).

TABLE 66.1. EFFICACY OF THE SSRIs IN THE ACUTE TREATMENT OF PANIC DISORDER BASED ON LARGE-SCALE, PLACEBO-CONTROLLED STUDIES

SSRI	Investigators	Study Design	Dose Range	Outcome
Fluoxetine	Michelson et al., 1998	Multicenter, 10-week study of 243 patients	Fixed dose: 10 or 20 mg/day	20-mg dose was most effective, demonstrating significant change versus placebo on panic attack frequency, CGI improvement scores, Hamilton Anxiety and Depression scores, phobic symptoms, and functional impairment as measured by the Sheehan Disability Scale (family life and social life); the two fluoxetine groups did not differ from placebo in the number of patients who were panic-free at endpoint
	Michelson et al., 2000	Multicenter, 12-week study of 180 patients	Flexible dose: 20–60 mg/day (mean dose = 20 mg)	A significantly greater percentage of patients on fluoxetine were panic-free at endpoint (42% versus 28% on placebo); significant change versus placebo were found for the CGI Severity, HAM-A, State Anxiety Inventory, and Sheenhan Disability Scale (work and social impairment)
Fluvoxamine	Black et al., 1993	Multicenter, 8-week study of 75 patients randomized to either fluvoxamine, cognitive therapy, or placebo	Flexible dose: up to 300 mg/day (mean dose = 230 mg)	Fluvoxamine was superior to placebo and cognitive therapy at endpoint as measured by the Clinical Anxiety Scale and CGI Severity and Improvement scales; fluvoxamine was superior to placebo as measured by a greater reduction in mean panic attack severity, and number of panic-free patients; fluvoxamine-treated patients demonstrated significant reductions versus placebo on several measures of the Sheehan Disability Scale (work, social/leisure)
Paroxetine	Oehrberg et al., 1995	Multicenter, 12-week study of 120 patients—all received cognitive therapy	Flexible dose: 20–60 mg/day	Number of patients with at least 50% reduction in panic attacks was significantly greater in the paroxetine-treated than placebo group, as was number of patients who had only one or no panic attacks during the final study week. The paroxetine group had significantly greater mean reductions in HAM-A and CGI scores versus placebo
	Ballenger et al., 1998	Multicenter, 10-week study of 278 patients	Fixed dose: 10, 20, or 40 mg/day	40-mg group demonstrated the greatest effects, with significant improvement versus placebo on measures of reduction in number of panic attacks, intensity of attacks, CGI Severity and Improvement scores, phobic fear score, HAM-A score, and MADRS
Sertraline	Pollack et al., 1998	Multicenter, 10-week study of 176 patients	Flexible dose: 50–200 mg	Significant decreases versus placebo at endpoint in number of panic attacks, CGI Improvement and Severity scales, PDSS scores; sertraline also demonstrated superiority on improvement in quality of life scores
	Sheikh et al., 2000	Pooled data from two 12-week studies with a total of 322 patients	Fixed dose: 50, 100, or 200 mg/day	All three doses of sertraline were superior to placebo on frequency of panic attacks, CGI Improvement, and change in panic burden (attack frequency X severity), with no consistent dose-response effect
Citalopram	Wade et al., 1997	Multicenter, 8-week comparative study with clomipramine and placebo of 475 patients	Fixed dose: citalopram 10 or 15 mg/day, 20 or 30 mg/day, 40 or 60 mg/day; clomipramine 60 or 90 mg/day	Patients treated with citalopram 20/30 or 40/60 mg/day were comparable to clomipramine and superior to placebo as measured by the number of patients panic-free in the final week of treatment, and by mean reduction in HAM-A total and psychic subscale, and the MADRS; only the 40/60-mg/day dose demonstrated superiority to placebo, along with clomipramine, on the HAM-A somatic subscale; on the Physician's Global Improvement Scale and Patient's Global Improvement Scale, the 20/30-mg dose exhibited greater effects; however, both the 20/30- and 40/60-mg/day doses were superior to placebo

CGI, Clinical Global Impression; HAM, Hamilton Anxiety Rating Scale; MADRS, Montgomery-Ashberg Depression Rating Scale; SSRI, selective serotonin reuptake inhibitor.

Newer Antidepressants

Among the newer antidepressants, several have demonstrated promise in PD. Venlafaxine, a serotonin-norepinephrine reuptake inhibitor, has shown efficacy (on some measures) in a small, placebo-controlled study (52). Nefazodone, a weak serotonin-norepinephrine reuptake inhibitor with serotonin receptor subtype 2C ($5\text{-}HT_{2C}$) antagonist properties, has been shown to reduce anxiety in depressed patients with comorbid PD (53). Mirtazapine enhances both noradrenergic and serotoninergic neurotransmission without reuptake inhibition. Results of an open study involving ten patients suggested that mirtazapine might be effective in the treatment of PD (54). More recently, in a double-blind randomized trial comparing mirtazapine and fluoxetine in the treatment of PD, both drugs showed comparable efficacy on the primary outcome measures and on most secondary outcome measures (55). Adverse events differed between treatments, with weight gain occurring more frequently in those patients receiving mirtazapine, whereas nausea and paresthesias occurred more often in those receiving fluoxetine.

Anticonvulsants

Among the anticonvulsants being used in the treatment of PD are valproate and carbamazepine, and the newest anticonvulsants gabapentin, lamotrigine, pregabalin, and vigabatrin. Valproate has shown promise in several open trials (56 ,57 and 58), and one small placebo-controlled study (59). It may be particularly effective when mood instability is comorbid (60). There is far less support for the use of carbamazepine in the treatment of PD, with uncontrolled studies in patients with PD with EEG abnormalities demonstrating some benefit from carbamazepine treatment (58). However, the only controlled trial of carbamazepine in a small number of PD patients (N = 14) did not report a significant difference for carbamazepine versus placebo in reducing panic attack frequency (61). Gabapentin has shown promise (62) and is recognized as having a benign side-effect profile. Lamotrigine, pregabalin, and vigabatrin are currently under investigation.

Beta-Blockers

Although the beta-blockers are more commonly used in the treatment of performance anxiety and as adjunctive treatment in PTSD, a small number of open studies suggest they may be effective in the treatment of PD (63), although they are not considered a first-line treatment.

Future Directions

Several classes of drugs, although initially viewed as promising, have shown limited efficacy in the treatment of PD. These include buspirone, bupropion, ondansetron, and the cholecystokinin (CCK) antagonists (64 ,65 ,66 and 67). A number of new classes of drugs are being studied, including the benzodiazepine partial agonists such as abecarnil and pagaclone, and the corticotropin-releasing hormone (CRH) inhibitors. Experimental agents showing promise in panic-like models in rodents include the group II metabotropic glutamate receptor agonist LY354740 (68) and drugs acting at the neuropeptide receptors, including neuropeptide-Y agonists and neurokinin substance P antagonists (69).

In summary, the expansion of the antipanic armamentarium suggests that, as with many of the psychiatric disorders, there is no single effective treatment of PD. Among the most commonly prescribed classes of drugs for the treatment of PD [benzodiazepines, SSRIs, tricyclic antidepressants (TCAs), and MAOIs], there are probably no major differences in treatment efficacy, with most reported differences in efficacy between classes probably attributable to differences in study design and samples (27). The use of antidepressants, however, and particularly the SSRIs, has supplanted the long-term use of benzodiazepines for this disorder. Antidepressant use has two main advantages over the benzodiazepines: (a) it provides antidepressant benefits in a population highly susceptible to depressive symptomatology and comorbid major depression (70), and (b) it eliminates the difficulties associated with withdrawal symptoms upon benzodiazepine discontinuation. In the case of comparable efficacy, medication choice is based on factors such as latency to onset of therapeutic action, safety, and the individual side-effect profiles of each medication. In this regard, the SSRIs are currently considered first-line treatment for PD, demonstrating comparable efficacy and superior tolerability to other treatment classes. Combination therapies are frequently used for treatment resistance, and an approach of prescribing a benzodiazepine at the initiation of treatment with an SSRI, and later tapering it, has proved to be popular with clinicians and has recently been demonstrated to be advantageous in the early stages of treatment over an SSRI alone (71).

GENERALIZED ANXIETY DISORDER

Part of "66 - Current and Emerging Therapeutics of Anxiety and Stress Disorders "

The diagnostic criteria for generalized anxiety disorder (GAD) have evolved over the past two decades, undergoing substantial revision to the current definition emphasizing excessive, unrealistic worry as the cardinal feature of this disorder. Defined in 1980 in DSM-III as a disorder of continuous or persistent worry symptoms of at least 1 month's duration, the diagnosis of GAD was reframed in DSM-III-R to require symptoms extended for 6 months or longer, and an emphasis on unrealistic worry was stressed. With DSM-IV, GAD was defined as excessive and persistent

worry, accompanied by three or more physical or psychological symptoms of anxiety, persisting 6 months or longer. Because of the shift in diagnostic criteria and required duration of symptoms over the years, comparison of pharmacologic treatment studies performed prior to the introduction of DSM-III-R is difficult.

In comparison with panic disorder, PTSD, and obsessive-compulsive disorder (OCD), there are fewer publications devoted to GAD overall, and only a limited number of published controlled clinical medication trials. Several reasons have been proposed for this deficiency, including underrepresentation in clinical settings and a view of GAD as a "mild" disorder (72). In reality, GAD is one of the most commonly diagnosed anxiety disorders, with a lifetime prevalence of 4.1% to 6.6% (73 ,74), which is often chronic (75), and associated with significant compromise in functioning (76 ,77). There remains substantial controversy surrounding the validity of GAD as a primary disorder, as opposed to a comorbid condition or a prodromal/residual phase of another disorder (78 ,79). Findings from epidemiologic studies of GAD suggest that current comorbidity with other disorders is as high as 58% to 65% (73 ,76), and lifetime comorbidity rates are between 80% and 90% (76 ,80). Non-comorbid, "pure" GAD lifetime prevalence was found to be only 0.5% in the National Comorbidity Survey (76). Overall, the sum of studies examining quality of life issues support the idea that non-comorbid GAD is relatively rare, but is associated with significant impairment in its own right (81 ,82).

Historical Notes

Prior to the introduction of the benzodiazepines, the main agents available for the treatment of anxiety were the tricyclic antidepressants (doxepin, imipramine, amitryptyline), antihistamines (diphenhydramine, hydroxyzine), barbiturates (mephobarbital), and the sedative antianxiety agent meprobamate (Milltown). The development of the benzodiazepines in the mid-1950s led to the introduction of chlordiazepoxide (Librium) in 1959, and ushered in an era of benzodiazepine use in the treatment of a wide range of anxiety symptoms related to anxiety and mood disorders, psychosis, and alcohol withdrawal. Greater tolerability and the superior safety profiles of the benzodiazepines resulted in a sharp decline in the use of barbiturates for anxiety disorders (83). The benzodiazepines have remained a common treatment choice for GAD throughout the past two decades. However, concerns about dependence and withdrawal, short-term memory impairment, interactions with alcohol, and psychomotor impairment have resulted in increased interest in alternative medications. The introduction of drugs such as buspirone (1986), SSRIs (from 1980 on), and the serotonin and norepinephrine reuptake inhibitor (SNRI) venlafaxine (1994) have broadened the available treatment armamentarium for GAD significantly.

Tricyclic Antidepressants

Tricyclic antidepressants (TCAs) have been in use in the treatment of GAD for many decades; however, data supporting their efficacy from controlled clinical trials are extremely limited. Imipramine is the only TCA shown to be effective in placebo-controlled trials of GAD patients without comorbid depression (84 ,85). In comparator trials, imipramine has been shown to have clinical efficacy comparable to the benzodiazepines (84 ,86 ,87).

Benzodiazepines

Five benzodiazepines (alprazolam, chlordiazepoxide, clorazepate, diazepam, and lorazepam) are currently labeled as treatments for anxiety (GAD) (88). Clonazepam and alprazolam are labeled specifically for the treatment of PD. There are a limited number of clinical trials demonstrating the efficacy of benzodiazepines in the treatment of GAD in its current (DSM-IV) definition (89 ,90); however, benzodiazepines have been shown effective in controlled studies using DSM-III criteria for GAD (91).

Buspirone

Buspirone is a serotonin receptor subtype 1A ($5\text{-}HT_{1A}$) partial agonist with anxiolytic properties. In a metaanalysis of placebo-controlled comparator trials with benzodiazepines, buspirone showed comparable efficacy to the benzodiazepines in eight trials in 735 patients meeting DSM-III criteria (1 month's duration of illness) for GAD (92). In a metaanalysis of eight placebo-controlled studies in over 500 GAD patients with coexisting depressive symptoms, buspirone demonstrated significant superiority to placebo (93). Prior recent treatment with a benzodiazepine (<1 month) has been shown to predict poor response to subsequent buspirone treatment in GAD (92). This may be due to a combination of factors including the presence of benzodiazepine withdrawal, exacerbation of benzodiazepine discontinuation symptoms by buspirone and its metabolite a-(2-pyridinyl)-piperazine via enhancement of noradrenergic activity (94), and psychological factors such as patient expectations.

SSRIs

The first published study of a medication with significant serotonin reuptake inhibition properties in GAD involved a small, open-label trial of clomipramine (95). The suggestion of efficacy in this study, along with the success of clomipramine in treating other anxiety disorders, raised interest in pharmacologic agents for GAD that target the serotoninergic system. Following several years later, the first comparison trial of an SSRI in the treatment of GAD was published by Rocca and colleagues (89). Treatment efficacy of paroxetine was compared with the tricyclic imipramine and the

benzodiazepine 2′-chlordesmethyldiazepam in 81 subjects with GAD. Of the 63 patients who completed the randomized, 8-week study, 68% of the paroxetine group, 72% of the imipramine group, and 55% of the 2′-chlordesmethyldiazepam group were judged to be responders as measured by a 50% or more decrease in Hamilton Anxiety Rating Scale (HAM-A) scores. The greatest improvement during the first 2 weeks occurred in the group receiving the benzodiazepine, as expected by the early relief of physical anxiety symptoms and insomnia provided by this class of medication. However, from the fourth week forward, the paroxetine and imipramine groups demonstrated superior benefits, particularly in the area of psychic symptoms of anxiety. More recently, the efficacy of paroxetine was demonstrated in a large, fixed-dose study of more than 500 patients with a DSM-IV diagnosis of GAD without major depression (96). Patients were randomized to receive paroxetine 20 mg/day, paroxetine 40 mg/day, or placebo for 8 weeks. Patients receiving both doses of paroxetine demonstrated significant differences in the primary outcome measure, reduction in HAM-A score, versus placebo, with 68% on 20 mg paroxetine and 81% on 40 mg paroxetine rated as responders based on a Clinical Global Impression (CGI-I) score of 1 or 2, versus 52% on placebo.

Venlafaxine

Venlafaxine is an inhibitor of SNRI. Venlafaxine has recently been demonstrated in humans, using peripheral measures, to have primarily 5-HT reuptake inhibition properties at low doses (75 mg/day), with increasing norepinephrine (NE) reuptake inhibition properties at higher doses (375 mg/day) (97). Shown to be effective in the treatment of anxiety symptoms associated with major depression (98 ,99), the extended release (XR) form of venlafaxine has been shown to be effective in the treatment of GAD (DSM-IV criteria) in several placebo-controlled studies (100 ,101). In a placebo-controlled multicenter comparator trial, 405 patients with GAD were randomized to receive venlafaxine XR (75 or 150 mg/day), buspirone (30 mg/day), or placebo for 8 weeks. For the 365 patients for whom efficacy measures were obtained, there was no significant difference between groups in improvement on the primary outcome measure, the HAM-A. However, both doses of venlafaxine were shown to be superior to placebo in improving HAM-A psychic anxiety and anxious mood scores at the endpoint (week 8), and venlafaxine demonstrated superiority to placebo and buspirone on the CGI-S at the same time point. More robust efficacy findings for venlafaxine were reported in a recent large, multicenter trial, involving 377 outpatients with GAD without comorbid depression (101). Patients were randomly assigned to receive either placebo or venlafaxine XR at one of three doses (75, 150, or 225 mg/day) for 8 weeks. Of the 349 patients included in the efficacy analysis, those receiving 225 mg/day demonstrated significant improvement across seven of the eight outcome measures, and the 225-mg/day group was the only group to show significant improvement in scores on both of the CGI subscales (severity, global improvement) versus placebo.

Other Agents (Trazodone, Nefazodone, Anticonvulsants, Partial GABA Agonists)

In a randomized, placebo-controlled comparator trial of trazodone, diazepam, and imipramine in the treatment of 230 patients with GAD, trazodone was found to be superior to placebo yet somewhat less effective than diazepam and imipramine at the study's endpoint (84). The antidepressant nefazodone, which antagonizes the 5-HT_{2C} receptor and inhibits the reuptake of both serotonin and NE, has shown promise in the treatment of GAD in an open trial (102). Anticonvulsants such as valproate and carbamazepine have been used in the treatment of GAD; however, evidence of their efficacy is primarily anecdotal, as there are no controlled clinical trials for either of these medications in the treatment of GAD (103). Other agents such as the partial GABA agonist abecarnil have not demonstrated significant efficacy versus placebo in GAD (101).

In summary, although the benzodiazepines have been the mainstay of pharmacotherapy for GAD since their introduction, significant concerns regarding their long-term use in GAD have fueled the search for other effective treatments. Given the chronic nature of GAD, medications such as buspirone, and the antidepressants venlafaxine and paroxetine, which have fewer effects on cognitive and psychomotor function, now represent first-line therapies for GAD.

SOCIAL PHOBIA

Part of "66 - Current and Emerging Therapeutics of Anxiety and Stress Disorders "

Social phobia (SP) (or social anxiety disorder) is reported to be the most common anxiety disorder with a 1-year prevalence of 7% to 8% and a lifetime prevalence of 13% to 14% in patients aged 15 to 54 years. Social anxiety disorder can be classified into two subtypes—discrete and generalized. Level of disability with SP can be high, and 70% to 80% of patients have comorbid psychiatric disorders, particularly depression and substance abuse (104). Given the high degree of burden of illness in SP, its treatment has become a major priority.

Historical Notes

Liebowitz et al. (105) noted that SP, like atypical depression (106), had a specific responsivity to the MAOIs, whereas TCAs, although effective for PD and “typical” major depression, were not effective for SP (107). The efficacy of the MAOIs, which block reuptake of dopamine in addition to NE and serotonin, prompted speculation about a potential

“dopaminergic” component to the neurobiology of SP. Several open clinical studies have attempted to utilize the “dopamine component” concept in phamacotherapy with some success, e.g., seligiline (108) and pergolide (109). However, as data accumulated, other systems were also implicated, and the pharmacologic dissection approach seemed less applicable (see above). Positive results with the high-potency benzodiazepine clonazepam (110) suggested a GABAergic component. However, the suitability of benzodiazepines for long-term treatment of a chronic condition such as social anxiety disorder has been questioned. In addition, the benzodiazepines are ineffective against comorbid depression.

RIMAs (Reversible Inhibitor of Monoamine Oxidase A)

Although phenelzine demonstrated efficacy, the need for dietary restrictions severely limited its use. Moclobemide is a RIMA with a much lower propensity to induce hypertensive crises and has a more favorable side-effect profile. Moclobemide had been reported to have efficacy in early studies in the treatment of social phobia (111). However, conflicting results have subsequently been reported in placebo-controlled trials. Some studies have shown moclobemide to be more effective than placebo, whereas two recent, large, randomized placebo-controlled trials conducted in the United States have reported less robust results (112 ,113). Brofaromine, another drug in the RIMA class, may still hold promise. The safety and efficacy of brofaromine were examined in a multicenter trial of 102 outpatients with SP (114). Brofaromine produced a significantly greater change from baseline in Liebowitz Social Anxiety Scale (LSAS) scores compared with placebo.

SSRIs

Based on clinical evidence, SSRIs are the first-line treatment in social anxiety disorder (115). The most extensive database for the treatment of social anxiety disorder exists for the SSRI paroxetine. Several large, multicenter, placebo-controlled trials have been completed on three different continents (116 ,117 ,118 and 119). In all cited studies, a significantly greater proportion of patients responded to paroxetine treatment compared with placebo. Paroxetine is currently the only SSRI licensed for use in this condition in the United States. The SSRIs are particularly attractive agents due to their favorable tolerance and safety profile, although typical SSRI side effects may nevertheless be problematic.

Despite promising open studies with fluvoxamine, fluoxetine, and citalopram (120 ,121) only fluvoxamine has been tested under double-blind, randomized, placebo-controlled trial conditions (122). Like paroxetine, fluvoxamine yielded efficacy data superior to placebo. A report on a multicenter sertraline trial was pending at the time of this writing.

As is the case with PD, buspirone does not appear effective for SP as monotherapy in placebo-controlled double-blind studies (123). It may, however, have a role in augmentation of the SSRIs.

Serotonin/Norepinephrine Reuptake Inhibitors

One open label study (124) aimed to evaluate the clinical response to venlafaxine in SP in 12 patients who were nonresponders to SSRIs, and to assess how the response could be influenced by Axis II comorbidity with avoidant personality disorder (APD). The duration of the study was 15 weeks using an open flexible-dosing regimen in individuals with or without concomitant APD. Venlafaxine improved SP and/or APD symptomatology, as demonstrated by decreasing LSAS total scores. Similar favorable open-labeled results have been reported for nefazodone (125 ,126). Placebo-controlled studies are warranted.

Anticonvulsants

A randomized, double-blind, placebo-controlled, parallel-group study was conducted to evaluate the efficacy and safety of gabapentin in relieving the symptoms of social phobia. A significant reduction in the symptoms of social phobia was observed among patients on gabapentin compared with those on placebo as evaluated by clinician- and patient-rated scales (127). Adverse events were consistent with the known side-effect profile of gabapentin. The efficacy of other novel anticonvulsants remains to be investigated, although encouraging results have been reported for the gabapentin-like compound, pregabalin (128).

POSTTRAUMATIC STRESS DISORDER

Part of "66 - Current and Emerging Therapeutics of Anxiety and Stress Disorders "

Despite the high prevalence, chronicity, and associated comorbidity of PTSD in the community, relatively few placebo-controlled studies have evaluated the efficacy of pharmacotherapy for this disorder. The symptom overlap between PTSD and other pharmacotherapy-responsive disorders has suggested that pharmacotherapy might be effective. Nevertheless, in those placebo-controlled trials investigating the pharmacotherapy of PTSD that have been carried out, statistically significant efficacy for the treatment being studied has traditionally been inconsistent. One of the key methodologic limitations has been the fact that most studies have been conducted with war veterans, who are likely to constitute a more treatment-refractory population.

SSRIs

More recently, a total of 187 civilian outpatients with DSM-III-R PTSD (73% were women, and 61.5% experienced

physical or sexual assault) were treated with the SSRI sertraline in a placebo-controlled design (129). Sertraline effectively diminished symptoms of PTSD of moderate to marked severity in comparison to placebo. Using a conservative last-observation-carried-forward analysis, treatment with sertraline resulted in a responder rate of 53% at the study's endpoint compared with 32% for placebo (p = .008). Sertraline is the first medication approved by the FDA for the treatment of PTSD. Similar positive results have been reported for the SSRI fluoxetine in civilian populations (130 ,131). In a study by van der Kolk et al. (132), fluoxetine was found to be most effective in the nonveteran versus veteran portion of his study sample. Although published placebo-controlled data for paroxetine are not available, Marshall et al. (133) have argued that this particular SSRI may have specific advantages because of its relatively low activating properties. Direct comparative studies are lacking.

Combat Veteran PTSD

Among combat veterans, PTSD is a highly prevalent and often chronic disorder, persisting in as many as 15% of Vietnam veterans for at least 20 years (134). Treatment response in veterans with combat-related PTSD has been disappointing. Although anxiolytics, anticonvulsants, antipsychotics, and antidepressants, including SSRIs, have been tried, none has been consistently associated with improvement in all primary symptom domains (i.e., intrusive recollections, avoidance/numbing, and hyperarousal). In an open study using nefazodone, at mean daily doses of 430 mg (range, 200 to 600 mg/day), 19 treatment-refractory PTSD patients demonstrated benefit after 12 weeks (134). Double-blind placebo controlled studies would be of interest.

The efficacy of the antidepressant drug bupropion in the treatment of male combat veterans with chronic PTSD was investigated in an open-label study of 6 weeks' duration (135). Improvement was seen in hyperarousal symptoms but was less significant than the change in depressive symptoms. Mirtazapine, a novel drug with both noradrenergic and serotoninergic properties, may be effective in individuals who demonstrate intolerance to side effects of, or a limited response to, SSRIs. Three of six severely refractory PTSD patients treated with mirtazapine were assessed as responders in a pilot study (136). Case reports have suggested benefit for refractory patients treated with venlafaxine (137) and risperidone (138). Raskind et al. (139) reported that the α_1-adrenergic antagonist prazosin ameliorated combat nightmares in a small sample of veterans with PTSD.

Monoamine Oxidase Inhibitors

Traditional MAOIs have shown efficacy in the treatment of PTSD, but their use is limited by serious drug and food interactions. Moclobemide, a RIMA, is relatively free of these limitations and is therefore potentially useful in the treatment of PTSD. Moclobemide was highly effective in an open-labeled design (140). However, in a double-blind, randomized, placebo-controlled, multicenter study, brofaromine, also a RIMA, failed to surpass efficacy levels seen with placebo. Thus, the role for RIMAs remains unclear at this time.

Anticonvulsants

Despite a long-recognized role for anticonvulsants in the treatment of PTSD (141), few placebo-controlled studies have been reported. An open study of divalproex reported favorable results (142). In a placebo-controlled study, patients treated with lamotrigine showed improvement on reexperiencing and avoidance/numbing symptoms compared to placebo-treated patients (143). The authors concluded that lamotrigine may be effective as a primary psychopharmacologic treatment in both combat and civilian PTSD and could also be considered as an adjunct to antidepressant therapy used in the treatment of PTSD. Further large-sample, double-blind, placebo-controlled trials are warranted.

Summary and Future Directions

Current management of PTSD is well summarized by Davidson et al. (144). Clearly, there are many challenges associated with the treatment of PTSD. Different patients with PTSD may not respond to pharmacotherapy in the same manner, and it is unclear whether this is related to gender, trauma type, or other factors. Antidepressants, particularly the SSRIs, are currently the form of pharmacotherapy for patients with PTSD with greatest support in the literature. Psychosocial techniques, such as cognitive-behavioral therapy or stress inoculation training, are effective and may be considered as adjunctive therapy with medication. Larger placebo-controlled studies for many different classes of medications would be desirable in moving the field forward. In addition, carefully conducted polypharmacy in which drug interactions are well understood may well be necessary for more difficult cases.

In a review by Shalev and colleagues (145), a synthesis of findings in PTSD studies is provided. Most studies explored a single treatment modality (e.g., pharmacologic, behavioral). The cumulated evidence from these studies suggests that several treatment protocols reduce PTSD symptoms and improve the patient's quality of life. The magnitude of the results, however, was often limited, and remission was rarely achieved. Given the shortcoming of unidimensional treatment of PTSD, it was suggested by the authors that combining biological, psychological, and psychosocial treatment yields the best results.

A host of novel compounds show promise for the treatment of PTSD (146). Such classes of compounds include corticotropin-releasing factor antagonists, neuropeptide-Y

enhancers, antiadrenergic compounds, drugs that down-regulate glucocorticoid receptors, more specific serotoninergic agents, agents that normalize opioid function, substance P antagonists, *N*-methyl-D-aspartate facilitators, glutamatergic antagonists, and antikindling/antisensitization anticonvulsants.

CONCLUSION

Part of "66 - Current and Emerging Therapeutics of Anxiety and Stress Disorders "

Antidepressants are the logical first choice for most patients with anxiety disorders, based on their efficacy and tolerability. Although maintaining a role, the use of benzodiazepines for first-line or long-term therapy is now less likely. Does this mean that anxiety disorders are a variant of depression? Certainly, anxiety disorders and depression are highly comorbid. Untreated, the majority of patients with anxiety disorders eventually develop depression, whereas a large fraction of depressed patients suffer from clinically significant comorbid anxiety, if not an overt syndromal anxiety disorder.

Pharmacologic dissection is clearly perilous, leaving us prone to inferences based on limited knowledge. Most of the antidepressants that successfully treat anxiety disorders manipulate the reuptake of serotonin, norepinephrine, or both. Altering the brain circuits through these modulatory neurotransmitters in turn has wide-ranging effects on many other systems in the brain. The release of CRH from extrahypothalamic sites like the amygdala is only one such system. Hence, there may be a common denominator among anxiety disorders and between anxiety disorders and depression at one or more points in these complex circuits.

The observation, then, that antidepressants work for the four anxiety disorders discussed in this chapter warrants, in our opinion, only the following inference: it is highly likely that some substrate of the serotonin and norepinephrine systems is malfunctioning in several anxiety disorders and depression. This could be the locus of a common genetic or environmental vulnerability to both categories of illness. Although it will not likely tell us that anxiety and depression are fundamentally the same thing, the search for such common substrates and vulnerabilities, suggested but not guaranteed by the psychopharmacologic findings, is likely to be very illuminating.

ACKNOWLEDGMENTS

The Economic Burden of Anxiety and Stress Disorders

Ronald C. Kessler

Paul E. Greenberg

Ronald C. Kessler: Department of Health Care Policy, Harvard Medical School, Boston, Massachusetts.

Paul E. Greenberg: Analysis Group, Cambridge, Massachusetts.

No society can afford to guarantee universal health insurance coverage for treatment of all illnesses for all of its citizens. The number of illnesses is simply too large and the costs of treatment too great for such a guarantee even in the most economically advantaged societies. Resource allocation rules are consequently needed (1). The most widely accepted of these rules emphasizes cost-effectiveness. According to this rule, medical interventions are appropriate only if their expected benefits clearly exceed the sum of their direct costs and their expected risks (2).

The difficulty in implementing this decision rule is that no obvious comparability exists between the single metric in which the costs of treatment are usually defined (i.e., dollars) and the many different metrics in which the benefits of treatment can be defined (e.g., physical pain, discomfort, psychological distress, and role impairment). To create transformations across these different metrics to allow for comparisons of costs and benefits on a single metric, a number of strategies have been developed, such as assessments of willingness to pay, time trade-off, standard gamble, and other utility or quasi-utility measures (3). In addition, a special interest has evolved in the indirect economic costs of illness and the benefits of treatment in terms of sickness absence and disability from work. The costs of these role impairments can be more easily assessed than the costs of other adverse effects of illness and represent the cost-benefit trade-off to purchasers of employer-sponsored health insurance plans (4).

The most ambitious effort to date to evaluate the costs of illness in terms of role impairments and disabilities is the World Health Organization (WHO) Global Burden of Disease (GBD) Study, an initiative designed to generate a rank ordering of the diseases that create the greatest societal burdens in terms of impairment and disability (5). The overarching goal of GBD is to help health policy planners prioritize disorder-specific resource allocation decisions. GBD focuses on economic costs of illness using a metric known as the disability-adjusted life year (DALY) (6), a weighted composite that combines expected years of lost life with expected years of decreased functioning due to a particular disease (or constellation of comorbid diseases).

The first generation of GBD estimates suggest that mental disorders, as a group, are the most costly diseases in the world and that major depression, in particular, is the single most costly disease among people in the middle years of life in terms of overall DALYs (5). Although the GBD rated mood disorders as considerably more costly than anxiety or stress disorders, focused cost-of-illness studies carried out subsequent to the publication of these estimates strongly suggest that the GBD underestimated the costs of anxiety and stress disorders and that the true costs of anxiety disorders are actually quite comparable to the costs of mood disorders (7 ,8).

Three reasons for the underestimation of the costs of anxiety and stress disorders in the GBD are worthy of note. The evidence to support all three of them is reviewed in this chapter. First, the epidemiologic studies used in GBD underestimated the prevalences of anxiety disorders. Second, the estimated effects of specific diseases on functioning were based on the judgments of experts rather than on objective evaluations of actual impairments in representative samples of people with the diseases. These judgments underestimated the impairments due to anxiety disorders. Third, comorbidities were ignored in making GBD cost estimates. As shown below, a consideration of comorbidities is critical in assessing the costs of anxiety disorders.

This chapter reviews available evidence on the economic burdens of anxiety and stress disorders. By focusing on eight factors that lead to the high societal costs of these disorders, we present evidence on the three sources of GBD underestimation listed above. These eight factors are as follows. First, anxiety and stress disorders are among the most commonly occurring of all chronic diseases. Second, the prevalences of

these disorders are increasing in recent cohorts in many countries. Third, these disorders have much earlier ages of onset than other commonly occurring chronic conditions. Fourth, anxiety and stress disorders are usually very chronic. Fifth, early-onset anxiety and stress disorders have a wide range of adverse effects on secondary outcomes, such as teen childbearing, marital stability, and educational attainment that have substantial economic implications. Sixth, these disorders are often associated with substantial impairments in role functioning. Seventh, anxiety and stress disorders are highly comorbid and usually temporally primary. Some of the disorders that are temporally secondary to anxiety and stress disorders, such as ulcers and substance abuse, have adverse economic effects that should be considered in part among the costs of anxiety and stress disorders. Eighth, despite the fact that effective treatments are available, only a minority of people with anxiety and stress disorders receives these treatments. Furthermore, those who receive these treatments usually do so only after many of the adverse effects of the disorders have occurred, making it very difficult to reverse the economic impacts of having had the disorders even with successful treatments. Based on all these factors, anxiety and stress disorders have to be considered among the most costly of all chronic physical and mental disorders.

PREVALENCES

Part of "67 - The Economic Burden of Anxiety and Stress Disorders "

A new generation of psychiatric epidemiologic surveys, which began with the Epidemiologic Catchment Area (ECA) Study in the early 1980s (9), has dramatically increased our knowledge about the general population prevalences and correlates of anxiety disorders. The ECA Study was the first psychiatric epidemiologic study to use a fully structured research diagnostic interview designed specifically for use by lay interviewers to operationalize the criteria of a wide range of mental disorders. This interview, known as the Diagnostic Interview Schedule (DIS) (10), was used throughout the 1980s and early 1990s to carry out parallel epidemiologic surveys in a number of countries (11 ,12). The DIS was also used as the basis for an elaborated interview developed by the WHO and known as the Composite International Diagnostic Interview (CIDI) (13). The CIDI was designed to generate diagnoses according to the definitions and criteria of both the International Classification of Diseases (ICD) and *Diagnostic and Statistical Manual of Mental Disorders* (DSM) systems. WHO auspices resulted in over a dozen large-scale, general-population CIDI surveys being carried out around the world over the past decade. Comparative analysis of these data has been facilitated by the creation of the WHO International Consortium in Psychiatric Epidemiology (ICPE) (14), which is currently coordinating national CIDI surveys in 25 countries around the world, with a combined sample size of over 150,000 respondents, as part of the WHO World Mental Health 2000 (WMH2000) Initiative (15).

The DIS and CIDI surveys show that anxiety and stress disorders are the most commonly occurring of all mental disorders. Clear illustration can be found in a recent report based on the results of six CIDI surveys carried out in Latin America, North America, and Europe (16). These surveys found that the lifetime prevalences of DSM third edition revised (III-R) anxiety disorders were as high as 25%, whereas prevalences in the year before the survey were as high as 17%. These prevalences were higher than those of any other class of mental disorders in the vast majority of the surveys. (The exceptions were a survey of adolescents in Germany and of residents of a large catchment area in Mexico City. In both of these surveys, substance use disorders were more common than anxiety disorders in the 12 months before the interview.)

It was noted above that the epidemiologic data available to the GBD researchers, which came from the DIS surveys carried out in the 1980s, underestimated the prevalence of anxiety and stress disorders. Three of the most prevalent and seriously impairing anxiety disorders were involved in this underestimation: generalized anxiety disorder (GAD), social phobia, and posttraumatic stress disorder (PTSD). The reasons for the underestimations differ from one of these disorders to the next. In the case of GAD, prevalence was underestimated in the early DIS surveys due to the fact that the excessively unrealistic criterion in the DSM-III was operationalized by requiring that respondents endorse a statement that they worried about things that were not really serious or about things that were not likely to happen. This requirement is overly restrictive in two ways. First, there is no requirement in DSM that people with GAD have insight into their worries being excessive or unrealistic. Although they must be aware that they worry more than other people do, they can perceive others as worrying too little rather than themselves as worrying too much. Second, even in the presence of a recognition that their worrying is excessive, there is no requirement in DSM that the worries of people with GAD must be exclusively focused on things that are not important or unlikely to happen. Indeed, the heterogeneous worries that are characteristic of most people with GAD (e.g., excessive concerns about job stability, how the children are going to turn out, neighborhood safety, global warming, etc.) often focus on serious matters that have nontrivial probabilities of occurring.

The restrictive assessment in the DIS led to the estimate that only about 3% of the population meet criteria for GAD at any time in their lives (17). Early CIDI surveys followed this same method of assessment and yielded similar prevalence estimates (18 ,19). Subsequent CIDI surveys expanded the assessment of excessive worry in GAD by asking respondents if there was ever a time in their lives when they were worriers or when they worried a lot more than most other people in their same situation, without requiring that

the worry be exclusively about things that are not serious or not likely to happen. Prevalence estimates were found to be considerably higher when this modification was introduced (20).

In addition, these new studies investigated the implications of the requirements in the DSM-IV and ICD-10 that the worry in GAD persists for a minimum of 6 months and found that this requirement might be too restrictive. In particular, many people with chronic excessive worry report having fairly short episodes, each of which lasts for several weeks or months, that continue in a chronic intermittent course for many years. Such individuals are currently excluded from a diagnosis of GAD and, because of their high comorbidity with depression, are classified as being depressed even though their most prominent symptoms are often associated with anxiety rather than depression. The new WHO WMH2000 Initiative is investigating this matter in some detail in an effort to evaluate whether the classification rules for GAD or mixed anxiety-depression should be modified to take these cases into consideration.

In the case of social phobia, the underestimation in the early DIS surveys was due to the fact that all phobias were assessed in a single question that presented respondents with a long checklist of feared situations and asked them if they ever had unreasonably strong fears of these situations. In addition to being mixed in with a number of specific fears, only five social phobic situations, all involving performance fears, were included in the ECA list.

This method of assessment led to the estimate that only 2.7% of the population meet criteria for social phobia at any time in their lives (21). Subsequent surveys that used the CIDI corrected this problem by screening for social phobia with a separate, longer list of social fears (both interactional and performance). These later surveys consistently found social phobia to be much higher than in the DIS surveys, with lifetime prevalences as high as 13% (18) and current prevalences as high as 8% (22).

Posttraumatic stress disorder was also wildly underestimated in the early DIS surveys. This seems to have been a result of including only a single extremely long and complex screening question for PTSD in the first version of the DIS. This question began with a statement that many people live through events that are outside the range of usual human experience, such as combat in a war or sexual assault, and that people who experience these events often have bad emotional reactions such as nightmares, flashbacks, and changes in mood. Respondents were then asked if they ever had such an event that caused such reactions and, if so, to tell the interviewer what this event was. Subsequent debriefing showed that this question was too complex for many respondents, that the absence of a detailed event list interfered with effective memory search, and that the requirement that the respondent describe the event out loud rather than give a yes or no response to event-specific questions led to underreporting of embarrassing events (23).

Assessments of PTSD in epidemiologic surveys that used the DIS led to the estimate that only about 1% of the United States population meet criteria for this disorder at any time in their life (24 ,25 and 26). Subsequent surveys that used the CIDI modified the assessment of PTSD by including a detailed traumatic event checklist and by asking respondents to give separate yes or no reports for whether each of these events ever occurred to them. In some CIDI surveys, a visual checklist was used that aimed at making it easier for respondents to report embarrassing events (e.g., “Did event number five on the list ever occur to you?” rather than “Were you ever raped?”). CIDI PTSD symptom assessment proceeded very much along the same lines as the DIS after documenting that trauma exposure had occurred. Yet the prevalence estimates obtained in the CIDI surveys were dramatically higher than in the DIS surveys, with lifetime prevalences as high as 12.2% (23 ,27).

It should also be noted that psychiatric epidemiologic surveys have not, up to now, attempted to assess either DSM acute stress disorder (a short-term disorder that occurs in reaction to traumatic stress) or adjustment disorder (a disorder that occurs in reaction to nontraumatic stress). This is important because epidemiologic surveys that include assessments of current nonspecific psychological distress typically find that a high proportion of the respondents who report clinically significant current distress in the anxiety-mood spectrum do not meet criteria for any of the anxiety or mood disorders typically assessed in these surveys (which usually include GAD, panic disorder, phobia, PTSD, obsessive-compulsive disorder, major depression, dysthymia, and mania). Given the extremely high prevalences of exposure to stressful events found in surveys of stress exposure (28), it is plausible to think that many of these people have a diagnosis of either acute stress disorder or adjustment disorder. The new WHO WMH2000 surveys mentioned earlier in this chapter are investigating this possibility by evaluating the link between stress and clinically significant nonspecific psychological distress among respondents who do not meet criteria for other anxiety or mood disorders.

Taken together, these results suggest that the combined prevalences of all anxiety and stress disorders make these among the most commonly occurring classes of seriously impairing chronic conditions. A rough comparison is provided by the recently completed Midlife Development in the U.S. (MIDUS) survey carried out by the John D. and Catherine T. MacArthur Foundation. In this survey, parallel assessments were made of commonly occurring physical and mental disorders, along with assessments of the effects of these disorders on day-to-day functioning (29). As in most other health surveys of

chronic physical conditions, of which a great many exist (e.g., 30,31), the significantly impairing physical disorders with the highest reported prevalences in the year before interview were back problems (20.3%), arthritis (19.4%), hypertension (18.2%), and seasonal allergies (15.7%). However, past health surveys of chronic physical conditions have seldom assessed emotional disorders along with these physical disorders. In doing so, the MIDUS survey found that 16.4% of respondents reported an anxiety or stress disorder exclusive of either major or minor depression, and that an additional 14.1% of respondents reported major or minor depression. These findings make anxiety-stress the fourth most commonly occurring impairing class of chronic disorders in the general population and major or minor depression the sixth most commonly occurring class of such disorders.

COHORT EFFECTS

Part of "67 - The Economic Burden of Anxiety and Stress Disorders "

In addition to anxiety and stress disorders having great importance because they are very common, they are also becoming increasingly prevalent over time. An illustration of this finding is presented in Table 67.1 , taken from ICPE surveys carried out in six countries (16). These results are based on synthetic cohort analyses using retrospective age-at-onset reports to evaluate intercohort differences in lifetime risk of anxiety disorders over a period of four decades. The data are clear in showing that the relative odds of having an anxiety disorder have steadily increased over this period in all six countries.

TABLE 67.1. THE EFFECTS (ODDS RATIOS) OF COHORT IN PREDICTING LIFETIME ANXIETY DISORDERS IN SIX COUNTRIES [a]

	Age Group				
	18–24	25–34	35–44	45–54	χ^2_3
Brazil	3.3*	3.1*	1.8*	1.0	64.4*
Canada	1.9*	1.7*	1.4*	1.0	20.7*
Mexico	2.1	2.0	2.0	1.0	2.3
Netherlands	2.2*	1.8*	1.5*	1.0	88.4*
Turkey	1.8*	1.7*	1.3	1.0	18.0*
United States	1.8*	1.4	1.1	1.0	27.9*

More detailed analyses of these and other data show that the increased prevalences of anxiety disorders are more pronounced than the increased prevalences of other mental disorders and that the apparent cohort effects for some other disorders, such as major depression, are largely due to increases in secondary disorders associated with primary anxiety (32). Furthermore, the increasing prevalences within the anxiety disorders have been found to be especially pronounced for GAD, generalized social phobia, and PTSD. Increases for panic, specific phobia, agoraphobia, and obsessive-compulsive disorder, in comparison, have been more modest. Although these studies have not investigated either acute stress disorder or adjustment disorder, separate evidence of secular increases in exposure to traumatic stress is consistent with the likelihood that the prevalences of these disorders have also been on the rise (33).

AGE AT ONSET

Part of "67 - The Economic Burden of Anxiety and Stress Disorders "

The discussion up to now has not clearly distinguished between lifetime and recent prevalences. This is an important distinction because the societal burden of a disorder is largely associated with its prevalence at a point in time. The latter, in turn, is a complex function of lifetime prevalence, age at onset, and chronicity. The comparatively high recent prevalence of anxiety-stress disorders found in the MIDUS survey indicates that the combined effects of these three components are strong. This is true, in part, because anxiety and stress disorders occur to a high proportion of the population at some point in the course of life. It is also true because these disorders have comparatively early ages at onset and high rates of chronicity. We focus first on age at onset.

Retrospective reports about age at onset are routinely collected in epidemiologic surveys and used to estimate synthetic onset distributions. Figure 67.1 presents Kaplan-Meier curves that show these onset distributions for any anxiety disorders in six countries the ICPE surveyed (16). The median age at onset of anxiety disorders in these surveys is less than 15 years of age. The only commonly occurring chronic physical disorder that has a similar age-at-onset distribution is hay fever. All other commonly occurring chronic physical disorders that have been shown to have an effect on role functioning have median ages at onset that occur much later, in some cases decades later, than anxiety disorders. Other mental disorders, including depression, substance use disorders, oppositional-defiant disorder, conduct disorder, and attention-deficit hyperactivity disorder, also have comparatively early ages at onset, although anxiety disorders are the temporally primary disorders in the vast majority of people with a lifetime history of any mental disorder (34). No information is available, in comparison, on age at onset of acute stress disorders or adjustment disorders.

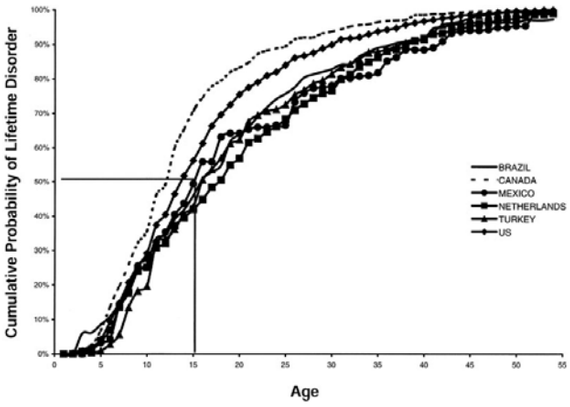

FIGURE 67.1. Age-at-onset distributions for any anxiety disorders in six countries. (Modified from WHO ICPE. Cross-national comparisons of the prevalences and correlates of mental disorders: an ICPE study. *Bull WHO* 2000;78:418, with permission.)

CHRONICITY

Part of "67 - The Economic Burden of Anxiety and Stress Disorders "

Although psychiatric epidemiologic surveys typically are cross-sectional, making it impossible to track illness course, indirect assessments of chronicity in these surveys have been carried out by comparing the ratios of current prevalence

to lifetime prevalence in subsamples of respondents with specific lifetime mental disorders. Results clearly suggest that anxiety disorders are the most chronic of all mental disorders (35). This indirect evidence is consistent with the results of longitudinal studies carried out in clinical samples, which uniformly show that anxiety disorders are typically very chronic (36 ,37 and 38). It is noteworthy that this high chronicity is not greater than that found among a number of impairing physical disorders, such as arthritis, asthma, and diabetes. However, the combined occurrence of high lifetime prevalence with early age at onset and high chronicity makes anxiety disorders unique. The one chronic physical disorder with comparable lifetime prevalence and early onset, hay fever, is active for only a few weeks each year. No systematic data exist on the chronicity of adjustment disorders, although epidemiologic data showing that PTSD is often a very persistent disorder (23 ,39) are consistent with the possibility that the same may be true for adjustment disorders.

ADVERSE EFFECTS ON SECONDARY OUTCOMES

Part of "67 - The Economic Burden of Anxiety and Stress Disorders "

Virtually all cost-of-illness studies focus on the effects of prevalent disorders on current role functioning, taking current roles as givens. The question implicitly addressed by these studies is whether it is in the financial interests of employers to invest in employee health care. Would the increased direct costs of treatment be offset by decreased indirect costs in such things as sickness absence, poor work performance, and accidents? This important question is discussed below. However, even when the focus is on narrow financial costs, the preceding is not the only question of importance in evaluating the societal costs of illness. Equally, if not more, important from a societal perspective is the question of whether the human capital potential of the individual is adversely affected by illness. Specifically, what difference does the existence of a particular chronic condition make to the individual's lifetime profile of productivity?

There is good evidence that anxiety disorders have long-term effects of this sort that are not captured in analyses of current role functioning. Both vital statistics (see Table 292A, Trend C in ref. 40) and prospective epidemiologic surveys (41) show that anxiety is associated with elevated risk of early death. Epidemiologic data also show that anxiety is associated with elevated risk of subsequent unemployment (42 ,43).

Clinical experience also suggests that anxiety is associated with more subtle decrements in role performance. It is common for patients with chronic GAD or PTSD, for example,

to work at low-paying jobs because they are unable to cope with the stresses of higher paying jobs. This would be considered a cost of illness from the societal perspective, but not from the perspective of the employer. Very little scientific evidence exists regarding opportunity costs of this sort. The most sustained examination of these costs was carried out in a series of reports from the National Comorbidity Survey (NCS) in which retrospective reports about the ages at onset of individual mental disorders were used to define time-varying predictors of subsequent transitions in educational attainment (44), teen childbearing (45), marital timing and stability (46), and earnings (42 ,43). The results clearly show that mental disorders, in general, and anxiety disorders, in particular, are associated with significantly elevated risks of several different life course events that have important adverse financial implications. In terms of standardized (for sociodemographics) odds ratios, NCS respondents with some early-onset anxiety disorders had 40% elevated odds of high school and college failure, 30% elevated odds of teenage childbearing, 60% elevated odds of marital instability, and 150% elevated odds of current unemployment at the time of interview.

It is important to recognize that this constellation of adverse individual life course consequences—especially school failure coupled with teen childbearing and marital instability—makes up the core components of welfare dependency. The costs of public assistance to single mothers with dependent children are paid by all taxpayers rather than by the welfare recipients themselves. For this reason, the component of welfare dependency costs explained by early-onset anxiety disorders should be considered a societal cost of anxiety. A number of innovative welfare-to-work programs are currently being carried out in response to welfare reform legislation in the United States (e.g., 47,48). Interestingly, early reports on these programs suggest that their success hinges on the mental health of welfare recipients (49).

EFFECTS ON CURRENT ROLE FUNCTIONING

Part of "67 - The Economic Burden of Anxiety and Stress Disorders "

As noted in the previous subsection, a number of cost-of-illness studies have evaluated the effects of chronic conditions on work role functioning. Most of these studies focus on physical disorders (e.g., 31). Most of those concerned with mental disorders focus on depression (e.g., 50). A small number of recent studies examined the effects of anxiety disorders on work functioning and found that these effects are quite substantial. These findings are an important element in the argument that anxiety disorders are among the most costly of all chronic conditions.

One of these studies, based on the NCS, examined the effects of individual mental disorders on work loss (missing a full day of work) and work cutback (either missing part of a day or working less efficiently than usual) during the month prior to the interview (51). Each of the six anxiety disorders evaluated in that study (GAD, panic disorder, specific phobia, social phobia, agoraphobia, and PTSD) had significant effects on work-cutback days, from a high of 4.9 days per month associated with PTSD to a low of 1.1 associated with social phobia. None of the six was significantly associated with work-loss days, implying that anxiety influences work largely by affecting the quality of performance on days at work rather than by reducing the amount of time spent at work.

The MIDUS survey yielded information that is even more interesting because it assessed both mental and physical disorders. Gross bivariate analyses showed that two mental disorders, both anxiety disorders, were among the top five of all chronic conditions in terms of average per capita number of past month work impairment days. These top five included GAD (6.0 work impairment days per month), thyroid disease (5.8 days), tuberculosis (5.4 days), varicose veins (5.4 days), and panic disorder (5.3 days). Furthermore, multivariate analyses controlling for age, gender, and other sociodemographic factors found that the same two anxiety disorders were among the top six in terms of unique effects on work impairment (29). Calculating the salary-equivalent magnitude of these effects, using self-reported salaries and partialing out the effects of other comorbid mental and physical disorders, led to the estimate that the excess absenteeism and lost productivity directly associated with anxiety disorders is approximately $4.1 billion per year in the United States (8).

PSYCHIATRIC COMORBIDITY

Part of "67 - The Economic Burden of Anxiety and Stress Disorders "

A number of studies in both treatment samples (52) and general population samples (35) document high rates of psychiatric comorbidity among people with anxiety disorders. Illustrative results from the NCS are reported in Table 67.2 . Shown here are odds ratios between anxiety disorders and other mental disorders both for lifetime comorbidities and for comorbidities of disorders that were active in the 6 months prior to the interview. As the latter odds ratios are generally larger than the former, there must be comorbidities between the persistence of anxiety disorders and the persistence of other disorders.

TABLE 67.2. COMORBIDITIES (ODDS RATIOS) BETWEEN DSM-III-R ANXIETY DISORDERS AND OTHER MENTAL DISORDERS ASSESSED IN THE NATIONAL COMORBIDITY SURVEY

	Panic Disorder	Phobias	GAD	PTSD
Lifetime comorbidities				
Major depression	6.6	4.1	9.4	5.2
Dysthymia	4.8	3.0	12.5	4.9
Mania	10.4	7.9	9.6	6.2
Alcohol abuse/dependence	1.6	1.7	2.0	1.7
Drug abuse/dependence	3.0	2.2	2.9	3.2
Nonaffective psychosis	20.1	4.7	15.0	9.4
Six-month comorbidities				
Major depression	14.4	6.4	17.8	7.1
Dysthymia	12.2	4.4	21.5	7.4
Mania	15.8	13.4	10.4	9.4
Alcohol abuse/dependence	1.4	2.3	2.7	2.2
Drug abuse/dependence	3.9	3.9	5.0	2.9
Nonaffective psychosis[a]	—	—	—	—

All values on table are significant at the .05 level, two-sided test.
DSM-III-R, *Diagnostic and Statistical Manual of Mental Disorders*, third edition–revised; GAD, generalized anxiety disorder; PTSD, posttraumatic stress disorder.
[a]Diagnostic hierarchy rules were suppressed in defining the disorders. Six-month nonaffective psychosis (NAP) was too rare to calculate odds-ratios with any of the anxiety disorders.
From Tsuang MT, Tohen M, Zahner GEP, eds. *Textbook in psychiatric epidemiology*. New York: Wiley, 1995:181, 183, with permission.

Several different possible explanations exist for these comorbidities. One is that prior history of other mental disorders might be associated, either as a risk factor or as a marker, with risk of the subsequent onset and persistence of anxiety disorders. The other is that anxiety disorders might be associated with the subsequent onset and persistence of other mental disorders. As briefly mentioned above, epidemiologic studies have found that the latter possibility is more consistent with the data. Comorbid anxiety disorders

are usually temporally primary to other comorbid mental disorders (34). In addition, survival analyses show that temporally primary anxiety disorders are powerful predictors of the subsequent onset and course of other mental disorders (35). In addition, panic disorder (53) and PTSD (54) are powerful predictors of suicidal behaviors.

It is not clear from these results that anxiety disorders are causal. Another possibility is that anxiety disorders are early outcomes of other causal factors, either environmental or genetic, that cause both anxiety disorders and the other mental disorders with which anxiety disorders are comorbid. To the extent that anxiety disorders are causal, the adverse effects of mental disorders that are secondary to anxiety disorders should be counted among the adverse consequences of anxiety disorders. A good case in point is secondary substance use disorders. Epidemiologic data show that early-onset anxiety disorders are significant predictors of subsequent substance use disorders, most likely mediated by self-medication (55). If these associations are causal, simulations suggest that the early intervention and successful treatment of anxiety disorders would prevent as many as one-fourth of all substance use disorders in the U.S. (56). The component of the costs of substance use disorders due to prior anxiety disorders, therefore, should be counted among the costs of anxiety in a comprehensive evaluation.

Whether anxiety disorders are causal and to what extent is an especially important issue in the case of depression, as many comparative cost-of-illness studies, including the WHO GBD study, suggest that depression is the most costly of all mental disorders (5). Yet epidemiologic data show that close to half of all cases of depression are secondary to one or more preexisting anxiety disorders (57). This priority of anxiety over depression is never taken into consideration in evaluating the costs of depression. Indeed, in those few instances where anxiety-depression comorbidity is considered, diagnostic hierarchy rules typically specify that the depression should be considered primary even though epidemiologic evidence consistently shows that anxiety is usually temporally primary.

The rationale for this hierarchy of depression over anxiety is usually that the impairments associated with such cases is thought to be due to the depression rather than to the anxiety (58), but available evidence argues against this claim. A good case in point involves comorbidity between GAD and depression. The results in Table 67.3 , taken from two U.S. national surveys, the NCS and the MIDUS, show that GAD without major depression is as important as major depression without GAD in leading to impairments in role functioning (20). Further analysis of these data showed that impairment is considerably higher among people with comorbid GAD and major depression than those with either GAD alone or major depression alone. Coupling the fact that GAD is temporally primary in the majority of these cases with the fact that GAD without major depression is associated with impairments equal to those of major depression

without GAD, argues that this interactive effect is due at least as much to GAD as to major depression.

	GAD Without Major Depression (MD)		Major Depression (MD) Without GAD		GAD Without MD vs. MD Without GAD	
	Survey 1	Survey 2	Survey 1	Survey 2	Survey 1	Survey 2
Fair/poor perceived mental health	6.0*	4.8*	3.3*	5.2*	1.6	0.8
High work impairment	3.5	3.5	3.5*	8.5*	0.9	0.5
High social impairment	2.5*	1.2	2.0*	1.6*	1.5	1.0

[a]The two surveys indicated here are the National Comorbidity Survey (Survey 1) (59) and the Midlife Development in the U.S. Survey (Survey 2) (19). Results are based on separate regression equations evaluating the effect of either GAD or MD in predicting one of the impairment measures in one of the samples controlling for sociodemographic variables (age, gender, education, race-ethnicity, employment status, marital status, and urbanicity) and other 12-month DSM-III-R disorders. Models in the first two columns evaluate the effect of 12-month GAD on the subsample of respondents who did not have 12-month major depression. Models in the middle two columns evaluate the effect of 12-month major depression on the subsample of respondents who did not have 12-month GAD. Models in the last two columns evaluate the relative impairments of GAD without MD versus MD without GAD in analyses that are confined to respondents in those two subsamples.
*Significant at the .05 level, two-sided test.

TABLE 67.3. THE EFFECTS (ODDS RATIOS) OF 12-MONTH GENERALIZED ANXIETY DISORDER (GAD) WITHOUT MAJOR DEPRESSION (MD) AND MAJOR DEPRESSION WITHOUT GAD IN PREDICTING IMPAIRMENTS IN TWO U.S. NATIONAL SURVEYS, CONTROLLING FOR SOCIODEMOGRAPHICS AND OTHER 12-MONTH DSM-III-R DISORDERS[a]

PHYSICAL COMORBIDITY

Part of "67 - The Economic Burden of Anxiety and Stress Disorders "

Although it has not been as extensively studied, evidence from clinical samples suggests that anxiety disorders have significant comorbidities with certain chronic physical disorders (60 ,61). Table 67.4 presents nationally representative general population data on some of these comorbidities. The results are odds ratios for the relationships between the 12-month prevalences of the DSM-III-R anxiety disorders assessed in the NCS and selected physical disorders assessed in the NCS chronic conditions checklist. As shown in the table, all but one of the odds ratios are greater than 1.0, indicating a positive relationship, and half are statistically significant at the .05 level.

	GAD	Panic Disorder	Simple Phobia	Social Phobia	Agoraphobia	PTSD
Arthritis	1.7	2.1*	1.4	1.2	1.5	2.0*
Asthma	1.9	2.1*	2.0*	1.4	1.2	1.7*
Hypertension	1.5	2.2*	1.5*	1.0	2.2*	1.6
Kidney/liver disease	2.0	1.4	3.5*	1.2	2.3	1.9
Ulcer	3.1*	2.7*	2.7*	2.7*	2.9*	2.0*

*Significant at the .05 level, two-sided test.

TABLE 67.4. COMORBIDITIES (ODDS RATIOS) BETWEEN 12-MONTH PREVALENCES OF DSM-III-R ANXIETY DISORDERS AND CHRONIC PHYSICAL DISORDERS IN THE NATIONAL COMORBIDITY SURVEY

The NCS did not obtain information about age at onset for these physical disorders, making it impossible to examine whether anxiety disorders are temporally primary. In some cases, such as the strong association of some anxiety disorders

with ulcers, the most plausible interpretation is that anxiety had a causal impact on the subsequent onset of the physical condition. In other cases, it is equally plausible that the physical condition helped promote the subsequent onset of anxiety. It is also possible that bidirectional causal influences were at work or that common causes led to both conditions. The eventual resolution of this uncertainty is important for an evaluation of the costs of anxiety disorders, as both the direct treatment costs and the indirect costs of physical disorders that are partly caused by anxiety should be included in evaluating the overall societal costs of anxiety.

Comorbidities of anxiety with physical disorders are also important because of evidence that anxiety disorders reduce the quality of life of patients with physical disorders (62) and complicate the expression and course of physical disease (63). The most plausible explanation for these findings is that anxiety heightens sensitivity about both physical signs and symptoms and adequacy of treatment. This possibility is consistent with the finding that adjunctive treatments for comorbid anxiety often increase adherence to physical disorder treatment regimens (64).

MENTAL HEALTH TREATMENT

Part of "67 - The Economic Burden of Anxiety and Stress Disorders "

Effective psychological (65) and pharmacologic (66) therapies exist for the treatment of most anxiety disorders. The indirect costs of anxiety disorders would consequently be expected to decline if a high proportion of people with these disorders sought treatment. However, a substantial part of the adverse effects of anxiety disorders are associated with secondary effects that occur early in life (e.g., teen childbearing, school failure), so it is important that treatment occur early in the course of the anxiety disorder. As anxiety disorders have early ages of onset, initial treatment must occur during childhood or adolescence to be maximally effective in preventing adverse effects.

We are aware of only two epidemiologic studies that investigated speed of initial treatment contact after first onset of anxiety disorders (67 ,68). These studies considered three anxiety disorders: GAD, panic disorder, and phobias. Both studies found that only a small proportion of people with childhood-onset or adolescent-onset anxiety disorders seek treatment prior to adulthood. Median delays between first onset and initial treatment contact were found to be more than a decade for some anxiety disorders. Furthermore, delays were found to be inversely related to age at onset.

Because of these delays, only a minority of people with active anxiety disorders receives treatment in a given year. This is shown clearly in Table 67.5 , which presents nationally representative U.S. data from the NCS on seeking professional help for DSM-III-R anxiety disorders during the 12 months prior to the survey. Only about one out of every four people with an anxiety disorder sought any type of treatment and only 13.3% received any type of mental health specialty treatment during this year.

	Help-Seeking in Health Care Sectors[a]						Help-Seeking in Other Sectors[a]					
	General Medical		Specialty Mental Disorders		Any		Human Services		Self-Help		Any Help-Seeking[a]	
Disorder	%	(SE)	%	(SE)	%	(SE)	%	(SE)	%	(SE)	%	(SE)
Generalized anxiety disorder	18.6	(3.8)	19.8	(3.5)	31.8	(4.8)	10.8	(2.1)	11.0	(3.0)	38.7	(4.3)
Panic disorder	21.5	(5.1)	24.3	(4.4)	35.2	(5.6)	21.0	(4.2)	12.5	(4.1)	46.4	(6.6)

TABLE 67.5. 12-MONTH PREVALENCE OF PROFESSIONAL HELP-SEEKING IN SEPARATE SERVICE SECTORS IN THE NATIONAL COMORBIDITY SURVEY, BY 12-MONTH DSM-III-R ANXIETY DISORDER

INAPPROPRIATE USE OF GENERAL MEDICAL SERVICES

Part of "67 - The Economic Burden of Anxiety and Stress Disorders "

Although anxiety disorders typically are not treated, it is a great irony that people with anxiety disorders are often high

utilizers of primary care services. Indeed, people with untreated anxiety disorders make up a large proportion of the people who overuse primary care for only vaguely defined physical complaints (69 ,70). A recent anxiety disorders cost-of-illness study estimated that unnecessary medical care costs represented the largest single component of the cost of anxiety disorders in the U.S., equal to $23 billion per year (8). There is good reason to believe that aggressive screening and outreach efforts in primary care could detect these people with untreated anxiety, channel them into appropriate treatment, and possibly have a major offset effect in reducing unnecessary primary care costs. Interventions to evaluate the magnitude of this offset effect are currently under way.

OVERALL COSTS

Part of "67 - The Economic Burden of Anxiety and Stress Disorders "

There have been two recent attempts to estimate the total annual cost of anxiety disorders in the U.S. The first, carried out by DuPont et al. (7) in 1996, estimated that the annual cost of anxiety disorders is $47 billion, whereas the second, carried out by Greenberg et al. (8) in 1999, estimated that this cost is $42 billion. These estimates are quite comparable to the annual cost of depression, which has been estimated to be between $44 billion (71) and $53 billion (72). The rough equivalence to the cost of depression is important because, as noted in the introduction, depression is generally considered the most costly of all physical or mental disorders among people in the early to middle years of life (5).

The true societal costs of anxiety disorders, however, are actually a great deal larger than these estimates suggest, as the estimates were based only on a limited set of cost components. The components included direct psychiatric treatment costs, unnecessary medical treatment costs, work performance costs in terms of sickness absence and work-cutback days, and mortality costs (evaluated as lost earnings potential). The major excluded costs were long-term opportunity costs (i.e., excess unemployment and underemployment) and costs associated with comorbidity. The first of these two excluded costs is likely to be in excess of $2,000 per year for each person with a lifetime history of anxiety disorder (42), which is equivalent to an annual cost of more than $100 billion in the total U.S. population. The second of the excluded costs is impossible to calculate with currently available data, but would have to include substantial components of the costs conventionally attributed to depression, alcohol, and drug abuse, and the many other mental and physical disorders with lifetime prevalences and courses that are influenced by the prior existence of anxiety disorders.

DISCUSSION

Part of "67 - The Economic Burden of Anxiety and Stress Disorders "

Anxiety disorders are unique among all chronic conditions, both physical and mental, in having a combination of very high prevalence, early age at onset, high chronicity, and substantial role impairment. Although our knowledge about the comparative costs of different illnesses is too primitive to make precise comparisons, this conjunction of factors arguably makes anxiety disorders one of the most costly classes of illness in existence. Increased treatment is the key to reducing these costs. Although an increase in treatment will add to direct costs, the fact that available treatments are effective and that the adverse effects of anxiety are chronic means that the costs of effective treatment can be amortized over many years.

The fact that most anxiety disorders have childhood or adolescent onsets means that early outreach and treatment could be carried out in collaboration with schools. Unfortunately, as most people with anxiety delay initial contact with the treatment system for many years and usually present for treatment only after the onset of secondary comorbid disorders, little is known about the long-term effects of early treatment of pure childhood and adolescent anxiety disorders. Demonstration projects and long-term follow-up studies are needed to evaluate these effects and to target opportunities for incremental cost-effectiveness associated with refinements in diagnosis and treatment. Although the outcomes of such studies are uncertain, it is difficult to think of another disorder where an investment in early intervention has as great a potential for long-term societal benefits.

Mechanism of Action of Anxiolytics

John F. Tallman

James Cassella

John Kehne

John F. Tallman, James Cassella, and John Kehne: Neurogen Corporation, Branford, Connecticut.

Drugs to reduce anxiety have been used by human beings for thousands of years. One of the first anxiolytics and one that continues to be used by humans is ethanol. A detailed description of ethanol's action may be found in Chapter 100 . A number of other drugs including the barbiturates and the carbamates (meprobamate) were used in the first half of the 20th century and some continue to be used today. This chapter focuses on current drugs that are used for the treatment of anxiety and approaches that are currently under investigation.

CORTICOTROPIN-RELEASING FACTOR (CRF)

Part of "68 - Mechanism of Action of Anxiolytics "

Corticotropin-releasing factor (CRF) is a 41 amino acid peptide that plays an important role in mediating the body's physiologic and behavioral responses to stress (1). Figure 68.1 illustrates that this role of CRF may be mediated by multiple sites of action. As a secretagogue, CRF stimulates the release of adrenocorticotropic hormone (ACTH) from the pituitary. In addition, CRF plays a neurotransmitter or neuromodulatory role through neurons and receptors distributed in diverse brain regions (2). CRF neurons, localized in the hypothalamic periventricular nucleus, are a major mediator of stress-induced activation of the hypothalamic-pituitary-adrenal (HPA) axis, whereas pathways innervating limbic and cortical areas are thought to mediate the behavioral effects of CRF.

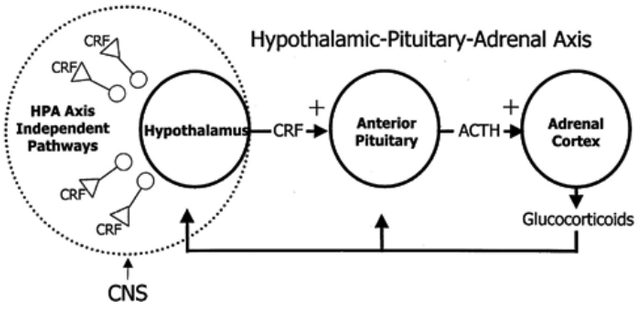

FIGURE 68.1. The role of corticotropin-releasing factor.

There is a large body of both preclinical and clinical literature implicating a key role of CRF in affective disorders such as anxiety and depression. A significant clinical literature suggests that dysfunctions of CRF in its role as a hormone in the HPA axis or as a neurotransmitter in the brain may contribute to the etiology of a variety of psychiatric conditions, including anxiety and depression (3). The link between CRF and depression is particularly strong, as numerous clinical studies have demonstrated that depressed patients show elevated cerebrospinal fluid (CSF) levels of CRF, elevated plasma cortisol, and a blunted ACTH response following intravenous CRF. Successful antidepressant treatment was shown to have a normalizing effect on CRF levels. A role of CRF in anxiety disorders has also been postulated, though the clinical evidence is not as strong as it is for depression (4).

Preclinical studies have demonstrated that CRF administered exogenously into the central nervous system (CNS) can produce behaviors indicative of anxiety and depression, for example, heightened startle responses, anxiogenic behaviors on the elevated plus maze, decreased food consumption, and altered sleep patterns. The anxiogenic effects of CRF are not blocked by adrenalectomy, suggesting that they are centrally mediated effects occurring independently of the HPA axis (5). Other studies strengthening the link between CRF and anxiety include recent work by Kalin et al. (6) demonstrating that a “fearful” phenotype in monkeys is associated with increased pituitary-adrenal activity and increased brain CRF levels. Other studies have shown that exposure to early postnatal separation stress in rat pups results in elevated levels of CRF messenger RNA (mRNA) in brain regions including the paraventricular nucleus (PVN) and the central nucleus of the amygdala (7 ,8).

Molecular Mechanism of Action

A substantial scientific effort has been directed toward characterizing the molecular biology of CRF pathways (9). Perrin and Vale (9) first isolated CRF and identified it as a secretagogue for ACTH in primary cultures of rat pituitary cells. CRF activity is shared by two nonmammalian peptides, sauvagine and urotensin I, which share a 50% homology with CRF, and by a new mammalian peptide, urocortin, which has a 45% sequence homology.

CRF acts through two G_s-protein coupled receptors, the CRF-1 and CRF-2 receptor subtypes (9, 10) . CRF-1 receptors show homology to a number of other neuropeptide receptors, including vasointestinal peptide (VIP) and calcitonin. Three splice variants of the CRF-2 receptor subtype, the CRF-2α, CRF-2β, and CRF-2γ, and two splice variants of the CRF-1 receptor, have been identified (9) . Molecular characterization studies have demonstrated that there is approximately a 70% sequence homology between CRF-1 and CRF-2 receptor subtypes. Cloning of the human *CRF-2a* gene revealed that it is 94% identical to the rat CRF-2α receptor and 70% identical to the human CRF-1 receptor. There is currently no evidence of the existence of the CRF-2β receptor in humans.

CRF-1 and CRF-2 receptors have different pharmacology and different localizations in the brain and periphery. *In situ* hybridization and receptor autoradiography techniques been used to map the relative distributions of CRF-1 and CRF-2 receptors in the rat brain (11, 12) . High expression of CRF-1 receptors was seen in the pituitary, and in a number of brain regions including the PVN of the hypothalamus, cerebral cortex, olfactory bulb, cerebellar cortex, and basolateral and medial amygdala. In contrast, high densities of CRF-2 are found in more circumscribed regions, including the lateral septum, ventromedial nucleus of the thalamus, and choroid plexus. Moderate densities of CRF-2 receptors were reported for the medial amygdala and dorsal raphe nucleus. Further characterization has indicated that the CRF-2α splice variant accounts for the brain localization of CRF-2 receptors, whereas the CRF-2β accounts for choroid plexus. Urocortin, rather than CRF, most closely maps to CRF-2 receptors, leading to the suggestion that it may be the endogenous ligand for CRF-2 receptors. Recent work has shown that the distribution of CRF-2 receptors may differ significantly in the nonhuman primate brain relative to the rodent brain such that the CRF-2 subtype may play a more significant role than previously thought (13) .

CRF receptors utilize 3′,5′-cyclic adenosine monophosphate (cAMP) as a second messenger in the pituitary and brain and can be regulated by chronic activation. Thus, desensitization following exposure to CRF has been demonstrated both *in vitro* (14) and *in vivo* (15) . Furthermore, chronic stress can down-regulate CRF receptors and decrease CRF-stimulated cAMP production in multiple brain areas (16, 17) . Down-regulation of pituitary CRF receptors following adrenalectomy presumably results from decreased ACTH mediated inhibitory feedback, which produces excess CRF stimulation.

There are a number of pharmacologic agents available for dissecting the functional significance of CRF-1 and CRF-2 receptors. Much work has been carried out using the peptide antagonists α-helical-CRF (9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40 and 41) and D-Phe CRF (12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37, 38, 39, 40 and 41) . However, these compounds have shortcomings in that they do not penetrate the CNS and therefore have to be administered intracerebrally. Furthermore, they do not discriminate between CRF receptor subtypes and therefore do not allow a determination of their relative contributions to behavior. More recently, the development of selective, nonpeptidic antagonists of the CRF-1 receptor such as CP 154,526 (18) have provided important pharmacologic tools for the analysis of CRF-1 receptor function. Mutation studies have demonstrated that peptide and nonpeptide antagonists bind to different domains of the CRF-1 receptor (9) . To date, selective CRF-2 antagonists have not been described, though recently, nonpeptide dual antagonists of the CRF-1 and CRF-2 receptors have been described (19) .

In addition to CRF receptor subtypes, another potential target for pharmacologic manipulation of CRF is the CRF binding protein (CRF-BP), a 322 amino acid peptide. CRF-BP is a specific carrier for CRF and related peptides found in human plasma and brain. CRF-BP is thought to be a modulator of CRF activity. The CRF-BP is found in high densities in the rat amygdala, cortex, and bed nucleus of the stria terminalis.

Genetically Altered Mouse Models

Studies utilizing transgenic and knockout mouse models have provided important information with regard to the contribution of CRF and CRF receptor subtypes to processes including energy balance, emotionality, cognition, and drug dependence (20) . This chapter focuses on the evidence implicating CRF and CRF receptors in anxiety states.

Overexpression of CRF in transgenic mice produced anxiogenic effects using either the black-white box test (21) or the elevated plus maze (22) . The latter effect was reversed by central administration of the CRF receptor antagonist α-helical CRF, but not by adrenalectomy, supporting the role of central CRF pathways independent of the HPA axis (22) . Studies using antisense directed against CRF in rats have produced evidence of anxiolytic activity (23) . Finally, overexpression of CRF-BP is anxiolytic, whereas binding protein knockout mice (in which free CRF levels are elevated) display an anxiogenic phenotype in the elevated plus

maze (24). These data generally support the link between CRF and anxiety.

More recently, several studies have highlighted the importance of the CRF-1 receptor subtype in anxiety. CRF-1 knockout mice demonstrated a diminished anxiogenic response on the elevated plus maze and decreased ACTH and corticosterone responses to restraint stress (25). Similar findings were reported by Timpl et al. (26), using the black-white box anxiety paradigm. Furthermore, inactivation of the CRF-1 receptor with an antisense oligonucleotide was shown to reduce the anxiogenic effect of intraventricularly administered CRF (23). Liebsch et al. (27) provided evidence of anatomic localization by showing anxiolytic activity from CRF-1 antisense that was chronically infused into the central nucleus of the amygdala, an area of the limbic system shown by Michael Davis, Joe LeDoux, and others to be important in mediating fear and anxiety processes. Finally, CRF-2 knockout mice show anxiety-like behavior and are hypersensitive to stress (28), indicating that the CRF-2 receptor has an opposite functional role to that of the CRF-1 receptor. Thus, it could be argued that CRF-2 agonists, rather than antagonists, might be potentially useful as anxiolytic agents.

Another potential use for CRF antagonists is in the treatment of drug abuse. Several lines of evidence suggest that during the period of withdrawal from drugs of abuse such as ethanol, morphine, and cocaine, there is an activation of central CRF pathways. Anxiety is among the many physical symptoms of drug withdrawal, and given the link that has been made between CRF and anxiety, it is not surprising that CRF-1 receptor knockout mice demonstrated decreased anxiety responses during withdrawal from alcohol (26).

Current Drugs in Development

A number of nonpeptidic, small-molecule compounds that show high selectivity for the CRF-1 receptor have been proposed for the treatment of depression, anxiety, and stress disorders (29 ,30 and 31). These include CP-154,526 (Pfizer), and a methylated analogue, antalarmin (Pfizer); SC 241 (Dupont); NBI 30775 (aka R-121919; Janssen-Neurocrine); and CRA 1000 and CRA 1001 (Taisho Pharmaceuticals). An extensive preclinical literature has investigated potential anxiolytic effects of these compounds. Studies using CP-154,526 have demonstrated anxiolytic-like effects in some (32 ,33 and 34) but not all (33 ,34) preclinical anxiolytic paradigms evaluated. Griebel et al. (33) proposed that high-stress conditions may be required to demonstrate efficacy of CRF-1 receptor antagonists. CP-154,526 produces an anxiolytic effect in the separation-induced vocalization assay (35), an animal model of anxiety in which a preweaning rat pup separated from its litter emits a series of ultrasonic vocalizations that can be dose-dependently suppressed by either benzodiazepine or nonbenzodiazepine anxiolytics (36).

Of the compounds listed above, the compound discovered by Neurocrine Biosciences and licensed by Janssen Pharmaceuticals, R-121919, has proceeded the furthest in clinical evaluation. A recent report (37) describes results from a phase II, open-label, dose-escalating trial in which 20 severely depressed (Hamilton Depression Score >25) patients were administered R-121919 in one of two dose ranges: 5 to 40 mg, or 40 to 80 mg. In the low-dose group, 50% of the patients responded positively to treatment as indicated by a reduction in the Hamilton Depression Score of at least 50%, and 20% were remitters (score ≤8). In the middle-dose group, 80% responders and 60% remitters were reported. In addition, no significant untoward side effects were reported, and basal or stress-induced levels of ACTH or cortisol where unaffected, suggesting that chronic blockade of the HPA axis might not necessarily produce untoward side effects. Although these preliminary data are promising, it is important to bear in mind that they were gathered using an open label design without placebo control. Firm conclusions regarding the efficacy and safety of CRF-1 antagonists in depression and anxiety will require more rigorous double-blind, placebo-controlled trials. R-121919 is no longer under development because of reported elevations in liver enzymes; however, Neurocrine Biosciences has announced that further candidates are being pursued for clinical evaluation.

As mentioned previously, selective CRF-2 antagonists have not been described, though recently, nonpeptide dual antagonists of CRF-1 and CRF-2 receptors have been described (19). As there is contradictory evidence regarding the role of CRF-2 receptors in mediating anxiety, careful preclinical and clinical evaluation of these compounds will be needed to validate the contribution of CRF-2 receptors.

Future Drugs and Directions

As indicated above, a number of drug companies have dedicated significant efforts to identifying potent and selective CRF-1 receptor antagonists suitable for clinical development. To date, no compounds have completed phase II evaluation. Clearly, a challenge for the future will be to achieve this milestone and, in the process, validate with carefully executed clinical trials the concept that CRF-1 receptor antagonists are novel anxiolytics and/or antidepressants. Also, given increasing evidence of the importance of CRF-2 receptors in the human brain, significant efforts should be dedicated to evaluating this target for anxiety. It will be of interest to determine if agonists, rather than antagonists, of the CRF-2 receptor have anxiolytic profiles. Finally, the prospect of identifying additional CRF receptor subtypes, as well as other receptors for peptides, such as VIP, that are involved in the regulation of stress, provides fertile ground for future investigations.

GABA$_A$ RECEPTOR MODULATORS (BENZODIAZEPINES AND RELATED DRUGS)

A majority of the synapses in the mammalian CNS use the amino acids l-glutamic acid, glycine, or γ-aminobutyric acid (GABA) for signaling. GABA is formed by the decarboxylation of l-glutamate, stored in neurons, and released, and its action is terminated by reuptake; GABA's action mimics the naturally occurring inhibitory transmission in the mammalian nervous system. Because of these findings, it has been accepted for over 20 years that GABA fulfills the characteristics of a neurotransmitter (38). Along with l-glutamate, acetylcholine, and serotonin, GABA possesses two different types of receptor conserved across different species and phyla that control both excitation and inhibition. Molecular biological studies of the receptors causing these effects have indicated that GABA's effects on ionic transmission (ionotropic) and metabolism (metabotropic) are mediated by proteins in two different superfamilies. The first superfamily ($GABA_A$ receptors) is a set of ligand-gated ion channels (ligand-gated superfamily) that convey GABA's effects on fast synaptic transmission (39). When a $GABA_A$ receptor is activated, an ion channel is opened (gated) and this allows chloride to enter the cell; the usual result of chloride entry is a slowing of neuronal activity through hyperpolarization of the cell membrane potential. The second superfamily ($GABA_B$) is slower, mediating GABA's action on intracellular effectors through a seven transmembrane spanning receptor (serpentine superfamily) that modulates the action of certain guanine nucleotide binding proteins (G proteins) (40). Through their activity on other effector systems, G proteins can change second messenger levels, altering signal transduction and gene expression, or open ion channels that are dependent on the G-protein subunit activities (41). Both excitatory and inhibitory activities are possible on a time scale that is longer than $GABA_A$ receptor mediated events. There is extensive heterogeneity in the structure of the $GABA_A$ receptor members of the ligand-gated superfamily. These receptors are the targets of a number of widely used and prescribed drugs for sleep, anxiety, seizure disorders, and cognitive enhancement; they may also contribute to mediating the effects of ethanol on the body.

Structure and Molecular Pharmacology of $GABA_A$ Receptors

It is well established that the $GABA_A$ receptors possess binding sites for the neurotransmitter GABA, as well as allosteric modulatory sites for benzodiazepines, barbiturates, neurosteroids, anesthetics, and convulsants (42 ,43 and 44). The initial cloning of complementary DNAs (cDNAs) coding for the subunits of $GABA_A$ receptors indicated that the chloride channel gated by GABA is intrinsic to the structure of the receptor and that each of the binding sites also possesses specific requirements for subunit composition (45 ,46). At present, almost 20 different cDNAs have been identified and classified into six classes based upon sequence homology. Cloned from vertebrates, there are six α, four β, four γ, one δ, one ε, and two ρ subunits and some splice variants; the subunits share a basic motif where the amino acids span the membrane four times. This four transmembrane spanning motif is shared with subunits that form other receptor members of the ligand-gated superfamily (39).

Extensive mutagenesis and structural examination has been carried out with the GABA and acetylcholine family of receptors (47 ,48). Acetylcholine receptors have been shown to possess a pentameric subunit structure with a heterogeneous subunit composition; evidence for this conclusion has been obtained through the use of monoclonal antibodies and through direct electron microscopic visualization of the densely packed receptor in the Torpedo eel. Similar electron microscopic analysis of $GABA_A$ receptors has been carried out (49). It is thought that the native $GABA_A$ receptors also possess such a pentameric structure with general composition of 2 α, 2 β, and one γ subunit forming the majority of the $GABA_A$ receptors in vertebrates. Evidence of this has been more circumstantial, generated by molecular biological and pharmacologic inferences, described below, and by the behavior of solubilized recombinant complexes on sucrose gradient centrifugation in the presence and absence of different subunit specific antibodies (50). The natural receptor in endogenous tissue appears to be also pentameric (51).

Evidence from studies of acetylcholine receptors has also indicated that the second transmembrane spanning sequence forms the actual ion channel of acetylcholine receptors, and that mutations of amino acids at the inner (cellular) side of the membrane are responsible for the ability of specific cation ions to pass through the channel pore (48). The ionic selectivity can be changed by altering the charge of some of these specific amino acids, and the acetylcholine receptor can be forced to gate chloride, rather than sodium, by such changes. Thus, a relatively firm case for the involvement of this spanning region in the formation of the ion channel can be made. Because the core ion pore is highly conserved among the large number of $GABA_A$ receptor subtypes, a number of drugs that interact nonspecifically with all the members of the $GABA_A$ receptor family were identified in the past. These include anesthetic barbiturates, picrotoxin, neurosteroids, and some organic insecticides (42 ,43 and 44). More recently, because the ion channel shows little variation between $GABA_A$ receptor subtypes, it has not been as active a target for pharmaceutical discovery as the convenient allosteric modulatory site for benzodiazepines, drugs discovered by chance almost 40 years ago.

Originally, two subunits of the $GABA_A$ receptor family were cloned and, when expressed in oocytes, were capable of forming a receptor that would gate chloride in response to GABA (45). At that time, some responses were seen to barbiturates, toxins, and benzodiazepines. It is now known

that a full response to the benzodiazepines requires the incorporation of a third subunit, the γ subunit (52). One of the major forms of native $GABA_A$ receptor in vertebrates probably has the structure $\alpha_1\beta_2\gamma_2$, most likely in a 2:2:1 stoichiometry. The α_1 subunit contains the major site that is photoaffinity labeled with the benzodiazepine ^{3}H-flunitrazepam at His 101 (53). For the functional modulation of GABAergic activity by benzodiazepines, in addition to the α subunit, a γ subunit must be incorporated into the complex. Thus, there is reasonable evidence that benzodiazepines and related drugs stimulate GABA activity without opening channels directly; depending on their ability to potentiate GABA activity, they are called full or partial agonists. The binding site for these drugs incorporates a binding site composed of components of both α and γ. Other drugs (called inverse agonists) may occupy the same site to negatively modulate the action of GABA, such as β-carboline derivatives. Yet a third class of compounds exist, drugs such as flumazenil, may occupy the site as antagonists of both agonist and inverse agonists. By themselves, these antagonists have no affect on GABAergic activity and are behaviorally silent. The important allosteric modulatory effects of drugs at the benzodiazepine site were recognized early and the distribution of activities at different receptor subtypes has been an area of intense pharmacologic discovery for many years (39 ,42 ,43 and 44). The details of some of these findings are described later.

Because the expression of an α or β subunit by itself does not form a functional receptor (54), but expression of both together constitute a functional $GABA_A$ receptor, the binding sites for GABA could be associated with the combination of the two subunits. Systematic mutagenesis of α and β subunits have identified a number of amino acids on both subunits that appear to contribute to the ability of GABA to bind to the $GABA_A$ receptor and modulate chloride conductance (53). Thus, the GABA binding sites are also complex, composed of a binding pocket that is made up of amino acids from both subunits; there are two GABA binding sites per receptor [located at the two identical (or homologous in the case of heterogeneous mixtures of subunits) αβ interfaces], and electrophysiologic studies indicate that both must be occupied for the chloride channel to open.

Perhaps the most interesting aspect of these mutagenesis studies is the observation that the GABA binding site (two per αβγ complex) and the benzodiazepine binding site (one site per αβγ complex) are structurally related to one another; homologous amino acids that contribute to binding in each case are found at similar positions in each subunit. They represent in the case of the GABA binding site αβ interfaces and in the case of the benzodiazepine binding site the αγ interface (Fig. 68.2). By binding to the benzodiazepine binding site, the drugs clearly give a positive allosteric signal to the receptor and/or to the GABA binding sites; this is reflected in a change in affinity at a low-affinity GABA binding site (43). This signal is analogous to the signal that a single GABA molecule binding to one of the GABA binding sites gives to the receptor and second GABA binding site. The original finding relating GABA and benzodiazepines allosterically showed evidence of a similar signal being transmitted from the occupied GABA binding site to the benzodiazepine site, resulting in a higher affinity state at the benzodiazepine binding site in the presence of GABA at its binding site (55). This type of pseudosymmetric binding site is characteristic of allosteric protein binding interactions and is found also in acetylcholine and in glycine receptors (46 ,56 ,57). The theoretical details of such interactions allow one to rationalize how a set of drugs like benzodiazepines could stabilize a channel open state but not be able to open the channel directly. Variations in these binding sites that are dependent on different α, β, and γ subunit amino acid sequences, particularly α and γ as the components of the benzodiazepine binding site, underlie the heterogeneity of $GABA_A$ receptors and point to the possibilities for $GABA_A$ receptor subtype–specific drugs.

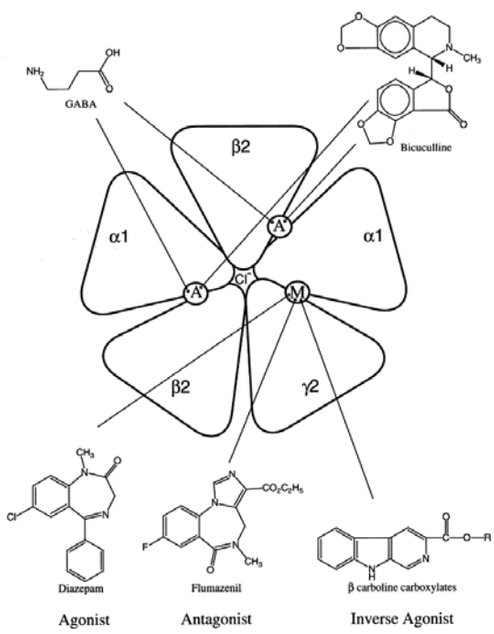

FIGURE 68.2. γ-Aminobutyric acid (GABA) binding site αβ interfaces.

Genomic Organization of $GABA_A$ Receptor Subunits

The natural association of αβγ compositions of $GABA_A$ receptors is also underscored by the genomic organization of the subunits. There is a cluster of the genes coding for α_1, β_2, and γ_2 subunits on chromosome 5 and similar clusters of other subunits on other chromosomes such as 4 and 15 (58 ,59). They point to the phylogenetic age of $GABA_A$ receptors, and similarities in organization point to the possibility that ancestral $GABA_A$ receptor gene cluster duplications spawned some of the different clusters coding for unique $GABA_A$ receptor isoforms, whereas mutations in individual subunits may have created additional diversity. Such an organization also points to probable coordinated control of subunit production and many interesting aspects of cellular and brain regional regulation of expression yet to be examined. Regional diversity also can mean functional diversity and drugs that affect certain aspects of behavior, but not others.

Functional Activities of Therapeutics at Individual Recombinant Constructs

One reason for the diversity of subtypes of $GABA_A$ receptors is that this is how neurons integrate information and change the behavioral status of the animal. Whereas $GABA_A$ receptors are found on many neurons, particularly local interneurons, some $GABA_A$ receptor subtypes are selectively localized to specific brain regions, specific cell layers within those regions, and even specific parts of cells (60 ,61 and 62). Each subtype has a unique set of electrophysiologic and pharmacologic properties. A number of factors can determine the response properties of $GABA_A$ receptor subtypes. The most

important determinant is subunit composition. Secondarily, these receptor subtypes can have unique profiles of modulation driven by membrane potential, ion gradients, biochemical conditions, and, last but not least, drugs.

Attempts have been made to categorize $GABA_A$ receptors pharmacologically in terms of responses to specific drugs that interact with the benzodiazepine binding site. Thus, in the original nomenclature, two subtypes of $GABA_A$ receptor were described (63). They were called type 1 and type II receptors and were defined in terms of differential affinity for CL 218,872 and a number of other compounds. We now know that type I $GABA_A$ receptors contain the composition $\alpha_1\beta_x\gamma_2$ and are responsive to CL 218,872, a related compound zaleplon, and zolpidem (64). Both zaleplon and zolpidem are marketed hypnotics. Type II receptors are a mixed heterogeneous class containing $\alpha_2\beta_x\gamma_2$, $\alpha_3\beta_x\gamma_2$, and $\alpha_5\beta_x\gamma_2$. α_4- and α_6-containing $\beta_x\gamma_2$ subunit combinations are generally agreed to constitute a separate category of $GABA_A$ receptors due to their lowered affinity for classic benzodiazepine site ligands (65). For example, flumazenil has a very low affinity for these α_4- and α_6-containing $GABA_A$ receptor recombinant constructs compared to α_1-, α_2-, α_3-, or α_5-containing $GABA_A$ receptors (100 nM versus 0.5 nM). The differences in amino acids between the α subunits pointed to the mutagenesis studies described above to delineate GABA and benzodiazepine binding sites.

Thus, affinity differences in the benzodiazepine binding site have been a primary method for differentiating $GABA_A$ receptor subtypes. In contrast to the affinity models of benzodiazepine binding sites, it is not clear that a simple molecular biologically based efficacy model will emerge to simplify our understanding of α_1-, α_2-, α_3-, or α_5-containing $GABA_A$ receptors.

The $GABA_A$ receptor subtypes with their benzodiazepine receptor sites are an example of a unique situation in biology. Compounds have been synthesized that can allosterically modulate GABA response over a wide range through this site. Modulation of GABA responses has spanned the range of >700% increase in response amplitude to inhibition as great as 60%. Control of efficacy by drugs with subunit specificity can be achieved. One approach of drug companies has been to develop drugs that increase GABA responses less than 100% and develop selectivity for some subunits without increasing responses at other subunit combinations. These have been called subtype-selective partial agonists and will probably represent the next generation of GABAergic modulators to enter the clinic and become drugs.

A number of studies suggest, by circumstantial evidence such as message distribution, genomic localization, and biochemical study, that the major subtype combinations in brain are $\alpha_1\beta_2\gamma_{21}$, $\alpha_2\beta_3\gamma_{21}$, $\alpha_3\beta_3\gamma_{21}$, and $\alpha_5\beta_3\gamma_{21}$. α_1 has been implicated in sedation by virtue of the fact that zolpidem, a marketed hypnotic under the trade name Ambien, is a type I (α_1) selective compound and can cause cognitive deficits (see next subsection). An ideal anxiolytic drug might have limited effects on this subtype while increasing responses at α_2- and α_3-containing subtypes, as they are located in the limbic parts of the brain directly implicated in generation and reduction of anxiety. The full examination of subtype selective drugs in humans is in the near future, and it will be interesting to see how these hypotheses fare in clinical trials.

Involvement of $GABA_A$ Receptors in Human Disease and Transgenics

The extensive investigation of the amino acids involved in the binding of GABA and benzodiazepines allows a specific and elegant approach to be made to the *in vivo* investigation of the involvement of $GABA_A$ receptor subtypes with specific neural pathways and specific behavioral activities. This approach can be made either through the examination of chromosomal deletions, the use of specific knockouts of subunit genes, or knock-ins of particular point mutations. These techniques naturally complement the development of drugs with specific activities at $GABA_A$ receptor subtypes.

Some naturally occurring chromosomal deletions of particular $GABA_A$ receptor subunits showed phenotypes of craniofacial deficits, mental retardation, and epilepsy. Deletion of large areas of human chromosome 15, containing α_5, γ_3, and β_3 subunit genes, results in this phenotype, which causes a human genetic disorder called Prater Willi/Angelman syndrome (66). In a targeted study in mice, animals with the specific deletion of the β_3 subunit shows a similar syndrome with cleft palate and neurologic abnormalities. These studies point to the importance of certain $GABA_A$ receptors in neuronal development (67 ,68). It is also clear that the deletion of an entire subunit does not result in the rescue of function by substitution of other subunits (69). Other rare genetic disorders of $GABA_A$ receptor function are likely to emerge as our knowledge of the genomic basis of neurologic disorders evolve. A very elegant approach, based on the molecular biological studies described above, has been taken to examine the significance of $GABA_A$ receptor subtypes by replacing an important amino acid for benzodiazepine binding (histidine) found in α_1, α_2, α_3, and α_5 with an arginine characteristic of α_4 and α_6. Through this conservative mutation, GABA sensitivity is retained, so the receptors function normally, but drug sensitivity is lost (70 ,71). From these studies, it appears that the α_1-containing subtypes are important in mediating the anticonvulsant, sedative, and amnestic effects of benzodiazepines, but to a smaller degree the muscle relaxant and anxiolytic effects. These animals are still susceptible to the development of tolerance to the sedative effects. In the near future, we may learn the consequence of deletion of the specific benzodiazepine modulatory sites from the other α subtypes. Thus, from a mechanistic point of view this class of drugs has a well-defined mode of action.

SEROTONIN RECEPTOR MODULATORS AND REUPTAKE INHIBITORS

Part of "68 - Mechanism of Action of Anxiolytics "

Preclinical Studies

Serotonin has long been viewed as a neurotransmitter involved in regulating emotional states. Of the 14 or so mammalian serotonin receptor subtypes that have been described in the literature, at least four have been implicated in anxiety in various animal models (72). As reported by Lucki (72) the original hypothesis implicating serotonin in anxiety surfaced from observations that reduced levels of serotonin can produce anxiolytic effects. One of the receptor subtypes implicated in anxiety is the serotonin 1A receptor subtype ($5\text{-}HT_{1A}$), which is an autoreceptor located presynaptically on serotonin neurons. When stimulated, this receptor inhibits the synthesis and secretion of serotonin. The $5\text{-}HT_{1A}$receptor agonist buspirone exhibits anxiolytic effects in

animals and was approved by the Food and Drug Administration (FDA) in 1986 for human generalized anxiety disorder. Other serotonin receptors potentially involved in anxiety include the 5-HT_{2A}, 5-HT_{2C}, and 5-HT_3 receptors. Antagonists for the 5-HT_{2A}receptor, like ritanserin, exhibit anxiolytic effects in some animal models (73 ,74). Likewise, blockade of the 5-HT_{2C} receptor produces anxiolytic effects in animals (75) and prevents the anxiogenic effects of m-CPP (76). Finally, the 5-HT_3receptor antagonist ondansetron was reported to be anxiolytic in some animal models (77).

Recent advances in molecular biology has led to the development of serotonin receptor gene knockout methodology, which generates mice lacking the 5-HT_{1A} receptor, allowing for the evaluation of this receptor subtype in a variety of measurable behaviors. Ramboz et al. (78) reported results consistent with the 5-HT_{1A} agonist's data cited above. Mice lacking this receptor displayed less exploratory activity in an open field and more anxious behavior than the wild types in the elevated plus maze. According to the serotonin hypothesis of anxiety (79), removing the negative feedback control of 5-HT with the 5-HT_{1A} receptor knockout animals should result in increased levels of 5-HT in the synaptic cleft, which would be expected to lead to the anxiogenic behavior. However, Ramboz et al. (78) reported normal levels of 5-HT, which confuses the issues related to anxiety modulation and serotonin levels. As David Julius (80) points out, the interpretation of standard gene knockout experimentation is complicated by the possibility of long-term development changes and this is true with the 5-HT_{1A}knockout animal. So despite the apparent consistency between the 5-HT_{1A} knockout animal and 5-HT_{1A} agonist studies in terms of the behavioral outcomes of each manipulation, the exact role of the 5-HT_{1A}receptor in anxiety is not absolutely clear at this time.

Clinical Studies

In 1986, the FDA approved the 5-HT_{1A} partial agonist for generalized anxiety disorder. This drug was the first to challenge the benzodiazepines for this patient group and was generally perceived as an improvement because of the lack of benzodiazepine side effects. The efficacy of buspirone, however, was not the same as that of the benzodiazepines in terms of its delayed onset of action, and it is generally accepted that when buspirone offers clinical benefit to generalized anxiety disorder (GAD) patients, it takes 3 to 4 weeks to match the efficacy of benzodiazepines such as diazepam and alprazolam (81). The 5-HT_{1A} partial agonist properties of buspirone are believed to account for its clinical effects, but it should be noted that the drug is also a D2 antagonist and is extensively metabolized. One of the major metabolites, 1-pyrimidinylpiperazine (1-PP), may contribute to the pharmacologic activity of buspirone (82). In a double-blind, placebo-controlled study of buspirone in GAD patients (83), the drug was reported to be as efficacious as lorazepam at the end of a 4-week treatment period. After the drugs were discontinued, however, the lorazepam-treated patients worsened whereas the buspirone-treated subjects maintained clinical improvement. Thus, there continues to be evidence that buspirone is effective in GAD.

The development of selective serotonin reuptake inhibitors (SSRIs) in the 1980s and 1990s widely expanded the treatment for depressive disorders, and these drugs (fluoxetine, sertraline, venlafaxin, paroxetine) have recently made inroads in treating anxiety disorders such as panic, obsessive-compulsive disorder, social phobia, and GAD. Successful treatment of GAD with a class of drugs working through the serotoninergic system will come from the SSRIs (84).

Obsessive-compulsive disorder (OCD) is a chronic, disabling anxiety disorder. In a review of the diagnosis and treatment of OCD, Goodman (85) states that the backbone of pharmacologic treatment for OCD is a 10- to 12-week trial with an SSRI in adequate doses. It is clear from a review of the role of the 5-HT_{1A} receptor (86) in OCD that partial agonists such as buspirone are generally ineffective in treating OCD. The authors also note that in studying the potential to augment efficacy of the standard OCD medication, buspirone was not different from placebo as an augmenting agent. Drugs that work through other serotonin receptor subtypes also appear to be ineffective in treating OCD. Thus, drugs modifying the 5-HT_{1A}, 5-HT_{1D}, and 5-HT_3 receptors appear ineffective in treating OCD symptoms and rule out a critical involvement of these receptor subtypes in OCD (87 ,88).

In the past, tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors, as well as high potency benzodiazepines, have been used to treat patients with panic disorder. The SSRIs have also been added to the list of effective agents for the disorder. In reviewing the pharmacotherapy of panic disorder, den Boer (89) notes that antidepressants are more effective than benzodiazepines in reducing associated depressive symptomatology and are at least as effective for improving anxiety, agoraphobia, and overall impairment. Bell and Nutt (90) remark that SSRIs improve 60% to 70% of panic patients, a similar percentage to those seen with the TCAs.

Like OCD, panic disorder is well treated by SSRIs but does not appear to be effectively treated by receptor specific compounds. Copland et al. (86) reviewed the role of 5-HT_{1A}drugs such as buspirone in panic disorder and reported that buspirone does not significantly treat panic in several well-controlled studies. Using the 5-HT_{1A} receptor agonist flesinoxan, van Vliet et al. (91) reported a worsening of symptoms in panic patients treated with high doses of the drug. It has also been reported that the 5-$HT_{2A/2C}$ antagonist ritanserin had no effects on panic attacks or phobic avoidance, and a similar negative finding has been reported with the 5-HT_3 antagonist ondansetron.

NEUROKININ RECEPTOR ANTAGONISTS

Part of "68 - Mechanism of Action of Anxiolytics "

Rationale

There is an extensive literature demonstrating that the peptide tachykinins such as substance P and their associated receptors have a widespread distribution in the brain, spinal cord, and periphery, and may play important roles in

chronic pain and inflammation processes (92 ,93 ,94 ,95 and 96). In addition, anatomic and physiologic evidence has also indicated that these peptides may affect limbic structures that are involved in the regulation of mood and affect, such as the amygdala, hypothalamus, and periaqueductal gray (97). This notion is supported by early positive clinical findings using a selective neurokinin-1 (NK-1) antagonist for the treatment of depression and anxiety (98).

Molecular Mechanism of Action

Tachykinins collectively refer to small peptides that include substance P (SP), neurokinin A (NK-A), and neurokinin B (NK-B). These peptides show preferential affinity for three receptors, designated NK-1, NK-2, and NK-3, respectively, which are members of the seven-transmembrane, G-protein–coupled family. Of these three receptors, NK-1 and NK-3 are found in the brain, whereas NK-2 is primarily localized peripherally in smooth muscle of the respiratory, urinary, and gastrointestinal tracts. Neurokinin receptors are localized in a number of different brain areas that are implicated in anxiety, including the amygdala, hypothalamus, and locus coeruleus.

Studies assessing the effects of direct administration of neurokinin agonists such as substance P into the nervous system are complicated by the findings that, depending on factors such as the site and dose, opposite effects on behavior may be achieved.

Current Drugs in Development

Numerous NK-1 antagonists have been described in the literature, including MK-869 (Merck) and an analogue, L-760,735 (Merck), SR140333 (Sanofi), CP-122,721 (Pfizer), RP67580 (Rhone-Poulenc), FK-888 (Fujisawa), SDZ NKT 343 (Novartis), and PD 154075 (Parke-Davis). NK-1 antagonists have been reported to demonstrate anxiolytic effects in animal models such as social interaction (99), though these effects are not consistently seen across all compounds (34). Researchers from Merck have reported that vocalizations elicited by maternal separation in guinea pigs are robustly blocked by NK-1 antagonists such as MK-869, an effect that is shared by a range of antidepressant and anxiolytic agents (98).

Of the compounds listed above, the primary indication has been for the treatment of conditions such as pain, chemotherapy-induced emesis, and migraine (94). MK-869, which progressed to phase III trials for emesis, has also been evaluated in a phase II depression trial in which it was reported that, in addition to showing a significant antidepressant effect, MK-869 also showed significant anxiolytic activity that emerged over the course of the 6-week study (98). The data supported the conclusion that NK-1 antagonists might be useful for the treatment of depression and anxiety. Further development of MK-869 for depression was discontinued, but these early clinical data will undoubtedly lead to further clinical evaluation of NK-1 antagonists.

NK-2 antagonists include SR48968 (Sanofi). Preclinical studies have shown that NK-2 antagonists such as GR159897 and SR48968 have also demonstrated activity in social interaction and exploration anxiolytic models, and activity has been reported in the marmoset monkey using the human “threat” test. Good therapeutic ratios were described for these agents.

NK-3 antagonists described in the literature include osnetant (Sanofi-Synthelabo), talnetant, PD-161182, and PD-157672 (Parke-Davis). The latter two have been designated for the treatment of anxiety disorders, though there have been no reports of clinical trials with any NK-3 antagonist for this indication. It should be noted that preclinical data described to date are sparse, and there is some suggestion that NK-3 agonism may produce an anxiolytic profile. Thus, intraventricular administration of the NK-3 agonist senktide produced anxiolytic effects in mice that could be blocked by administration of the NK-3 antagonist SR 142801, and SR 142801 was found to have some anxiogenic activity (100).

Future Drugs and Directions

Further depression and anxiety clinical trials with centrally active NK-1 antagonists are needed to provide further validation of the role of NK-1 receptors in treating depression and anxiety disorders. In addition, further assessment of the role of NK-2 and NK-3 subtypes is needed to determine the possible relevance, if any, of these receptor subtypes.

GLUTAMATE RECEPTOR AGONISTS AND MODULATORS

Part of "68 - Mechanism of Action of Anxiolytics "

Rationale

Glutamate is the major mediator of excitatory neurotransmission in the CNS. Despite this ubiquity, the elucidation of numerous glutamate receptor subtypes with differential localizations in the brain, and the development of selective pharmacologic agents, has led to the realization that glutamate receptors might be viable targets for a number of different neurologic and psychiatric disorders, including anxiety and depression (101 ,102 and 103).

Molecular Mechanism of Action

The molecular biology of glutamate receptors has been the subject of numerous reviews (101 ,102). Glutamate receptors are classified as either ionotropic or metabotropic. Ionotropic receptors, which mediate fast synaptic transmission, are coupled to cation-specific ion channels and bind the agonists *N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-4-isoxazole

propionic acid (AMPA), and kainic acid (KA). These receptors gate both voltage-dependent and voltage-independent currents carried by Na^+, K^+, and Ca^+.

NMDA receptors, which are selectively activated by NMDA, form a receptor/channel complex that is allosterically regulated by several sites. Receptor activation results in depolarization and Ca^+ influx. Allosteric binding sites include a strychnine-insensitive glycine site, a polyamine site, a zinc site, and a channel site that binds agents such as MK-801 or phencyclidine to block channel opening. The NMDA receptor has been cloned and has two families of subunits, the NR1, with seven splice variants (1A–1G), and NR2, with four splice variants (2A–2D). NR1 receptors possess the receptor/ion channel complex, whereas the NR2 receptors lack the ion channel and appear to be modulatory. NR2 receptors, however, can form functional heteromeric channels by combining with NR1 subtypes. NMDA antagonists include competitive antagonists at the NMDA receptor such as AP5, CPPene, and CGS 19755; noncompetitive antagonists at the ion channel site such as MK-801 and phencyclidine; and noncompetitive antagonists that bind to the glycine site such as 5,7-dichlorokynurenic acid, L689,560, ACEA 1021, and MDL 105,519 (104).

“Non-NMDA” receptors refer to the class of ionotropic glutamate receptors activated by kainic acid or AMPA, agonists that activate voltage-independent channels that gate a depolarizing current mediated primarily by Na^+ ions. There are four AMPA subunits (GluR1–GluR4) and five KA subunits (GluR5–GluR7 and KA-1–KA-2). Functional channels can be produced by homomeric expression of GluR5 or GluR6 subunits, or by heteromeric expression of KA-1 or KA-2 with GluR5 or GluR6. KA sites are found in the hippocampus, cortex, and thalamus, whereas AMPA receptors are additionally localized in septal and cerebellar sites. Pharmacologic agents for blocking non-NMDA receptors include the competitive antagonists CNQX, DNQX, and NBQX, and the noncompetitive antagonist GYKI 52466.

Metabotropic glutamate receptors (mGluRs) mediate slower synaptic transmission and utilize phosphatidyl inositol (PI) and cAMP as second messengers. Opposite effects on cAMP may be mediated by either G_i or G_s stimulation. Agonists include a conformationally restricted glutamate analogue, 1-aminocyclopentane-*trans*-1,3-dicarboxylic acid (*trans*-ACPD). Metabotropic receptors have been classified into three subgroups: group I (mGluR1, mGluR5), which stimulate PI hydrolysis; and two groups that inhibit adenylate cyclase, group II (mGluR2, mGluR3) and group III (mGluR4, mGluR6). Metabotropic receptors are widely distributed throughout the brain, in areas such as the hippocampus, cerebellum, thalamus, olfactory bulb, and striatum, though the precise distribution varies considerably between groups. In addition to the agonist trans-ACPD, other agonists that are more specific for receptor subtypes include LY354740 (group II), L-AP4 (group III), and L-CCG-I (mGluR2). Pharmacologic agents for antagonizing metabotropic glutamate receptors are currently limited.

Genetically Altered Mouse Models

Site-directed mutagenesis studies have indicated that point mutations in the glycine binding site of the NR1 subunit result in mice that have reduced glycine affinity and have an anxiolytic profile as seen by decreased natural aversion to an exposed environment (105). These data supported other pharmacologic lines of evidence (see below), indicating that blockade of the glycine site can have anxiolytic actions.

Current Drugs in Development

LY354740 is an orally active group II metabotropic receptor agonist (106) currently in clinical development. Preclinically, the compound has anxiolytic activity in fear-potentiated startle (107), the elevated plus maze (107), conflict testing (108), the four-plate test (108), and in a lactate-induced panic attack model (109). LY354740 has also been shown to decrease withdrawal signs seen during naloxone-precipitated morphine withdrawal (110).

Future Drugs and Directions

Competitive and noncompetitive NMDA antagonists have primarily undergone clinical evaluation for the treatment of stroke and trauma (103). Unfortunately, clinical development for many of these compounds was halted because of severe side effects, including psychotic-like symptoms. The potential for these side effects has been a major deterrent for using NMDA antagonists for the treatment of psychiatric disorders. Although there are currently no drugs reported to be in development, preclinical studies have suggested that selective antagonists of the strychnine-sensitive glycine site can have anxiolytic properties with reduced side-effect potential relative to competitive and noncompetitive NMDA antagonists such as AP5 and MK-801 (36 ,111). Recent work has supported such a profile (112 ,113).

Antagonists of AMPA receptors have also been proposed to have anxiolytic actions in preclinical models. Thus, LY326325 was shown to have anxiolytic activity in the elevated plus maze and in a conflict test (punished drinking) in rats (114), and CNQX injected directly into the periaqueductal gray produced anxiolytic effects on the elevated plus maze (115). The antagonists CNQX and GYKI 52466 were also able to block the anxiogenic responses produced by bicuculline injected into the basolateral amygdala (116).

CCKB ANTAGONISTS

Part of "68 - Mechanism of Action of Anxiolytics "

Cholecystokinin (CCK) is a peptide found extensively both in the gut (where it was originally identified) and in the

brain (117). CCK exists in multiple forms, the most predominant of which is CCK octapeptide (CCK8) and, to a lesser extent, CCK tetrapeptide (CCK4) (118). CCK is co-localized with a number of different neurotransmitters, including serotonin, dopamine, GABA, substance P, neuropeptide Y, and VIP. CCK-like immunoreactivity has been demonstrated in anatomic regions that include the amygdala, cerebral cortex, hippocampus, striatum, hypothalamus, and spinal cord (119). There are two subtypes of CCK receptor, CCKA (sulfated CCK) and CCKB (unsulfated CCK) (120). CCKA receptors are localized in the nucleus accumbens, posterior hypothalamus, and area postrema. CCKB receptors are localized in cortex, olfactory bulb, nucleus accumbens, and other brain areas (121).

A number of selective antagonists for the CCKB receptor have been synthesized, including LY288513 (Lilly), PD 135158 (Parke-Davis), L-365,260 (Merck), and CI-988. Griebel (34) reviewed the extensive literature on the effects of CCK antagonists in models of anxiety and concluded that the results were contradictory and did not lead to a clear conclusion. L-365,260 and CI-988 have been evaluated clinically in panic disorder, but neither of these agents had significant anxiolytic effects (122 ,123 and 124).

CONCLUSION

Part of "68 - Mechanism of Action of Anxiolytics "

Many different neurotransmitter receptor systems have been shown to modulate anxiety and possess anxiolytic effects. This is not surprising because many of these transmitters control anatomic circuitry important in anxiety. The next generation of marketed anxiolytics will be determined more by their side-effect profile than by their anxiolytic activity. It will be interesting to see which of the mechanisms described in this chapter will provide the most useful anxiolytics in human populations.

> Raze out the written troubles of the brain,
>
> And with some sweet oblivious antidote,
>
> Cleanse the stuffed bosom of that perilous
>
> Stuff which weights upon the heart?
>
> --William Shakespeare, *Macbeth*

The advances in neurobiology documented comprehensively elsewhere in this volume have been applied to no area of research more so than affective disorders. This is not surprising, considering the magnitude of the public health problem these disorders represent and the long way yet to travel before an understanding of their pathophysiology is realized and optimal treatments are developed. Although the task is daunting, recent progress is heartening and informative. Major depression and bipolar disorder, the most common and severe of the mood disorders, are responsible for much of the suicide in the United States—now the eighth leading cause of death, surpassing HIV infection, in the last 2 years. The Global Burden of Disease report, a collaborative effort of the World Health Organization and the Harvard University School of Public Health, indicated that depression would be the leading cause of morbidity in the developing world in this next century. Between a fourth and a fifth of all women in the United States will experience a major depressive episode in their lifetime. It is now well established that depression is an independent risk factor for the development of coronary artery disease, stroke, and perhaps cancer. This section provides succinct yet comprehensive reviews of the most critical areas in mood disorders research by some of the leading investigators in the field. Each contribution highlights one or more major advances in the field.

Thus, there is an appropriate emphasis on the longitudinal course of affective illness and a corresponding criticism of cross-sectional studies. With the maturation of psychiatric epidemiology and the Human Genome Project comes anticipation of elucidation of both risk factors, and susceptibility and resistance genes, respectively. The pathophysiology of these disorders is being scrutinized by a myriad of techniques ranging from cellular and molecular approaches, to structural and functional brain imaging, to light and electron microscopic neuroanatomic investigations. Similar techniques are being utilized to elucidate the mechanism of action of antidepressants, mood stabilizers, and newer treatments including rapid transcranial magnetic stimulation, as well as to identify novel treatments including hormones and hormone antagonists. The data reviewing the efficacy of current and novel treatments are presented, with the realization that too many patients are improved by the current treatment regimens, but far too few achieve complete remission. Appropriately, there is also attention to the pharmacoeconomics of mood disorder treatment.

I am grateful to all of the authors for their painstaking contributions and accept all responsibility for any shortcomings in this section. This section contains much information unknown when the last edition of this book was published. We can all be heartened by the fact that the next edition will similarly replace this present effort.

The Course of Depression

Robert J. Boland

Martin B. Keller

Robert J. Boland: Department of Psychiatry and Human Behavior, Brown University; Department of Psychiatry, Miriam Hospital, Providence, Rhode Island.

Martin B. Keller: Department of Psychiatry and Human Behavior, Brown University; Department of Psychiatry, Butler Hospital and Brown Affiliated Hospitals, Providence, Rhode Island.

Long-term naturalistic studies have changed the way we view depression. Whereas it was often previously viewed as an episodic disease, the past two decades of research have underscored the importance of understanding depression as a lifelong disease, with a number of possible courses.

An appreciation of this longitudinal data is crucial to understanding all aspects of depression. Cross-sectional judgments of symptomatic severity provide limited prognostic information. A full understanding of a patient's prognosis or likely treatment response also requires a longitudinal perspective. Which patient is likely to recover fully, and who will suffer from a chronic mood disorder? What length of treatment will be sufficient for such patients?

Studies within the last decade have helped to shed light on these questions. This chapter examines some of these studies, and discusses their implications for our approach to depression. Limitations of the data will be discussed as well.

THE CHANGE POINTS OF DEPRESSION

Part of "69 - The Course of Depression "

Considerable confusion has resulted from the use of various terms to denote the different change points in the course of depression. Similar terms, such as “relapse” and “recurrence” have been used interchangeably and inconsistently in different studies. As a result, the MacArthur Foundations Research Network on the Psychobiology of Depression (1) recommended using the following terms:

1. *Episode*, defined as a certain number of symptoms for a certain period of time.
2. *Remission*, defined as a period of time in which an individual no longer meets criteria for the disorder. In partial remission, an individual still has more than minimal symptoms. Full remission is defined as the point at which an individual no longer meets criteria for the disorder and has no more than minimal symptoms.
3. *Recovery*, defined as a full remission that lasts for a defined period of time. Conceptually, it implies the end of an episode of an illness, not of the illness per se.
4. *Relapse*, defined as a return of symptoms sufficient to satisfy full criteria for an episode. It occurs in an interval of time before what is defined as “recovery.” Conceptually, this refers to the return of an episode, not a new episode.
5. *Recurrence*, defined as a return of full symptomatology occurring after the beginning of the recovery period. Conceptually, this represents the beginning of a new episode of an illness.

REPRESENTATIVE STUDIES

Part of "69 - The Course of Depression "

A relatively small number of studies have been particularly influential in shedding light on the course of depression.

The Collaborative Depression Study (CDS)

The CDS (2) is a prospective long-term naturalistic study of the natural course of depression. Subjects were recruited from patients with depression seeking psychiatric treatment at one of several sites (university or teaching hospitals in Boston, Chicago, Iowa City, New York, and St. Louis). This study included programs in biological and clinical studies. The data presented here are from the clinical studies program; 555 subjects in the clinical studies program had an index episode of unipolar major depression. Subjects were examined at 6-month intervals for 5 years and then annually for a minimum of 18 years. Recent National Institute of Mental Health (NIMH) funding will extend the follow-up to at least 23 years on all subjects.

The Zurich Study

Angst (3), in Zurich, has conducted the only other long-term prospective study of mood disorders. In that study, 173 hospitalized patients with unipolar depression were identified between 1959 and 1963. This group was then evaluated every 5 years for up to 21 years of follow-up.

The Medical Outcomes Study (MOS)

The MOS (4) examined the course of several diseases (myocardial infarction, congestive heart failure, hypertension, diabetes, and depression) in a variety of health care settings, including large medical group practices, small group practices, and solo practices, in three cities (Los Angeles, Boston, and Chicago). A representative sample of different medical specialties—including psychiatry—was chosen, and all patients seen from February through October 1986 were asked to participate in the study. In all, over 20,000 patients participated, and were evaluated yearly for 3 years.

THE COURSE OF DEPRESSION: CHANGE POINTS

Part of "69 - The Course of Depression "

Traditionally, depression was pictured as an acute illness, self-limited, and lasting approximately 6 to 9 months from time of onset to full recovery. A number of studies, including those mentioned above, however, show the potential for great variation from this traditional model. Recovery may take much longer, or not occur at all (i.e., chronic depression). Furthermore, the risk of relapse and recurrence of illness must be considered.

Recovery

In the CDS, approximately 70% of patients recovered from the index episode of major depression within the first year (5). However, for those patients who did not recover in the first year, most still had not recovered within 5 years. Thus by 2 years, about 20% of the original sample were still depressed—two-thirds of those still depressed at 1 year were still in their index episode of depression at 2 years. At 5 years, 12% of patients had still not recovered (6), by 10 years 7% had not recovered (7), and by 15 years, the numbers seem to have leveled off at 6%. These data are presented in Fig. 69.1 .

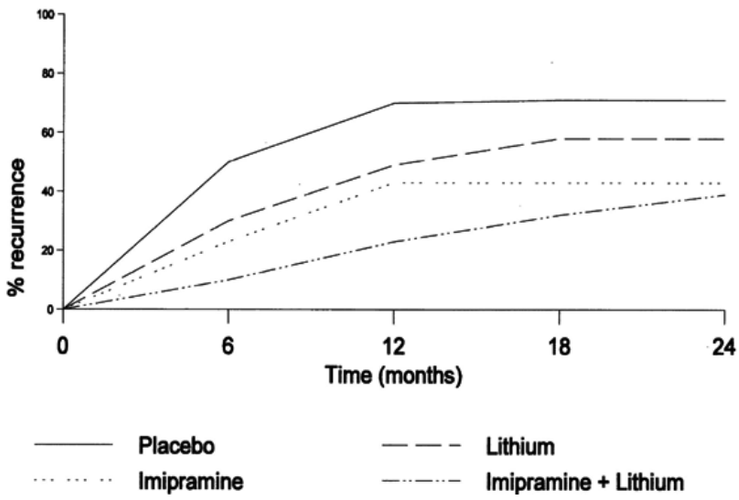

FIGURE 69.1. Outcome of maintenance therapy for depressed patients initially stabilized on imipramine plus lithium.

The long duration of the CDS allowed the investigators to observe subsequent episodes of major depression beginning during the study. This was particularly useful, as the onset of symptoms could be identified more accurately than for the retrospective determination done for an index episode. It was found that, for each new episode of depression, the rates of recovery were similar to that seen during the index episode. Thus, for the second episode (first prospectively observed episode) approximately 8% of subjects did not recover after 5 years. An analysis of subsequent episodes (second, third, and fourth prospectively observed episodes) showed similar findings. By the fifth episode, the rate decreases, but not significantly so (8). It appears that for each episode of depression, some individuals—about 10%—remain ill for at least 5 years.

The seemingly high rate of chronicity was surprising. A reasonable concern about this result was that the patient population studied may have been unusually treatment resistant. The study used a convenient sample of patients seeking inpatient or outpatient treatment at any one of five major medical centers. However, most patients studied received either no treatment or subtherapeutic doses given for very brief durations (9). Thus, the CDS cohort does not seem to be biased in the direction of treatment resistance.

Furthermore, other studies show comparable data. In the Zurich study, Angst et al. (10) reported that during the

follow-up evaluations, about 13% of patients did not recover from their episode of major depression. In the MOS, patients were divided by severity: of those with milder depression, about 65% recovered within 2 years, whereas 54% of the more severely depressed group recovered in the same period (11).

Shorter studies also give similar results. Rounsaville and colleagues (12), in a prospective follow-up of 96 patients with major depression, found that 12% of subjects had not recovered after 16 months. Kerr et al. (13), following initially hospitalized patients, found that 6% remained ill for the 4 years of the study.

Relapse

For the 141 patients in the CDS who recovered from their index episode of major depression, 22% relapsed within 1 year of follow-up (14). Factors predicting relapse included multiple episodes of major depression, older age, and a history of nonaffective psychiatric illness. The characteristics of this relapsed group were also examined, and it was found that the likelihood of remaining depressed for at least a year after relapse was 22%. Predictors of prolonged time to recovery included a longer length of the index episode, older age, and a lower family income.

Most studies look at relapse in terms of how it is affected by treatment (see below).

Recurrence

Angst (15), reporting on a 10-follow of patients in the Zurich study, found that only 25% of patients had only a single episode of depression. Thus, three-fourths of the sample had a recurrent depression, with one or more recurrences. Though Angst examined a number of sociodemographic variables, none significantly predicted the likelihood of recurrence.

Similarly high rates of recurrence have been found in other long-term studies. Weissman and Kasl (16) found that two-thirds of woman seen over 1 year had a recurrence of depression. Rao and Nammalvar (17), examining over 100 cases of depression in India for a follow-up of between 3 and 13 years, found that only about a fourth of the original group reported no recurrence of symptoms.

The rate and timing of recurrence seems most dependent on the type of recovery. Patients in the CDS who fully recovered (i.e., were asymptomatic on follow-up evaluation) had a much lower rate of recurrence (66%) than those with some residual symptoms (87%). The time to recurrence was also much longer in the asymptomatic group: mean of 180 weeks in the asymptomatic group compared with 33 weeks in the group with residual symptoms (18).

MITIGATING FACTORS

Part of "69 - The Course of Depression "

Comorbidity

Medical Illness

There are few longitudinal studies looking at the outcome of depression in medically ill patients, partly because of the difficulties inherent in recruiting such an unstable population. Studies that exist suggest that comorbid medical illness predispose individuals to a worse course of depression. The MOS, for example, found an additive effect on patient functioning when depression and other chronic medical illnesses were combined (19).

Double Depression

Double depression refers to the presence of concurrent dysthymia and major depression. In this disorder, the episodes of major depression are superimposed on a more chronic depressive disorder. It appears to be common—studies suggest that between one-fourth and two-thirds of patients with major depression will also have a comorbid dysthymia.

The comorbid presence of dysthymia can have an important effect on the course of depression. In the collaborative study, it was found that patients with double depression recovered more rapidly from episodes of major depression than those with major depression alone. However, the authors also found that the recovery tended to be not to one of “normalcy,” but to one of dysthymia. Relapse is also more frequent in patients with double depression than those with major depression alone—almost twice as likely in one study of 32 double-depressed subjects followed for 2 years (20). The MOS also found that full recovery was less likely for patients with double depression—these patients had a threefold risk of continued disease when compared with those with major depression alone (21).

Other Psychiatric Illnesses

Substance Abuse

Clearly, comorbid substance abuse has a detrimental effect on the course of depression. The CDS found that subjects who were currently alcoholic were half as likely as nonalcoholic depressed subjects to recover from their episode of major depression (22). Patients with a previous, but not current, history of alcoholism had a recovery rate comparable to those with no such history.

Anxiety Disorders

Anxiety disorders are commonly comorbid with depression. The presence of such comorbid disorders appears to exert a negative effect on the course of depression. Coryell and colleagues (23) found that depressed patients with panic disorder had a slower time to recovery than those without

comorbid panic. The CDS similarly found that patients with higher symptom ratings of anxiety had longer times to recovery from major depression (24).

Family History

A family history of depression appears to predispose an individual to depression. Two studies have looked at the relationship between parental history of depression and course of depression in the offspring. Though these studies had relatively small sample sizes, they both suggested that patients with a parental history of depression had a longer time to recovery than other patients (25 ,26).

Treatment Variables

Clearly, one of the questions of most practical interest is whether pharmacologic treatment is capable of significantly altering the course of depression for a patient. Antidepressants are generally used at all stages of depression—to hasten recovery, prevent relapse, and prevent recurrence of depression. However, as will be discussed, the further one looks down the course of depression, the less is really known about the ability of antidepressant and other pharmacologic treatments to alter the course of depression.

A wealth of data supports the efficacy of all available antidepressants in shortening the time to recovery from major depression. However, when one goes beyond the acute phase and examines pharmacotherapy during later points in the course of depression, the data become more meager.

Data support the efficacy of most of the serotonin reuptake inhibitors for continuation therapy, including fluoxetine (27), paroxetine (28), sertraline (29), citalopram (30), and mirtazapine (31). Nefazodone has also been shown in continuation treatment (32). These studies are summarized in Table 69.1 . However, when looking beyond continuation therapy to the maintenance treatment of recurrent depression, much fewer data exist.

Drug (Reference)	Weeks of Treatment	Relapse (Drug) %	Relapse (Placebo) %	*P* Value
Fluoxetine (27)	52	26	57	<.01
Paroxetine (28)	52	16	43	<.001
Sertraline (29)	44	13	46	<.001
Citalopram (30)	24	11	31	<.05
Nefazodone (32)	36	17	33	<.05
Mirtazapine (31)	20	4	23	<.0001

TABLE 69.1. RELAPSE RATES VS. PLACEBO: CONTINUATION STUDIES

Prien and colleagues (33) reported on a 2-year maintenance trial for depression. Patients who were successfully treated for acute depression were randomized to receive lithium carbonate, imipramine, both, or placebo. Treatments were continued for 2 years with doses maintained at acute treatment levels. Of 150 patients beginning maintenance treatment, 36% were successfully treated. The lowers rate of recurrence was found it the group treated with imipramine (Fig. 69.1). However, even this group had a 47% recurrent rate.

A second study, the Pittsburgh Study of Maintenance Treatment for Recurrent Depression (34), reports on up to

5 years of maintenance treatment. In this study, subjects first underwent open treatment for acute depression, using imipramine with interpersonal therapy (IPT). Patients who achieved recovery for at least 4 months were then randomized into one of five treatment conditions: (a) IPT alone, given monthly; (b) imipramine treatment alone; (c) IPT plus placebo; (d) placebo plus medication clinic; and (e) imipramine plus IPT. This portion of the study was continued for 3 years. Results from this study are summarized in Fig. 69.2 .

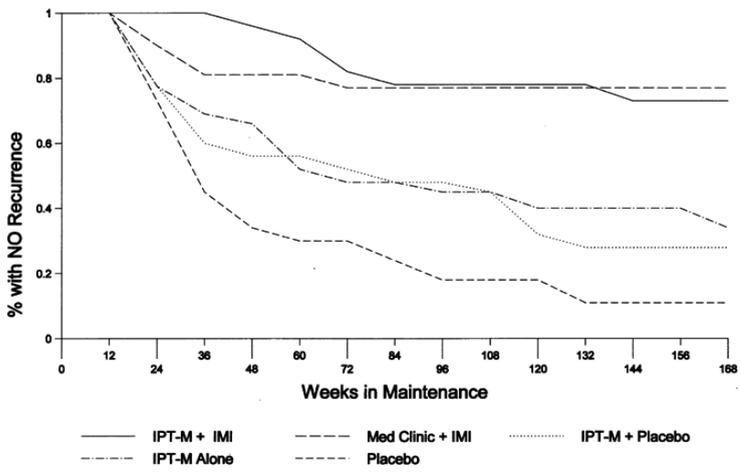

FIGURE 69.2. Pittsburgh Study of Maintenance Therapies in Recurrent Depression.

The authors intentionally chose patients who had highly recurrent depression (to maximize the likelihood of seeing a statistical difference in the groups). They found that patients who received imipramine (with or without IPT) had an approximately 20% risk of recurrence after 3 years. This compares significantly with the other conditions: IPT alone had a 60% risk of recurrence, and the placebo condition had an 80% risk.

This study was extended, with a smaller sample, for another 2 years. The subjects who had remained well during the first 3 years of the study were randomized to receive either imipramine or placebo. At that point only 20 patients remained in the study. After the two additional years, less than 10% of the patients (one patient out of 11) receiving imipramine had a recurrence, where approximately two-thirds of the placebo group had a recurrence.

Thus, the world literature of placebo-controlled studies of the treatment of recurrent depression beyond 3 years consists of only 200 subjects, who had a history of highly recurrent depression and received a medication that is rarely used by most psychiatrists today.

OTHER SUBTYPES OF DEPRESSION

Part of "69 - The Course of Depression "

The data are also limited when one considers the effect of treatment on the course of specific subtypes of depression. Two such subtypes will be considered here: chronic major depression and dysthymia.

Treatment Of Chronic Depression

Chronic depression is thought to respond more poorly to antidepressant treatment. Thus, studies of the acute and long-term treatment for this subtype are of great importance. Particularly lacking are studies of psychotherapy in this population.

Keller and colleagues (35) recently compared antidepressant treatment and cognitive-behavioral therapy, both alone and combined. For the 519 subjects completing the study, 55% of the antidepressant (nefazodone) group and 52% of the psychotherapy group responded to treatment. However, when treatment was combined, the response rate jumped to 85%. Thus, this study gives strong support to the clinical wisdom that combined treatment is preferable to either medication or psychotherapy alone.

To date, there are only two published studies on the long-term treatment of chronic depression. Kocsis and colleagues (36) report on a placebo-controlled trial of desipramine for the treatment of chronic depression. The study included patients with chronic major depression (*n* = 14).

After successful acute-phase and continuation treatment, patients were continued on treatment for a total of 2 years. During this maintenance period, patients on the placebo had four times the recurrence rate of those receiving desipramine. This rate was consistent for all diagnostic groups, including those with chronic depression.

Keller and colleagues (37) investigated the treatment of chronic depression in a larger sample of patients. Here, 161 patients who were successfully treated during an acute-phase and continuation phase were randomized to receive with sertraline or placebo for a 76-week maintenance period. The study included both chronic major depression and double depression patients in roughly equal numbers; as the results did not differ between the groups, the data was pooled.

Patients who received the placebo during the maintenance phase of treatment were four times more likely to have a recurrence of depression than those receiving sertraline. The time to recurrence was delayed for patients treated with sertraline compared to those treated with the placebo. Using a less stringent criterion of reemergence of depressive symptoms (though no necessarily meeting full criteria for depression), it was found that only 26% of patients taking sertraline experienced a reemergence of depressive symptoms, compared with 50% of those on the placebo. Similarly, only 34% of patients on sertraline maintenance therapy shored first symptoms of depression, compared with 60% of patients taking the placebo (Table 69.2).

TABLE 69.2. RECURRENCE RATES OF MAJOR DEPRESSION DURING MAINTENANCE STUDY TREATMENT

	Sertraline (*n* = 77)	Placebo (*n* = 84)	*P* Value
Suffered recurrence by strict protocol criteria (%)	6	23	.002
Suffered depression reemergence by consensus assessment (%)	26	50	.001
Showed first symptoms of reemergence of depression by consensus assessment (%)	34	60	.001

From Keller MB, Kocsis JH, Thase ME, et al. Maintenance phase efficacy of sertraline for chronic depression: a randomized controlled trial. *JAMA* 1998;280:1665–1672, with permission.

Treatment Of Dysthymia

Few studies have examined the pharmacotherapy of dysthymia, possible because of long-held beliefs that nonmajor depressions were less responsive to pharmacotherapy. What data do exist, however, do not support this belief. Most studies are of a relatively short duration of treatment, ranging from 4 to 12 weeks. For this time period there are data to support the use of most classes of antidepressants. These studies are summarized in Table 69.3 . Thus, the weight of evidence suggests that most agents that are effective for major depression are also effective for dysthymia, at least in the acute phase of treatment.

Epidemiology is the study of the distribution of diseases and disorders in human populations and the variation in these distributions in different population subgroups. An observation that a disease is higher in one group or another helps to identify risk factors or correlates of these high rates whose alteration will interrupt the causal sequence that produces the disorder. Epidemiologic methods have been grouped into descriptive studies, which provide basic estimates of rates and their variation or increased risk in a population; analytic studies, which explore the variations in rates among different groups and identify risk factors; and experimental studies, which test an association between a risk factor and a disorder and seek to control or reduce the occurrence by controlling the risk factor.

Epidemiologic methods used in psychiatry are identical to those used in other branches of medicine. In psychiatry there are few clearly defined and modifiable risk factors, so studies have focused on largely unmodifiable ones such as age and gender, although even these risk factors can be useful in providing a clue to etiology.

The evidence of risk factors for depression came primarily from descriptive (large-scale epidemiologic) studies and analytic (family and high-risk offspring) studies. The former is useful as a first step because the samples include subjects regardless of treatment and thus are unbiased. The latter are useful as they include control groups and can be used to calculate relative risks.

This chapter reviews the current evidence for risk factors associated with major depression (MD) and bipolar disorder primarily based on cross-national community surveys and some family studies.

MAJOR DEPRESSION

Part of "70 - Risk Factors for Major Depression and Bipolar Disorder "

Prevalence

Data on prevalence of unipolar MD based on epidemiologic community surveys using the same diagnostic assessment, the Diagnostic Interview Schedule (DIS), are now available from different parts of the world. These population-based epidemiologic studies were conducted in the 1980s, and a cross-national collaboration was formed to analyze the data together in a standardized way. Ten countries across the world, including North America, Europe, Asia, and New Zealand, participated. These data provide the first information on cross-national rates for risk factors using the same methods. The lifetime prevalence rates of MD range from 1.5 per 100 adults in Taiwan to 19.0 per 100 in Lebanon. The results showed considerable variation in rates, but consistency in sex differences and age of onset.

In the United States, the National Institute of Mental Health (NIMH) Epidemiologic Catchment Area (ECA) study conducted in 1980 reported an overall lifetime prevalence of 5.2 per 100 and a 1-year prevalence of 3.0 per 100, which was somewhat lower than the rate reported by other studies across the world (1). In the National Comorbidity Survey (NCS) conducted a decade later in the United States, a substantially higher lifetime prevalence of MD was reported—17.1 (2). All prevalence rates have been published individually, but for the purpose of comparison between the countries they have been standardized to the U.S. age and sex distribution (Table 70.1).

Country	Lifetime Rate/100			F/M Ratio	Mean Age at Onset
	Overall	Females	Males		
United States (ECA, 1980)	5.2	7.4	2.8	2.6	25.6
United States (NCS, 1990)	17.1	21.3	12.7	1.7	23.8
Canada	9.6	12.3	6.8	1.9	24.8
Puerto Rico	4.3	5.5	3.1	1.8	29.5
France	16.4	21.9	10.5	2.1	29.2
Germany	9.2	13.5	4.4	3.1	29.7
Italy	12.4	18.1	6.1	3.0	34.8
Lebanon	19.0	23.1	14.7	1.6	25.2
Taiwan (Taipei)	1.5	1.8	1.1	1.6	29.3
Korea (Seoul)	2.9	3.8	1.9	2.0	29.3
New Zealand	11.6	15.5	7.5	2.1	27.3

CIDI, Composite International Diagnostic Interview; DIS, Diagnostic Interview Schedule; ECA, Epidemiologic Catchment Area Study; NCS, National Comorbidity Survey.
[a]Rates have been standardized to the U.S. age and sex distribution (adapted from ref. 1). All studies used the DIS with the exception of the NCS, which used the CIDI.

TABLE 70.1. CROSS-NATIONAL LIFETIME PREVALENCE OF MAJOR DEPRESSION[a]

The disparity between the rates reported in the ECA and the NCS has generated considerable controversy and discussion. Whether the differences are real (reflecting a substantial change in the prevalence rate over the decade) or artifactual (due to differences in methodology) has prompted careful examination. It is now believed that the difference is due to methodology (e.g., different diagnostic assessment, sample age, and size), and not to a true increase in the rate over the decade.

Gender

Despite the variation in rates, the most consistent finding in the cross-national studies and the two U.S. studies is the increased rate of MD in women (Table 70.1). The reasons for this disparity are not clear, but the disparity is also found in clinical studies. Interestingly, prior to puberty there are no sex differences in rates of depression. However, following puberty there is a dramatic shift in the prevalence rates, with a twofold increase in the prevalence of depression among women compared to men. A higher risk of depression in women is probably accounted for primarily by the higher risk of first onset in women. A series of analyses of the NCS data shows that there is little difference in the probability of acute recurrence in women and in men with a history of depression (3). Many theories, biological, psychosocial, and artifactual, attempt to explain this dramatic increase in the prevalence of depression among women, but none is fully satisfactory.

Age Of Onset And Secular Changes

The age of first onset of MD is fairly consistent across studies (Table 70.1). Of the ten major population-based epidemiologic studies reported by Weissman et al. (1), eight reported the age of onset between 25 and 30 years. In the NCS, the age of onset was 24 (3). Although there is consistency across studies regarding the age of onset, there is some evidence that the age of onset of depression has decreased over the last half century (4). In 1985, using the data from the NIMH Collaborative Program on the Psychobiology of Depression, the cumulative probability of a first episode of MD in female relatives of patients with MD by age 30 was less than 10% in individuals born before 1929. This rate doubled in cohorts born between 1930 and 1949, and among those born after 1950 the rate skyrocketed to 60%. The rate in males also increased in younger cohorts, but not nearly as dramatically as in women (Fig. 70.1 and Fig. 70.2).

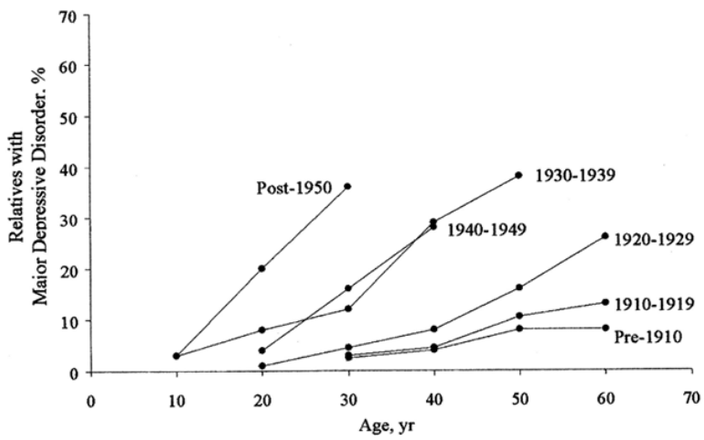

FIGURE 70.1. Cumulative probability of diagnosable major depressive disorder in male relatives by birth cohort. (Adapted from Klerman GL, Lavori PW, Rice J, et al. Birth-cohort trends in rates of major depressive disorder among relatives of patients with affective disorder. *Arch Gen Psychiatry* 1985;42(7):689–693.)

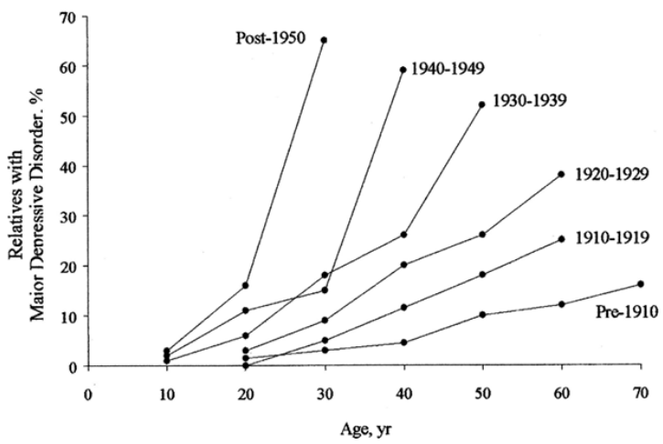

FIGURE 70.2. Cumulative probability of diagnosable major depressive disorder in female relatives by birth cohort. (Adapted from Klerman GL, Lavori PW, Rice J, et al. Birth-cohort trends in rates of major depressive disorder among relatives of patients with affective disorder. *Arch Gen Psychiatry* 1985;42(7):689–693.)

An analysis of the ECA data by Wickramaratne and colleagues (5) showed an increase in the rate of MD in the cohort born between 1935 and 1945. The rates for females stabilized after this increase. However, rates for males continued to rise in the cohort born between 1945 and 1954, and then decreased in the most recent cohort of the study,

those born between 1955 and 1964. In the NCS (2), lifetime risk of MD increased consistently through increasingly younger cohorts. In the youngest cohort (born between 1966 and 1975) there was a substantial increase in the risk of first onset in early adulthood compared to all other cohorts. The finding was true for both men and women.

With regard to prevalence across adulthood in the NCS, 30-day prevalence was fairly constant between the ages of 15 and 44, but dropped by nearly half in the decade between 45 and 54. As has already been mentioned, among women the prevalence was very high, 8.2% in the 15 to 24 cohort, and then dropped off to between 4% and 6% in subsequent decades, without a reduction as they age (6).

Marital Status

Marital status has been found to be highly associated with onset and prevalence of depression, but not with treatment outcome. In the ECA and the NCS, married and never-married persons were found to have lower rates of depression than those divorced, separated, and widowed. For example, in the ECA study, divorced and separated individuals had over a twofold increase compared to those married and never married (Table 70.2). Two countries with the lowest rate of MD in the ECA study—Korea and Taiwan—also had the lowest divorce and separation rate. Although Beirut also has a low rate of separation/divorce but a high rate of depression, the increased rate of depression may be more likely attributed to the civil war in the country that occurred around the same time as the study (1). Divorce and separation also increased the likelihood of the first depressive episode (7). The direction of the association is not clear.

	Marital Status		Lifetime Rate/100 Major Depression		
Country	Separated/ Divorced (%)	Married (%)	Separated/ Divorced (%)	Married (%)	OR (95% CI)[b]
United States	12.2	57.3	11.0	4.3	2.5 (2.0–3.2)
Canada	11.4	59.1	23.8	7.6	4.1 (2.9–5.7)
Puerto Rico	9.6	59.0	7.7	3.8	1.9 (0.9–4.3)
France	6.1	75.5	39.6	14.2	3.8 (2.4–5.4)
Germany[c]	9.5	78.1	18.4	7.8	2.2 (0.8–6.1)
Lebanon[d]	0.3	50.6	100	19.4	NA
Taiwan (Taipei)	3.7	71.9	3.8	1.2	2.9 (1.6–5.5)
Korea (Seoul)	0.7	69.6	5.3	3.0	1.6 (0.3–7.3)
New Zealand	9.4	61.4	26.5	9.8	3.5 (2.1–5.9)

NA, not available.

[b]Odds ratios (ORs) compare the rate of major depression in separated or divorced vs. married and are standardized to U.S. age and sex distribution and adjusted for age and sex within each site. CI, confidence interval.
[c]Data from former Federal Republic of Germany (West Germany) based on ages 26 to 64 years.
[d]Both cases of major depression in separated or divorced study participants (2/2).

TABLE 70.2. LIFETIME RATE PER 100 OF MAJOR DEPRESSION BY MARITAL STATUS: AGES 18 TO 64 YEARS[a]

Social Class

In the NCS, the odds ratios for MD were significantly higher for those individuals earning less than $20,000 a year, and declined as income increased (6). With regard to employment status, homemakers had a very high risk of MD (odds ratios 2.8), but it is not clear whether the employment status has been adjusted for sex. Blazer et al. (6) reported no significant association in adjusted odds ratios for

household income. In the ECA study, no association was found between socioeconomic status and MD. Although these findings are not conclusive, they suggest that socioeconomic status is not a strong risk factor for depression.

Race And Ethnicity

The prevalence of MD does not vary significantly with race and ethnicity, and in most cases can be explained by socioeconomic and educational factors. Both major epidemiologic studies (ECA and NCS) controlled for socioeconomic status and education, and both showed that race was not a significant predictor of MD.

In the NCS the lifetime prevalence of MD was lower overall among African-American subjects, except for African-Americans 35 to 44 years of age. The highest prevalence, however, was in African-American women 35 to 44 years of age. No significant association was found in adjusted odds ratios for race/ethnicity in the study, which is consistent with the ECA study. The 10-country study (1) found the lowest rate of MD in the two Asian countries included—Korea and Taiwan. Neither the ECA nor the NCS studies had sufficient Asian samples to determine whether the risk increases for Asians living in the U.S.

Familial Factors

Methods used to assess possible heritability of MD are family, twin, and adoption studies. Although these studies are suggestive of a genetic vulnerability to MD, their design does not allow identifying the genetic variables involved in the mode of transmission. More direct genetic strategies include genetic linkage and association studies.

Family Studies

Family studies assess the rate of an illness in relatives of patients with the illness as compared with the rate in a control group. The greater the difference in rates, the more likely it is that a genetic component exists. Gershon and colleagues (8) assessed rates of illness in relatives of unipolar probands and normal controls. They reported a lifetime risk of unipolar depression of 16.6% in the first-degree relatives of probands and 5.8% in those of normal controls (Table 70.3). Using these results and additional ones involving bipolar I, bipolar II, and schizoaffective disorder, the authors argued for a multifactorial genetic vulnerability model, ranging from unipolar to bipolar II, to bipolar I, and finally to schizoaffective disorder.

		Rate/100	
Form of Depression	**Study**	**Proband**	**Control**
Unipolar MDD	Gershon et al., 1982 (8)	16.6	5.8
Mild depression	Weissman et al., 1984 (9)	14.7	5.1
Severe depression		16.4–16.5	
Recurrent depression	Kupfer et al., 1989 (11)	20.7	NA
Single-episode, late onset	Bland et al., 1986 (10)	3.4	NA
Recurrent depression, late onset		8.2	
Single-episode, early onset		7.5	
Recurrent depression, early onset		17.4	
Early onset (age <20)	Weissman et al., 1984 (12)	24.2	4.8

MDD, major depressive disorder.

TABLE 70.3. FAMILY STUDIES OF MAJOR DEPRESSION

In a family study of 335 probands and 2,003 first-degree relatives, Weissman and colleagues (9) reported a lifetime rate of MD of 14.7 per 100 in the relatives of probands with mild depression, and a rate of 16.4 to 16.5 per 100 in the relatives of probands with severe depression, whereas the rate of MD in the relatives of control subjects was 5.1 per 100 (comparable to the rate in the general population). The distinction between mild and severe depression was made on the basis of hospitalization. Persons hospitalized for more than 5 days for a depressive episode met the criteria for severe depression, whereas persons with mild depression were those never hospitalized for depression.

The risk of depression is higher among the relatives of probands with early-onset recurrent MD. Bland et al. (10) reported a morbidity rate of 17.4% in relatives of probands with early-onset recurrent unipolar depression. This contrasted with 3.4% rate in relatives of probands with a single episode of depression and late age of onset. A study of 179 probands with recurrent depression found a morbid risk of 20.7% for nonbipolar depression (11). Consistent with Bland et al.'s study, relatives of probands with early-onset recurrent unipolar depression (before the age of 20) had a significantly higher risk of depression than relatives of late-onset probands (11). Similar results were obtained by Weissman et al. (12). The rates of MD were highest (24.2

per 100) in the relatives of probands with early age of onset (younger than 20) and decreased to 7.6 per 100 in relatives of probands with late age of onset (over 40).

These findings have formed the rationale for an NIMH-sponsored multisite genetic sib-pair study of early-onset recurrent MD. Nearly 1,000 sib pairs will be diagnosed and DNA made available to the scientific community for genetic study.

A variant of family studies are studies of offspring of depressed parents. These studies consistently show a threefold increased risk of MD in the offspring of depressed parents that is persistent as the offspring age and into the next generation (13 ,14 and 15). Interestingly, when parental divorce, parent-child bonding, and relationships were examined only, parental depression remained the only significant risk factor in the offspring of depressed parents. In the offspring of nondepressed parents, these factors were predictive of offspring depression. However, the rates of depression were low (16).

Twin Studies

In the early 1990s Kendler and his colleagues (17 ,18) reported a number of analyses of the data collected from female-female twin pairs identified through the population-based Virginia Twin Registry. The proband-wise concordance was 37.3% in monozygotic (MZ) twins, and 23.9% in dizygotic (DZ) twins; the estimated heritability of liability to MD was 46% (17). However, when the model was corrected for unreliability of measurement, the heritability of liability to MD was estimated at 71% (18). In a more recent study that included female-female and male-male twin pairs identified through the same registry, Kendler and Prescott (19) found proband-wise concordance of 31.1% in MZ and 25.1% in DZ male twin pairs, and 47.6% compared to 42.6% in female twin pairs. These differences were statistically significant. The estimated heritability in male twins was 39%, comparable to the only other general population twin study of lifetime MD in men (20), who reported an estimated heritability of 36%. The estimated heritability in female twin pairs was 42% as measured in the previous report by the same authors (21). These rates are approximately twice those in the general population, reflecting a genetic component to MD.

In a hospital-based twin registry study conducted by McGuffin et al. (22), the proband-wise concordance was 46% in MZ and 20% in DZ twins, a statistically significant difference. The estimates of heritability were between 48% and 75%, based on the assumed population risk.

Personality

In contrast to most of the previously discussed risk factors that are fixed and clearly antedate the onset of depression (e.g., age and sex), personality is not fixed and in fact may interact with depression. Methodologic issues have confounded the study of this issue. For example, when depressed, patients may not provide valid reports of their premorbid functioning (23). In a comparison of patients' self-report personality measures first during their depressive episode and again following complete recovery 1 year later, the depressed state significantly influenced assessment of emotional strength, interpersonal dependency, and extraversion (24).

The most methodologically clear approach is to evaluate persons before they develop a depressive disorder. Hirschfeld et al. (25) conducted a premorbid personality assessment in a large sample at risk for the development of MD. The personality features most predictive of first onset of depression among middle-aged adults (age 31 to 41) were decreased emotional strength and increased interpersonal dependency. Among younger adults (age 17 to 30) no personality features were associated with subsequent MD. This may reflect that psychosocial factors become more important in late-onset depression, whereas genetic factors are more important in early-onset depression.

Life Events

Clinicians have long described a relationship between life events (particularly adverse interpersonal events) and the onset of depressive episodes. A series of studies conducted between the middle 1960s and 1990 using standardized instruments and diagnostic procedures did find corroboration of this relationship (26). Jenaway and Paykel (26) report that events involving loss (e.g., divorce, death) and threat of separation are associated with depression. There is little specificity to this relationship, as these events precede other illnesses as well.

Kendler et al. (27) investigated how genetic liability to MD and stressful life events interact in the etiology of MD in a study of 2,164 female twins. They found that the incidence of depression increased significantly in the month of occurrence of 13 stressful events. Four of the events termed "severe"—death of a close relative, assault, serious marital problems, and divorce/breakup—predicted the incidence of MD with the odds ratios of greater than 10. Genetic liability also had a significant impact on the onset of MD. The lowest probability of onset of MD was found in individuals with the lowest genetic liability (MZ, co-twin unaffected) for those exposed and unexposed to a severe event. Probabilities of the onset of MD were substantially higher in individuals with the highest genetic liability (MZ, co-twin affected). Kendler et al. concluded that genetic factors influenced the risk of MD in part by influencing the susceptibility of individuals to the depressive effect of life events.

Early Trauma

Trauma in early life has long been considered an etiologic factor in the pathogenesis of depression by clinical theorists.

This issue has been examined in a series of studies by Brown's group (28 ,29) at the University of London. In one study of 286 working-class mothers in England, 9% reported childhood sexual abuse (28). Of these 64% suffered a depression during the period of study. In a subsequent prospective study the same investigators (29) found that childhood neglect or abuse was strongly associated with early-onset (before age 20) depression. McCauley and colleagues (30) also found that childhood physical or sexual abuse was predictive of a variety of adult afflictions, including depression. Heim and colleagues (31) found that childhood abuse causes persistent hypothalamic-pituitary-adrenocortical (HPA) hyperactivity in adulthood, which is consistent with depression. In a review of this area, Kessler and colleagues (32) concluded that adverse childhood events were associated with early-onset depression. Caution is in order in interpreting these findings because multiple-year retrospective withdrawal can be flawed, and controlling for all relevant covariates (such as family history of depression) is often impossible.

General Medical Illness

Increased rates of depression have been reported among patients with several general medical illnesses. Among these are cardiovascular disease, AIDS, respiratory disorders, cancer, and several neurologic conditions (Parkinson's disease and stroke in particular) (33 ,34). The relationship is most striking in cardiovascular disease; 13 prospective studies using structured clinical diagnostic interviews evaluating antecedent depression on subsequent cardiovascular disease were reviewed by Musselman et al. (35). Almost all the studies found a strong association between depression and subsequent cardiovascular morbidity and mortality. Several important physiologic aspects of depression may account for this association. They include HPA dysregulation, sympathomedullary hyperactivity, and diminished heart rate variability (35).

BIPOLAR DISORDER

Part of "70 - Risk Factors for Major Depression and Bipolar Disorder "

Prevalence

The lifetime prevalence rate of bipolar I disorder reported in the NCS (2) was 1.6%, and the ECA study conducted in the United States reported a lifetime rate of 0.9% (36). In contrast to MD, the prevalence rates were remarkably consistent among countries (Canada, Finland, France, Germany, Hong Kong, Italy, Korea, New Zealand, Puerto Rico, Taiwan, and the United States), and there was little variation in rates by gender (Table 70.4). The rates of bipolar spectrum disorder (bipolar I, bipolar II, cyclothymia, and others) may be considerably higher than bipolar I alone (37). The prevalence rates reported in 11 studies of bipolar II disorder were between 0.3% and 3% (38). The lifetime prevalence rates for bipolar spectrum disorder were reported between 3% and 6.5% (38).

	Lifetime Rates/100				
	Overall	Females	Males	F/M Ratio	Mean Age at Onset
United States (ECA 1980)	0.9	1.0	0.8	1.2	18.1
United States (NCS 1990)	1.6	1.7	1.6	1.1	21.0
Canada, Edmonton	0.6	0.5	0.7	0.7	17.1
Puerto Rico	0.6	0.5	0.8	0.6	27.2
Germany[b]	0.5	1.0	0.0	NA	29.0
Taiwan	0.3	0.3	0.3	1.0	22.5
Korea	0.4	0.2	0.6	0.3	23.0
New Zealand	1.5	1.2	1.7	0.7	18.2

NA, not applicable.
[a]Rates have been standardized to the U.S. age and sex distribution (adapted from ref. 1).
[b]In Germany (former Federal Republic of Germany) the one study participant in Munich with bipolar disorder was female.

TABLE 70.4. LIFETIME PREVALENCE OF BIPOLAR DISORDER

Gender and Age

In contrast to MD, epidemiologic data show no significant sex differences in rates of bipolar disorder (Table 70.4). No sex differences were reported in the ECA study (39). Similarly, the NCS reported no sex differences in either the mean number of total episodes of mania and depression combined (75.4 in men and 60.4 in women), and not a large sex difference in median number of total episodes (38 in men and 30 in women) (40). Additionally, no differences in male to female ratios of bipolar disorder were found internationally (1). Mean age of onset for bipolar depression was generally younger than for MD, ranging from 18 to 27 years of age in different countries (1). The NCS places the age of onset at 21.

Other Sociodemographic Variables

Historically bipolar disorder was thought to be more frequent among higher socioeconomic classes, and there were some pilot data to support this (e.g., 41). However, population-based studies over the last two decades have not replicated this finding. In the ECA, occupation, income, and education were not found to influence prevalence (42). In the NCS, those with bipolar I disorder were more likely to have annual incomes less than $20,000. The notion of higher rates of bipolar disorder among higher income levels was probably due to misdiagnosis of bipolar patients as schizophrenics in lower income groups.

In the ECA, bipolar disorder was much less frequent among married people, as contrasted with divorced or never-married people. Bipolar disorder was more prevalent among those with multiple divorces (42). In the NCS, bipolar disorder was more frequent among unmarried, poorly educated people.

Genetic and Familial Factors

In a review of the eight family studies of bipolar I disorder that included a control group, a metaanalysis (43) showed that bipolar I disorder was seven times more likely among relatives of bipolar I probands than of controls. These studies also demonstrate an increased risk of MD in relatives of bipolar probands, although the relative risk is lower than for bipolar I. Early age of onset and number of ill relatives increases the risk of illness in relatives, but other variables (e.g., type of relative) appear not to affect it (43).

In a pooled analysis of the six twin studies of bipolar I disorder conducted between 1962 and 1999, Craddock and Jones (43) calculated an estimate of proband-wise concordance of 50%, although the authors believe this to be an underestimate. They believe it is probably around 60%. Integrating the results of family, twin, and adoption studies, Craddock and Jones conclude that there is a substantial genetic predisposition to bipolar disorder.

There have been a number of investigations aimed at determining the actual genes involved in bipolar illness. Attempts to demonstrate linkage to the X-chromosome, to color blindness, to chromosomes 4, 11, 18, and others have not been conclusive (43). The most likely explanation for lack of success is that these strategies assume a single genetic mode of inheritance for a complex multiple-gene interaction with environmental factors.

Environmental Factors

Although biological and genetic factors have long been known to play a major role in the etiology of bipolar disorder, psychosocial factors are gaining attention. In particular, many studies have identified the association between stressful life events and social rhythm disruptions and onset of recurrence. It is unlikely that psychosocial factors play a major role in the risk of first onset of bipolar disorder, but they may have an important role in increasing the risk of recurrence.

Chrono-biological disturbances have long been associated with bipolar disorder (44). Sleep-wake and other circadian rhythm disturbances are core symptoms of bipolar episodes for both manic and depressive episodes (e.g., insomnia, and decreased need for sleep). Some have theorized that disruption in social zeitgebers (i.e., social demands or tasks that set the biological clock by environmental events) can lead to instability in circadian rhythms, which can in turn trigger bipolar episodes (45). Malkoff-Schwartz and colleagues (46) found than severe social rhythm disruptions (e.g., returning from international trips, moving, losing a job) were associated with onsets of mania, but not depression, in bipolar patients.

DISCUSSION

Part of "70 - Risk Factors for Major Depression and Bipolar Disorder "

Beliefs and hypotheses about risk factors for depression (such as undue interpersonal dependency) emerged from clinicians treating individual patients and from studies done in psychiatric settings. Both suffer from sampling bias: those presenting for treatment are evaluated, but many factors in addition to the illness itself affect treatment seeking (e.g., income and psychological mindedness).

This chapter's introduction described the value of epidemiology in testing these hypotheses. The descriptive epidemiologic studies from around the world with their unbiased population samples have supported the validity of some of the hypotheses and have not supported others.

For MD there is strong evidence that women have twofold the prevalence of men, an age of onset between 25 and 30 years, an increase following separation and divorce, and an increase in families of those with MD. There are significant differences in lifetime rates around the world. There is little support for racial, ethnic (with the possible exception of Asian), and income factors. Personality factors are nonspecific. Early life trauma, particularly sexual abuse, is associated with early-onset depression in women. Increased rates of depression are found in several general medical illnesses. The association between depression and cardiovascular illness is strong, with depression predicting increased rates of morbidity and mortality among cardiovascular patients.

Analytic studies (such as twin studies) have suggested some interaction among genetic and environmental factors. The incidence of depression was increased when several life events (such as death of a close relative) occurred in the prior month in individuals with high genetic liability. The ongoing NIMH sib-pair study of early-onset depression will shed light on the possible genetic etiology of early-onset recurrent MD.

For bipolar disorder, there are substantial differences in

risk factors compared to MD. There is little variation in lifetime rates around the world (about 1%), and nearly equal prevalence in men and women. Bipolar spectrum is much more frequent, in the range of 3% to 6%. Age of onset is in the late teens and early twenties, earlier than in MD. A range of studies strongly support a genetic predisposition to bipolar disorder, but specific replicable genetic factors have yet to be demonstrated. A complex multiple gene interaction with environmental factors is most likely, a situation that is challenging to research and to isolate. Life events, especially disruptions in social zeitgebers, increase the likelihood of manic, but not depressive, recurrences in bipolar subjects.

An intriguing new area of interest is emerging in risk factors for depression—that of differences in consumption of fish oils around the world. Hibbeln (47) documented a strong negative correlation (-0.84) between the prevalence of MD and the annual apparent fish consumption per person in nine countries worldwide. He argued that this may be related to varying amounts of long-chain polyunsaturated fatty acids in diets in different cultures (48).

An experimental epidemiologic study is under way that will test genetic risk factors for bipolar disorder. Calabrese is prophylactically treating familially high-risk adolescents with a mood stabilizer in a longitudinal double-blind placebo-controlled study.

ACKNOWLEDGMENTS

Bipolar Disorders: Review of Molecular Genetic Linkage Studies

Wade Berrettini

Wade Berrettini: University of Pennsylvania School of Medicine, Center for Neurobiology and Behavior, Philadelphia, Pennsylvania.

This chapter reviews evidence of the heritability of bipolar (BP) and recurrent unipolar (RUP) disorders. This evidence has accumulated through family, twin, adoption, linkage, and candidate gene studies. Both the twin and family studies suggest that unipolar and bipolar disorders share some fraction of genetic susceptibility. Data from the twin and family studies can be used for genetic counseling, and this will be discussed briefly from a clinical perspective.

Efforts to find susceptibility genes through linkage studies have yielded several confirmed regions of the genome where such genes will be found. These linkage studies will be discussed and summarized from methodologic perspectives.

Candidate gene approaches to BP and RUP disorders will be reviewed, with some suggestions for improving methods. A few of the most promising candidate genes will be noted.

Mechanisms on nonmendelian inheritance may be involved in the complex genetics of BP and RUP disorders. Imprinting, triplet repeat expansion, and mitochondrial inheritance are reviewed briefly as examples of nonmendelian mechanisms possibly involved in these disorders.

Finally, the implications of the Human Genome Project for future progress will be discussed.

GENETIC EPIDEMIOLOGY

Part of "71 - Bipolar Disorders: Review of Molecular Genetic Linkage Studies "

Family Studies

Family studies can answer three critical questions concerning the inheritance of a human phenomenon:

1. Is the phenomenon found more frequently among the biological relatives of an affected individual compared to biological relatives of unaffected persons? Alternatively, are relatives of an affected subject at increased risk for the disorder compared to relatives of control subjects?
2. What other phenomena (possibly genetically related) are also found more frequently among relatives of an affected individual? Alternatively, what other disorders (or clinical characteristics) may share a common genetic vulnerability with the phenomenon in question?
3. Can a specific mode of inheritance be discerned?

Family studies are executed as follows. A proband that (most likely) has the phenomenon in question is examined to determine its presence. This person's biologic relatives are similarly examined for its presence. Simultaneously, relatives of unaffected probands are examined in the same fashion for its presence. The importance of simultaneous examination of control families cannot be overestimated, as the risk of psychiatric disorders in the general population varies according to the diagnostic criteria and according to the judgment of specific interviewers and diagnosers. Thus, it is rarely acceptable to rely on data collected by others to estimate risk for a control population. The risk of a particular disorder can then be calculated for the relatives of both affected probands and control probands. If the disorder in question is heritable, a family study should show that relatives of a proband with the disorder are at significantly higher risk to show the disorder themselves, compared to relatives of control probands. Often, the risk for a certain class of relatives of affected probands is expressed as a ratio. Shown below is an example for siblings:

$$\text{Sibling relative risk} = \frac{\text{[Risk for siblings of affected probands]}}{\text{[Risk for siblings of control probands]}}$$

A family study is not the same as a “family history” study, in which the relatives are not directly examined, but information from the proband or other persons is used to establish the affections status of relatives. The reliability of the family history method is not as high as the family study

method. The discrepancy in reliability is a function of the phenomenon under study, but for psychiatric diseases the discrepancy is often great enough to render the family history method undesirable.

As with any disorder with a variable age of onset, the prevalence of illness among relatives must be corrected for the fraction of the age of risk that each relative has yet to live through. There are several ways of performing this correction. Commonly, using age-at-onset data from the relevant population, the number of relatives in a particular age decade is multiplied by the fraction of affected people who became ill by that decade of life. This product is known as the *bezugziffer*. A bezugziffer is calculated for each decade of life and the sum of them represents the total number of relatives at risk. When the total number of ill relatives is divided by this sum of bezugziffers, a morbid risk value (risk of developing the illness at some point in life) is determined for the relatives.

Family studies of bipolar disorder (BPD) show that a spectrum of mood disorders is found among the first-degree relatives of BPD probands: BP I disorder, BP II disorder with major depression (hypomania and RUP illness in the same person), and schizoaffective (SA) disorders and RUP depression, as described by multiple investigators (1 ,2 ,3 ,4 ,5 ,6 ,7 ,8 ,9 and 10). Nearly all family studies of BPD probands reveal that their biologic relatives are at increased risk for BPD, SA, and RUP diagnoses. These results suggest that RUP and SA diagnoses, within a familial context of BPD disorders, may be alternative phenotypic expressions of the same genetic susceptibility. Thus, this spectrum of mood disorders represents a reasonable BPD affection status model, in that it can be expected that some genetic susceptibility to BPDs may partially explain genetic susceptibility to SA and RUP disorders.

The first-degree relatives of RUP probands are at increased risk for BPD and RUP disorder (1 ,2). If the general population risk for BPDs is ˜1%, then the risk to first-degree relatives of BPD probands is ˜10%. Similarly the first-degree relatives of BPD probands are at increased risk of RUP disorders: if the general population risk if ˜8% (1 ,2), the RUP risk to first-degree relatives of BPD probands is ˜15% (1). Historically, SA disorder has been defined as a nosologic category that may describe psychotic affective disorders in some diagnostic systems. This makes estimates of risk of SA disorder among relatives of BPD probands difficult to compare across family studies.

Several family studies have also reported a higher risk of RUP illness among the first-degree relatives of RUP probands (2 ,4 ,11 ,12 ,13 and 14). The first-degree relatives of RUP probands also show significant increases in risk for BPD diagnoses (1 ,2). Thus, first-degree relatives of RUP and first-degree relatives of BPD probands are at increased risk for both RUP and BPD diagnoses. These data suggest that the two nosologic entities may share some genetic susceptibility and/or environmental risk. This tentative conclusion, which must await molecular studies, is supported by twin studies (see below).

Thus, family studies of BPD suggest that the first-degree relatives are at increased risk of BPD, SA disorder, and RUP disorder. Similarly, a review of SZ family studies reveals that the first-degree relatives of schizophrenia (SZ) probands are at increased risk of SZ, SA, and RUP disorders (10 ,15). Kendler et al. (16) describe an increased risk of psychotic affective illness among relatives of SZ probands. Despite numerous carefully conducted investigations, no family study of SZ reports increased risk for BPD among first-degree relatives of SZ probands. However, the first-degree relatives of SZ probands *and* the first-degree relatives of BP probands are at increased risk of SA and RUP disorders. The overlap in elevated risk of SA and RUP diagnoses is evident. Therefore, these family studies are consistent with *partial* overlap in familial susceptibility for BPD and SZ disorders. It will be instructive to determine whether putative BPD susceptibility loci are mapped to regions of the genome at which SZ susceptibility loci are thought to exist (see below).

Twin Studies

A phenomenon that is under genetic control should be more “concordant” (similar) in monozygoric (MZ) twins compared to dizygotic (DZ) twins. By comparing the concordance rate (how often the second member of a twin pair demonstrates the phenomenon in question when the first member has it) for MZ and DZ twin pairs, evidence of the genetic determination of a phenomenon can be obtained. There are two methods for calculating concordance rates in twin studies. “Pairwise concordance” involves a simple calculation of the percentage of twin pairs in which both members demonstrate the phenomenon in question. In “proband-wise concordance” every affected person is considered a proband (within a family, a proband is usually the first person who comes into contact with the investigators), independent of status within a twin pair, meaning that twin pairs in which both are affected are counted twice. Studies in which twin subjects are selected at random from a population most appropriately apply the pairwise method. However, in most twin studies of psychiatric diseases, the twins are not selected at random, but are selected because one member has the disease in question. Therefore, these studies most appropriately use the proband-wise concordance, although both types of analyses can yield similar results. The results of both types of analyses are often reported. Differences between the MZ and DZ concordances are usually larger when the proband-wise calculation is used.

If the variable being measured is genetically determined, then the concordance rate may be significantly higher in MZ twins compared to that for DZ twins. This suggests, but is by no means conclusive, that the variable in question may be heritable. The magnitude of the difference for the

MZ versus DZ concordance rates may provide an estimate of the heritability of the variable in question. Although there are several methods for calculating this heritability, one of the most simple is Holzinger's index:

$$\text{Heritability} = \frac{[\text{MZ Concordance (\%)} - \text{DZ Concordance (\%)}]}{[100 - \text{DZ Concordance (\%)}]}$$

When the MZ concordance rate is 100% and the DZ rate is 50%, the variable is a purely genetically determined phenomenon. More complex path modeling of heritability estimates from twin data is commonly used today (e.g., 16 ,17). MZ concordance rates lower than 100% suggest reduced penetrance (the gene is present but the disease is not expressed because of protective environmental events) or the presence of phenocopies (individuals appear to exhibit the variable in question but do not have the genetic diathesis for it).

Twin studies conducted over the past 70 years have indicated greater MZ twin concordance compared to DZ twin concordance for BPD and RUP disorders (for review see ref. 18). More recent twin studies (16 ,17 ,19), conducted with operationalized diagnostic criteria, validated semistructured interviews, and blinded assessments, confirm the earlier research, showing significantly greater MZ twin concordance. The MZ twin concordance rate (˜65%) indicates decreased penetrance of inherited susceptibility or the presence of phenocopies (nongenetic cases). Among MZ twin pairs concordant for mood disorder, when one twin has a BPD diagnosis, RUP illness is present among 20% of the ill co-twins (20 ,21). This suggests that BPD and RUP syndromes share some common genetic susceptibility factors. This result is nicely concordant with the family study results reviewed above, which demonstrate that the first-degree relatives of BPD and the first-degree relatives of RUP probands are at increased risk for both BPD and RUP disorders. The twin and family study data suggest that BPD and RUP disorders share genetic susceptibility.

This has some clinical implications. For example, these genetic epidemiologic data suggest that RUP individuals who have lithium-responsive BPD relatives should be treated with lithium for prophylaxis of RUP, if maintenance treatment with an antidepressant is not successful.

Adoption Studies

Most adoption studies proceed through identification of affected probands that have been adopted early in life. Similarly, a control group of unaffected, adopted probands is identified. Risk for the disorder is compared in four groups of relatives: the adoptive and biological relatives of affected adoptees and the adoptive and biological relatives of unaffected adoptees. For partially genetic phenomena, there will be an increased risk among the biological relatives of affected probands, compared to the other three groups of relatives. Alternatively, risk for illness in adopted-away children of ill parents can be compared with risk for illness in adopted-away children of well parents.

In the “cross-fostering” design, researchers ascertain two groups of adopted-away children—those of ill parents and those of unaffected parents—both of whom are adopted away early in life and are raised by well parents. Researchers also ascertain two additional groups of adopted-away children—those of ill parents and those of unaffected parents—both of whom are similarly adopted away early in life and raised by affected adults. If the presence of the illness in the family environment increases risk for development of the disease, then the risk for children raised by affected parents will be greater than the risk for children raised by unaffected parents. If only genetic factors are important in the pathogenesis, then children with ill biologic parents will be at increased risk for illness, independent of the presence of illness in the adoptive parents. These adoption studies cannot exclude intrauterine or perinatal events, which may yield results similar to those of genetic diseases.

Mendlewicz and Rainer (22) reported a controlled adoption study of BPD probands, including a control group of probands with poliomyelitis. The biological relatives of the BPD probands had a 31% risk for BPD or RUP disorders, compared to 2% risk in the relatives of the control probands. The risk of affective disorder in biological relatives of adopted BPD patients was similar to the risk in relatives of BPD patients who were not adopted away (26%). Adoptive relatives do not show increased risk compared to relatives of control probands.

Wender et al. (23) and Cadoret (24) studied RUP and BPD probands. Although evidence of genetic susceptibility was found, *adoptive* relatives of affective probands had a tendency to excess affective illness themselves, compared with the adoptive relatives of controls. Von Knorring et al. (25) did not find concordance in psychopathology between adoptees and biological relatives when examining the records of 56 adoptees with unipolar (UP) disorders. Sample size may have limited the conclusions of this study. It is also possible that heritable factors may be more prominent for BPD disorders, compared to RUP disorders.

Genetic Counseling

Frequently, patients with BPD or RUP disorder are aware of the genetic component to these illnesses, and, quite naturally, they are concerned about risks of illness to other members in the family, most often children. Clinician responses to these requests for genetic counseling properly use risk estimates derived from controlled family studies (e.g., 1,2). Family studies of BP and RUP illness have established the risk for offspring of affected parents. When one parent is BP (and the other parent is unaffected), the risk for a child of developing BP illness is ˜9%, whereas the risk of RUP

disorder is ˜18%. When one parent is UP (and the other parent is unaffected), there is ˜16% risk of RUP illness and a ˜3% risk of BPD. These risks are elevated compared to the general population risk of ˜1% for BP and ˜8% for RUP disorders. When both parents are BP or one parent is BP and the other RUP, risk of either BPD or RUP disorder is ˜75%.

In the near future, when BP and RUP susceptibility genes are identified, and risks of the common variants (alleles) at those genes are estimated (through large-scale population studies), it may be possible to assay patient DNA samples to determine which of the common susceptibility gene alleles are present in an individual at risk. With this information, it may be possible to provide improved estimates of risk.

METHODOLOGIC CONSIDERATIONS IN LINKAGE

Part of "71 - Bipolar Disorders: Review of Molecular Genetic Linkage Studies "

Linkage and association analyses are commonly employed methods to locate and define susceptibility genes for diseases. In the family shown in Fig. 71.1 , a BPD mother has alleles X,Y at some anonymous DNA marker, while unaffected father has alleles U,V. Mother transmits allele Y to affected children and allele X to the unaffected children. The probability that a parent will transmit a specific allele to each child within a family is 50%. A logarithm of odds (LOD) score statistic assesses the probability that, *within a family*, co-segregation of illness and a marker allele has occurred randomly, versus the probability that the co-segregation of illness and a marker allele has occurred because the marker allele is located near a disease gene on the same chromosome, such that the two are transmitted together more often than expected by chance (= 50%). In a single family, as shown, segregation of BPD illness with an allele at this marker locus could be a random event. However, if such a segregation was observed in >25% of 50 such BPD families, the probability that this is a random event would be remote. LOD scores for individual families can be summed to provide evidence that a region contains a susceptibility gene.

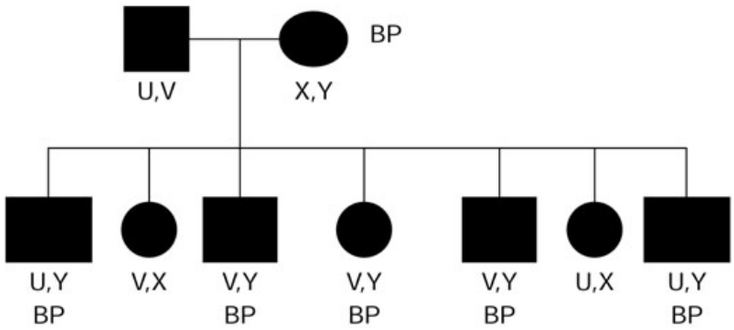

FIGURE 71.1. A family in which the bipolar disorder (BPD) mother has alleles X,Y at some anonymous DNA marker, whereas the unaffected father has alleles U,V.

LOD score calculations require specification of the disease allele frequency in the population, the mode of inheritance (dominant or recessive or some intermediate model), and the penetrance. If the mode of inheritance is misspecified, then the LOD score may not detect linkage when it is present (26). For psychiatric diseases, none of these parameters is known. In practice, investigators usually calculate LOD scores under dominant and recessive models of inheritance with reduced penetrance.

A commonly employed analysis in complex trait studies is the affected sibling pair (ASP) statistic. Pairs of siblings will share 50% of their alleles randomly, and the expected distribution of this allele sharing is as follows:

No. of alleles shared:	0	1	2
Percent of all sibling pairs:	25%	50%	25%

Pairs of affected siblings will tend to share alleles to a greater extent when the DNA marker alleles are located near a disease gene that contributes to the illness in the affected siblings pairs. Consider the ten possible affected siblings in the pedigree diagram above. Whereas four affected sibling pairs share two alleles, six pairs share one allele, but none share no alleles. This skewing of the expected random distribution of allele sharing toward greater sharing is consistent with the hypothesis that the DNA marker is located near a BPD susceptibility gene (i.e., linkage is present). This statistical method has been extended to all types of affected relative pairs (27 ,28). Because this approach does not require specification of several *parameters*, including mode of inheritance, penetrance, and disease allele frequency (as is necessary for the LOD score method), these statistical methods are often described as *nonparametric* methods.

The validity of a linkage study is demonstrated by delineation of the functional DNA sequence variants that explain the linkage statistics, or through independent confirmation in another set of families. Statistical guidelines for judging validity of linkage reports in complex disorders have been described (29). These guidelines suggest thresholds for an initial report of “significant” linkage (LOD score = 3.6 or nominal p = .00002) and for confirmation (LOD score = 1.2 or p = .01). These guidelines should limit false positives to less than 5%. It should be remembered that these guidelines refer to analysis of a single phenotypic definition (e.g., BP I and BP II disorders). If multiple phenotypes are analyzed, some statistical adjustments for multiple hypothesis testing may be necessary.

In genetic linkage analysis of common complex disorders, failure of subsequent studies to confirm previously nominated susceptibility loci has become commonplace. This is as true for diabetes mellitus (30 ,31) as it is for SZ and bipolar disorders. This failure to confirm has multiple origins most probably the manifestations of multiple susceptibility loci, within an affected individual, which interact

with each other and the environment to produce these well-known syndromes. For these disorders, no single susceptibility locus has a major effect on risk for illness in a majority of the ill population. Loci that increase risk by factors greater than 2 are unusual for common, complex disorders. Despite Herculean efforts in numerous disorders, only two loci that increase risk by a factor >2 in a large fraction of ill people have been detected: one is human leukocyte antigen (HLA) for insulin-dependent diabetes mellitus [increased risk = ˜3 (32)], and the other is apolipoprotein E in late-onset Alzheimer's disease (33 ,34 and 35 ,79 ,80). Substantial sample sizes are required to detect such loci that increase risk by factors ≤ 2. As Hauser et al. (36) have shown, ˜400 affected sibling pairs are needed to have >90% power to detect (p <.0001 or LOD >3) loci, which increases risk by a factor of 2. No single linkage study of BPD or SZ disorders published in the 1990s has exceeded this sample size, although metaanalyses of multiple independent data sets have larger sample sizes.

A second major reason for lack of confirmation in linkage studies of common complex disorders has been delineated by Suarez et al. (37), who conducted simulation studies to evaluate the power to replicate linkage. They simulated linkage data for a complex disease caused in part by six equally frequent independent (unlinked) disease loci. They found that a larger sample size was required to confirm linkage of a previously detected locus, because independent pedigree samples might (through sampling variation) contain an overrepresentation of different susceptibility loci, rather than the locus initially detected. Given that investigators often draw their pedigrees from different ethnic backgrounds (in which prevalence of a particular susceptibility locus might vary), sampling variation is an important origin of confirmation failure. Thus, expectations of universal agreement (even when sample size is adequate) regarding susceptibility loci for common complex traits are unrealistic.

If three loci of equal effect size are used in an interactive, multiplicative model to explain the increased relative risk in BPD disorder (each locus increases relative risk by ˜2), then these three hypothetical interactive loci explain most of the relative risk (2 × 2 × 2 = 8). Thus, loci that increase risk of BPD disorder will have minor to moderate effects. Substantial sample sizes are required to detect such loci of minor effect. As Hauser et al. (36) have shown, ˜400 affected sibling pairs are needed to have >95% power to detect initially (LOD ≥3.6, or p ≤.00002) loci that increase risk by a factor of 2, whereas 200 pairs are needed to have >95% power to provide confirmation (p ≤.01) of a previously detected locus.

Linkage Studies of Bipolar Disorder

To focus attention on the most promising linkage reports in BPD, this chapter limits consideration to those BPD linkages that meet criteria for validity (29), as noted above. Table 71.1 describes those BPD linkages that have at least one principal report with p = ˜.00002 and at least one independent confirmation at p = ˜.001. It is undoubtedly true that each of these confirmed linkages has been the subject of multiple negative reports. This is unavoidable when detecting loci of modest or minor effect, where the locus-specific relative risk is less than 2. Nearly all the negative reports are perhaps secondary to inadequate power to detect the initially described evidence of linkage. These negative reports will not be reviewed here.

TABLE 71.1. CONFIRMED LINKAGES IN BIPOLAR DISORDER

Berrettini et al. (38 ,39) reported evidence of a BPD susceptibility locus on 18p11 using ASP and affected pedigree member (APM) methods (p = 10^{-4} to 10^{-6}). Independent evidence of confirmation of this finding was reported

by Stine et al. (40), Nothen et al. (41), and Turecki et al. (42). Evidence of linkage was found most often among those families with paternally transmitted illness (40 ,41 ,61). As part of Genetic Analysis Workshop no. 10, independent BPD chromosome 18 linkage data sets, including ~1,200 samples, were assembled for metaanalyses (62). An affected sibling pair (*N* = 382 sibling pairs) metaanalysis yielded $p = 2.8 \times 10^{-8}$ at marker D18S37 (63).

In light of the family studies suggesting partial overlap in susceptibility for BPD and SZ (see above), it is of interest to determine whether any of these confirmed BPD loci might overlap with confirmed SZ susceptibility loci. Schwab et al. (43) employed ~20 chromosome 18 markers in a linkage study of 59 multiplex German and Israeli SZ pedigrees, in which there were 24 affective disorder cases (two were BP). When these data were analyzed in two-point parametric methods, the maximum LOD score was 3.1 at D18S53. A multipoint nonparametric analysis using Genehunter (28) revealed *p* = .002 at D18S53.

One possible explanation for the results of Schwab et al. (43) is that their kindreds were misdiagnosed or unusual in some undetected characteristics. If the SZ kindreds of Schwab et al. (64) were nosologically unique (perhaps misclassified affective disorder kindreds), then one would not expect to find confirmations of other SZ loci in those kindreds. For example, these kindreds show linkage to chromosome 6p (65), as reported in other series of multiplex SZ kindreds (66 ,67). Similarly, Faraone et al. (68) and Straub et al. (69) report SZ linkage to 10p14, as did Schwab et al. (64). Nosologic misclassification does not explain the chromosome 18p11.2 linkage to SZ detected by Schwab et al. (43). Thus, one region of partial overlap in genetic susceptibility to BPD and SZ may be 18p11.2.

Straub et al. (44) initially described linkage of BPD disorder to 21q21 markers, in a study of American and Israeli BPD kindreds. One BPD pedigree with a LOD score of 3.41 was reported from a series of 57 BPD kindreds; further nonparametric analysis provided evidence of linkage (*p* <.0003 for the phosphofructokinase locus). An emendation of this original work has been published by Aita et al. (70). A confirmation has been described in a two-locus analysis of genotypic data from 21q21 and 11p15.5 (46). This 21q21 BPD susceptibility locus has been confirmed by Detera-Wadleigh et al. (45), who employed multipoint nonparametric analyses (*p* <.001). Kwok et al. (47) described confirmatory evidence for linkage to this region in nonparametric analyses. Kelsoe et al. (49) report a LOD >2 in this region. Morisette et al. (48) also report a confirmation for this locus in a population isolate of French ancestry.

Lachman et al. (71), Edenberg et al. (72), Kelsoe et al. (49) described evidence of a BPD susceptibility locus on chromosome 22q11-13, near the velocardiofacial syndrome (VCFS) locus. Kelsoe et al. (49) report a LOD score of 3.8 at D22S278. Detera-Wadleigh et al. (51) report *p* = .008 for markers in this region. This VCFS has been associated with microdeletions of the 22q region. These individuals have a psychosis in ~30% of cases. The syndromal form of the psychosis has been termed schizophrenia-like (73), whereas others have described it in terms of bipolar disorder (74 ,75).

Another region of the genome that harbors a BPD susceptibility locus is 18q22. McMahon et al. (53) initially reported linkage to this region in 28 American BPD kindreds (LOD is 3.51 for D18S41) and the ASP method (*p* = .00002 at D18S41). In an extension of this work, McMahon et al. (53) provided additional evidence for linkage to 18q21-2 in 30 new BPD kindreds. This locus may have been detected by Freimer et al. (55) and McInnes et al. (52) who studied Costa Rican BPD kindreds. McInnes et al. described evidence of increased allele sharing at some of the same markers identified by McMahon et al. For example, at D18S55, McMahon et al. (53) reported a nonparametric LOD score of 2.2, whereas McInnes et al. (52) at this same marker reports a maximum likelihood estimate of the LOD score as 1.67. Although the genetic map position of greatest significance for these two studies are not identical, there is sufficient map location overlap so that the simplest conclusion is that the two studies have detected the same locus.

Morissette et al. (48) reported evidence of a chromosome 12q24 BPD susceptibility locus, detected through the study of a population isolate (French ancestry) from the Saguenay River region of Quebec province. Detera-Wadleigh et al. (51) observed modest support for this locus in a study of 22 American kindreds of European origin.

An extended Scottish kindred showed linkage (LOD 4.1 at D4S394) to 4p16 DNA markers (57). Confirmation of the 4p locus has been reported in a paper by Nothen et al. (59), in which increased allele-sharing was noted at D4S394 (*p* = .0009). Another confirmation was described by Ewald et al. (58), who noted a LOD of 2.0 at D4S394. Ginns et al. (60) reported linkage to this region for a *mental health locus*, meaning absence of any psychiatric disorder. This requires additional investigation. Thus, the 4p16 region has a confirmed BPD susceptibility locus.

CANDIDATE GENE APPROACHES

Part of "71 - Bipolar Disorders: Review of Molecular Genetic Linkage Studies "

The confusing array of disputed claims for association of candidate genes with psychiatric disorders becomes more comprehensible (and expected) if we recall two key issues. First, these candidate genes confer a small risk (if any), so that adequate power to confirm the originally described effect size is frequently absent in subsequent reports. Second, because the population genetics history of our species is unknown, associations detected in one ethnic group may not be detected so easily in another ethnic group. For example, the protective effect of aldehyde dehydrogenase deficiency on risk of alcoholism is easily demonstrated in

Chinese, Korean, and Japanese populations, because the deficiency allele has a frequency of ~30% (76 ,77). Much larger sample sizes are required to detect this influence in European populations, because the protective allele frequency is lower by an order of magnitude.

Candidate gene influences on risk of disease can be detected by demonstrating that certain candidate gene alleles are found more frequently among affected individuals compared to unaffected individuals. These studies are often termed “case-control association” investigations. This process is quite reliable when the effect size is robust. Candidate gene effect sizes can be considered as genotype relative risk (GRR), in which the risk associated with a particular genotype is compared to the general population risk. In general, there are four possible models of GRR: dominant, recessive, additive, and multiplicative. Let us consider each of these models for the general population risk, R, for a given disease, caused partially by a disease allele D, which triples the general population risk (the normal allele being d):

Model/genotype	DD	Dd	dd
Dominant	3R	3R	R
Recessive	3R	R	R
Additive	6R	3R	R
Multiplicative	9R	3R	R

An often-cited example of a multiplicative effect is apolipoprotein E4 in Alzheimer's disease (33 ,35 ,50 ,51 ,52 ,53 ,54 ,55 ,56 ,57 ,58 ,59 ,60 ,61 ,62 ,63 ,64 ,65 ,66 ,67 ,68 ,69 ,70 ,71 ,72 ,73 ,74 ,75 ,76 ,77 and 78), where one copy of the E4 allele increases risk for Alzheimer's disease by a factor of ~4 (at age 75), whereas homozygosity for E4 increases risk by a factor of ~14. Thus the influence of E4 on Alzheimer's disease risk may follow a multiplicative model.

Thus, one can genotype cases and unaffected individuals, comparing risk for disease across the three possible genotypes. However, in complex diseases such as BPD and RUP illness, the same disease allele may act in dominant or recessive mechanisms, depending on genetic background and environmental influence. Thus, a straightforward comparison of disease allele frequency in cases and controls can be recommended.

The major difficulty in comparing genotypes (or allele frequencies) in cases and controls is the risk of false positives because of subtle genetic differences between the case and control populations, differences that are independent of disease risk (81). Sometimes this is termed “population stratification.” This danger can be illustrated by the following example. Suppose we are interested in testing the hypothesis that glucose-6-phosphate dehydrogenase (G6PD) is a disease gene in diabetes mellitus, using the case-control method. Let us also suppose that we are unaware that G6PD deficiency protects against malaria, and is found at increased frequency among individuals of Mediterranean origins. We select cases from a population enriched with individuals of Mediterranean origin, where G6PD deficiency is fairly common. Our controls also come from a population of individuals of European ancestry, but mostly northern Europe, where G6PD deficiency is relatively uncommon. We test our cases and controls, and find that the diabetics have increased frequencies of alleles that result in marked enzyme deficiency. We conclude falsely that these G6PD alleles are risk factors for diabetes mellitus.

One method to protect against such errors is known as a family-based association test (82 ,83 and 84). Such methods generally employ DNA samples from an affected individual and his/her parents. In one form, the transmission disequilibrium test (TDT) (84), the putative susceptibility allele is examined for excess transmission from heterozygous parents to affected children. Consider this nuclear family (Fig. 71.2), consisting of an affected child and two parents, whose affection status is unknown. Genotypes at a putative candidate gene are listed. Randomly, the affected child has a 50% probability of inheriting allele 1 from her heterozygous father. Let us hypothesize that allele 1 increases risk for the disorder present in the child. If this hypothesis is true, allele 1 should be inherited from heterozygous parents by affected offspring greater than 50% of the time. If DNA samples are collected from 500 parent-affected child trios, and those samples are genotyped at the candidate gene, the hypothesis can be tested. Note that this method does not require any diagnostic information from parents, only their DNA samples. Clearly, this method is not applicable to disease with onset late in life, such as Parkinson's disease or Alzheimer's disease. However, derivatives of this approach that use discordant siblings have been described (85 ,86 and 87).

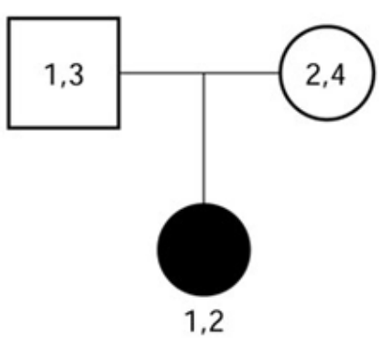

FIGURE 71.2. A nuclear family consisting of an affected child and two parents, whose affection status is unknown. Genotypes at a putative candidate gene are listed.

The disadvantages to the family-based association methods include the greater difficulty in collecting parent-child trios, compared to unrelated cases and controls. Also, only those parents who are heterozygous are informative. Given that most variants in the human genome have only two alleles, parental homozygosity can be a significant problem. One compromise paradigm is to conduct a large case-control association study of candidate gene polymorphisms. Where one sees a positive result, it can be confirmed in a smaller family-based confirmation. If the family-based sample provides confirmation, one can have greater confidence that the original case-control positive result was not due to population stratification.

Although a multitude of candidate genes have been examined in populations of BPD and RUP patients, there are no candidate genes that have been unequivocally established. It is instructive to review one candidate gene intensively studied, monoamine oxidase A (*MAOA*), located on the short arm of the X chromosome, Xp11.23. These studies exemplify the difficulties outlined above, including possible population stratification, limited power, and different ethnic groups. Although no linkage studies have suggested Xp11 as a genomic location of a susceptibility gene for affective disorder, the role of *MAOA* in the deamination of serotonin and norepinephrine and the therapeutic efficacy of MAO inhibitors suggest that this gene should be evaluated as a potential risk factor for affective disorders.

There have been numerous independent association studies of BPD and RUP and an *MAOA* (CA)n repeat polymorphism in European (88 ,89 ,90 ,91 ,92 ,93 and 94) and Asian (95 ,96) studies. Those studies reporting a positive association (89 ,92 ,94 ,95) generally detect an overrepresentation of allele 5 or 6 of the *MAOA* (CA)n repeat among BPD patients, compared to controls, an observation that may be particularly evident among women. The effect size is small, the odds ratio being 1.49 (94), and the sample size required for adequate power to detect is larger than most of the negative studies (88 ,90 ,91 ,93 ,96). There is also an *MAOA* promoter polymorphism (97). These studies involve multiple ethnic groups, case-control methods, and family-based designs, with some studies having limited power to detect a small effect size. Thus, it is understandable that conflicting studies are reported.

PARENT-OF-ORIGIN EFFECTS

Part of "71 - Bipolar Disorders: Review of Molecular Genetic Linkage Studies "

Parent-of-origin effects refer to unequal rates of transmission of a disorder from fathers, compared to mothers. In BPD, McInnis et al. (98) first observed an excess of maternal transmission in multiplex kindreds selected for a linkage study. This observation was confirmed by Gershon et al. (15) in an independent series of multiplex BPD kindreds. Although this observation has not been confirmed by other investigators (99), it raises the possibility that the complex genetics of BPD may involve mitochondrial inheritance and/or imprinting.

Mitochondrial DNA is a nonnuclear circular 16,500 base pair molecule that is solely maternal in origin. It contains genes for oxidative phosphorylation and genes for transfer RNA (tRNA) molecules, among others. Defects in mitochondrial DNA sequence can contribute to genetic susceptibility for complex disorders, such a diabetes mellitus (100) and some forms of nonsyndromic deafness (101). If a fraction of all BPD included a mitochondrial susceptibility gene, then this would be consistent with the excess maternal transmission observed in BPD (15 ,98). However, variations in mitochondrial DNA have not been associated with BPD.

Another mechanism consistent with excess maternal transmission is that of imprinting (see ref. 102 for review). Imprinting results in the transcriptional silencing of the allele of a sex-specific parent. For some genes, imprinting is *paternal*, meaning that the paternal allele is not transcribed into messenger RNA (mRNA). For other genes, *maternal* imprinting is present, and the maternal allele is transcriptionally silent. This results in a "functional hemizygosity," so that defects in the single active allele may have a greater impact on the phenotype. How might this mechanism give rise to an apparent excess of maternal transmission, as has been observed by McInnis et al. (98) and Gershon et al. (15)? If the putative BPD susceptibility gene is *paternally* imprinted, then the paternal allele is transcriptionally silent, and defects in the expressed maternal allele may be more often detected in the phenotypes of the offspring. In the embryonic gonads of each generation, the imprinting mark is reset, so that the alleles can be properly regulated in the next generation. Consider an example of *paternal* imprinting (Fig. 71.3). Note that individuals are heterozygous at the DNA level, but they are hemizygous at the mRNA level, expressing only the maternal allele. Note also that the imprinting mark is reset with each generation, so the woman who inherits (and expresses) allele 3 from her mother transmits allele 2 to her son, and this allele is transcriptionally active in the son, who does not express allele 5, which he inherits paternally. Thus if allele 2 is a BPD susceptibility gene, it will be expressed in the third generation, and influence the risk of disease, due to maternal imprinting. However, allele 2 is not expressed in the second generation, and will not influence risk of BPD.

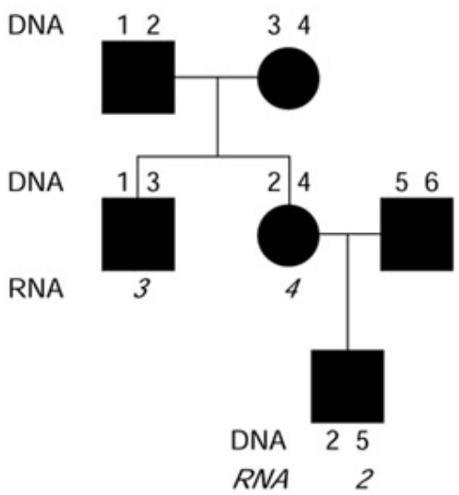

FIGURE 71.3. An example of paternal imprinting.

Molecular mechanisms of imprinting are complex, but involve methylation of the promoter regions of the target genes (102), resulting in nontranscription. Imprinting defects give rise to human diseases, the classic examples of which are Prader-Willi and Angelman's syndromes. Imprinting can be tissue-specific, such as the serotonin receptor subtype 2A (5-HT_{2A}) gene (103), which is imprinted in specific brain regions. Imprinting has been described for

˜50 human genes. It is likely that imprinting will explain some of the complex inheritance of BPD.

ANTICIPATION AND TRIPLET REPEATS

Part of "71 - Bipolar Disorders: Review of Molecular Genetic Linkage Studies "

Anticipation is the term used to define an observation that a familial disorder occurs with earlier age at onset and/or increasing severity among younger generations, compared to older generations. Anticipation occurs in several neurodegenerative diseases, including Huntington's disease, fragile X, myotonic dystrophy, spinocerebellar ataxias, and others (see ref. 104 for review). The molecular explanation for anticipation in these disorders involves unstable intragenic trinucleotide repeats, which expand in subsequent generations, giving rise to increasing levels of gene disruption and thus to earlier age at onset and increasingly severe phenotype in younger generations.

Evidence of anticipation has been reported in several family studies of BPD illness (98 ,105 ,106 and 107), but some authorities suggest that there is intractable ascertainment bias (108 ,109). Individuals with earlier age-at-onset BPD disorder may have reduced capacity to reproduce, so parents with such early-onset disorders may be underrepresented in the general population. Individuals with familial BPD disorder may come to treatment earlier than those with sporadic disease, such that less severe mood disorder episodes are detected medically, and an earlier age at onset is defined. Such individuals (by virtue of their familiarity with mood disorder symptoms) may be more likely to report minor mood disturbance in terms of “diagnosable syndromes.” Some evidence of anticipation in BPD comes from extensive studies of multiplex BPD families for linkage studies. These linkage studies select for earlier age-at-onset cases, because preference is given to densely affected kindreds. Among broader cultural factors possibly underlying the evidence of anticipation, if stigma concerning mood disorders is less among younger affected persons (compared to older individuals), then younger cohorts might describe their experiences more easily in terms of a diagnosable mood disorder, because denial (due to stigma) is less prevalent among the younger cohorts. These potential confounding factors make detection of anticipation in BPD disorder difficult.

The hypothesis that anticipation in BPD disorder reflects causative expanding trinucleotide CTG repeat sequences has generated genomic searches for such sequences (110 ,111 ,112 and 113), using the repeat expansion detection method (114). These three groups have noted increased lengths of CTG repeats in BPD disorders, especially among those with familial disease. However, not all studies have reported this difference (115), and no report shows transmission of an expanding repeat within BPD families, the definitive evidence. Furthermore, greater than 90% of the expanded CTG repeats detected by the method of Schalling et al. (114) are from two apparently nonpathogenic unstable CTG repeats on 17q and 18q21 (116). The hypothesis that unstable trinucleotide repeats represent BPD susceptibility factors warrants continued study.

IMPLICATIONS OF THE HUMAN GENOME PROJECT

Part of "71 - Bipolar Disorders: Review of Molecular Genetic Linkage Studies "

The Human Genome Project is nearing completion of one of its primary goals, the sequence of the human genome. However, the additional goal of defining all expressed sequences (genes) may require several additional years of work. Once this goal is achieved, the most important task will be the definition of function for each expressed sequence (functional genomics). Implied (but not included) in this goal is the function of each protein (functional proteomics), involving interactions between proteins. A third goal of the Human Genome Project is the definition of ˜300,000 common single nucleotide polymorphisms (SNPs), including several within each gene.

The cloning of individual susceptibility genes for BPD and RUP disorder will be facilitated remarkably by the completion of these Human Genome Project milestones noted above. At present our knowledge base regarding central nervous system (CNS) function and the biochemical etiology of BPD and RUP disorder is so poor that too many brain-expressed genes may be considered candidates. This limitation is made more severe by the fact that linkage studies of all complex traits result in genomic regions of interest that typically span 20,000,000 base pairs of DNA. Because ˜20 to 50 genes (most of which are unknown today) are usually found in every 1,000,000 base pairs of DNA, the task of discovering a single disease gene within such a region, implicated by linkage, is the proverbial equivalent of finding a needle in a haystack, with currently available DNA technologies. However, once all expressed sequences are known, and their functions are understood, it is possible to focus on the few best candidates. This reduces an intractable problem (from a DNA technology perspective) to a manageable size. Thus, finding susceptibility genes implicated by linkage results will become progressively less difficult as the Human Genome Project goals are approached.

SUMMARY

Part of "71 - Bipolar Disorders: Review of Molecular Genetic Linkage Studies "

Despite the extensive data (from twin, family, and adoption studies) for genetic factors in BPD, gene identification through linkage studies has been elusive. There are multiple confirmed BPD linkage regions across the human genome, but the effect sizes are uniformly small at each locus. Cloning genes from these small effect size regions is a challenge for current molecular techniques. Part of the complexity of BPD genetics may be due to imprinting, mitochondrial

inheritance, and trinucleotide repeat expansion. These nonmendelian influences require additional research.

Alan F. Schatzberg: Departments of Psychiatry and Behavioral Sciences, Stanford University, Palo Alto, California.

Over the past three decades, considerable progress has been made in our understanding of the biology of depressive disorders. Still, there are a great number of unanswered questions regarding the relative roles specific biological systems may play in pathogenesis. This debate in part reflects a number of methodologic factors: a possibly over broad definition of the clinical syndrome of major depression; limitations inherent in studies using indirect measurement of brain neuronal activity; problems inherent in postmortem studies; and an overemphasis on cross-sectional rather than longitudinal studies. In this chapter, we review the current status of the neurochemical and cellular features of depressive disorders.

BACKGROUND

Part of "72 - Molecular and Cellular Mechanisms in Depression "

Although Freud put forth a hypothesis for understanding the psychological causes of depression in his classic paper, “Mourning and Melancholia,” he noted that some depressions were clearly biological in etiology. Research over the past 40 years has done much to point to likely “culprits” that are involved in the etiology of the disorder as well as in the mediation of treatment response; these have been reviewed several times recently (1 ,2).

Early research revolved around monoaminergic theories with particular emphasis first on norepinephrine and later serotonin. The basis for invoking these systems rested largely on a number of pharmacologic observations that have been termed “the psychopharmacologic bridge.” These observations included: reserpine, an early antihypertensive, caused depression in some patients and depleted monoamine stores in rat brain; iproniazid, a drug studied as an antitubercular agent, elevated depressed mood and inhibited monoamine degradation by the enzyme, monoamine oxidase; imipramine, a tricyclic compound originally studied as an antipsychotic, had potent antidepressant effects and blocked the reuptake of norepinephrine (and to some extent serotonin) into presynaptic neurons.

These observations led two groups of investigators (3 ,4) to argue that norepinephrine (NE) activity was decreased in depressive disorders and elevated in manic or excited states. Although a low norepinephrine state was the cornerstone of Schildkraut's catecholamine hypothesis (30), he also argued for other types of dysregulation, including altered receptor functioning. Indeed, more recent data have pointed to biological heterogeneity of norepinephrine activity in depression with some patients demonstrating low and others apparently elevated activity (5). Serotonin (5-HT) theories, in contrast, have emphasized decreased production or reuptake in depression.

As research has continued, investigators have noted a number of other alterations in depressed patients, including among others: elevated corticotropin-releasing hormone (CRH); elevated acetylcholine activity; increased γaminobutyric acid (GABA) levels; excessive glucocorticoid activity in psychotic major depression; hippocampal volume loss, perhaps reflecting the effects of excessive glucocorticoids on neurogenesis, and so on. These have in turn led to or been associated with a number of new biological hypotheses regarding why some individuals become depressed or develop specific symptoms. In the following sections we review the current status of these approaches.

NOREPINEPHRINE

Part of "72 - Molecular and Cellular Mechanisms in Depression "

Norepinephrine is a catecholamine that is found in various tissues, including brain, plasma, sympathetic nervous system, heart, and so on. It is synthesized from the amino acid tyrosine, which forms L-Dopa via the enzyme tyrosine

hydroxylase. L-Dopa is converted to dopamine via dopa decarboxylase and then in turn is converted to norepinephrine via dopamine ß-hydroxylase. In the adrenal and other tissues, norepinephrine is converted to epinephrine via phenyl-*N*-methyltransferase (PNMT). NE is degraded by the enzymes catechol-o-methyltransferase and monoamine oxidase.

Norepinephrine measured in urine or plasma is largely derived from non-central nervous system (CNS) sources. In contrast, much early work in this area emphasized 3-methoxy-4-hydroxyphenylglycol (MHPG), 20% to 30% of which is derived from brain. The earliest studies on urinary MHPG reported significantly lower levels in depressed patients than healthy controls (6). Further research revealed low urinary MHPG levels were seen, particularly in bipolar depressives and a subgroup of unipolar patients. As diagnostic nomenclature differentiated bipolar I from II patients, investigators reported low MHPG levels were characteristic of bipolar I and not II patients (5 ,7 ,8).

Unipolar depressed patients are heterogeneous in their MHPG levels. As indicated previously, a subgroup of unipolar patients demonstrate low MHPG levels, similar to those seen in bipolar I patients. In contrast, some unipolar patients demonstrate elevated MHPG levels (9). In these patients, urinary free cortisol is similarly elevated (10).

Catecholamine levels have been reported to parallel the state of the disorder in bipolar patients. Bipolar patients demonstrate significantly lower plasma NE and E levels when depressed than when euthymic or manic. Manic bipolar patients demonstrate elevated CSF, urine, or plasma MHPG levels than depressives or healthy controls (11 ,12 and 13). These data provide a rationale for measuring catecholamine output in mood disorder and invoking NE as playing an etiologic role; however, critics argue that some of the changes in levels may be secondary to such features as activity or agitation.

Urinary MHPG levels have been explored as possible tests for predicting antidepressant response. The earliest studies (14 ,15) pointed to low MHPG levels predicting positive responses to imipramine but not amitriptyline. High-MHPG patients responded to amitriptyline (14 ,15). These findings led Maas (14) to hypothesize that there were two forms of depression—one a low MHPG state reflected a norepinephrine depression; another characterized by high MHPG levels signified a serotonin depression. This hypothesis, although heuristic, has not been borne out. Subsequent studies failed: (a) to demonstrate that high MHPG levels predicted amitriptyline response (16); and (b) in the light of the development of selective serotonin reuptake inhibitors (SSRIs) the serotonergic potency of amitriptyline was also thrown into question. In contrast, several studies have reported that low urinary MHPG levels do indeed predict response to noradrenergic agents—nortriptyline, desipramine, and maprotiline (17 ,18). Application of urinary MHPG levels has been limited in part because of: difficulty collecting 24-hr urine samples; the need for patients being drug free when studied; and the lack of surety of the optimal treatment for high-MHPG patients.

Tyrosine Hydroxylase/Locus Ceruleus

The locus ceruleus (LC) is the nucleus of the NE system in brain. Neurons project from the LC to various parts of the brain, particularly the frontal cortex. The LC has been the focus of several postmortem studies of depressed patients or suicide victims. Tyrosine hydroxylase activity has been reported to be up-regulated in brains of suicide victims, perhaps reflecting the effect of chronic stress (19). In another study, NE neurons were reported to be modestly decreased in suicide victims relative to controls (20). A third study reported that NE transporter sites were decreased in depressed subjects who committed suicide but NE neurons were not (21). These studies are somewhat contradictory in direction of NE changes in suicide but suggest the system is altered in suicide. A possible unifying hypothesis revolves around up-regulation of TH in some neurons in an attempt to compensate for loss of neurons or transporter sites.

Receptors

Receptors for NE are grouped into α_1, α_2, $ß_1$, and $ß_2$ subtypes. α_2 Receptor numbers and activity can be studied using platelets; ß receptors, using leukocytes. Both have also been explored in postmortem brain. α_2 Receptors are found both presynaptically and postsynaptically. Presynaptic α_2 receptors act as thermostats to regulate NE production and release. α_2 Receptors are universally connected to adenylate cyclase second messenger systems such that agonists inhibit cAMP formation. In contrast, ß receptors, which are entirely postsynaptic, stimulate adenylate cyclase and cAMP formation.

α_2 Receptor numbers and activity have been reported in multiple studies to be increased in the platelets of depressed patients (22 ,23), although there is also at least one negative study (24). α_2 Receptor activity can be explored by measuring cAMP responses to challenges with agonists. Mooney and associates (25) reported that epinephrine suppression of prostaglandin-E induced cAMP formation is decreased in the platelets of depressed patients. Siever and colleagues (26) reported norepinephrine stimulation results in blunted adenylate cyclase responses in an E_1–α_2 prostaglandin coupled model. Platelet aggregation that results from α_2 stimulation has also been reported to be altered in depressed patients (27). Mooney and colleagues (25) using stimulation of α_2 receptors with a variety of agents, including NaF, which directly affects G_1 coupled proteins have hypothesized that this down-regulation is not agonist specific and have argued that a fundamental uncoupling of the receptor–G-protein–AC complex occurs in some depressed patients.

Growth hormone (GH) responses to challenge with clonidine, an α_2 agonist, has also been employed as a functional test of α_1 activity. Consistent blunting of GH responses in depressed patients has been reported (28 ,29). Blunted GH response appears to be a trait marker; it is found in remitted patients (30). The significance of blunted GH responses to clonidine is not entirely clear, however. Clonidine could be affecting presynaptic or postsynaptic receptors (31). Also, somatostatin, an inhibitor of GH release, may play a role in the GH response to clonidine challenge.

α_2 Receptors have also been explored in postmortem brain of suicide victims. Increased binding sites have been reported in several studies (32 ,33 and 34), although findings regarding the specific isoform and location of the increased binding sites have not been consistent.

ß Receptors have been studied in both leukocytes and postmortem brain. Results have been less consistent than with the α_2 receptor. Decreased binding in leukocytes of depressives has been reported inconsistently (35 ,36). Similarly, in postmortem brain tissue, increased ß-adrenergic receptor density has been reported by Mann and colleagues (37); however, decreased Bmax was reported by Crow and co-workers (38) in the hippocampus of depressives. Effects of previous medication may enter into these discrepant findings, as could biological heterogeneity of catecholamine secretion in depressed patients.

Depletion Strategies

α-Methylparatyrosine (AMPT) inhibits TH and ultimately synthesis of norepinephrine. When given to healthy controls or depressives it does little to lower mood (39 ,40); however, remitted depressed patients on noradrenergic antidepressants show a worsening of symptoms when challenged with AMPT, suggesting that norepinephrine availability or tone is needed for maintaining response to NE agents (41). In contrast, patients on SSRIs do not relapse when challenged with AMPT challenge. AMPT in previously depressed patients who are not currently on medication causes a recurrence of depressive symptoms (42). Taken together, these data suggest the test could be a possible trait marker for depressive vulnerability and that maintaining NE tone is important for sustaining responses to noradrenergic drugs.

SEROTONIN

Part of "72 - Molecular and Cellular Mechanisms in Depression "

Serotonin (5-HT) is a monoamine neurotransmitter involved in mood and appetite regulation. In brain, it is synthesized within the raphe from l-tryptophan. Serotonin itself does not cross the blood–brain barrier. Synthesis includes an initial conversion to 5-hydroxytryptophan (5 HTP) via the enzyme, tryptophan hydroxylase. 5-HTP is decarboxylated by L-aromatic-amino acid decarboxylase to form 5-HT. The principal metabolite of 5-HT is 5-hydroxyindole acetic acid (5-HIAA), which is easily measurable in cerebrospinal fluid (CSF) and urine. MAO mediates part of the metabolism of serotonin.

Metabolite Studies

Much of the early interest in serotonin was generated by observations that low CSF 5-HIAA levels in hospitalized depressives were associated with an increased risk for suicide (43). Further studies revealed a relationship, particularly with violent methods of suicide (e.g., hanging) (44) and subsequently with difficulties with impulse control in subjects with antisocial personality (45). Current theories emphasize a more general relationship between low serotonin metabolite concentrations and impulse control problems; the latter may predispose to suicide in subjects who become depressed (46).

Transporter

The serotonin transporter (SERT), a 12-transmembrane molecule, actively pumps 5HT into the presynaptic neuron. Originally, the transporter was studied in platelets using tritiated (^{3}H) imipramine and more recently with the higher affinity (^{3}H)-paroxetine. Numerous studies have reported decreased binding (Bmax) in the platelets of depressed patients as compared to healthy controls. A metaanalysis by Ellis and Salmond (47) of 70 studies demonstrated an overall significant difference between patients and controls, although not all studies concur. Medication did not appear to account for these differences. Although mean values appear to differ between patients and controls, there is considerable overlap in values among patients and controls such that there are numbers of patients who do not appear to have decreased binding; this overlap limits the use of the test as a diagnostic measure.

Decreased ^{3}H imipramine binding was once thought to be a trait marker, that is, did not normalize with treatment. Further study, however, has revealed that decreased ^{3}H-imipramine binding does normalize with treatment but one must wait for sufficient periods to allow for protein regeneration.

The transporter has also been the subject of examination in postmortem brain tissue. Early studies in this area pointed to decreased binding in suicide brains (48); however, more recent studies have failed to confirm these findings (49). These data raise questions regarding the significance of abnormalities in the activity SERT in the pathophysiology of depression and the relationship of peripheral and central forms of the transporter. There are a number of methodologic problems inherent in postmortem tissue that may account for differences among studies, including accuracy of diagnosis, time from death to collection of brain tissue preparation of tissue, and so on.

One approach to studying the activity of the transporter has been to apply functional imaging (e.g., SPECT to determine relative activity). The development of ligands (e.g., ^{123}I-ß-CIT), that bind selectively to the transporter has allowed *in vivo* study in humans. In one study, a significant difference in binding using SPECT was observed between depressed patients and controls (50). In this study, significant differences were not observed in platelet binding to ^{3}H-paroxetine, raising questions regarding whether the transporter is regulated differently in the two tissues.

Receptors

Presynaptic and postsynaptic 5HT receptors have also been studied in depressed patients. Over a dozen serotonin receptors have been identified, although the possible roles for many have not. Two that have attracted most study for the longest periods are the $5HT_{1A}$ and $5HT_{2a}$ types.

$5HT_{2a}$ receptors are located postsynaptically in the CNS and can also be found in platelets as well as in other non-CNS tissue. As with the transporter, multiple studies have investigated $5HT_{2a}$ binding sites in the platelets of depressed patients. An increase in binding sites (B-max) has been reported in depressed and suicidal patients with some suggestion that increased binding in suicidal patients may be independent of a diagnosis of major depression (51 ,52 and 53). Generally, $5HT_{2a}$ binding has been thought to be a state marker, although one recent study has suggested binding may not normalize with SSRI treatment (54).

$5HT_{2a}$ binding has also been studied in postmortem brain tissue. As with the serotonin transporter, results here have been mixed with some studies demonstrating increased prefrontal cortical binding but others not (37 ,55 ,56 and 57). $5HT_{2a}$ receptors are found in frontal cortex suggesting a role in the cognitive aspects of depression.

PET ligands have been developed to study $5HT_{2a}$ activity in brain. One study employed [^{18}F]- altanserin and reported a reduction in activity in right posterolateral frontal, orbitofrontal, and anterior cingulate regions in depressives (58). In another study, no differences were found between nonsuicidal depressives and controls using [^{18}F-] setoperone (59). The exclusion of patients with recent suicidal ideation may have played a role in not finding differences between patients and controls. Studies on effects of antidepressants on $5HT_{2a}$ binding using PET have also yielded mix results. One group reported that SSRIs appear to increase ^{18}F-setoperone binding (60), whereas another recently reported that 3 to 4 weeks of desipramine treatment resulted in a significant decrease in $5HT_{2}$ activity in multiple areas, particularly in frontal cortex (61). This group was unable to conclude whether the ligand was binding to $5HT_{2a}$ or $5HT_{2c}$ receptors.

$5HT_{2A}$ receptors are coupled to the phosphoinositide second messenger system. When $5HT_{2a}$ receptors are activated by agonists, phosphatidyl inositol 4,5 bisphosphate is hydrolyzed by phospholipase C to form two second messengers, diacylglycerol and inositol 1,4,5-triphosphate. Protein kinase C is activated by diacylglycerol. This system has been studied in the brains of suicide victims. Pandey and associates reported [^{3}H] phorbol dibutyrate binding to protein kinase C in prefrontal cortex was lower in teenage suicide victims (62). More recently they observed that both phospholipase C activity and the $ß_{1}$ isozyme protein level were decreased of teenage suicide victims (63). Depression per se did not appear to affect the differences between suicide victims and controls. In contrast Hrdina and associates (64) reported unaltered protein kinase C activity in antidepressant free depressives who suicided, and Coull and colleagues (65) reported that phorbol dibutyrate binding sites were increased in the prefrontal cortex of adults with similar histories. Age, diagnosis of depression, antidepressant use, and time to collection of brain may play a role in these disparate findings.

The $5HT_{1a}$ autoreceptor controls release of serotonin from the presynaptic neuron. Over the past few years, multiple groups have explored the potential use of pindolol, a $5HT_{1a}$ antagonist, to hasten response to antidepressants or bring out responses in refractory patients. These studies have yielded mixed results suggesting that pindolol may hasten response to antidepressants in milder or first-episode patients seen in primary care settings. $5HT_{1a}$ receptor number and activity have been studied in postmortem brain. Increased $5HT_{1a}$ Bmax has been reported in suicide victims using nonviolent means compared to violent completers or controls but others have failed to find alterations in $5HT_{1a}$ activity in suicide victims (66 ,67 and 68).

Genetic Studies

A number of studies have explored the possible role of genetics may play, particularly vis-á-vis transporter activity. Long and short forms of the transporter gene appear to be relatively common in the general population. An early study indicated a relationship of the short form with an increased frequency of a variety of neurotic or behavioral traits (69). Allelic variation has also been applied to predicting drug response. In three studies in Europe and the United States, homozygotes or heterozygotes for the S-form were reported to show sluggish responses to SSRIs (70 ,71 and 72). The opposite was found in a Korean study (73). Clearly, further work is needed to understand the importance of genetic forms of the transporter in major depression. More recently, Mann and colleagues (69) reported that the short form genotype was associated with a diagnosis of major depression but not with suicide or 5HT-transporter binding in postmortem tissue.

Depletion Studies

Brain concentrations of serotonin are highly dependent on circulating levels of tryptophan, which competes with other

amino acids for transport into the brain. Charney and Delgado have pioneered in the use of an amino acid cocktail that is relatively devoid of L-tryptophan to rapidly decrease plasma tryptophan and ultimately brain serotonin. In these studies, the drink was first administered to subjects who had responded to various antidepressants and who were being maintained on medication. Diphenhydramine has been commonly used as the comparison cocktail. Euthymic patients on SSRIs but not TCAs rapidly experienced depressive symptoms when depleted of L-tryptophan, suggesting the need for maintaining adequate serotonin levels to ensure continued drug response (74 ,75). Parallel decreases in glucose utilization in frontal and thalamic regions using PET have also been reported in depressives who experience a relapse in symptoms (76). In contrast, there are multiple reports of depletion not causing a clear recurrence of symptoms in patients treated with bupropion or electroconvulsive therapy (75 ,77 ,78 and 79). Studies have used a variety of different methods (e.g., patients' being on or off medication, inclusion or exclusion of suicidal patients, etc.), and these differences may account for the discrepant findings. The degree and duration of response observed before the depletion challenge is administered may be of particular importance (79). Patients who are in remission or have shown a prolonged response are unlikely to demonstrate significant worsening of moods (79). These data suggest recent responders are those who are susceptible to experiencing relapse with depletion strategies. Depletion of unmedicated euthymic depressives does not appear to induce recurrence, indicating maintaining serotonin tone is important primarily for continuance of response in recently remitted patients (79).

Of interest is a recent report that women controls show much lower rates of 5HT synthesis and a greater decrease in response to depletion than men do (80). This gender-based difference is consistent with a recent observation that chronically depressed women are more responsive to an SSRI than men are (81).

Fenfluramine Challenge

Fenfluramine, previously marketed as an appetite suppressant, causes a release of serotonin from presynaptic neurons and results in an elevation of prolactin. Prolactin responses to fenfluramine challenge are blunted in depressed patients (82 ,83) and there are some data to suggest this may be a trait marker (84). However, bipolar manic and axis II patients may also demonstrate blunted prolactin responses, raising questions regarding the specificity of the test. (See refs. 1 and 2 for further review.)

DOPAMINE

Part of "72 - Molecular and Cellular Mechanisms in Depression "

As indicated, dopamine (DA) is a precursor for norepinephrine. Although NE has played a central role in etiologic theories of depression, DA has been emphasized far less in depression in spite of its being widely distributed in brain.

CSF levels of homovanillic acid (HVA), a major metabolite, are decreased in depressives (2 ,85 ,86), although some studies have reported elevated CSF DA, but not HVA levels (87). Urinary DOPAC levels are decreased in depressives compared with controls (88); in one study, DOPAC levels appeared associated with suicidal behavior (85). Dopaminergic agents such as psychostimulants, nomifensine, and the dopamine agonist pramipexole all have antidepressant effects in nondelusional patients.

In contrast, elevated mesolimbic DA activity has been hypothesized to play a role in delusional depression (89). Elevated CSF HVA levels have been associated with psychotic symptoms and agitation in major depression (89), and increased plasma DA and HVA levels have also been reported in delusional depression (90 ,91). Increased mesolimbic DA activity has been postulated to occur secondary to elevated hypothalamic–pituitary–adrenal (HPA) axis activity (89). Recent studies in rats, nonhuman primates, and psychotic depressives suggest elevated glucocorticoid activity could also result in altered or decreased prefrontal cortical dopamine metabolism and to alterations in attention and response inhibition (92 ,93). These data suggest increased HPA axis activity could affect DA turnover differently in specific brain regions—alterations that have been suggested in schizophrenia. Antipsychotic drugs appear to play a key role in treatment of delusional depression and glucocorticoid receptor antagonists are being actively studied in the disorder.

GABA

Part of "72 - Molecular and Cellular Mechanisms in Depression "

GABA has become a focus of greater study over the past several years with the increasing use of anticonvulsants in mood disorders. GABA is a major inhibitory neurotransmitter in brain and regulates seizure threshold as well as norepinephrine and dopamine turnover. There are two types of GABA receptors. $GABA_A$ receptors have been studied in anxiolysis because of their location within a benzodiazepine–GABA receptor complex that is coupled to chloride channels. $GABA_B$ receptors are coupled to Ca^{+2} channels. In rats, antidepressants and mood stabilizers appear to up-regulate frontal-cortical $GABA_B$, but not $GABA_A$, receptors (94 ,95). $GABA_B$ agonists may enhance cAMP responses to norepinephrine and ß-adrenergic down-regulation in response to tricyclic antidepressants, suggesting a facilitative role for $GABA_B$.

GABA is also enhanced by anticonvulsants such as valproic acid, which act as mood stabilizers. GABA levels have been reported to be decreased in the CSF of depressed patients in some but not all studies (96 ,97). Plasma GABA levels have also been reported to be lower in unipolar depressives (98 ,99), and this may not normalize with treatment (100).

Alcoholism can also be associated with low plasma GABA levels (101). In refractory depressed patients undergoing cingulotomy, GABA levels are inversely related to degree of depression (102). A number of groups are actively exploring using fMRI to image GABA in the brains of patients with mood disorders, both before and after treatment.

NEUROENDOCRINE SYSTEMS

Part of "72 - Molecular and Cellular Mechanisms in Depression "

Neuroendocrine systems were originally studied as gateways to the exploration of neurotransmitter activity, such as norepinephrine and serotonin, in depression. Over time, emphasis has shifted to exploring the roles components of several of these axes may play in the pathogenesis of specific symptoms or disease states. Three axes, hypothalamic–pituitary–adrenal (HPA), hypothalamic–pituitary–thyroid (HPT), human growth hormone (HGH), in particular have been examined in major depression.

HPA Axis

The hypothalamic–pituitary–adrenal (HPA) axis is frequently activated during periods of stress and depression. The axis consists of three major components: (a) corticotropin releasing hormone (CRH), which is located in the paraventricular nucleus of the hypothalamus and stimulates the pituitary to release adrenocorticotropin hormone (ACTH); (b) ACTH which stimulates the adrenal cortex to release cortisol; and (c) cortisol, which feeds back to the pituitary, hypothalamus, and hippocampus to decrease release of CRH and ACTH.

Multiple lines of evidence point to abnormalities of the axis in depression. Initial studies focused on excretion of cortisol and its precursors in patients with depression. Activation of the axis was also associated with suicidal ideation. Sachar in a classic study reported elevated serum cortisol levels over a 24-hour period in severely depressed patients (103). Elevations were particularly seen in the evening and overnight, times when the axis should be quiescent. These data generally were interpreted as indicating that the depressed patient was highly stressed.

One method for challenging the axis is to administer the synthetic steroid dexamethasone (DEX) (104). The expected response is to suppress the axis because the pituitary and perhaps the hypothalamus read the DEX signal as indicating sufficient glucocorticoid activity, and shuts off production or release of cortisol. Depressed patients demonstrate a significantly higher nonsuppression rate than do controls, although the rates of nonsuppression are relatively low in many studies (105). Patients with severe or psychotic depression demonstrate relatively high rates of nonsuppression or high postdexamethasone cortisol levels (106). Indeed, psychosis appears to be the greatest symptom or syndrome contributor to DEX nonsuppression, greater than the effect of severity or melancholia (107). Outpatients with milder and nonpsychotic disorders show much lower rates of nonsuppression. This difference in types of patients studied may help explain the variability in DEX nonsuppression rates across studies. DEX responses have also been used to assess adequacy of treatment with patients who are nonsuppressors after treatment showing a significantly increased risk for relapse (108).

Glucocorticoid overactivity has been hypothesized to play a direct role in the development of cognitive impairment and delusions in patients with psychotic major depression (89). Trials are currently underway exploring the efficacy of glucocorticoid antagonists in psychotic depression (109). Moreover, glucocorticoids have been hypothesized to cause increases in glutamate activity, decrease nerve growth factor activity, and hippocampal volume loss on MRI in patients with a history of severe depression, but there are no studies that have simultaneously explored these various dimensions in depressed patients (110). Recently, Rojkowska and colleagues did report that neuronal size and density and glial densities were reduced in prefrontal cortical regions in postmortem tissue from subjects with major depression as compared to controls (111). Overall, there has been a shift from viewing excessive glucocorticoid activity in major depression as an epiphenomenon to its having specific effects on cognition or symptom formation.

Study of more proximal components of the axis have also pointed to marked abnormalities in major depression. In most of the relevant studies, CRH levels have been reported to be elevated in the CSF or plasma of depressed patients (1 ,112). Challenge with ovine or human forms of CRH results in blunted ACTH responses in depressives suggesting increased central CRH release (113). Remission of episodes appears to be associated with normalization of CRH studies. Postmortem studies have reported that CRH mRNA expression was increased (114) and CRH Bmax was decreased in the frontal cortex of suicide victims (115). These data suggest CRH release from the hypothalamus may be associated with a down-regulation of CRH in other brain regions (2).

Imaging studies have reported increased pituitary and adrenal size during depression, which appear to normalize with recovery (116 ,117). Increased pituitary size and elevated CSF CRH levels are associated with DEX nonsuppression (118). Elevated plasma ACTH levels have been reported in psychotic depression (119).

ACTH release is not only stimulated by CRH. For example, arginine vasopressin (AVP) may enhance CRH's stimulation of ACTH. AVP neurons are increased in the PVN of suicide victims (120) and serum AVP has been reported in one study to be elevated in hospitalized depressives (121).

CRH is also found in extrahypothalamic brain regions. In the amygdala, CRH appears to play a key role in fear responses and over-activation of these systems may lead to panic and depression (2). Amygdala CRH has been reported

to be under positive (stimulatory) feedback by cortisol and this observation has spurred on much research to develop specific CRH antagonists to treat anxiety and depressive disorders. A recent report on an open label trial suggested that a CRH antagonist might be effective in hospitalized depressives (122).

Although the literature has emphasized elevated CRH and cortisol activity in major depression (in part because of the emphasis on DST nonsuppression), there is emerging evidence that CRH and cortisol activity may only be elevated in some subtypes of major depression and that some depressed patients may actually have low HPA activity. Recent data suggest that depressed patients with a history of early abuse (as well as those with psychosis) may be most consistently at risk for demonstrating elevated ACTH levels in response to social stress (123). Depressives who were not abused as children did not show similar responses. In a recent study, we reported *decreased* levels of ACTH or cortisol activity over 24 hours in nonpsychotic depressives as compared to controls (119). Similarly, low values have been reported in several other types of patients, including atypical depression, posttraumatic stress disorder, so-called burn out syndromes, and so on. Thus, both decreased and elevated HPA axis activity may be found in specific depressive subtypes. In many ways this parallels the findings in catecholamine activity in depressed patients.

This seeming contradiction in findings or emphasis over time may have several explanations. First, the DST as we use it may not measure cortisol overactivity as much as it does central CRH overdrive in response to suppressing the pituitary because DEX poorly penetrates brain at the doses used in the test. Second, previous studies have often not explored the role of psychosis or early abuse. Third, relatively few studies on the HPA axis in depression have explored cortisol activity over the full 24-hour period.

HPT Axis

The overlap in symptoms between patients with hypothyroidism and those with major depression has led to number of studies on the hypothalamic–pituitary–thyroid (HPT) axis in patients with mood disorders. These studies have yielded intriguing, although at times, conflicting results.

Thyrotropin-releasing hormone (TRH) is released from the hypothalamus and stimulates TRH receptors in the pituitary to release thyroid-stimulating hormone (TSH), which in turn stimulates specific receptors in the pituitary to release triiodothyronine (T_3) and thyroxine (T_4) hormones. Thyroid hormones provide feedback to both the hypothalamus and pituitary to regulate the axis.

Activity of the axis can be measured in several ways: circulating levels of T_3 and T_4—both bound and unbound; TRH levels in the CSF; TSH responses to TRH administration (TRH-stimulation test); and circulating TSH levels. In addition some patients demonstrate antibodies to thyroid tissue suggestive of an autoimmune thyroiditis, often in the face of normal T_4, T_3, or TSH levels.

TRH is found in extra-hypothalamic regions in brain. CSF TRH was increased in two small studies of depressed patients as compared to controls (124 ,125), although not all studies agree (126). Elevated TRH levels should be accompanied by a blunted TSH response to TRH because TRH levels in the pituitary would be expected to be down-regulated in the face of elevated TRH. Indeed, multiple studies have reported such blunting in a relatively high percentage (approximately 25%) of patients with major depression. A recent review concluded that 41 of 45 studies reported blunted TSH responses to TRH in major depression (127). Blunting of TSH responses to TRH in these patients is not owing to clinical or subclinical hypothyroidism because thyroid parameters were generally within normal limits in these patients.

Type I hypothyroidism is characterized by decreased levels of T_3 and/or T_4, increased TSH, and increased TSH responses to TRH (1). Antithyroid antibodies may be present. Type II hypothyroidism is characterized by normal T_3 or T_4 levels but otherwise similar abnormalities as in Type I disease (1). Rates of Type III or IV subclinical hypothyroidism have been reported to be elevated in depressed patients. These syndromes are both characterized by normal circulating levels of T_3, T_4, and TSH but have other abnormalities such as elevated TSH responses to TRH or the presence of antithyroid antibodies. In one study, depressed patients with high normal thyroid levels were also reported to demonstrate exaggerated TSH responses to TRH (128). These data have been interpreted as indicating some patients with major depression may have subclinical hypothyroidism. Indeed, asymptomatic autoimmune thyroiditis with positive antibodies has been reported to be relatively high (9% to 25%) in several surveys of depressed patients (127 ,129). Taken together, TSH stimulation test data suggest elevated or decreased TRH activity could be involved in major depression, depending on whether patients met criteria for subclinical hypothyroidism.

T_3 has been reported to be an effective augmentor of responses to antidepressants and appears to exert greater effects than does T_4 (130). Patients with a history of thyroid disease (e.g., adenoma) who were taking suppressing or replacement doses of thyroxine or T_4 demonstrated an improvement in mood and cognitive function when T_3—but not placebo—was added (131). One possible explanation for the differential effects of T_4 and T_3 on mood rests with local tissue conversion of T_4 to T_3 that in brain is mediated by Type II 5′ deiodinase and may be dysregulated in some patients. Depressed patients have been reported to demonstrate increased reversed T_3 levels in CSF (130), which suggests inhibition of the Type II 5′ deiodinase and subsequent increased activity of the Type III of the enzyme. Cortisol can inhibit Type II of the enzyme and may play a role in the increased rT_3 levels. Of interest is a recent report (133)

that in depressed patients low T_3 levels predicted earlier relapse, pointing further to an important role for T_3 in mood relation.

Transthyretin is a protein that transports thyroid hormone from the periphery to the brain via the choroid plexus. Transthyretin levels have been reported to be low in refractory depressed patients (134). This may also help explain possible CNS enhancing effects of T_3 in the face of normal circulating thyroid hormone levels.

Overall, research on the HPT axis has produced some intriguing leads for understanding the pathophysiology of depression and improving its treatment. However, there are still a number of seeming contradictions regarding the direction and specific nature of HPT alterations in depression. Data point to both elevations in central TRH activity and subtle forms of hypothyroidism (suggestive of low T_3 and TRH activity) as playing potential roles in major depression.

Human Growth Hormone

Growth hormone (GH) is synthesized in the anterior pituitary. Two hypothalamic hormones, growth hormone releasing factor (GRF) and somatostatin modulate its release from the pituitary. GRF is stimulating; in contrast, somatostatin inhibits release. Somatostatin is also found in extra-hypothalamic regions, and appears to act as a neurotransmitter. The major neurotransmitters involved in mood regulation (e.g., norepinephrine, serotonin, and dopamine) all affect GH release, and these systems can be challenged by specific compounds (e.g., apomorphine, clonidine, etc.).

Diurnal rhythms of GH, as measured in plasma, are disrupted in depression. Nocturnal GH is elevated in depression (135), but daylight-stimulated GH levels are increased in both unipolar and bipolar depressives (136).

As indicated, GH responses to clonidine are blunted in depression (28). GH responses to GRF have also been explored in patients with major depression with several, but not all, groups reporting blunted GH responses (137 ,138 and 139). CSF levels of somatostatin, which inhibits GH, CRH, and ACTH release, are also reduced in depression (140 ,141), such that somatostatin does not appear to provide an explanation for the blunted GH responses to GRF in depression. Low somatostatin levels in depression may reflect increased cortisol activity (1 ,142) and appear to normalize with treatment (2). Low CSF somatostatin has also been observed in various neurological disorders (e.g., Alzheimer's disease).

CONCLUSION

Part of "72 - Molecular and Cellular Mechanisms in Depression "

Proliferation of research into the biology of depression has resulted in a number of intriguing leads for understanding the pathophysiology of major depression. Most studies have focused on single biological systems such that there is a dearth of studies that simultaneously explore multiple systems and their complex interactions in depression. Also, research has tended to emphasize cross-sectional rather than longitudinal designs such that we have little understanding of the biological underpinnings of initiation, maintenance, and termination of depressive episodes. Future research that combines genetic risk factors with longitudinal study of multiple systems will likely lead to breakthroughs in our understanding of the biology of the disorder. Also, greater emphasis on the biology of specific depressive subtypes (e.g., delusional depression) or of symptom dimensions may provide greater insights.

J. John Mann: Department of Neuroscience, New York State Psychiatric Institute, New York, New York.

One of the first neurochemical theories of depression was the monoamine deficiency hypothesis (139 ,143 ,153). Over the past 30 years, this hypothesis has been the most scrutinized of any theories regarding the biology of depression. Unfortunately, the biology of depression remains an elusive issue, despite intense biological research. It is widely held that most, if not all, antidepressant drug treatments produce their therapeutic antidepressant effects, at least in part, by modulating monoamine systems (noradrenergic, serotonergic, and dopaminergic); however, less is known about the neurochemical pathology of these monoamine systems in depression. Early attempts to evaluate monoamine systems in depressive disorders led to diverse and not clearly integrated findings. As a result, many other neurochemical theories have been generated in efforts to explain the biological basis of depression. These theories include HPA axis hyperactivity (111), the GABA hypothesis (132), the galanin hypothesis (186), the substance P hypothesis (82), the glutamate hypothesis (162), the neurotrophin hypothesis (39), and many others. A substantial portion of the evidence supporting these “other neurotransmitter” theories derives from studies of the pharmacologic and behavioral effects of antidepressant drugs in laboratory animals. Of course, these antidepressant drugs have prominent actions on norepinephrine (NE), serotonin (5HT), and to a lesser extent, dopamine (DA). Hence, originators of new hypotheses are continuously forced to place new theories in the context of the old monoamines. The principal reason for this is that, despite years of pharmaceutical development, drugs with primary actions on monoamine systems remain the mainstay of treatment for depressive disorders. In fact, evidence that there has been an improvement of medication over the past 20 years is highly debated, in terms of greater efficacy or even faster onset of action. If improvements are evident in antidepressant medications, then they are as a result of a reduction of adverse side effects with newer antidepressant compounds, rather than novel pharmacologic mechanisms with enhanced activity. For this reason, as research on depression biology progresses into this new century, the monoamine hypotheses continue to be among the most popular biological theories and continue to be heavily investigated and debated.

Much of the past 10 years of research in the biology of mood disorders has led to advancements in our understanding of the role that monoamines play in these disorders. New modern approaches have been applied, including the use of *in vivo* imaging techniques in live patients, morphologic and neurochemical investigations with high levels of anatomic resolution, use of postmortem brain tissues from psychiatrically characterized subjects, and genetic studies. Considerable evidence has accumulated implicating multiple system pathology in mood disorders, including abnormalities of monoamine as well as other neurotransmitter systems. These approaches and findings have led researchers to propose broader theories regarding depression biology (e.g., depression as a spreading neuronal adjustment disorder or limbic–cortical dysregulation disorder) (67 ,102). In this chapter, the authors reconcile new findings of multiple system pathologies specifically with regard to monoaminergic systems. Emphasis is placed on the cellular sources of monoamine systems and their circuitry, the communication between these monoamine nuclei, and the influence of other neurotransmitter systems that are putatively disrupted in depression on monoaminergic neuronal activity.

NORADRENERGIC CIRCUITRY AND DEPRESSION

Part of "73 - Neurocircuitry of Mood Disorders "

The original speculation that NE is deficient in depression hinged partly on clinical observations of depression in some

individuals receiving reserpine for hypertension. Reserpine depletes brain monoamines by blocking vesicular monoamine storage; however, only a fraction of individuals administered reserpine develops depression. In fact, short-term depletion of NE by administration of alpha-methyl-*p*-tyrosine to normal control subjects does not result in a significant change in mood (152). These findings, along with a history of inconsistent findings regarding levels of NE and its metabolites in depressive disorders (19 ,138 ,147 ,180), casted doubt about NE's role in depression for many years. Recently, however, Charney and co-workers (28) demonstrated that rapid pharmacologic depletion of NE in patients taking noradrenergic antidepressants causes a rapid relapse of depression. This latter finding demonstrates that NE is critical to the therapeutic action of noradrenergic antidepressant drugs. Most recently, and of considerable significance, is the demonstration that depletion of catecholamines (NE and DA) in unmedicated fully remitted subjects with histories of major depression resulted in relapse into depression (21). Together, these studies demonstrate that acute NE depletion is insufficient to induce depressive symptoms by itself, but depletion in a susceptible individual induces depressive symptoms.

The neurobiological relationship between NE and mood is poorly understood. Most of the NE in the brain arises from cell bodies in the locus ceruleus (LC). The projections of these neurons are diffuse and overlapping with respect to the brain regions innervated. Some of the brain regions that are most densely innervated by the LC are limbic brain regions, including the amygdala and hippocampus. The LC is part of the reticular activating system and neurons of the LC have tonic pacemaker activity. LC activity is elevated during states of arousal. In contrast, LC activity slows during sleep and is inactive during random eye movement (REM) sleep. The LC is robustly activated by stress, contributing to the alerting of the organism to stimuli relevant to survival. In addition to innervation of forebrain regions, the LC densely innervates other monoaminergic nuclei, including the serotonergic raphe nuclei and the dopaminergic ventral tegmental area (VTA) (10 ,116). Given the large number of brain regions innervated by the LC, noradrenergic transmission is in an ideal position to globally modulate brain function, and modulate the activity of other monoamines. Foote and colleagues (51) and Aston-Jones and associates (10) have extensively reviewed the physiologic consequences of LC activation.

The hypothesis that NE plays a role in the neurochemical pathology of depression raises the possibility that the activity and biochemistry of the noradrenergic LC is abnormal in this illness. Recent studies using postmortem brain tissues from psychiatrically characterized subjects reveal a complex pathology of the noradrenergic LC in major depression. These studies are unique with respect to many previous postmortem research studies on the noradrenergic system in depression because of the focus on neurons that are the source of NE and because brain tissues utilized were from subjects whose psychiatric status was rigorously characterized (80 ,195). Prominent among exclusion criteria for subjects is the absence of any antidepressant (or antipsychotic) drug use, determined both by next-of-kin interview and from a toxicology examination. Elevated amounts of tyrosine hydroxylase (TH) (195) elevated binding to α_2-adrenoceptors (119 ,122) and reduced amounts of NE transporter binding (80) have been reported in the LC of major depressive subjects as compared to psychiatrically normal control subjects. In contrast, other proteins measured in the LC of major depressives appear to occur in normal amounts (e.g., monoamine oxidase A, MAO-A) (118). Interestingly, a lower number of noradrenergic neurons have been observed in the rostral LC from victims of suicide relative to normal control subjects (5). In contrast, Klimek and co-workers (80 ,195) report no differences in noradrenergic neuron cell counts in the middle to caudal portion of the LC between depressed suicide victims and psychiatrically normal control subjects, or in psychiatrically uncharacterized suicide victims compared to control subjects (120). Elevation of radioligand binding to some (3), but not all, noradrenergic receptors (4 ,79) has also been identified in some projection areas of the LC, comparing suicide victims to control subjects.

To interpret these postmortem findings, it is very useful, if not necessary, to utilize information from studies of NE in laboratory animals. In animals, stress activates the LC (130) and exposure to repeated stress elevates the demand for NE (110 ,124) revealed by increases in LC TH (105 ,175 ,183). Uncontrollable shock, a stress-based animal model of depression, increases the release of NE (187) and reduces NE stores (187). Because TH is the enzyme catalyzing the rate-limiting step in the synthesis of NE, increased tyrosine hydroxylase in the LC may adjust the set point of basal activity in the NE system, to keep pace with increased demand. Similar examples of up-regulation of TH expression in the LC occur after administration of reserpine (31) and intraventricular infusion of 6-hydroxydopamine (106), both of which cause loss of brain NE. Pharmacologic depletion of NE also up-regulates binding to α_2-adrenoceptors (60 ,172) and down-regulates binding to NE transporter (86). Hence, postmortem findings of LC biochemistry (e.g., elevated tyrosine hydroxylase and α_2-adrenoceptor binding) and reduced NE transporter binding are predictive of premortem increases in LC activity and decreases of NE availability. Decreased NE availability could also contribute to compensatory up-regulation of ß-adrenoceptors in LC projection areas, such as has been observed in the frontal cortex from suicide victims (3). As mentioned, the link between reduced brain NE and depressive symptoms, at least in susceptible individuals, has been made (21). Moreover, the relevance of stress-induced biochemical abnormalities in the LC is underscored by studies demonstrating a relationship between life stress and development of depression (26), and

that stress plays a role in the etiology of depression (131). A shortcoming of the cited postmortem studies, however, is that most of the depressive subjects who have been studied died as a result of suicide, and the relationship between the biological abnormalities found in the central noradrenergic system and behaviors related to suicide that are distinct from those related to depression has not been investigated.

If one accepts that biological abnormalities in the noradrenergic LC are relevant to the symptoms of depression, then it follows that treatment with antidepressant drugs might reverse these abnormalities. Again, it is presently necessary to look to laboratory animal studies to examine this issue. Repeated treatment of rats with antidepressants from many different pharmacologic classes (including 5HT uptake inhibitors), but not with non-antidepressant drugs, down-regulates LC tyrosine hydroxylase (114). Antidepressant drug treatment blocks stress-induced elevation of tyrosine hydroxylase mRNA in the rat LC (154). Repeated antidepressant drug treatment also down-regulates α_2-adrenoceptors in the rat LC (154). These findings demonstrate that repeated antidepressant treatment down-regulates tyrosine hydroxylase and α_2-adrenoceptors, proteins that are apparently up-regulated in the LC of human major depressives. Returning to the suggestion that LC activity may be elevated in depressives, recent studies demonstrate that repeated treatment of rats with antidepressant drugs of many different pharmacologic classes (including 5HT uptake inhibitors) reduces LC activity (58 ,68). Hence, animal data strongly support the contention that drugs produce antidepressant effects, at least in part, by reducing demand for NE, that is, reducing biochemical measures of demand (reduced biosynthetic enzyme for NE) and reducing LC activity.

In summary, evidence of: 1) norepinephrine depletion-induced depression in susceptible human subjects, 2) abnormal levels of noradrenergic proteins in the LC of human major depressives, 3) the ability of antidepressant medication to produce effects that would be expected to reverse noradrenergic pathology in depression provide strong support for the venerable theory that norepinephrine plays a role in the pathobiology of depression.

SEROTONERGIC CIRCUITRY AND DEPRESSION

Part of "73 - Neurocircuitry of Mood Disorders "

The biological basis for the indoleamine hypothesis was similar to that for the catecholamine hypothesis (178). That is, reserpine depletes not only catecholamines, but also 5HT. Since that time, several (but not all) studies have found reduced levels of CSF 5-hydroxyindole acetic acid (5-HIAA) in depressed patients (101 ,179); however, the degree of reduction of CSF 5-HIAA does not correlate with severity of depression. Oddly, many antidepressant medications, particularly 5HT reuptake inhibitors and monoamine oxidase inhibitors (MAOIs), reduce CSF 5-HIAA, possibly because of feedback inhibition resulting from increased synaptic concentrations of 5HT. Levels of CSF 5-HIAA are lower in depressed patients with a history of serious suicidal behavior, as compared to depressed patients with no history of suicide attempts. (See ref. 99 for review.) CSF 5-HIAA levels appear to exhibit a bimodal distribution in depressed patients. CSF 5-HIAA is not distinguished by more severe depression, but by a history of serious suicide attempts (55). Rapid tryptophan depletion causes transient, mild, nonclinical increases in negative mood in healthy young men (36). In depressed patients who had recent therapeutic responses to antidepressant medications, tryptophan depletion causes a transient depressive relapse (35). Rapid tryptophan depletion of many, but not all, patients with a history of depression and that are antidepressant drug-free causes a depressive relapse (35 ,164). In symptomatic, medication-free patients with depression, tryptophan depletion causes no significant behavioral effects (36), perhaps because of a floor effect (36). Together, these findings suggest that depression is often, but not always, associated with a serotonergic deficit.

A number of neuroendocrine challenge tests have demonstrated impaired serotonergic activity in depressed patients (49 ,56 ,69), although conflicting findings have also been reported. (See ref. 98 for review.) Numerous researchers have utilized postmortem brain tissues to study the serotonergic system in depression. Measurement of both $5HT_{1A}$ and $5HT_{2A}$ receptors in the prefrontal cortex from suicide victims has yielded no clear conclusions. Most of the studies cited in a recent review of these data by Stockmeier and colleagues (165) utilized tissues primarily from victims of suicide. Because there is an association of serotonergic abnormalities with suicidal risk, it is difficult to determine what effects are attributable to the presence of major depression from those associated with suicidal behavior (98). Significant increases in $5HT_{2A}$ receptor binding and a decrease in 5-HIAA in major depressives dying of causes other than suicide have been reported (47 ,103).

Given substantial evidence that 5HT plays a role in the pathology of major depression, it is expected that neurons supplying affected areas of the brain would display neuronal or neurochemical pathology. Two major nuclei in the brain, from which the majority of brain serotonergic innervation originates, are the dorsal raphe and median raphe nuclei. These nuclei provide an extensive innervation of cortical and subcortical target areas. The dorsal and median raphe nuclei give rise to separate axonal pathways to different brain regions. For example, the septum and hippocampus are innervated predominantly by the median raphe nuclei. In contrast, the striatum and substantia nigra are innervated by the dorsal raphe nuclei. Serotonergic terminals densely innervate various components of the limbic system. The widespread innervation of the brain by serotonergic neurons is the anatomic basis for the influence of 5HT on many diverse brain functions.

Several recent studies have investigated the serotonergic raphe in depression. Using single photon emission computed tomography (SPECT), Malison and associates (97) reported a decrease in 5HT transporter availability in the brainstem of living subjects with major depression. Because of issues related to spatial resolution, it is difficult to conclude from this study that the reduction in 5HT transporter occurred in raphe nuclei and/or other brainstem nuclei where the 5HT transporter occurs (e.g., substantia nigra or VTA). Little and co-workers (90) found no significant change in mRNA for the 5HT transporter in the dorsal raphe and median raphe nuclei from depressed persons who had committed suicide. Consistent with these findings, Bligh-Glover and colleagues (25) found no significant differences between depressed suicide victims and normal control subjects in [^{3}H]paroxetine binding to the 5HT transporter in the entire dorsal raphe or in its constituent subnuclei, as determined using postmortem tissues from psychiatrically characterized subjects. An increase in radioligand binding to $5HT_{1A}$ autoreceptors in dorsal raphe nuclei from depressed suicide victims has been observed (166). In apparent contrast, a decrease in the binding potential to $5HT_{1A}$ receptors in the midbrain raphe nuclei has been observed using positron emission tomography (PET) in patients with familial mood disorder (38). Recent studies also provide evidence of morphologic abnormalities of brainstem serotonergic nuclei. Underwood and associates (173) have demonstrated elevated numbers and densities of 5HT neurons in the dorsal raphe of suicide victims, most of whom had major depression. In addition, Becker and colleagues (18) have demonstrated significantly low echogenicity of the dorsal raphe nucleus in patients with major depression using a novel transcranial ultrasound technique. Together, these findings are strongly suggestive of a neuropathologic involvement of brainstem serotonergic nuclei in depression, but the study by Underwood and associates ruled out a loss of serotonergic neurons in depressed suicides, suggesting that the postulated hypofunction of the serotonergic system is not owing to fewer serotonergic neurons, but dysfunction of serotonergic neurons. As is the case with noradrenergic pathology, the specificity of serotonergic pathology for major depression versus suicidal behavior is yet to be clarified.

Evidence of a serotonergic deficit in depression predicts that drugs that are effective antidepressants should enhance serotonergic transmission. In fact, repeated treatment of rats with antidepressant drugs results in a net enhancement of serotonergic transmission (24). This effect is regardless of the primary pharmacologic site of action of the drug and includes selective 5HT transporter inhibitors, MAOIs, tricyclic antidepressants, and electroconvulsive shock. Selective 5HT transporter inhibitors and MAOIs enhance serotonergic transmission by desensitizing the somatodendritic $5HT_{1A}$ autoreceptors (23 ,24) and enhancing responsiveness of postsynaptic $5HT_{1A}$ receptors (63). Chronic administration of some tricyclic antidepressants or a course of electroconvulsive shock to rats does not appear to desensitize somatodendritic autoreceptors, although these treatments enhance the responsiveness of postsynaptic 5HT receptors (24 ,107). Hence, the mechanism by which different antidepressant drugs regulate serotonergic activity appears to differ, but the net effect of enhancing serotonergic transmission is similar. These preclinical findings are consistent with the hypothesis that there is a deficit in serotonergic transmission in depressive disorders that is normalized or corrected by antidepressant drug administration.

DOPAMINERGIC CIRCUITRY AND DEPRESSION

Part of "73 - Neurocircuitry of Mood Disorders "

Since the discovery that tricyclic antidepressant drugs can block DA reuptake *in vitro* (66), and that elevation of the functional activity of DA has antidepressant efficacy (142 ,143), there has been interest in the potential role of DA in the pathophysiology of depression. The contribution of DA to emotion-laden behaviors such as reward seeking, motivation, and environmental responsiveness also raises speculation that DA plays a role in the pathobiology of depression (48 ,167). In fact, clinical, pharmacologic, and laboratory animal evidence suggests that dopaminergic neurotransmission is decreased in depression. Lower concentrations of homovanillic acid (HVA), a DA metabolite, have been observed in CSF of patients with depression, and depression-inducing effects of DA-depleting agents or DA antagonists have been reported (143 ,144 ,189). In contrast, agents that enhance DA transmission, at least in part, such as bupropion, nomifensine, and amineptine, exert antidepressant effects in humans. Given that DA is intimately involved in motivational process and affect (73 ,167), these findings suggest that a deficiency of mesolimbic and/or mesocortical DA is a leading candidate for the etiology of core symptoms of depression, such as difficulty in the experience of pleasure (anhedonia), social isolation, loss of motivation (lack of interest), and psychomotor retardation (190).

At least three DA systems putatively involved in neurologic and psychiatric disorders have been extensively characterized in the brain: the nigrostriatal, mesolimbic, and mesocortical systems. A loss of nigrostriatal DA neurons causes the motor impairment of Parkinson's disease (PD), whereas dysfunction or activation of mesolimbic and/or mesocortical DA systems are implicated in psychiatric disorders, including depression, schizophrenia, and psychostimulant drug abuse disorders. However, some overlap in the pathology of PD and psychiatric disorders apparently occurs because cell loss in the VTA (in addition to substantia nigra) has been observed in patients with PD who have complications of co-morbid mood and cognitive disorders (171).

Anatomic, electrophysiologic, and neurochemical studies have delineated reciprocal pathways linking various limbic

and cortical regions with dopaminergic brainstem nuclei. Kalivas and Nakamura described the neuronal circuit that mediates the integration of reward perception and adaptive behavioral responses (75). This circuit includes the nucleus accumbens, amygdala, prefrontal cortex, mediodorsal thalamus, ventral pallidum, and midbrain neurons located in the VTA. Of brain limbic structures, the nucleus accumbens (ventral striatum) has been considered an important anatomic substrate of psychiatric illness, because of its established role in motivation and affect (167 ,75). Neurons in the nucleus accumbens receive a highly compressed input from the amygdala, hippocampus, cingulate gyrus, and prefrontal cortex (68 ,194). Ascending to synapse onto the same neurons in the nucleus accumbens are DA-containing fibers from the VTA (68), suggesting that the nucleus accumbens may integrate information coming from the prefrontal cortex and limbic regions with those originating from the VTA. Besides projecting to the nucleus accumbens, DA neurons ascending from the VTA project to other limbic structures, including discrete regions of amygdala, to cortical areas, and to the septum (116). Prefrontal, orbitofrontal, and cingulate cortices receive robust innervation from the VTA. Interestingly, most of the areas receiving DA projections from the VTA project back to the VTA.

If DA neurotransmission were disrupted in depression, then antidepressant drug treatment would be expected to produce effects on the brain dopaminergic system. Numerous studies demonstrate that antidepressant drugs enhance mesolimbic DA activity. Repeated treatment of rats with antidepressant drugs (tricyclics, mianserin, or citalopram) enhances DA agonist-induced locomotor hyperactivity, an effect observed when DA agonists are administered either systemically or injected directly into the nucleus accumbens (94 ,95 and 96). It is noteworthy that stereotypy (a behavioral effect reflecting the activity of nigrostriatal system) induced by D-amphetamine or apomorphine, is not increased by repeated treatment with antidepressant drugs (156); therefore, it has been assumed that the mesolimbic DA system mediates the increased behavioral responses to DA agonists following antidepressant treatments. Consistent with this effect, antidepressant drug treatment increases the affinity of D_2 receptors for their agonist in the limbic forebrain, but not in the striatum (78) and chronic treatment with antidepressant drugs results in postsynaptic DA receptor supersensitivity in the nucleus accumbens (40). Recent autoradiography studies confirm these findings by showing that when [^{3}H]raclopride, an antagonist at $D_{2/3}$ receptors, is used as a radioligand, no significant differences in the density of $D_{2/3}$ receptors are observed after chronic antidepressant drug administration. In marked contrast, when [^{3}H]quinpirole, an agonist at $D_{2/3}$ receptors is used as a radioligand, a significant increase in its binding is observed in the caudate and NAC of antidepressant-treated rats (146).

The level of mRNA encoding the D_1 receptor and [^{3}H]SCH 23390 binding to D_1 receptors are decreased in the limbic regions following these antidepressant drug treatments (42 ,37). A lower density of D_1 receptors induced by chronic antidepressant medication might contribute to enhancement of D_2 receptor functions as a result of a reduction in the inhibitory interactions between these two receptors at the level of the βγ subunit of G proteins (182).

Behavioral models in laboratory animals also point to a role for DA in antidepressant drug action. Following exposure to uncontrollable foot shock, an animal model of depression, rats display a pronounced reduction of responding for electrical brain stimulation of the nucleus accumbens. This response is attenuated by repeated treatment with the antidepressant drug desipramine (193). Rats exposed to chronic mild stress, another animal model of depression, experience decreased responsiveness to rewards (anhedonia), which is antidepressant-reversible (191). These behavioral changes are accompanied by lower $D_{2/3}$ receptor binding in the limbic forebrain that is reversed by 5 weeks of imipramine treatment (127). Overall, preclinical findings imply that a putatively important pharmacologic effect of antidepressant treatment is the augmentation of mesolimbic DA activity.

A few recent studies have measured the DA receptors in depressed patients *in vivo* using brain imaging techniques. Two studies demonstrate an increase of D_2 receptor density in the striatum in depression, possibly reflecting reduced DA function and a consequential up-regulation of these receptors (33 ,157). On the other hand, Ebert and associates, 1996 (43) found striatal D_2 receptor binding unchanged in major depression.

INTERACTIONS BETWEEN THE MONOAMINE NUCLEI AND MONOAMINES AND OTHER NEUROTRANSMITTERS

Part of "73 - Neurocircuitry of Mood Disorders "

Abnormalities of the biochemistry of one or more monoamine systems may cause depressive disorders. Alternatively, disrupted monoamine biochemistry may be secondary to other root biological, environmental, and/or psychological causes. A multitude of experimental approaches will be required to determine the core cause(s) of depressive disorders, even as considerable evidence of monoamine dysfunction in depression accumulates. Nevertheless, it is interesting to consider the relationship of the monoamines with other neurotransmitters that modulate monoaminergic chemistry. The LC, raphe nuclei and VTA receive a variety of neuronal inputs, including the monoamines themselves, that regulate their activity (Fig. 73.1). Several neurotransmitter inputs to monoamine nuclei are of particular relevance to major depression because of the accumulation of evidence that these systems are also disrupted in depression. For example, abnormalities in GABA, substance P, corticotropin releasing factor (CRF) and glutamate neurochemistry have been implicated

in depression. Theoretically, disruption of the activity of monoamine systems could result from disease-related abnormalities in neurotransmitter input to the monoamine nuclei. In addition, disruption of serotonergic activity in depression could be secondary to deficient noradrenergic input to the serotonergic raphe nuclei. That is, disruption of one monoamine would be expected to result in general monoamine imbalance because of the inter-connectivity between these nuclei. Hence, the relationship between the monoamine systems, and between monoamines and other neurotransmitter systems suspected of playing a role in depression biology, is worthy of discussion.

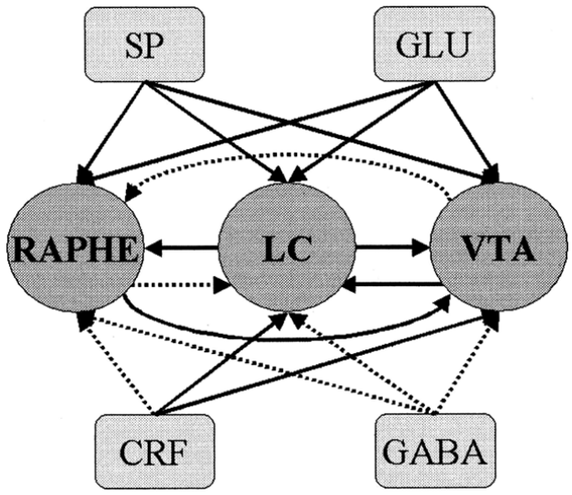

FIGURE 73.1. Neurotransmitter interactions at the level of monoaminergic cell bodies. Solid lines represent excitatory inputs to the raphe nuclei, LC, and VTA; dashed lines represent inhibitory inputs. In some cases, neurotransmitter inputs may be both direct and indirect via synapses with other neurons projecting to the nuclei. Neurotransmitters inputs shown are only those that are discussed in this chapter.

Monoamine Interactions at the Level of the Monoaminergic Nuclei

The monoaminergic nuclei are highly interconnected and physiologically integrated. For example, noradrenergic neurons innervate the serotonergic raphe nuclei and the dopaminergic VTA. Both the dorsal and median raphe nuclei receive noradrenergic innervation (15 ,121). In fact, the rat dorsal raphe receives one of the richest noradrenergic innervations in the brain (15 ,89 ,150). Overall, NE appears to be excitatory at serotonergic raphe neurons. For example, interruption of noradrenergic transmission by systemic administration of an α-adrenoceptor antagonist or iontophoretic application of an α-adrenoceptor antagonist in the vicinity of serotonergic neurons completely suppresses their spontaneous firing (14). Iontophoretic application of NE during the suppression of serotonergic cell activity produced by phentolamine or WB-4104, antagonists of α-adrenoceptors, can rapidly restore firing of these neurons to their normal activity (14). Most of the noradrenergic innervation of the VTA arises from LC neurons and noradrenergic input to the VTA is excitatory, mediated by excitatory α_1-adrenoceptors (59). In rats, chemical denervation of noradrenergic projections by DSP_4 treatment suppresses mesolimbic DA release (83) and reduces the effectiveness of positive reinforcers (109). Hence, if noradrenergic transmission is reduced, as has been hypothesized to occur in major depression, then reduced noradrenergic input to the raphe nuclei and VTA would be expected to contribute to reductions in serotonergic and dopaminergic transmission (109).

The LC and the VTA receive serotonergic terminals originating in the raphe nuclei. Serotonergic innervation to the LC originates from several sources including the dorsal and median raphe nuclei (93 ,108 ,181). The effects of 5HT on the activity of the LC are complex, and depend on whether drugs used to manipulate the serotonergic system are administered directly into the LC or whether they are administered systemically. Systemic administration of $5HT_1$ and $5HT_2$ receptor agonists or antagonists modulates the activity of the LC. These effects appear to be mediated indirectly, at least in part, rather than by actions at these receptors within the LC (30 ,57 ,64). 5HT affects LC activity, at least in part, by attenuating glutamatergic activation of the LC (8 ,159). Messenger RNAs encoding $5HT_{1A}$, $5HT_{1C}$, and $5HT_{2C}$ receptors are found in rat LC neurons (137 ,192). Interestingly, neurotoxic destruction of serotonergic terminals results in an increase in firing of the LC (71) and increases in LC mRNA and tyrosine hydroxylase activity (71). Based on these findings, the overall effect of 5HT release in the LC appears to be inhibitory.

The VTA receives afferent projections from 5HT-containing axon terminals originating in the dorsal and median raphe nuclei (70). Moreover, 5HT neurons innervate both dopaminergic and nondopaminergic (e.g., GABA) neurons in the VTA and may influence mesocortical and mesolimbic efferent systems through synaptic as well as nonsynaptic mechanisms (70). 5HT-induced release of [^{3}H]DA from rat VTA slice preparations is blocked by methysergide, but not cyproheptadine, suggesting an involvement of the $5HT_1$ receptor (17). Local application (in the VTA) of agonists at 5-HT_{1A} receptors increases the firing of DA neurons in the VTA (6 ,87) and administration of a $5HT_{1A}$ receptor agonist systemically increases DA release in the medial PFC (7). Microinfusion of 5HT into the VTA in rats results in an increased release of DA in the NAC (61). It is tempting to speculate that the firing mode of VTA DA neurons is dependent, among other factors, on the activity of serotonergic terminals originating in the raphe. Because 5HT increases extracellular DA (128), a serotonergic deficit, which has been suggested as one primary abnormality in depression, would also lead to a DA deficit.

High levels of DA are found in the dorsal raphe and LC (89). Moreover, D_2 receptors and D_2 receptor mRNA are expressed in both regions (185). Lesions of the VTA cause LC DA levels to fall by about 50%. DA neurotransmission is important for the rewarding effects of LC stimulation, without which such stimulation appears to be aversive (41). In the dorsal raphe nuclei, a moderate number of DAimmunoreactive fibers cover rather homogenously all subdivisions of the region (136). It has been postulated that dopaminergic neurotransmission to the dorsal raphe inhibits the activity of dorsal raphe neurons by increasing extracellular concentrations of 5HT in the dorsal raphe and, consequently, by increasing somatodendritic 5HT autoreceptor stimulation in this nucleus (46).

Monoamine Systems and Other Neurotransmitters

CRF

Much evidence has accumulated implicating a state of CRF hypersecretion in major depression (112 ,113 ,125). Interestingly, the LC, raphe nuclei and VTA receive moderate to dense innervation by CRF neurons. The LC receives excitatory CRF input from several sources, and these afferents appear to be topographically organized with respect to the type of information conveyed (177). The nucleus paragigantocellularis and Barrington's nucleus sends afferents directly to the nuclear elements of the LC. The LC also receives CRF input from limbic brain regions, including the central nucleus of the amygdala, as well as the bed nucleus of the stria terminalis and hypothalamic subregions (177). These limbic CRF neurons project to the peri-cerulea area, and in particular to the rostrolateral peri-LC. CRF terminals form direct contacts with noradrenergic dendrites (176). CRF, injected intracerebroventrically or directly into the LC, activates LC neurons and enhances release of NE in projection areas (163). Internal and external stressors are known to activate the LC via CRF, including colonic distension, hypotensive challenge, and foot shock. The ability of these stressors to activate the LC is blocked by CRF antagonists (32 ,85 ,104 ,174). In general, the pontine-medullary CRF projections to the LC are thought to coordinate cognitive and autonomic responses to internal physiologic challenges, whereas the limbic CRF projections mediate LC activation by external stressors that have emotional content (81). Interestingly, administration of a CRF antagonist blocks stress-induced increases in LC tyrosine hydroxylase (104), an effect shared by antidepressant drugs (105).

The serotonergic raphe nuclei also receive CRF innervation. CRF terminals in raphe nuclei originate from local and distant cell bodies (148 ,151). The effects of CRF on raphe firing are complex (77). At low doses, CRF produces primarily inhibitory effects on raphe discharge. In contrast, higher doses of CRF excite raphe neurons. Likewise, the effects of intracerebroventricularly administered CRF on striatal 5HT release are biphasic (140). Low doses of CRF decrease 5HT release in the striatum, whereas high doses increase striatal 5HT. Price and associates (140) suggest that CRF has predominantly inhibitory actions at the level of the raphe. Hence, a putative hypersecretion of CRF in major depression could contribute to the deficit in serotonergic transmission at the level of the raphe nuclei.

The VTA is densely innervated by CRF-positive fibers, whereas the substantia nigra receives only scattered CRF innervation (11). Intracerebroventricular administration of CRF to mice produces behavioral activation and a “stress-like” increase in DA metabolism in several brain regions. Direct injections of CRF into the VTA produces dose-dependent increase in locomotor activity, an affect that is not antagonized by the DA receptor blocker, haloperidol (74). Intracerebroventricular or intraperitoneal administration of low doses of CRF increases DA and DA metabolite levels in the rat medial prefrontal cortex (84). Together, these findings suggest that CRF exerts an excitatory action in the VTA. The long-term effects of CRF administration on DA metabolism have not been studied.

Substance P

Recent studies suggest that substance P antagonists may have antidepressant properties (82), although there have been questions regarding their efficacy (45). Interestingly, there is a relatively dense network of substance P immunoreactive fibers in the human LC and surrounding regions (50). Many of these fibers may originate from the nucleus of the solitary tract (50 ,100 ,145). In addition, there is a high density of binding of radiolabeled substance P to neurokinin-1 receptors in the LC (34). Substance P potently stimulates the firing of LC neurons (62). There is considerable evidence that substance P plays a role in the central response to stress (13 ,65). Interestingly, substance P antagonists (in particular, selective neurokinin-1 receptor antagonists), when administered intracerebroventricularly, attenuate restraint stress-induced biochemical indices of LC activation (65). Repeated administration of rats with antidepressant drugs (perhaps not all types) down-regulates substance P in several brain regions (27 ,158).

Substance P is co-localized with 5HT in 25% to 50% of the neurons in the human median and dorsal raphe nuclei, respectively (12 ,155). Substance P-containing serotonergic neurons are not randomly located within the raphe nuclei, but are localized to specific subregions, suggesting that substance P co-releases with 5HT in specific brain regions. The dorsal raphe nuclei also receive innervation from substance P-containing neurons with cell bodies occurring outside the region of the raphe (92). There is a high density of substance P receptors in the region of the dorsal raphe nuclei (91). Substance P appears to activate raphe neurons and microinjection

of substance P into the dorsal raphe increases hippocampal levels of 5HT.

Substance P receptor mRNAs (NK1 and NK3) are found in DA neurons of the human and rat midbrain (188); substance P-immunoreactive terminals, making synaptic contacts with TH-positive neurons in the VTA, also have been demonstrated (169). Infusion of a substance P receptor agonist into the VTA stimulates locomotor activity and increases DA turnover in the nucleus accumbens (149), indicating an excitatory action of substance P on DA neurotransmission.

Glutamate

NMDA receptor antagonists have antidepressant actions in animal models of depression (129) and demonstrated antidepressant effects in humans (20). High levels of serum glutamate levels in depressed subject have been reported (2 ,76) with exception (1). In addition, alterations in the allosterism of NMDA receptor binding in the frontal cortex of suicide victims (115), and elevated levels of CSF glutamine (glutamate metabolite/precursor) in depressed patients have been reported (88). Such findings have led to speculation that there may be excessive glutamate neurotransmission in depressive disorders. Glutamatergic neurons provide the major excitatory neurotransmitter input to the LC. Glutamatergic innervation of the LC derives largely from the nucleus paragigantocellularis (9). Glutamate activates the LC through activation of both NDMA and non-NMDA (aspartate) receptors (117). Handling and immobilization stress increases glutamate measured in the rat LC by microdialysis (161 ,170). Interestingly, noise stress-induced enhancement of glutamate release in the LC is abolished by superfusion of the LC with a CRF antagonist (160), demonstrating an important interaction between CRF and glutamate systems at the level of the LC (88). It is tempting to speculate that a deficit in noradrenergic transmission in major depression is secondary to a chronic elevation in glutamatergic input into the LC and a resulting depletion of central NE.

The raphe nuclei also receive glutamatergic input. At least part of the glutamatergic input to the dorsal raphe nuclei originates in the habenula (72). As is the case for the LC, glutamate is excitatory in the raphe nuclei. The activity of DA neurons in the mesolimbic and mesocortical circuitry can also be modulated by excitatory amino acids (73). DA neurons in the VTA receive direct glutamatergic innervation from the prefrontal cortex (73). Glutamate excites DA cell activity via inotropic and metabotropic receptors (167).

GABA

There is considerable preclinical and clinical evidence that depression is associated with reduced GABA function. Petty has reviewed this topic (135). To summarize, plasma GABA is low in patients with major depression (133 ,134 and 135). GABA agonists have activity in animal models useful for identifying antidepressants (16 ,196). Finally, GABA agonists appear to have some antidepressant activity in humans (135).

GABA provides a major inhibitory input to the LC. GABAergic neurons arriving in the LC originate largely from the nucleus prepositus, stimulation of which inhibits the firing of LC neurons (44). There are apparently no GABA cell bodies intrinsic to the LC, but glutamic acid decarboxylase immunoreactive nerve terminals are present, closely juxtaposed to noradrenergic cell bodies and dendrites (22). GABA inhibits the firing of LC neurons primarily by activation of $GABA_A$ receptors (123), and these receptors have been autoradiographically identified in the LC (29 ,126). The dorsal raphe nuclei receive GABAergic innervation from local interneurons and from multiple distant sources (54 ,184) and dorsal raphe neurons express $GABA_A$ receptors (53). Iontophoretic application of GABA strongly inhibits the firing of dorsal raphe nuclei neurons (52). DA neurons in the VTA are innervated by GABAergic afferents projecting mainly from the forebrain. GABA terminals also synapse on GABA interneurons that themselves synapse onto DA neurons (73). GABA inhibits the activity of DA neurons by acting through GABA receptors ($GABA_B$) on DA neurons (167).

INTEGRATION OF MONOAMINE AND OTHER NEUROTRANSMITTER THEORIES

Part of "73 - Neurocircuitry of Mood Disorders "

Investigations of the neurochemical pathology of depressive disorders reveal abnormalities in monoamine systems as well as other neurotransmitter systems. Nevertheless, it is conceivable that a root cause of depression is a failure or deficit in a single neurotransmitter system. Because of the interconnectivity of the monoamine systems, it is likely that failure in one system to adequately respond to demand would quickly lead to compensations, or possibly failure, of the other monoamine systems, as well as changes and/or biochemical compensations of numerous systems that are directly regulated by the pathogenic neurotransmitter system. Hence, evidence suggesting that there is dysfunction of monoaminergic, as well as nonmonoaminergic, neurotransmitter systems in depression compels us to integrate neurotransmitter interactions into theoretical models of the neurochemical circuitry of depression. This is a difficult undertaking and requires translation and integration of clinical, preclinical, and basic research findings. The postulate that depression is associated with a deficiency of NE or an increase in the demand for NE (as discussed) provides a good example of concatenation of clinical/postmortem findings, experimental/laboratory animal findings, and basic research findings regarding transmitter interactions. That is, elevated tyrosine hydroxylase in the LC, as observed in major depressive suicide victims, can be experimentally produced

by pharmacologically depleting NE or chronically stressing rats. Depletion of 5HT can also up-regulate tyrosine hydroxylase in the LC, as can chronic administration of CRF. Interestingly, CRF is reported to be elevated in depression, is released by stress, and CRF excites LC neurons. Together, these data suggest that elevated CRF in depression increases demand for NE, probably leading to elevated tyrosine hydroxylase expression. Elevated CRF may also contribute to reduce serotonergic transmission in depression, given the CRF can inhibit dorsal raphe neurons. Furthermore, it is conceivable that other excitatory inputs to the LC, such as substance P, might also exhibit elevated activity in depression. If so, substance P antagonists with antidepressant actions may elicit their effects on mood, at least in part, through actions at the LC. In contrast to excitatory transmitters, elevated demand for NE could also result from reduced inhibitory input to the LC. Here, of interest is the putative association of low levels of GABA with major depression (discussed in the preceding) and the fact that GABA provides an inhibitory input to the LC.

Another interesting possibility is that disruption of a single neurotransmitter system may be common to depressive disorders, whereas different mood disorders or subtypes of major depression itself may be a result of the type of altered neuronal input to that particular system. Using the hypothesis of increased demand for NE in depression as an example, elevated activity of the LC may be a result of elevated CRF input to the LC in some depressives, whereas others may experience elevated LC activity as a result of overactive substance P or glutamate input or decreased GABA input. Presently, there is little evidence to support the idea of serotonergic or noradrenergic depressives that respond selectively to serotonergic or noradrenergic antidepressant drugs, respectively. However, NE and 5HT containing neurons may be downstream of disrupted input systems that may actually differentiate subtypes of depressive disorders at a neurochemical/neuroanatomic level. Future research on neuropathology of psychiatric disorders should benefit greatly if designed to simultaneously measure multiple neurotransmitter systems. Ultimately, a thorough understanding of neurotransmitter interactions and integrated neuronal systems as they relate to the neurochemical pathology of depressive disorders will likely yield novel therapeutic interventions.

Structural and Functional Imaging of Affective Disorders

Yvette I. Sheline

Mark A. Mintun

Yvette I. Sheline: Department of Psychiatry, Washington University School of Medicine, St. Louis, Missouri.

Mark A. Mintun: Department of Radiology, Washington University School of Medicine, St. Louis, Missouri.

With advances in imaging technology it is now possible to examine subtle changes in both structure and regional function that are associated with the pathophysiology of affective illness. Understanding how these changes fit together with findings from clinical studies, postmortem findings, and animal studies will yield insight into the neuroanatomic pathways involved in affective illness. Combining anatomic MRI studies with functional studies has improved the localization of abnormalities in blood flow, metabolism, and neurotransmitter receptor function and has the potential to provide a better-integrated model of depression. Functional and structural mapping also provide a bridge between the hypotheses stemming from rapidly increasing knowledge of molecular biology, psychopharmacology, and clinical and treatment applications. In this chapter we review studies of structural brain changes associated with early-onset recurrent depression (EORD), late-onset depression (LOD), bipolar disorder, and potential etiologic mechanisms. We also review functional studies in affective illness, including positron emission tomography (PET), functional magnetic resonance imaging (fMRI), and single-photon emission computed tomography (SPECT) studies.

STRUCTURAL STUDIES

Part of "74 - Structural and Functional Imaging of Affective Disorders "

Historically, the major psychiatric illnesses, including affective disorders, were not thought to be associated with structural brain pathology. With the development of new imaging tools in the last two decades, increasing evidence has accumulated that challenges this assumption. Studies using high-resolution three-dimensional (3D) magnetic resonance imaging (MRI) now have a resolution of 1.0 mm or better and are available to examine smaller brain structures with precision. Initially primarily focused on older subjects, structural studies have found both generalized and localized structural brain changes in major depression and bipolar disorder across the age spectrum.

Recurrent Unipolar Major Depression

Studies of neuroanatomic structure in early-onset recurrent depression (EORD) have recently found evidence for depression-associated structural change (Table 74.1). Brain changes associated with early-onset major depression have been reported in the hippocampus, amygdala, caudate, putamen, and frontal cortex, structures that are extensively interconnected (20). They comprise a neuroanatomic circuit, which has been termed the limbic-cortical-striatal-pallidal-thalamic (LCSPT) circuit (21). As discussed herein, functional aspects of this circuit are also altered in depression as measured by blood flow and metabolism.

Author	Brain Region	Sample (Number and Diagnosis)	Age (Mean ± SD)	Methods and Resolution	Findings
Krishnan et al., 1992 (1)	Frontal lobe	50 NC 50 MDD	49.3 ± 18 48.3 ± 17	1.5 T 5 mm	Bifrontal distances smaller Bifrontal brain widths smaller
Coffey et al., 1993 (2)	Frontal lobe	76 NC 48 MDD (44 unipolar; 4 bipolar) ECT referred	62.4 ± 16.4 61.6 ± 15.9	1.5 T 5 mm 5.2 interval	Smaller frontal lobe volumes in major depression

TABLE 74.1. BRAIN STRUCTURAL CHANGES REPORTED IN MAJOR DEPRESSIVE DISORDER

Several studies have examined hippocampal volume in depression. In some (9 ,10 ,11 and 12) but not all (13 ,14 ,16 ,17 ,19) significant reductions in hippocampal volumes were found with depression. In some studies the volume loss appears to have functional significance with an association between acute depression and abnormalities of declarative memory (22) as well as an association between severe depression in remission and lower scores on tests of verbal memory (11). One study (10) found hippocampal atrophy in patients with chronic depression but not in patients with remitted depression. Vakili and colleagues (14) also observed correlations between depression severity and hippocampal volumes, although no group differences between depressed and control subjects.

Methodologic differences may account for some of the discrepancies. The studies reporting negative findings typically had lower resolution, ranging from 3 to 10 mm (6 ,14 ,16 ,17 ,19), compared with 0.5 mm to 3 mm (9 ,10 ,11 and 12) for studies reporting significant differences. Some studies have reported negative findings for the amygdala–hippocampus complex (16 ,17 and 18), using methodology that does not separate

the two structures. Clinical selection of subjects may also contribute to different findings. Most of these studies used a mixed group of early-onset and late-onset depression, which may therefore have different contributing etiologies. In some studies (9 ,11 ,12) subjects were case control-matched for age and education, whereas in other studies subjects were group-matched or the results were corrected statistically for significant covariates. Some but not all studies excluded subjects with other physical illness or any current or past drug or alcohol abuse. In summary, in most studies that assessed depression severity in unipolar subjects and used high-resolution MRI techniques (Fig. 74.1), depression was associated with hippocampal atrophy, ranging from 8% to 19%. The significance and source of the volume loss has not been demonstrated. It is intriguing that a recent postmortem study (23) has found glial cell loss in the dentate gyrus of the hippocampus as well as in the amygdala in major depression.

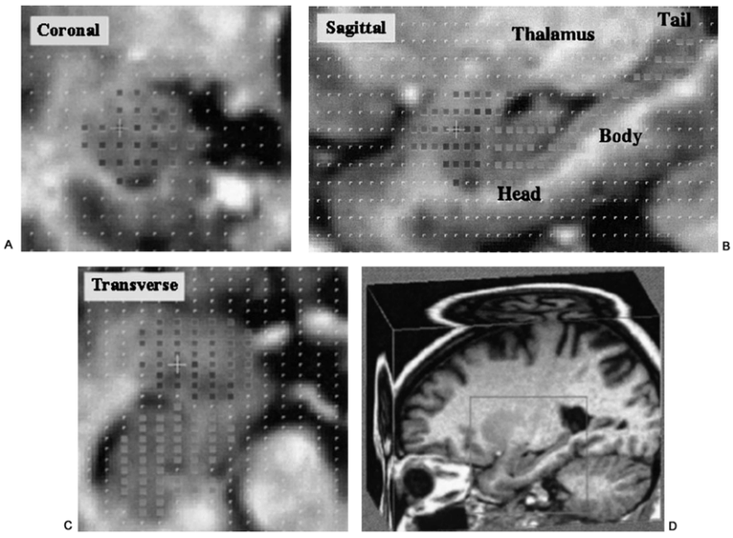

FIGURE 74.1. Orthogonal views (coronal, sagittal, and transverse) represent hippocampal and amygdala volumes as they are shown using stereological techniques. A 5 × 5 mm^2 grid with a 0.5-mm slice thickness is used to determine volumes for each structure. The total amygdala is made up of green plus blue. Labels for orientation of the hippocampus are included on the sagittal view. These measurements are derived from a cubic subvolume depicted in the last panel. See color version of figure.

Study of the amygdala has yielded inconsistent results with depressed subjects exhibiting an increase in volume in the right amygdala (12), loss of normal asymmetry (13), or reduction in the bilateral core nuclei (15). The amygdala is a difficult structure to measure, because in many areas the “cortical amygdala” merges with surrounding cortex. Particular boundaries selected can vary widely.

A number of studies have found decreased volume of basal ganglia structures in major depression, particularly late-onset depression (1 ,4 ,5 ,24), as further discussed. One study has reported negative findings in caudate and putamen in depressed subjects who were otherwise physically healthy (7), a criterion not clearly present in other studies.

Volume reductions in frontal cortex have been reported, ranging from 7% overall reduction in frontal lobe volume in major depression (25) to 48% in the subgenual prefrontal cortex (3). A postmortem study of prefrontal cortex in major depression (26) showed that depressed subjects differed significantly from controls in several prefrontal cortical areas. These included rostral orbitofrontal cortex decreases in cortical thickness, neuronal size decrease, and loss of glial cells in layers II to IV. In caudal orbitofrontal cortex there were reductions in glial cells in layers V to VI and decreases in neuronal sizes. Reductions in glial and neuronal cells throughout all layers as well as reduction in cell size were reported in dorsolateral prefrontal cortex. Glial cell loss in the subgenual region of prefrontal cortex has also been reported in major depression (27). Neuropathologic changes such as these could account for some of the MRI volumetric findings in frontal cortex. The prefrontal cortex is particularly important as a target of monoamine projections. Abnormalities in monoamine receptors, transporters, and second messenger systems (28 ,29 ,30 ,31 and 32) are reported to occur in major depression. It is also possible that overactivation in one part of the interconnected LCSPT neuroanatomic circuit may lead to over excitation in the other components, resulting in excitotoxic damage. The orbitomedial prefrontal cortex has high concentrations of glucocorticoid receptors, potentially rendering it vulnerable to stress-mediated damage (see the following).

Potential Mechanisms for Volume Loss in Early-Onset Recurrent Depression

It has been proposed that hypothalamic–pituitary–adrenal (HPA) axis dysfunction can produce repeated episodes of hypercortisolemia. Currently volume studies do not routinely include measures of cortisol, nor can they ascertain past episodes of hypercortisolemia. However, several different mechanisms could explain volume loss including neuronal loss through exposure to repeated episodes of hypercortisolemia, glial cell loss, resulting in increased vulnerability to glutamate neurotoxicity, stress-induced reduction in neurotrophic factors, and stress-induced reduction in neurogenesis. A mechanism that could account for hippocampal, amygdala, and prefrontal cortex volume loss, areas that have high concentrations of GC receptors is GC-mediated neurotoxicity (33), with repeated hypercortisolemic episodes of depressions giving rise to atrophy. Early life stress may produce a permanent hypersensitivity to stress (34), with the production of ongoing HPA axis dysregulation, particularly in subjects who develop depression. In the case of hippocampal volume loss, the inverse correlations between the total amount of time patients have been depressed and hippocampal volume (9 ,11) found in some studies but not all (12) supports recurrent depressive episodes having a causal relationship. Further, a study by Lupien and colleagues (35) demonstrated a correlation between higher cortisol levels measured longitudinally and greater hippocampal volume loss in normal human aging.

Glial cell loss either directly or indirectly is another potential mechanism for producing volume loss. Gray matter atrophy in the prefrontal cortex in an area ventral to the genu of the corpus callosum (3), an area associated in postmortem studies with glial cell loss (27) has been reported. Glial cell loss was also found in another postmortem study of depressed subjects in two different areas of prefrontal cortex (26). In addition, glial cell loss has been reported in postmortem studies of major depression in the amygdala and hippocampus (23).

Through excitatory connections between the amygdala and hippocampus (36) it is possible that damage in one structure could produce damage in the connected structure. Similarly, interconnections between prefrontal cortex and hippocampus (37) could produce excitotoxic damage. Glial

cells sequester glutamate, maintain metabolic and ionic homeostasis, and produce trophic factors, including brain derived neurotrophic factor (BDNF) (38 ,39). Therefore, loss of glial cells could increase vulnerability to neurotoxic damage, supporting the idea that glutamate neurotoxicity may be involved in the volume loss in the limbic–cortical–striatal–pallidal–thalamic (LCSPT) circuit.

A recently developed concept—stress-induced inhibition of neurogenesis (40)—may also explain depression-related volume loss, although high rates of baseline neurogenesis would be needed to produce atrophy of the scale required by volume loss in depression. Psychosocial stress was shown to suppress neurogenesis in the tree shrew (40). Likewise, corticosterone treatment in adult rats produced suppression of neurogenesis, which was reversed by removal of the adrenal gland (41). More recent findings (42) indicate that neurogenesis may occur in the frontal cortex as well as the hippocampus and subventricular zone. Thus, if depression inhibits neurogenesis, this could potentially explain both cortical and hippocampal volume loss.

Late-Onset Major Depression

Partly because of the increased prevalence of comorbid illness with age (including cerebrovascular disease, Parkinson's disease, etc.), patients with late life depression have an increased prevalence of structural brain changes relative to EORD. Depression onset in late age frequently occurs in patients with medical and neurologic disorders and compared with EORD it is characterized by greater medical morbidity and mortality (43), higher rates of neuroradiologic abnormalities, particularly white-matter hyperintensities (44 ,45), and lower familial frequency of affective disorders (46). In some studies, it is associated with higher rates of neuropsychological impairment and treatment refractoriness (47 ,48).

Both computed tomography (CT) and MRI studies have shown diffuse cortical and subcortical atrophy and ventricular enlargement in late life depression (18 ,49 ,50 and 51). Specific illnesses that have been associated with brain atrophy include hypertension (52), diabetes (53), Cushing's disease (54), and alcohol abuse (55). Any condition that produces neuronal ischemia or neurotoxicity is a potential candidate for producing brain atrophy.

Neurologic illnesses associated with both cortical and subcortical atrophy are associated with unusually high rates of depression, including Huntington's disease (56), post-stroke syndromes (57), dementia of the Alzheimer's type (58), and Parkinson's disease (59). Each of these illnesses produces damage to brain structures critical in emotional functioning. Importantly, these same brain structures are involved in more classical or early-onset major depression, namely frontal cortex, hippocampus, thalamus, and basal ganglia. Some studies do not find evidence for generalized atrophy in addition to volume loss in structures of the LCSPT circuit. Kumar and colleagues (60), for example, have found loss in prefrontal lobe volume in late-onset depression in the absence of generalized atrophy, suggesting that as in early-onset depression some subjects with late-onset depression may also have focal volume loss. It is not known whether this focal volume loss involves the same etiologic mechanisms.

A well replicated finding in elderly subject groups with depression is the increased numbers of hyperintensities seen on T2-weighted scans (T2H) (51 ,61 ,62 ,63 ,64 and 65). Some studies that included younger subjects with depression have also found increased T2H (2 ,66), although negative findings have also been reported with younger groups (5 ,67). The underlying causes of T2H are unknown, and indeed, it is important to note that T2H also occur at rates of up to 60% in healthy elderly (68), in whom their significance is unknown (69). Fujikawa and associates (70 ,71) found a higher rate of “silent” cerebral infarctions (T2H) in late- compared to early-onset MDD. Clinical correlates of MRI-defined T2H in late-life depression have included older age, vascular risk factors, neuropsychological impairment, and late age of onset (2 ,48 ,72). A subtype of “vascular depression” with increased CVD risk factors and increased T2H has been proposed (47 ,73).

Bipolar Disorder

Structural abnormalities reported in bipolar disorder have been intermittently reported. These include diffuse gray matter tissue loss, enlarged ventricles, increased numbers of T2-signal hyperintensities (T2H), and regional tissue loss in basal ganglia, lateral and mesial temporal structures, and cortical regions. Studies in bipolar subjects have also found structural changes in the same neuroanatomic circuit (LCSPT) as in major depression but these changes have been less consistent and often involved increases in structure volumes rather than decreases. In addition there is a substantial body of evidence for manic-like affective disorders following focal brain damage.

Most MRI studies have not found generalized cortical gray matter volume loss in bipolar disorder (6 ,74 ,75 ,76 ,77 and 78). A recent study in geriatric bipolar disorder (79) found increased cortical sulcal widening which was related to age of illness onset. In a small study in middle-aged bipolar subjects, Lim and co-workers (80) also found enlarged cortical sulci. In the same study, bipolar subjects had generalized decreased cortical gray volume that was intermediate between control and schizophrenia values. This finding could result from differences in segmentation algorithms, differences in covarying the data, and a more chronically ill population. In addition, lateral ventricles were enlarged; however, the difference was not significant in this small sample. Lateral ventricle findings from other groups included increases (45 ,74 ,81) and no difference from control (75 ,82).

Several groups have investigated the question of an overall

change in temporal lobe volume. Altshuler and colleagues (83) found bilateral temporal lobe reductions comparing bipolar patients to controls. Swayze also found temporal lobe abnormalities in bipolar disorder, but in symmetry rather than in volume—he found that bipolar subjects did not have the usual right greater than left volume asymmetry found in normals (16). In contrast, Harvey and associates (75) found increased left temporal lobe volume in bipolar disorder compared with controls and Johnstone and associates (84) found no differences.

In examining localized structural abnormalities, Strakowski and colleagues examined the circuit comprised of the prefrontal cortex, thalamus, hippocampus, amygdala, globus pallidus, and striatum (LCSPT) and found a significant difference in the overall structural changes. Some of these changes were increases (amygdala, striatum), whereas others were decreases (prefrontal cortex, hippocampus). Others have also examined structural changes in amygdala in bipolar disorder, finding larger (85), smaller (77), or equal (16) volumes. As mentioned, amygdala volumes are difficult to compare between studies. Prefrontal cortex volume decreases (74 ,76 ,86) generally have been small but significant in bipolar disorder and are supported by postmortem findings of decreased glia in prefrontal cortex in bipolar subjects (27). Results have been mixed for the basal ganglia. Larger caudate volumes were found in men (87) and larger globus pallidus volumes but not striatal volumes were found in another study (88) in bipolar patients compared to healthy individuals. Other MRI studies did not find any significant differences in bipolar subjects compared to controls in caudate, putamen, or lenticular nuclei (6 ,16 ,74). Results have also been mixed for hippocampus (16 ,85 ,89) and thalamus (6 ,74).

A finding that may shed some light in interpreting the contradictory findings is the recent report that chronic lithium treatment is neuroprotective and may prevent volume loss in treated patients (90). Lithium up-regulates the neurotrophic protein Bcl-2 in rat frontal cortex, hippocampus, and striatum. In analyzing reports of volume loss in bipolar patients it may be critical to know the cumulative medication history, especially regarding lithium.

The relationship between bipolar disorder and increased hyperintensities seen on T2-weighted MRI scans (T2H) is complex. The presence of hyperintensities has been associated with hypertension; however, T2H also are increased in asymptomatic elderly. In manic patients who developed bipolar disorder after age 50, Fujikawa and associates (91) found that compared with age- and sex-matched subjects who had developed affective illness prior to age 50 there was a significantly higher incidence of T2H, comparable to the incidence in subjects with late-onset depression. These results are similar to those of McDonald and colleagues (82), who found a higher incidence of subcortical hyperintensities in late-onset bipolar disorder. In younger subjects with new onset bipolar illness Strakowski and colleagues (74) found a rate of subcortical hyperintensities 1.7 times higher than control subjects, but this was not significant. Aylward and associates (87) also found a higher rate of hyperintensities in bipolar subjects, 34% versus 3% in controls; however, the bipolar subjects were 12 years older on average. In contrast, Figiel and colleagues (45) and Dupont (92) found higher rates of hyperintensities and no age differences. One study did not find differences between bipolar subjects and controls (93).

Most MRS studies have found increased levels of choline-containing molecules in basal ganglia of bipolar subjects compared with controls (94 ,95); however, Ohara and associates (96) did not find significant differences. Similarly, PET studies have also found functional abnormalities in basal ganglia in bipolar subjects (97 ,98).

Conclusion

Although advances in technology have allowed high-resolution studies of individual brain structures, understanding the organization of brain systems has been limited by the lack of noninvasive investigation of neuronal connections between functional regions. The recent development of noninvasive neuronal fiber tracking using water diffusion properties (99) will allow increasingly sophisticated reconstruction of fiber trajectories throughout the brain. The continuing development of automated tissue segmentation methods allowing determination of gray and white matter volumes using computer-generated algorithms will provide faster and more standardized volume measures. It will be important to combine structural studies with functional studies to determine the functional significance of brain structure changes. Combining MRI and functional studies such as PET, SPECT, and fMRI has the potential to more precisely localize abnormalities in blood flow/metabolism, and neurotransmitter receptors. This integrated perspective will allow further development of a structural–functional model of depression.

Studies in high-risk populations, such as first-degree relatives of affected individuals, will assist in determining whether focal structural and functional changes are genetic/neurodevelopmental or acquired and whether they predate or follow the development of depression. Additional postmortem studies in larger samples with careful clinical screening for comorbidity are also needed to examine ultrastructural correlates of volumetric and functional changes. Neuroprotective strategies aimed at preventing the damage associated with depression are likely to be an important future direction for research. Preclinical studies provide preliminary strategies for preventing stress-induced damage. These include for example prevention of stress-induced decreases in brain-derived neurotrophic factor (BDNF) with antidepressants (100 ,101 and 102), prevention of stress-induced excitotoxic injury with phenytoin (Dilantin) (103), prevention of stress-induced decreases in neurogenesis with antidepressants (104 ,105),

and increase in dendritic branching with serotonin reuptake inhibitors (106).

FUNCTIONAL STUDIES

Part of "74 - Structural and Functional Imaging of Affective Disorders "

Functional imaging extends the sensitivity and specificity of structural imaging. As it can safely be assumed that genetic, molecular, and biochemical changes precede changes in structure, the promise of functional imaging in affective disorder is to more accurately define the pathophysiology of affective diseases, better predict potential treatments and, in general, further our knowledge of mood regulation by the human brain. Despite its development over a decade ago, functional imaging has only begun to address these primary issues. The principal reason for this slow progress is the need for extensive methodologic development in both major divisions of functional imaging. In the mapping of brain function, the imaging techniques per se have not been a major factor. Rather, the limitation has been in the development and validation of relevant affective “tasks” to selectively activate the brain regions of interest. However, the widespread lack of suitable tracers and probes is the limiting factor in molecular imaging. Sufficiently selective and sensitive probes for the different receptors, enzymes, and transporters that are putatively implicated in affective disorder must be individually developed and validated. Often such probes fail after reaching the level of human application. However, advances in imaging the serotonergic system, for example, have been reported despite these difficulties. It is in this context that we can examine the contribution of functional imaging to our understanding of affective disorder and understand the promise it holds for the future.

Mapping Brain Function in Affective Disorders

Imaging of regional neuronal activity in affective illness has yielded intriguing, but heterogeneous, findings. Some of the variability in findings may rest in the different methodologies employed and a clear understanding of the limitations of the imaging techniques is important. Cerebral blood flow (CBF) and cerebral metabolic rate of glucose (CMRG) are well accepted as markers of general regional brain activity (107). As such, increased neuronal firing is reliably associated with increased CBF and CMRG allowing the spatial distribution of either CBF or CMRG to serve as a proxy measure for brain activity.

Some early studies of quantitative regional CBF in patients with major depressive disorder studied at rest reported global reductions (108 ,109). Regional changes have been reported as well with decreased CBF and metabolism in depressed subjects relative to controls in the dorsolateral prefrontal cortex (110 ,111). However, these regional changes are small (typically 5% to 10%) and are not consistently seen (112). One conclusion from these early studies is that no visually identifiable pattern of CBF or CMRG is associated with depression, even severe depression. This is in contrast to the altered patterns of CBF and CMRG identified for some other diseases, such as Alzheimer's disease and Huntington's chorea. For this and other reasons, functional imaging appears to have no current role in the clinical diagnosis or management of affective illness. However, an important role for functional brain mapping in depressive illness is to elucidate the neuroanatomic systems involved with the symptomatology of this disease. One example has been the characterization of decreased activity in the dorsal prefrontal cortices as being related to negative symptoms (111 ,113). This finding may best be interpreted as representing the relative hypofunction of these systems clinically in some patients with depression because there is much evidence that this brain area plays an active role in working memory and related executive functions.

This last point underscores the nonuniformity of the baseline state as the likely cause of the highly variable results in functional imaging studies of affective illnesses. Different cognitive and emotional states in control subjects are well known to result in regional brain activation. Thus, depressed patients imaged in a “resting” state could have highly variable internal ruminations, emotional states, and cognitive activities. This problem is usually addressed by large sample sizes in most clinical research in which these variations average out; however, as imaging studies are expensive most research studies have been limited to small sample sizes. Combining image data across sites is frustrated by differing instrumentation and approaches to data collection (image resolution, scan timing, etc.). Further complicating imaging studies is the large potential number of regions that can be independently sampled. Only in the last few years have techniques for multiple comparison correction been fully incorporated into data analysis strategies.

Imaging research into altered brain function in affective illnesses does not have to be based solely on a single image, or snapshot. Functional brain imaging of the depressed patient in a single state, a snapshot of brain function, can be complemented by examining the functional changes during a specific task or stimulus (114). The regional brain *responses* to a cognitive or emotional task could be highly informative in understanding the brain during depression. As detailed in Chapter 29 , the most sensitive manner in which to demonstrate such brain responses is by comparing two images, on a voxel-by-voxel basis, obtained in two different states in the same individual; effectively subtracting a control image from the test image (115 ,116). Increased or decreased neuronal activity in the test state will be reflected by increased or decreased CBF in the subtraction image; thus, the pattern of increased activity “maps” the processing areas used by the brain for the task. However, many tasks pertaining to uniquely human activities (e.g., language, declarative memory, emotion) clearly involve numerous brain systems

operating simultaneously and inseparably. Interpretation of a brain-mapping image resulting from such mental activity is problematic. Activated areas assumed to be involved in low-level processing of sensory information (e.g., visual or auditory cortex) may actually contain high-level processing or be critically modulated by other attentional and cognitive processes. Interpretation of brain-mapping studies in which complex tasks are employed require careful use of specific control tasks as opposed to simple “rest” state images. The best control tasks will differ from the task of interest in only the parameter of interest.

Unfortunately, designing tasks suitable for the PET or MRI scanning environment *and* relevant to the major depressive state have been difficult. Important work has been done, however. For example, induction of different emotions via different strategies has been accomplished and demonstrates neuroanatomic systems independent of the induction strategy (117 ,118). One difficulty with many emotional tasks is that the subject is highly aware of the investigators' efforts. An alternative to inducing a consciously perceived emotion is to present affect-laden stimuli at an unconscious level (119). This work developed a technique for presenting fearful faces with masking to prevent conscious processing of the visual stimuli. Fearful faces, in contrast to neutral or happy faces, have been reported by multiple investigators to invoke an increase in amygdala activity. By masking the briefly presented (<40 msec) fearful faces with neutral faces, Whalen and colleagues (119) developed a task that isolates the subconscious processing of affect laden stimuli without the confounding variable of individual cognitive processing. Despite the inability of the normal volunteers to report the emotions of the masked faces, amygdala activation was identified with fMRI during the fearful faces presentation. Such paradigm design may prove useful in investigation of affective illnesses such as depression and anxiety disorders.

The application of brain mapping to research in affective disease is still in its infancy because of only recent development of some appropriate task paradigms; however, the area has substantial promise. For example, functional MRI was used to map changes in brain activity in depressed patients and normal controls while viewing a film segment chosen to induce sadness (120). The depressed patients had significantly more activation in areas of the prefrontal cortex. Increased activation in the prefrontal cortex of the depressed cortex could be secondary to increased processing of the stimuli and associated emotions. For many tasks increased prefrontal activation accompanies an increase in task difficulty; however, several issues, including the potential for differences in cognitive response or attention level to the film being shown, must temper the interpretation of this work. Further fMRI work on the processing of emotional stimuli in depressed patients is ongoing and will certainly shed more light on this fascinating area of research.

Some consensus has begun to emerge pointing to abnormal function of specific limbic/paralimbic regions in the depressed patient. Drevets and colleagues (3) detected decreased activity in the subgenual region of the anterior cingulate in a group of depressed bipolar patients compared to controls using an image-wide search of PET measures of CBF. Importantly, the finding replicated with a second group of depressed bipolar patients. The finding was again seen when extended to a group of depressed bipolar using CMRG measures and, then again, when extended to a group of unipolar depressed patients with familial pattern. The authors point out that the subgenual anterior cingulate is heavily interconnected with autonomic structures (including the hypothalamus), ventral striatum, amygdala, and brainstem serotonergic systems; all systems implicated in mood and behavior regulation. Mayberg and associates (121) also detected decreased CMRG in the rostral anterior cingulate of unipolar depressed patients compared to control subjects. The actual center location of this region was approximately 15 mm more dorsal than the subgenual region found by Drevets and colleagues. However, in a highly creative approach, Mayberg and associates (122) examined the regional changes in neural activity with multiple PET scans after improvement of symptoms in depressed patients and compared those to the regional changes in neural activity induced by script-induced sadness in control subjects (see Fig. 74.2). Affective symptom remission was associated with an increased activity within dorsolateral prefrontal cortex, inferior parietal, dorsal anterior cingulate, and posterior cingulate and decreases in ventral limbic and paralimbic sites, including the subgenual anterior cingulate and posterior insula.

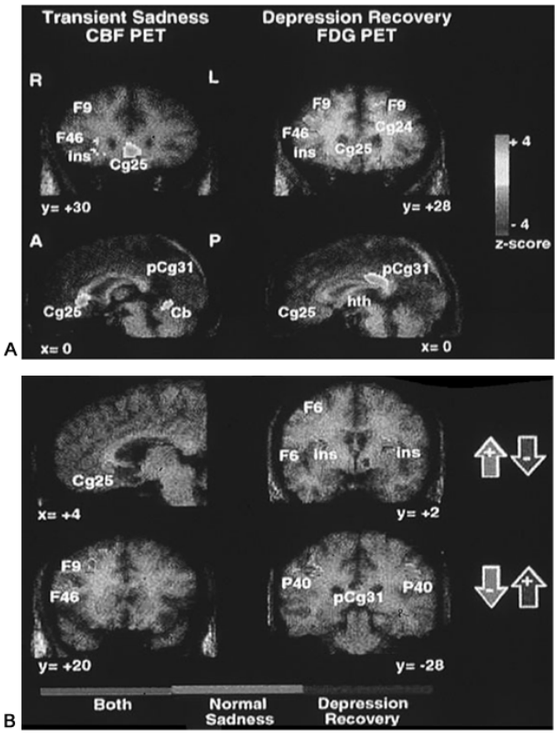

FIGURE 74.2. A: Left images show changes in regional cerebral blood flow (CBF) (with [^{15}O]water PET) associated with transient sadness in eight healthy volunteers. Right images show changes in regional glucose metabolism (with FDG PET) after six weeks of treatment in eight unipolar depressed patients. Coronal (*top row*) and sagittal (*bottom row*) views. Sadness is associated with increases in ventral paralimbic regions and decreases in dorsal frontal regions. With recovery from depression, the reverse is seen: ventral decreases and dorsal cortical increases. Slice locations are in millimeters relative to the anterior commissure. Numbers are Brodmann area designations. R, right; L, left; A, anterior; P, posterior; F, prefrontal; ins, anterior insula; Cg24, dorsal anterior cingulate; Cg25, subgenual cingulate; pCg, posterior cingulate; Cb, cerebellum; hth, hypothalamus. Color scale: red indicates increases and green indicates decreases in flow or metabolism. **B:** Logical images showing anatomical overlap of significant changes common to both experiments. *Top row:* Concordant areas with increased flow during sadness and decreased metabolism during remission. *Bottom row:* Areas with decreased flow during sadness and increased metabolism during remission. Numbers are Brodmann area designations. F, premotor; p, parietal. Red indicates changes unique to sadness; dark blue indicates changes unique to remission of depression; lighter blue indicates changes common to both. Arrows signify direction of change associated with each condition. See color version of figure.

The relevance of this particular constellation of brain regions to mood was made more certain by the findings of a similar pattern of regional brain activity, but in the opposite direction, in the normals during induced sadness. Sadness induced increases in a region of the subgenual cingulate and decreases in many of the same dorsal cortical regions. For depressed patients, the increases in dorsal cortical regions may reflect increased cognitive function in the remitted state. The decreases in the subgenual anterior cingulate as symptoms resolve appears more complicated. It is not yet possible to conclude from the data presented in Mayberg and associates (122) that the depressed state reflects an *increased* and abnormal functioning of the subgenual cingulate that returns to baseline during remission. The finding of Drevets and colleagues (3) clearly showing *decreased* metabolism in the subgenual cingulate during a depressive episode needs to be reconciled. One explanation is that the decreased activity is conceivably an actual increase in functional activity that only appears decreased on PET imaging owing to partial volume effects. This region was also reported by Drevets and colleagues to have sizable decreases in volume by MRI, a change known to decrease the measured activity. Nevertheless, the subgenual cortex and adjacent anterior

cingulate appear to play an important role in emotional regulation and expression.

Molecular Imaging of Neurotransmitter Systems in Affective Disorders

Numerous hypotheses have been proposed relating monoamine systems and depression. Serotonin, dopamine, and norepinephrine have all been implicated to various degrees in the behavioral changes and treatment of depression. Of these three, reports indicating a constellation of specific serotonergic dysfunctions in major depressive disorders have been the most convincing. For this reason, much effort in the imaging community has been focused on developing tools for imaging different aspects of the serotonergic system *in vivo*. Generally, these tools have involved the development and validation of radioligands specific for serotonin receptor subtypes (with more than 14 serotonin receptors isolated to date); however, alternative approaches to image serotonergic function have been reported as well. A report by Mann and co-workers (123) demonstrated reduced serotonin responsivity in depressed patients. In that work, fenfluramine, an indirect serotonin agonist, was used as a pharmacologic challenge and FDG PET imaging was used to image the brain responses. Depressed patients showed much less FDG uptake changes in response to fenfluramine than normal controls. Such an approach is limited, however, by the uncertainty in the relationship of the FDG changes and specific aspects of the serotonergic system.

Before reviewing the progress in this rapidly moving field, it is important to note that there is considerable difficulty in synthesizing the literature in both PET and SPECT imaging of receptor function owing to a lack of common data analysis procedures among various imaging groups. As the different data analysis techniques have specific inherent assumptions and limitations, it is useful to briefly review the pertinent issues. For the sake of brevity, we will limit this review to receptor imaging; however, the issues are often identical for imaging of other systems.

Generally, the PET or SPECT imaging device records the brain distribution of a radiotracer that binds selectively at the receptor (or transporter). In many applications a brain region is identified and a time–activity curve for that region is estimated from the images. Multiple factors directly influence the amount of tracer that accumulates in any given brain region: concentration of receptors (B_{max}), dissociation constant between the receptor and ligand (K_d), and nonspecific binding to brain tissue (corrected for in some models). In addition, the amount of uptake in the entire brain is dependent on the level of radiotracer in plasma and the degree to which the radiotracer nonspecifically binds to plasma proteins. To measure the B_{max} separately from K_d, the experiment must include some measurements with partial saturation of the receptors; this is rarely done for both logistical and ethical reasons. To address this issue, Mintun and associates (124) proposed a term binding potential (BP)

that combined both terms in the form BP = B_{max}/K_d. The binding potential reflects in a single value the ability of the regional brain receptors to bind to free radioligand during equilibrium and, importantly, is linearly related to the B_{max}. Thus, if K_d can be assumed to be constant in the experimental conditions or the different patient populations, the BP can be an adequate substitute for the regional receptor density.

The calculation of BP requires knowledge of the nonspecific binding in plasma and the brain tissue. If the nonspecific binding in plasma is measured or can be assumed, most investigators estimate the nonspecific brain binding of the tracer from a brain region that has negligible amounts of specific binding. A second requirement for calculation of BP is that the kinetics of receptor–ligand interaction be distinguishable from the transport kinetics into the brain. This is true for most tracers, with the receptor binding occurring more slowly than the transport. However, when both processes are of similar rates the BP is difficult to calculate and an alternative term, the distribution volume (DV) has been proposed (125). Conceptually, the DV of a given brain region equals the ratio of brain activity divided by plasma activity at equilibrium and includes the effects of both specific and nonspecific binding. The DV also can be calculated as a parametric image in which each pixel is assigned the appropriate calculated DV value (126). As the DV includes the effect of both specific and nonspecific binding, the DV is usually "corrected" by dividing by the DV of a region where only nonspecific binding occurs. The result, the DV_{ratio}, is a frequent form of reporting PET and SPECT receptor data. The use of the DV_{ratio} is also applied when the DV values for the areas of interest are not actually calculated from kinetic or equilibrium data, but are estimated from single images. The single image is usually standardized as being at a given time after injection of tracer but may be highly susceptible to individual differences in plasma clearance or transport into the brain.

Further complicating the use of the DV_{ratio} is that it is occasionally mistaken as being proportional to B_{max} and BP. Actually, the BP is proportional to the term DV_{ratio} - 1, which can be substantially different when the DV_{ratio} is low. Finally, the calculation of DV and DV_{ratio} is usually done without the measurement of plasma binding as it can be shown that the DV_{ratio} is mathematically independent of plasma binding. Indeed, the BP differs from the DV_{ratio} - 1 only by the incorporation of the plasma binding into the BP. Thus, if plasma binding is unknown the use of DV_{ratio} - 1 is quite appropriate and will remove all individual and group effects of plasma binding in the receptor data. What is usually not appreciated is that individual variations in *brain* nonspecific binding are *not* corrected in the DV_{ratio} - 1 calculation. This limitation of the DV_{ratio} - 1 term is rarely discussed and even more rarely quantitatively examined.

The lack of suitable radioligands for human PET imaging has significantly slowed research in affective disorders. The serotonin receptor subtypes with the highest brain densities, 5-HT_{1A} and 5-HT_{2A} receptors, do have PET radioligands with sufficient selectivity and affinity suitable for imaging (Fig. 74.3). In the 5-HT_{2A} system some initial work in depression was done using tracers with limited selectivity. Labeled spiperone (127) demonstrated alterations in binding in depressed post-stroke patients but interpretation must be limited owing to the very high affinity of this tracer for dopamine-2 receptors. 2-^{123}I-ketanserin demonstrated increased binding in the right parietal cortex of depressed patients (128), but again, the work is limited by the nonselectivity of ketanserin. Since these initial reports, methodologic development to image 5-HT_{2A} receptors has been successful using highly selective agents including [^{18}F]altanserin (129), [^{18}F]setoperone (130) and labeled MDL100,907 (131 ,132).

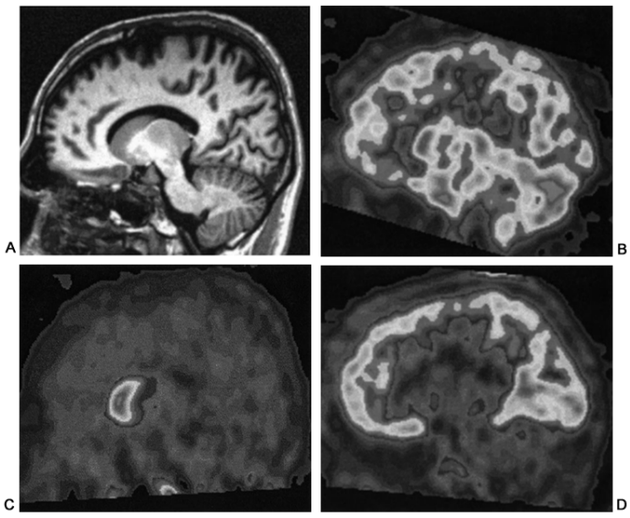

FIGURE 74.3. Parasagittal views through the head of the caudate of an anatomic magnetic resonance imaging scan and three different types of functional positron emission tomography scans. All images were collected in normal control subjects and have been converted to a standard atlas coordinate system using linear affine transformation. The upper right image is from a 60-second scan after injection with [^{15}O]water and represents the distribution of cerebral blood flow (CBF). The lower left image is from a 30-minute scan obtained 30 minutes after injection of [^{11}C]raclopride. The scan shows widespread low nonspecific binding (e.g., cerebellum) and focal increased specific binding to D_2 dopamine receptors in the caudate. The lower right image is from a 30-minute scan obtained 60 minutes after injection of [^{18}F]altanserin. Again, the cerebellum shows low nonspecific uptake, whereas the cortical gray matter shows the specific binding to the 5-HT_{2A} serotonin receptors. These images demonstrate the ability to visualize distinct aspects of brain function using different radiotracers. Relatively high CBF is seen throughout the cerebellum and cortical and subcortical gray matter. In contrast, D_2 receptors are seen to be highly concentrated in the caudate, whereas 5- HT_{2A} receptors are concentrated in the cortical gray matter with only small amount of receptor binding in basal ganglia. With the appropriate quantitative processing, these differences in radiotracer uptake can be expressed as relative or absolute receptor density. See color version of figure.

The application of these radioligand techniques in mood disorders has begun with some interesting results. Biver and associates (29) found apparent decreased [^{18}F]altanserin binding in the right insular and adjacent orbital cortices in eight medication-free depressed patients. However, as the data processing approach normalized for global [^{18}F]altanserin uptake the method cannot distinguish between a true decrease and an increase that is proportionally less than the [^{18}F]altanserin binding in the remaining brain. Nonetheless, the detection of a regional change in [^{18}F]altanserin binding suggests some type of regional difference in receptor density. Several other studies, however, have not shown altered radioligand binding to 5-HT_{2A} receptors during depression. Meyer and co-workers (133) used [^{18}F]setoperone to compare 14 medication-free depressed patients with 19 control subjects and found no difference in binding in a large prefrontal cortex region of interest. The data was reported as DV_{ratio} and quantitation using plasma activity was not done. Interestingly, the prefrontal cortex value was 1.6 in the depressed group and 1.8 in the control group. After correction of the DV_{ratio} to yield a term proportional to receptor density (the BP is proportional to DV_{ratio} - 1) this trend represents a rather large 25% decrease in the depressed group.

Yatham and colleagues (134) used [^{18}F]setoperone to measure 5-HT_{2A} binding in 20 depressed and 20 controls. All images were first normalized by cerebellar activity to account for differences in nonspecific uptake and then processed using statistical parametric mapping (SPM). Unfortunately, the actual DV image was not calculated, nor the DV_{ratio}, as only raw PET activity from a single time frame was used. SPM performed a pixel-by-pixel ANCOVA to detect pixels with significant group differences and showed generalized decreased binding in the frontal and parietal cortices of the depressed patient group. Yatham and colleagues reported that in some voxels the decrease in uptake was 20% to 27%. As the study was done without an equilibrium state or kinetic analysis, it is unknown whether transport

issues could be responsible for some of these results. In another study, Attar-Levy and associates (135) used [^{18}F]setoperone to measure 5-HT_{2A} binding in seven depressed patients and seven age-matched controls. Regions of interest over multiple cortical areas were used to measure radioligand uptake at a given time after injection and the data were normalized by first subtracting cerebellar activity and then dividing by injected dose. This result is a nonstandard term that is not corrected for variations in plasma nonspecific binding (but may be corrected for variations in brain nonspecific binding). There was little difference between depressed and control values with only the frontal region demonstrating a significant decrease in bindings (approximately 6%). However, most of the patients were concurrently being treated with benzodiazepines (six of seven), which may have further confounded the results. Finally, Meltzer and colleagues (136) used [^{18}F]altanserin to image eleven late-life depressed patients and age-matched controls. Logan graphical analysis was used to analyze regional activity data and quantitate DV and the DV_{ratio} - 1. Meltzer and colleagues reported no difference between the depressed and control groups.

The preceding data have the common thread that regional measures of 5-HT_{2A} binding appear to yield slight, nonsignificant decreases in depressed populations compared to controls. The image-wide processing methods using SPM, which had different methods of normalizing the radioligand uptake data, appeared to yield more dramatic decreases in the depressed populations. As these parametric methods are not well validated with these radiotracers, the significance of the findings will be uncertain until further work, likely using conventional analyses, is done.

The 5-HT_{1A} receptor distribution has been imaged in humans using the high-affinity antagonist [^{11}C]WAY 100,635 (137 ,138). The images are unusual because of the very high ratio of specific to nonspecific binding in the brain. Compared to images from labeled setoperone or altanserin, in which approximately one-half of all of the brain activity is not bound to the receptor of interest, the [^{11}C]WAY 100,635 PET images have less than 10% of the activity in nonspecific binding and 90% specific activity. The ratio of receptor-rich brain regions to the cerebellum, assumed to be devoid of 5-HT_{1A} receptors, is typically greater than 15, depending on the timing of the scan (compared to a ratio of 2 to 3 for altanserin or setoperone). This very high “target-to-background” allows the imaging and even quantitation of 5-HT_{1A} receptor content in very small structures, such as the midbrain raphe. Early reports show that 5-HT_{1A} receptor binding of [^{11}C]WAY 100,635 in a variety of cortical regions and in the raphe is decreased in depressed patients compared to controls (139 ,140). The observed decreases are substantial, ranging from 20% to 40% in some regions. As 5-HT_{1A} receptors are involved in widespread modulation of function in limbic and paralimbic regions, these findings are of considerable importance. Furthermore, the 5-HT_{1A} receptors are part of the autoregulation of serotonergic innervation in the raphe, increasing the significance of these findings.

Work on imaging serotonin reuptake sites, the target of the most commonly used antidepressants, is ongoing. The radioligand that has undergone the most study is [^{11}C]McNeil 5652. However, nonspecific binding with this tracer is high, and separating the receptor binding from nonspecific binding has been challenging (141 ,142). One alternative tracer is [^{123}I]B-CIT SPECT imaging. This tracer binds to other reuptake sites but has simpler kinetics and can be used in brain regions that have predominantly serotonin reuptake binding. This property was exploited in a study by Malison and co-workers of unipolar, unmedicated depressed patients in which brainstem serotonin reuptake site binding was significantly reduced by nearly 20% compared to controls (143). Another area of interest is in the *in vivo* measure of serotonin synthesis. This has been achieved using α-^{11}C-methyl-tryptophan (144). The tracer is converted to α-^{11}C-methyl-serotonin within neurons and then accumulates, unable to be degraded by monoamine oxidases. The rate of accumulation is argued to be proportional to endogenous serotonin synthesis (144). However, validation is problematic because there are few tools for verifying rates of serotonin synthesis. Also, it has been noted that the synthetic rates appear to be highly dependent on plasma tryptophan levels.

Dopaminergic innervation in depression may be altered. D'haenen and Bossuyt (145) imaged 23 depressed patients and 11 controls using SPECT and ^{123}I-iodobenzamide (IBZM), a high-affinity ligand for the D_2 receptor. The activity in the basal ganglia after normalizing with cerebellar activity was 10% greater in the depressed subjects ($p < 0.025$). The authors suggest that this increase reflects decreased dopaminergic neurotransmission. Decreased synaptic dopamine could then result in decreased occupancy of the D_2 receptors and D_2 up-regulation, both factors could lead to increased IBZM binding. In two other reports the IBZM uptake in the striatum was shown to decrease during treatment with antidepressants (146 ,147), although decreased D_2 receptor binding at baseline in depression was not seen. However, the striatal dopamine system may not be the most critical in affective disorders. With the advent of radioligands able to image extrastriatal D_2 receptors (e.g., [^{18}F]fallypride) (148), investigation of dopaminergic function in limbic cortical regions will be possible.

Conclusion

The last decade has produced numerous advances in our ability to image brain function. Although the application to affective disorders has been limited to date, the data are tantalizing. Findings have identified abnormalities in the function of limbic cortical structures and the location of these structures overlap with those areas involved with generation of emotion. With increasing sophistication of emotional paradigms, a more precise picture of the role these structures play in mood regulation may emerge. Serotonergic alterations are being further identified with existing techniques and new radioligands will be introduced over the next decade that will greatly expand our imaging capabilities. Novel methods will be explored, leading to agents able to image aspects of gene expression, perhaps even with the spatial and temporal resolution of MRI (149).

Current and Emerging Therapeutics for Depression

A. John Rush

Neal D. Ryan

A. John Rush: Department of Psychiatry, University of Texas Southwestern Medical Center, Dallas, Texas.

Neal D. Ryan: Western Psychiatric Institute & Clinic, University of Pittsburgh Medical Center, Pittsburgh, Pennsylvania.

This chapter discusses critical conceptual and practical issues confronting clinicians who must distill the massive neuroscientific, psychopathologic, and clinical research information about the basis for clinical depression and its treatment and who must apply that knowledge to individual patients. This chapter does not provide an encyclopedic review of antidepressant treatments. (See refs. 1 and 2 for recent reviews.) Rather, we focus on major recent conceptual shifts in our understanding of depression and its treatment, and on practical dilemmas encountered in daily practice. The latter often calls for types of information not usually provided by standard clinical research protocols designed to obtain regulatory approval of new antidepressant agents.

After highlighting recent revisions in our knowledge about depressive disorders, we discuss the implications of that knowledge for the treatment of these conditions. We highlight the gaps in our knowledge about how to implement treatments so as to obtain optional patient outcomes. We then examine several commonly held beliefs that, rightly or wrongly, guide current treatment selection and patient care. A brief introduction to agents in development (e.g., corticotropin-releasing factor [CRF] or substance P antagonists), to alternative therapies (e.g., S-adenosyl-methionine [SAMe], St. John's wort [*hypericum perforatum*]), and to the treatment of depression in children and adolescents is provided. We conclude with suggestions for further research.

RECONCEPTUALIZING DEPRESSION AND ITS TREATMENT

Part of "75 - Current and Emerging Therapeutics for Depression "

Only two decades ago, clinical depression was seen as a transient, typically self-limited reaction to “untoward” events. Today, as detailed by Keller and Kovacs (3), clinical depressions are now recognized as far more chronic, more often recurrent (typically with a waxing and waning course), and more disabling. Historically, symptom severity has been used to distinguish different forms of depression (e.g., major depressive disorder versus dysthymia). More recent evidence, however, indicates substantial functional impairment in both “major”(4 ,5 and 6) and “minor” forms of depression (7 ,8). A more chronic course and greater symptom severity both contribute to greater levels of disability. Furthermore, prevalence rates and the degree of disability found in nonmajor forms of depression provide a basis for regarding even modest levels of nontransient depressive symptoms as a major target for treatment. Consequently, efficacy studies have been undertaken with more chronic forms of depression (9 ,10 and 11) and with “nonmajor” forms of depression (e.g., dysthymic disorder) (12 ,13 ,14 ,15 ,16 and 17).

Chronicity is often reflected in persistent residual symptoms (i.e., depressive symptoms that do not meet formal diagnostic criteria for major depressive disorder between major depressive episodes). Such residual symptoms between episodes predict a worse prognosis compared to full symptom remission between episodes (18 ,19 ,20 ,21 ,22 and 23). Second, residual symptoms are associated with increased levels of morbidity (5), as well as mortality—especially when these symptoms occur in the context of a general medical condition, such as with myocardial infarction (24 ,25), stroke (26), dementia (27), diabetes (28 ,29), or asthma (30). (See ref. 31 for review.)

Third, there is a concern (yet to fully evaluated) that more chronic forms of depression may be more likely associated with the development of treatment resistance over time. That is, a chronic course may entail the development of an underlying neurobiology that renders treatments less effective acutely or over the longer term. Such an inference is suggested by apparently longer times to develop responses and remissions in studies of chronic (10 ,11) as opposed to nonchronic forms of depression (32 ,33). This recent emphasis on the presence of modest levels of depressive symptoms,

on residual symptoms, and on a chronic course of illness has led to rethinking treatment studies. Full symptom remission and full functional restoration (not simply response) are the targets of treatment.

This conceptual shift has profound implications for practice and development and use of newer agents. It also provides a rationale for combining treatments when a monotherapy does not lead to remission. For example, subsyndromal forms of depression (i.e., those not meeting criteria for dysthymic or major depressive disorder) have recently become a focus of efficacy trials given the disabling nature of these conditions. Whether different levels of functional impairment in the context of equivalent levels of residual symptoms herald a worse prognosis has yet to be demonstrated. Furthermore, recent studies (21 ,22 and 23) suggest psychotherapy that effectively removes residual symptoms also improves prognosis, which in turn may reduce the need for long-term maintenance medication.

Treatment is divided into acute, continuation, and maintenance phases (34 ,35 ,36 and 37). Acute treatment aims at symptom remission and full functional restoration. The need to most aggressively pursue full symptom remission (also called complete response), rather than to accept a clinically significant reduction in symptoms (a response) is now accepted because of the worse prognosis and functional impairment associated with residual symptoms noted in the preceding. Earlier intervention can also be strongly recommended because major depressive episodes that have a greater duration are more likely to end with residual symptoms.

Continuation phase treatment aims at preventing a return of the most recent (index) episode—a relapse. Maintenance aims at preventing a new depressive episode—a recurrence. When continuation ends and maintenance begins for an individual is unclear, although classically recovery from the episode is estimated by when the episode would have spontaneously ended based on the duration of prior episodes, if such information is available. The need for more prolonged (i.e., continuation/maintenance phase) treatment, especially for more chronic (9 ,38 ,39 and 40) or more highly recurrent (41 ,42) forms of depression, has been recognized over the last decade (34 ,35 ,36 and 37).

Although the need for maintenance treatment for some patients with highly recurrent forms of depression is clear, exactly how long to provide antidepressant treatment remains a focus of research. Consensus strongly recommends prolonged (multiyear) maintenance treatment for those with a high likelihood of recurrence over the subsequent (1- to 3-year) period of time (34 ,35 ,36 and 37). These recommendations rest on several major, long-term, randomized, placebo-controlled, double-masked maintenance trials in adults (41 ,42) or in the elderly (43) with highly recurrent depressions, and in adults with chronic forms of major depressive disorder (9). Whether patients with two episodes of major depression *plus* a risk factor for recurrence should also be strongly encouraged toward maintenance therapy— although recommended based on clinical consensus—has not been empirically validated. In many such cases, patient preference with careful clinical monitoring, once therapy is discontinued, is recommended (34 ,35 ,36 and 37).

TRANSLATING KNOWLEDGE TO PRACTICE

Part of "75 - Current and Emerging Therapeutics for Depression "

Present practice currently relies on a trial and error approach that is only infrequently informed by well-established empirical evidence. Only a few clinical clues that recommend one treatment over another have been established scientifically. For example, the greater acute phase efficacy of monoamine oxidase inhibitors (MAOIs) as compared to tricyclic antidepressants (TCAs) in depressions with atypical symptom features is well established in double-blind, placebo-controlled trials (44 ,45). Furthermore, the greater efficacy of TCAs combined with an antipsychotic agent as compared to TCAs alone is well known for psychotic depressions (46 ,47 ,48 and 49).

On the other hand, many practical dilemmas are confronted in routine practice, yet knowledge is sparse to address these issues. This lack of practical knowledge grounded in empirical evidence, can be attributed to several factors: (a) insufficient investment in clinical research that goes beyond classic efficacy trials obtained for regulatory approval worldwide (50); (b) incomplete understanding of the neurobiological basis for clinical depressions such that specific treatment plans can be devised; and (c) substantial differences in the populations, procedures, and aims of efficacy studies conducted for regulatory purposes and representative practices.

Patients with minimally treatment-resistant, or nonchronic forms of depressions enter trials. These patients are: (a) rarely severely ill; (b) rarely inpatients; (c) never psychotic; (d) rarely encumbered by common concurrent Axis III (general medical) or other Axis I (psychiatric) disorders; (e) not affected by depressions that have been unresponsive to more than one prior medication in the current episode; and (f) without significant suicidal risk. In fact, many patients who enter efficacy randomized controlled trials (RCTs) for regulatory purposes are often symptomatic volunteers. Perhaps as a consequence, placebo response rates are often substantial (e.g., 25% to 35%) with drug effects providing a 50% to 60% response rate (34).

Notable differences exist between clinical procedures that are typically used to conduct RCTs designed regulatory approval and the procedures characteristic of current practice. Efficacy studies often: (a) use structured interviews, or highly trained staff using specific lists of diagnostic criteria for diagnostic purposes; (b) use itemized clinician-completed symptom ratings to assess treatment effects (therefore, also to adjust dosages); (c) use more frequent treatment visits; (d) limit acute phase trial durations (e.g., 6 to 8 weeks of acute phase treatment in efficacy RCTs); and (e) use

response (typically a ≥50% reduction in overall depressive symptom severity with or without residual symptoms), rather than remission (virtual absence of depressive symptoms with normalization of function) to define a clinical "success," contrary to clinical practice recommendations (34 ,35 ,36 and 37).

Routine clinical diagnoses often sharply disagree with those established by structured interviews (51) (Kashner et al., personal communication). In addition, global judgments of the severity of illness, even if codified by the Clinical Global Impression-Improvement Scale (CGI-I) (52), may relate only modestly to symptom severity ascertained by itemized clinician ratings, such as the Montgomery-Åsberg Depression Rating Scale (MADRS) (53) or the Hamilton Rating Scale for Depression (HRS-D) (54 ,55) or the Inventory of Depressive Symptomatology (IDS) (56 ,57). These differences in clinical procedures used in efficacy RCTs and those used in daily practice could well lead to radically different clinical outcomes.

Most important, however, is the fact that efficacy trials for regulatory approval are not designed to answer many key clinical questions addressed in routine practice (see the following). For example, there is a reasonably strong basis to believe that medications differ in their spectrum of actions (1). That is, some patients/depressions respond to one agent, whereas others respond to a different agent (58 ,59), especially if the medications differ regarding presumed mechanisms of action.

We do not know under what conditions one agent is preferred over another, however. Where one agent might "fit" into a multistep treatment plan is often left to tenuous inferences based on presumed mechanisms of action, to "expert" clinical opinion (34 ,35 ,36 and 37), or to marketing efforts. How to treat depressions that respond minimally or partially to one agent is now well known.

Perhaps pharmaceutical companies are reluctant to search for specific indicators of when an agent is preferred or to study agents used as second or third steps in treatment-resistant depression for fear of being "niched" by competitors. Without specific indications of when to use an agent, a "broad" spectrum of action can be claimed. Even comparative, randomized, double-masked trials to determine whether one agent is preferred over another for patients without sufficient clinical benefit to an initial agent are largely avoided by the pharmaceutical industry, perhaps in fear of finding that their agent will not fare as well as a competing agent in such treatment-resistant cases. Thus, economic forces within the industry provide a strong impetus to *not* inquire about highly salient—indeed clinically vital—information (e.g., when to select one agent over another; when to use a particular agent within a multistep therapeutic treatment program or sequence).

In spite of these knowledge gaps, the industry has developed a large number of newer antidepressants that are simpler to take, better tolerated, and safer in overdose. Antidepressant agents with new and different presumed mechanisms of action are also currently under development (see the following). Furthermore, recent regulatory and market forces have encouraged studies in depressed children, adolescents, and geriatric patients.

The National Institute of Mental Health (NIMH) has recently begun to address some of the knowledge gaps noted in the preceding by emphasizing effectiveness trials of antidepressant treatments in children/adolescents, adults, and geriatric patients. The emphasis (50) was based on the realization that efficacy trials for regulatory approval are only the first step in defining a treatment. That is, they establish the safety and efficacy of an agent in carefully conducted, highly internally valid designs. Generalizability of tolerability and efficacy findings requires different study designs. When to use one as opposed to another agent (alone or in combination) requires still different study designs.

Let us now turn to some of the vexing questions encountered in daily practice, and the knowledge available to address these issues.

CLINICAL ISSUES IN TREATING DEPRESSION

Part of "75 - Current and Emerging Therapeutics for Depression "

Clinicians routinely confront a host of practical questions that are not addressed in efficacy RCTs designed for regulatory approval. These questions include the following:

1. What is the best agent for initial treatment (i.e., predictors of response)?
2. What is the "next best" treatment following either an unsatisfactory clinical response or intolerance to the first agent?
3. What is a sufficient trial duration beyond which response is not likely (minimal duration)?
4. What is a sufficient trial duration for those benefiting from the treatment beyond which further treatment (unchanged) is unlikely to produce any more symptomatic or functional improvement (maximal duration)?
5. When is it best to augment the first agent with a second treatment? When is it best to switch from the first agent to a new, different agent?
6. What are the best ways to enhance adherence?
7. When and in what form should psychotherapy be used?
8. Do antidepressants differ in their ability to produce response or remission, and if so, for which depression is each better?
9. Do different medications differ in the time to onset of clinical benefit or time to remission?
10. What treatments are recommended if there is a return of symptoms in previously responsive patients?

Selecting the Initial Treatment

All antidepressant medications have established efficacy in major depressive disorder. Some even have placebo-controlled

evidence supporting efficacy in dysthymic disorder (sertraline) (15) or other “nonmajor” disorders, such as premenstrual dysphoric disorder, including fluoxetine (60), paroxetine (61), and sertraline (62 ,63). However, when to select one over another agent is not well defined. Clinicians use “rules of thumb” to make these judgments, but such reasonable guesses are rarely supported by prospective RCT evidence.

For example, more recently, efficacy for some antidepressants has been established for other psychiatric conditions commonly found in the presence of major depressive disorder, including: (a) venlafaxine for generalized anxiety disorder (64 ,65); (b) paroxetine (66) and sertraline (67) for posttraumatic stress disorder; (c) fluoxetine (68) and sertraline (69) for obsessive compulsive disorder; and (d) fluoxetine (70), paroxetine (71 ,72), and sertraline (73) for panic disorder. It is logical to argue that if a clinical depression is accompanied by a concurrent additional psychiatric disorder for which an antidepressant has established efficacy, then that agent is preferred (because it should be effective for both disorders) (34 ,35 ,36 and 37). However, this logical inference has not been evaluated prospectively in double-blind comparative trials.

Another clue used to select among antidepressants is cross-sectional symptom features. As noted, depressions with atypical symptom features do less well on TCAs than MAOIs (44 ,45) Depressions with psychotic features do better with a combination of an antipsychotic agent and a TCA than with a TCA alone (46 ,47 ,48 and 49).

Although atypical or psychotic symptom features are useful in selecting among the TCAs, other cross-sectional symptom features have generally not been so useful. For example, a common belief is that selective serotonin reuptake inhibitors (SSRIs) should be more effective than selective noradrenergic reuptake inhibitors (SNRIs) for major depression with marked anxiety. However, this contention has not withstood empirical study. Bupropion was as effective as sertraline in outpatients with major depressive disorder, whether pretreatment anxiety was high or low (74). Similarly, higher levels of pretreatment insomnia are *not* associated with lower efficacy for fluoxetine or with preferential response to imipramine as compared to fluoxetine (75). Reboxetine, an SNRI, is effective in both panic disorder (76) and depression (77 ,78).

Although family history of response to a MAOI or TCA should point the clinician to choose between these two classes (79), studies of family history and patient responses to newer agents are not available.

In sum, only psychotic or atypical symptom features have established value in selecting among treatments. Concurrent comorbid conditions logically recommend an initial agent, but this recommendation has not been evaluated prospectively. It would appear that other parameters such as safety in overdose, longer-term tolerability, the potential for drug–drug interactions, or likelihood of remission play a major role in selecting the first agent.

How to Select the “Next Best” Treatment following an Unsatisfactory Response (or Intolerance) to the First Agent

A major clinical problem is selecting the “next” agent if the first is ineffective, only partially effective, or not well tolerated. When TCAs fail, the MAOIs have roughly a 50% response rate based on both open and randomized trials (58 ,59).

When newer agents are used as first treatments, however, only open case series are available to define the next step (following intolerance or nonresponse). Based on open trials (80 ,81 ,82 and 83), a second SSRI is associated with a 40% to 60% response rate following failure with the first SSRI, although not all studies agree (84 ,85). Open trials (following initial SSRI failure) also support switching “out of class” to venlafaxine (86 ,87), bupropion (88 ,89), nefazodone (90 ,91), mirtazapine (92 ,93), or reboxetine (94). However, no randomized, comparative studies of a second SSRI (as compared to a non–SSRI) following nonresponse or intolerance to the first SSRI are available. Thus, both within and out of class switches following initial SSRI failure can be recommended, but the strength of the evidence is weak (95).

A recent double-masked trial, using a crossover design, in outpatients with nonpsychotic, chronic forms of major depressive disorder (96) revealed that about 50% of those who did not respond to (but did tolerate) 12 weeks of sertraline in the acute phase trial did respond to imipramine. Interestingly, similar response rates were found with sertraline for those who tolerated but who did not respond to imipramine. This large, double-blind, definitive study, provides substantial evidence for an “out-of-class” switch as a second step following unsatisfactory response to an SSRI or TCA. It also reveals that an SSRI (in this case sertraline) is effective even if a TCA (imipramine) is not—a finding that does not agree with the suggestion of greater efficacy of TCAs versus SSRIs. However, whether a within SSRI class switch (e.g., sertraline to paroxetine) would have been as effective as the out-of-class switch was not studied.

When to Augment or Switch

Inadequate benefit to an initial treatment comes in degrees that range from literally no benefit whatsoever, to a clinically significant response but without full remission (i.e., with residual symptoms). In such cases, clinicians and patients must choose between switching (i.e., discontinuing the first and starting a second treatment) and augmenting (adding a second treatment to the first). This decision, in part, rests on patient and clinician preference, desirability of simple (i.e., monotherapy) versus a more complex (i.e., two or more treatments) regimen, prior history of response/nonresponse

to other agents, and the desirability of not losing a partial, albeit modest, benefit with the first agent. With a history of no or only one prior unsuccessful treatment attempt, monotherapy (i.e., a switch) may have clinical appeal (simplicity). For more resistant depressions, even a modest benefit to the first treatment may recommend augmentation.

The best-studied augmentation methods are with lithium or thyroid used in combination with a TCA or MAOI (58 ,97). More recently, open trials or small case series suggest a benefit of adding bupropion to an SSRI (98), venlafaxine (99), mirtazapine, or nefazodone. (See ref. 97 for an extensive review of both the augmenting and switching literature.) Notable, however, is the lack of randomized comparator trials pitting one augmentation treatment against another, each used with the newer antidepressant agents. Furthermore, whether augmentation is as effective for patients who have a minimal response, as opposed to at least a partial response, or a response with residual symptoms with newer agents is not known.

What Is an Adequate Trial Duration to Reliably Declare "Failure?"

Clinicians confront two critical decision points during a treatment trial with an antidepressant. First, one wishes to stop the trial at the earliest point in time after which the patient has minimal or no chance of responding (i.e., at this point, a change in the treatment strategy—either a switch or augment is called for). Second, if some benefit has occurred, but remission has not yet been attained, then one needs to know how much more time should pass (and whether dose increases are needed) before deciding to augment or switch the treatment. That is, after what point in time are those who benefit in part unlikely to benefit any further? These two critical decision points occur at different times.

Let us consider the first critical decision point. Beyond what point in time is a clinically meaningful response *unlikely* to occur? A few post hoc analyses reveal that (a) there are both faster and slower responders in samples treated with TCAs (32), nefazodone (33), bupropion (100), MAOIs (101), fluoxetine (102 and 103), and the combination of interpersonal psychotherapy (IPT) (104) with imipramine (105) or nortriptyline (106), and likely all other antidepressants. These reports suggest that about one-fourth to one-third of depressions that do not respond by 4 weeks will do so by week 8. For example, Nierenberg and associates (103) found only 18.9% of patients treated with fluoxetine who did *not* have a less than 20% decrease in pretreatment HAM-D total score by week 4, ultimately responded (≥50% decrease in baseline HAM-D) by week 8. It seems that in some *post hoc* analyses, those with later responses are more likely to be more severely depressed at baseline, to have more Axis II disorders and possibly other psychiatric comorbidities, or to have a more chronic prior course of illness (e.g., longer episodes or residual symptoms between episodes) (32 ,106). However, some reports indicate that various agents, such as mirtazapine (107 ,108 and 109) or venlafaxine (64 ,110) may have an earlier onset of action compared to more selective agents. Whether they differ from other agents with a smaller proportion of patients evidencing later response is not yet clear.

What Is a Sufficient Trial Duration Beyond Which Further Improvement Is Unlikely?

When to decide that longer (unchanged) treatment will produce no more benefit in patients already having some symptom reduction is less clear. Remission follows response after 0 to 6 weeks (33). Thus, although response is unlikely to begin after 8 weeks of medication treatment, remission may not occur until 12 weeks (or even longer) with treatment involving a single agent. Indeed, in a recent study of outpatients with chronic major depressive disorder, 40% of acute phase responders who had residual symptoms (i.e., responders but nonremitters) at exit from a 12-week acute trial of imipramine or sertraline attained a full remission over four ensuing months of continuation phase treatment. Thus, perhaps especially for more chronically depressed, a longer trial duration—even up to more than 3 months following attainment of response—may be needed to determine if full remission will occur, or if a change in treatment is indicated.

How to Enhance Adherence?

Adherence, both in acute and later phases of treatment, is a major clinical problem (111). Clearly, better-tolerated, lower side effect, easier to use agents should increase adherence. Indeed, the newer agents (SSRIs, venlafaxine, nefazodone, bupropion, and mirtazapine) are better tolerated in acute phase trials (112). Gradual dose adjustments, as well as the sustained or extended release formulations (compared to immediate release versions) of newer agents (e.g., venlafaxine XR) (113 ,114 and 115)—enhance adherence by both creating better side-effect profiles and by reducing the number of times the medication must be taken.

A major assist in increasing adherence is patient education. Now evaluated in several randomized controlled trials, patient education clearly improves adherence, and consequently clinical outcomes as compared to minimal education (116). However, what types of education particularly benefit which patients remains to be determined.

When and How to Use Psychotherapy?

Research on psychotherapy for depressive disorders has, until recently, been focused nearly entirely on acute phase treatment studies that compare a symptom-reducing, time-limited

psychotherapy (e.g., cognitive, behavioral, interpersonal, or brief dynamic therapy) against a specific, depression-targeted medication monotherapy, the combination, or a control group. Evidence for the efficacy of acute phase psychotherapies against wait list controls is robust (2 ,35 ,117). In most trials, medication alone and psychotherapy alone have comparable efficacy (35). In a recent 10-week acute trial, Jarrett and colleagues (118) found CT to equal phenelzine and both to exceed pill placebo in outpatients with MDD and atypical symptom features.

These trials are limited, however, to outpatients with moderately severe depressive symptoms. Some argue that more severely depressed outpatients may fair better with medication as opposed to psychotherapy alone (119), whereas other data (120) suggest that depressive symptom severity is not particularly predictive of comparative treatment efficacy.

Turning to the combination of both medication and psychotherapy, six trials have not found the combination to show an advantage over either treatment alone (35). However, a very important recent 12-week acute phase trial of outpatients with chronic forms of major depressive disorder (11) was the first to find far greater acute phase efficacy for the combination of medication (nefazodone) and psychotherapy (Cognitive Behavioral Analysis System of Psychotherapy) (CBASP) (121) in chronic depression than for either nefazodone or CBASP alone. The acute response rates in the intent-to-treat sample (*n* = 662) were 48% (nefazodone), 48% (CBASP), and 73% (combination), and for patients who completed the study (*n* = 519), the response rates were 55%, 52%, and 85%, respectively. Importantly, remission rates in both the ITT and completer samples were higher with the COMB (48% and 42%, respectively) than with either nefazodone alone (29% and 22%, respectively) or CBASP alone (33% and 24%, respectively).

These findings indicate that psychotherapy increases the likelihood of responding *and* increases the magnitude of symptom reduction found with medication (nefazodone) alone and vice versa. The combination did not have a lower premature discontinuation rate than either monotherapy. In the context of prior literature on combination treatment, it appears that the combination is clearly indicated (either at the outset or in sequence) for more chronic depressions. Interestingly, approximately 50% of patients who did not respond to nefazodone acutely ultimately responded to CBASP, and vice versa in a crossover study following the acute trial (Keller, personal communication). Thus, psychotherapy may have substantial clinical utility even in those who do not respond acutely to medication.

Another role for psychotherapy may be the elimination of residual depressive symptoms for those depressions that respond, but do not remit with, medication alone. Two important recent controlled trials (21 ,22) examined the effect of adding cognitive therapy to antidepressant medication in patients with response, but with residual depressive symptoms. In both studies, cognitive therapy was compared (randomized) to treatment as usual without a formal psychotherapy. In essence, patients in the intervention group ultimately received both treatments, but in sequence with medication first. In one study (22), medications were gradually discontinued, whereas in the other (21), medications were continued while psychotherapy was provided. Both studies found a better prognosis for those who received psychotherapy. Thus, formal psychotherapy may increase the remission rates obtained with medication alone. It may also, perhaps as a consequence, improve longer-term prognosis (i.e., reduce relapse/recurrence rates) when combined with medication or during medication discontinuation.

How long to provide psychotherapy alone for those who respond to it in the acute phase has recently been evaluated (122). Continuation phase CT was associated with a lower relapse rate than no continuation phase CT for outpatients with MDD who at least responded to acute phase CT alone. This nonrandomized comparison has led to an ongoing prospective, randomized trial.

Finally, the role of IPT as a maintenance treatment alone or in combination with nortriptyline was evaluated in the elderly with major depressive disorder (43). Medication exceeded the effects of pill placebo and medication clinic visits in preventing recurrences—similar to a maintenance phase trial in adults (41). IPT had a better effect than pill placebo. The combination of IPT and nortriptyline was no better than nortriptyline alone. Psychotherapy may help to sustain medication-free periods during maintenance phase treatment (e.g., in women wishing to become pregnant).

Do Antidepressants Differ in Acute Phase Efficacy?

Recent acute phase trials have begun to examine whether medications, especially those with direct effects on multiple neurotransmitter systems, might have greater efficacy than more selective reuptake blocking agents. Note, however, that two agents may appear to have different degrees of efficacy if they are compared early in the course of acute phase treatment, whereas later (e.g., after 6 to 12 weeks of treatment), they could display equivalent efficacy (i.e., if one agent “acts more rapidly” than another). For example, the Danish University Antidepressant Group (DUAG) studies, one each lasting 5 and 6 weeks with severely depressed inpatients, revealed better outcomes for those severely depressed inpatients with nonpsychotic major depressive disorder with clomipramine than with paroxetine (123) or citalopram (124). These brief inpatient studies may have been too short in duration, however, to gauge the full benefits obtainable with longer treatments with either agent, however.

More recently, additional studies in both inpatients and outpatients have compared venlafaxine with fluoxetine (125 ,126 ,127 ,128 and 129), venlafaxine with paroxetine (130 ,131), venlafaxine

with sertraline (132), and mirtazapine with fluoxetine (109) in studies lasting 4 to 24 weeks. Several have revealed either higher response or remission rates with the dual action agents as compared to the SSRI comparator (125 ,126 ,130 ,131 and 132). Although not all studies confirm these findings (107), it would appear that for severely ill patients, dual action agents may offer somewhat better efficacy in selected patient populations. In addition, a response without remission to an SSRI might arguably lead to either the use of an augmenting medication to create a "dual action," or a switch to a dual-action agent.

Do Medications Differ in the Time to Onset of Benefit?

Some studies report that some agents have a faster onset of response (107 ,108 and 109). These findings depend on the doses used, the population under study (e.g., less versus more severe; more versus less treatment-resistant), and the length of the trials. Obviously, if one agent is dosed/titrated more gradually than another the former could *appear* to have a slower onset of action, when such might not be the case with more aggressive dosing. Several recent, double-masked, randomized trials, especially in more severely depressed patients suggest faster onset of action for mirtazapine (107 ,108 and 109) or venlafaxine (64 ,110) than comparator SSRIs. Whether more aggressive dosing of the SSRI might have produced different results remains an open question.

How to Manage Symptomatic Breakthrough?

During continuation or maintenance phase treatment, a return of clinically significant depressive symptoms, even while on medication, is not uncommon. Full relapses/recurrences range from 10% to 40% over 12 to 16 months following response to acute phase treatment. This symptom breakthrough appears to occur with all antidepressants (133). Whether it is more likely with one or another medication or medication class has not been well defined. Those who attain remission (not just response) to acute phase treatment appear more likely to remain in remission (or to at least sustain a response) over continuation phase treatment than are those who with a response but with residual symptoms at exit from acute phase treatment (40). Some studies suggest that patients with an earlier, more complete, and more sustained symptom benefit in acute treatment are less likely to encounter symptomatic breakthrough at least in the continuation phase (134 ,135 and 136).

How to manage symptom breakthrough in continuation/maintenance phases is unclear. Although clinical consensus suggests dose increases (137), others suggest dose decreases (138). Still others add a second agent (e.g., bupropion) to the first (e.g., an SSRI), whereas others recommend discontinuing the first agent and switching out of class to another agent. (See ref. 97 for review.) The question of how to manage symptomatic breakthrough is of substantial public health significance because it is commonly encountered in clinical practice. In addition, these patients likely will have increased use of the health care system, function more poorly, and will have a worse prognosis. Yet, no randomized trial data and very few case reports are available. Whether agents differ in the likelihood of symptom breakthrough has also not been studied in comparative trials.

How to Define and Manage Treatment Resistance?

The degree of treatment resistance may be based on the number of treatments (or classes of treatments) that have not led to a response or a sustained response, or to a remission or sustained remission (58). Clinically, it is often difficult to accurately define what treatments, at what doses, and used for how long produced what benefits for a particular patient, especially for patients with a history of multiple treatments, multiple providers, or longstanding depressions. The Antidepressant Treatment History Form (ATHF) provides a validated tool by which to gauge the degree of treatment resistance for research (139).

Once the level of treatment resistance is defined, however, we are still left with a large number of possible treatments, few of which have been subjected to randomized, comparative trials for treatment-resistant depression. Most studies are open trials (see the preceding). The recently launched, NIMH supported multisite, national effectiveness trial, *Sequenced Treatment Alternatives to Relieve Depression (STAR*D)*, will begin to define, using randomized comparisons, which among several treatments used as augmenting or switching strategies have greater efficacy in a large cohort of patients recruited from primary and specialty care clinical sites (for a detailed description, see http://www.edc.gsph.pitt.edu/stard).

POTENTIAL NEW ANTIDEPRESSIVE MEDICATIONS

Part of "75 - Current and Emerging Therapeutics for Depression "

Two new classes of possible antidepressant medications are under development: substance P antagonists and CRF antagonists. A single, positive, 6-week double-blind trial in outpatients with MDD study found a substance P antagonist (MK 869) as effective as paroxetine, and both exceeded the effects of pill placebo (140). The mechanism of antidepressant action of substance P antagonists is not clear; however, it seems that neither norepinephrine nor serotonin systems are directly affected. Direct effects on the substance P NK receptors, perhaps in the stratum or amygdala, to modify stress response may play a role.

Corticotropin releasing hormone (CRH) also plays a key role in modulating the neuroendocrine, autonomic, and behavioral

responses to stress (141). CRH produces signs and symptoms of depressive and anxiety disorders by activation of the CRH_1 receptors (142 ,143). These findings provide a rationale for attempts to develop medications that antagonize the CRH_1 receptor. Zobel and colleagues (144), using R121919 (an agent that binds to CRH_1 receptors) in an open trial of 20 patients, reported improvements in anxiety and depressive symptoms. CRH_1 receptor blockade did not impair corticotropin and cortisol secreting activity either at baseline or after an exogenous CRH challenge.

These early reports are tantalizing. The field awaits more definitive, placebo-controlled clinical trials for both CRH and substance P antagonists. Whether these agents will have predictable, substantial, and prolonged antidepressant or anxiolytic (e.g., posttraumatic stress disorder) is yet to be determined. In theory, if they modify stress responses, such agents may be important in the treatment of residual symptoms or symptomatic breakthroughs that occur with currently available agents. Alternatively, they may prevent the onset of a depressive episode following a stress in vulnerable individuals.

Combinations of standard medications, especially the use of atypical antipsychotic agents, alone or combined with antidepressants, have begun to be a focus of research for treatment-resistant depression (145 ,146). The rationale for the use of olanzapine combined with fluoxetine, for example, is provided by evidence of increases in norepinephrine and dopamine levels using microdialysis in the raphe prefrontal cortex. In a recently completed, 8-week, double-blind trial in 28 patients with treatment-resistant depression, large reductions in MADRS scores were obtained with the combination, as compared to either agent alone (146). Whether such findings are replicated, and/or generalize to other atypical antipsychotic agents, other SSRIs, or to other newer agents remains to be seen.

ANTIDEPRESSIVE TREATMENTS IN CHILDREN AND ADOLESCENTS

Part of "75 - Current and Emerging Therapeutics for Depression "

The psychotherapeutic approaches of cognitive behavioral therapy (CBT) and IPT appear to have specific efficacy in adolescent depression (147 ,148 ,149 ,150 ,151 and 152), whereas psychotherapeutic approaches to preschool depression are relatively less developed and have not been tested in randomized trials. (See ref. 153 for review.) The very limited available evidence does not show long-term change from these acute psychotherapeutic interventions (2).

Quite surprisingly, SSRIs appear to have adult-like efficacy in children and adolescents with major depressive disorder, whereas TCAs do not and may be no better than placebo. As reviewed elsewhere (154), RCTs of TCAs versus placebo have been uniformly negative in both children and adolescents. Many of these negative studies were relatively small. However, when considered in aggregate, the data best support the hypothesis that TCAs are either ineffective or much less effective in this age group than in adulthood. Furthermore, TCAs are particularly toxic in deliberate or accidental overdose in youth, and they are all off patent; therefore, more studies of TCAs in this population are unlikely.

To date, two large studies have found SSRI superiority to placebo (155 ,156) and they appear equally efficacious in prepubertal children as in adolescents and in both sexes (155). Encouraged by regulatory changes, randomized, placebo-controlled trials in youth are planned or underway for essentially all antidepressants now on patent.

One of us has argued, post hoc, that because the TCAs as a group are all relatively noradrenergic in youth because of their relatively more rapid metabolism, it may be that noradrenergic antidepressants as a class will prove less useful in youth, whereas serotonergic antidepressants will show efficacy throughout the lifespan. There are as yet no available RCTs on newer agents other than SSRIs in youth to further address this question (157).

Although available and ongoing work in antidepressant pharmacology in youth with MDD provides guidance for the initial treatment step for depression, the field is only now considering the arguably more important studies of chronic maintenance, combination treatment, treatment of refractory depression, and the other questions that arise in this recurrent disorder.

“ALTERNATIVE” THERAPIES

Part of "75 - Current and Emerging Therapeutics for Depression "

St. John's Wort (Hypericum perforatum)

Extracts of the plant St. John's wort, *hypericum perforatum*, appear to have antidepressant effects. These extracts contain at least 10 biologically active substances. One study has suggested that hyperforin may be the critical active constituent (158). Extracts of hypericum inhibit reuptake of serotonin, norepinephrine, and dopamine and lead to down-regulation of B-adrenoceptors and serotonin ($5\text{-}HT_2$) receptors (159). However, limiting the studies to date is the lack of a standardized concentration of the active ingredient(s) in the preparation of hypericum extract.

Several recent metaanalyses have aggregated available data (160 ,161 and 162) but did not include one additional recent study (163) to find that hypericum extract: (a) appears to be significantly better than placebo in the treatment of mild to moderate depression, and (b) appears, in general, not statistically different from relatively low doses of TCAs (e.g., amitriptyline 75 mg QD, imipramine 100 mg QD, imipramine 150 mg QD) given for a brief duration (6 weeks or less in all but the Philipp study that used 100 mg of imipramine for 8 weeks). A recent comparison of St. John's wort and the SSRI fluoxetine also found no statistically significant difference between treatments (mean decrease in

HAM-D score = 10.2 for St. John's wort versus 12.5 for fluoxetine) (164).

In a recent double-masked randomized study (165) of 201 outpatients with major depression and a baseline 17-item HAM-D score ≥20 treated for 8 weeks with either St. John's wort or placebo for 8 weeks, St. John's wort was significantly better than placebo when examining the rate of remission (defined as HAM-D score ≤7) (19.3% versus 8.7%) ($p < 0.04$). However, there was no significant difference seen between St. John's wort and placebo on any of the continuous outcome measures, including the HAM-D, CGI-I, CGI-S, or the Hamilton Rating Scale for Anxiety (HRS-A) (166). The very low rate of response both to active medication and placebo in this study are atypical when compared to most modern studies of antidepressants.

Thus, although the randomized clinical studies using placebo suggest that hypericum has some antidepressant effect in humans (and has effects in animal models for depression), the data are simply inadequate to say how well St. John's wort works compared to current standard dosages of antidepressants or data as to efficacy of this compound for maintenance. The NIMH and National Institutes of Health Office on Alternative Medicine is currently funding a study of *hypericum perforatum* versus SSRI or placebo, which may further elucidate the efficacy of this compound.

S-adenosyl-L-methionine

S-adenosyl-L-methionine (SAMe) has been tested as a potential antidepressant over the past 25 years. It is the primary methyl donor in the CNS for methyl acceptor molecules including catecholamines and phospholipids. A 1994 metaanalysis (167) examined the literature through 1992, and found six adequately controlled studies comparing SAMe (oral, intravenous, or intramuscular) to placebo with a total of 99 subjects on SAMe and 101 on placebo and seven studies comparing SAMe to TCAs with a total of 105 patients on SAMe and 96 on TCAs. Although those authors found the aggregate data to show statistically significant superiority of SAMe to placebo and equivalence of SAMe to TCAs, all but two of the comparisons with placebo and two of the comparisons with TCAs were 21 days or less in duration. Equivalence to TCA for such a short interval (before most of the TCAs effects have been realized) is unconvincing. Of the two placebo comparisons of longer duration, one trial of 30 days was positive and one of 42 days was negative.

Of studies not considered in the metaanalysis, one small study suggested more rapid onset of antidepressant response (by day 4) for SAMe + imipramine compared to placebo plus imipramine (168). A large open investigation (169) suggested, as did earlier studies, efficacy and very rapid onset of antidepressant effect of parenteral SAMe in humans. One study found imipramine-like “antidepressant” effects of SAMe compared to vehicle in a rat model of stress-induced anhedonia (170).

In aggregate, these data seem to point toward efficacy and perhaps very rapid onset of SAMe in the treatment of adult major depressive disorder. On the other hand, the total number of patients studied to date in placebo-controlled trials is quite modest, and the relative efficacy of SAMe compared to other treatments is quite unclear because almost all comparison studies were conduct for far too short an interval to reach full TCA effect. The roles of either SAMe or St. John's wort to treat residual symptoms (i.e., as augmenting agents to standard antidepressants as well) may be a useful focus of study.

Acupuncture

As reviewed in Ernst and colleagues (171), several case series and open clinical trials suggest possible efficacy of acupuncture for depression with electroacupuncture appearing to have greater effect than standard acupuncture and two randomized controlled trials have compared electro-acupuncture to amitriptyline. One study (172) compared 5 weeks of amitriptyline (average daily dose 142 mg) to electro-acupuncture in a total of 47 subjects and found no significant difference in HAM-D endpoints. A larger replication found no significant difference in outcome between amitriptyline and electro-acupuncture in a 6-week RCT in a total of 241 depressed inpatient subjects (173). As is well understood, lack of statistically significant difference of a putative treatment from a “known effective” treatment is not strong evidence for the efficacy of a treatment. In addition, the duration of treatment was relatively short, which would underestimate the maximal amitriptyline effect in these studies.

More recently, Röschke and associates (174) compared 70 adult inpatients with major depressive disorder, all treated with mianserin and then randomly assigned to the addition of acupuncture (with needling points proposed to be specific to the treatment of depression), placebo acupuncture (acupuncture at nonspecific locations) or no acupuncture. Both the specific and control acupuncture treatments showed statistical superiority to the no acupuncture group on several of the measures, although the differences were not large. There was no difference on any measure between the specific and control acupuncture treatments in this study. Thus, the results of this study are compatible with a nonspecific effect of the additional attention and expectancy and do not necessarily point toward specific efficacy of acupuncture.

In summary, data to date do not yet give a strong answer as to whether or not acupuncture has meaningful specific efficacy in the treatment of major depression. However, results of a recently published small, but randomized, controlled, and double-masked study of women with major depression ($n = 38$) suggest that acupuncture can provide

significant symptom relief from depression, at rates comparable to those of psychotherapy and pharmacotherapy (175).

FUTURE RESEARCH

Part of "75 - Current and Emerging Therapeutics for Depression "

The aim of treatment is remission, not simply response, given the better prognosis and better function associated with remission. Clinical issues raised by this recognition include: (a) Do medications truly differ in their ability to create remission, or do they differ more in the time it takes to establish an equivalent prevalence of remission? (b) Are the chances of remission increased if dual-action agents (or combinations of more selective monotherapies) are used compared to more neurotransmitter-selective agents? (c) How much time and effort should be expended to attain remission? (d) With which medication sequences is the likelihood of remission highest? (e) Does adding psychotherapy to medication increase remission rates or improve prognosis?

The importance of functional recovery, in addition to symptom remission, is now recognized. Do medications differ in their effects on day-to-day function? Some preliminary reports suggest that SNRIs (e.g., reboxetine) as opposed to SSRIs may lead to better functional recovery (176 ,177 and 178). This contention deserves more thorough and careful scrutiny in subsequent medication comparative trials.

We have yet to fully develop evidence as to when and for which patients such treatments are especially beneficial. Although several multi-step sequences, disease management pathways, or medication algorithms have been developed, only a single trial in primary care has evaluated the clinical and economic effects of using these sequences compared to treatment as usual. More research to develop evidence to establish valid pathways *and* to test their impact compared to treatment as usual is needed.

Given the range of treatments, can we better select or match a treatment to a person or to types of depression? Does a particular treatment history (or family history of treatment) recommend one versus another next step in the sequence of treatments to be provided to a particular patient?

Additionally, earlier intervention with less complex treatments, perhaps in the prodromal stages of the disorder, deserves further evaluation—especially with the potential availability of CRF antagonists. If these agents modify the stress response, could they be given quickly, close in time to the stress, before a full depressive episode appears in those with an established vulnerability to such a stress response?

Finally, we still are hampered by having to rely on symptoms and signs to gauge the adequacy of our treatments. Most of medicine can rely in part on laboratory measures to also inform clinicians about modifying the treatment plan or managing the illness. Research to find clinically obtainable measures of the disease process would remarkably improve the quality of care by better informing providers and patients.

Electroconvulsive Therapy: Sixty Years of Progress and a Comparison with Transcranial Magnetic Stimulation and Vagal Nerve Stimulation

William M. McDonald

W. Vaughn McCall

Charles M. Epstein

William M. McDonald: Department of Psychiatry and Behavioral Sciences, Emory University, Atlanta, Georgia

W. Vaughn McCall: Department of Psychiatry, Bowman Gray Medical Center, Winston Salem, North Carolina

Charles M. Epstein: Department of Neurology, Emory University, Atlanta, Georgia

The science of electroconvulsive therapy (ECT) has progressed rapidly over the last 20 years, providing new insights into the mechanisms of action of ECT, improving both the acute and long-term efficacy of the treatments, and decreasing cognitive problems associated with the treatments. The anticonvulsant hypothesis unifies many of the scientific findings in electroencephalography, neuroimaging, and clinical studies to provide a coherent testable hypothesis of the therapeutic mechanism of ECT. This hypothesis assumes that ECT enhances the transmission of inhibitory neurotransmitters and neuropeptides and that the active process of inhibiting the seizure is essential to the therapeutic action of ECT. New data are presented on improvements in the acute efficacy of ECT with suprathreshold (eight to 10 times the seizure threshold) right unilateral ECT, and three NIMH-supported studies are discussed that examine the efficacy of maintenance therapies. Decreasing cognitive side effects of ECT is another area of active research; changes in techniques and medication treatments are highlighted. Finally, two new treatments using subconvulsive stimuli, repetitive transcranial magnetic stimulation, and vagal nerve stimulation are discussed and compared to ECT.

Cerletti and Bini (1) first investigated ECT as a treatment for psychosis in 1938, theorizing that epilepsy and schizophrenia were incompatible. They hypothesized that the artificial induction of seizures in nonepileptic persons with schizophrenia would relieve psychosis. ECT was developed at approximately the same time as frontal leukotomy (2) and insulin coma therapy (3), but these treatments carried a high morbidity, and were replaced by modern psychopharmacology in the 1950s and 1960s. The indications for ECT were established during this time, and its use in conditions other than mood disorders and schizophrenia diminished.

ECT has remained as an accepted medical treatment for depression and was one of the most significant medical advances in the twentieth century. However, in 1950 the mortality and morbidity from ECT were unacceptably high and most of the early research in ECT focused on the safety and efficacy of the treatments. The death rate was approximately 0.1% (4) and the risk of fractured bones estimated to be as high as 40% (5). Over the last half century, the mortality from ECT has decreased dramatically because of a number of advances, including the widespread use of modern anesthetic agents (e.g., methohexital) (5) and succinylcholine (6), the introduction of cardiac and electroencephalogram (EEG) monitoring during treatments (7), and medications used to decrease the acute hemodynamic response during ECT (8). Abrams put the risk of mortality from ECT into perspective in 1997. He noted that ECT was ten times safer than childbirth and an order of magnitude less that the spontaneous death rate in the population (9).

Today, ECT is recognized as a safe treatment for depression and, despite the advances in pharmacotherapy in the last four decades, ECT continues to be the most effective treatment for severe melancholic depression. Four areas of research are important as we move into the twenty-first century: developing a scientific understanding of the mechanisms of action of ECT, optimization of the efficacy of acute courses of ECT, treatment of the cognitive side effects

of ECT, and continuing research into the efficacy of different ECT techniques, including novel electrode placements and continuation/maintenance ECT.

MECHANISM OF ACTION OF ECT

Part of "76 - Electroconvulsive Therapy: Sixty Years of Progress and a Comparison with Transcranial Magnetic Stimulation and Vagal Nerve Stimulation "

Salzman asserts that the psychiatric community continues to show ambivalence toward ECT and ECT research has suffered as a consequence (10). Although there are active steps within the NIMH to address these issues and provide more focused research in ECT (10), an understanding of the basic mechanisms by which ECT exerts its effect is still unclear. This fact is an irony given that ECT is one of the few treatments in psychiatry that was theoretically based (11). Although the original hypothesis that epilepsy and psychosis could not coexist in the same patient was later proven incorrect, the treatment of depression by inducing seizures in patients first with camphor monobromide and later by electrically induced convulsions is one of major medical breakthroughs of the past century.

One of the most confusing aspects of accepting ECT as a treatment for depression in the lay public and patients is the inability of clinicians to clearly explain how ECT is effective in relieving symptoms of depression. Patients have difficulty understanding how a treatment that is so seemingly toxic to the brain (i.e., causing a seizure) could actually be therapeutic. Patients readily accept that the therapeutic effect of antidepressants is to replete a serotonin deficit. However, the antidepressant medications have a number of other effects on a variety of neurotransmitters, regulatory hormones, and cellular mechanisms.

The mechanism by which a convulsive stimulus acts as one of the most powerful antidepressants is equally complex but the explanation may be as simplistic: ECT works by increasing natural brain substances that decrease the excitability of the brain. The unique therapeutic action of ECT is that the induced-seizures last only seconds and not minutes or hours. The physician’s contribution to the ECT treatment is the induction of a seizure; the patient’s contribution is turning the seizure off. Seizure termination is an active process that underlies the therapeutic mechanism of the treatment. This idea is elaborated on in the following but may give us a plausible explanation for patients on the mechanism of action of ECT.

The earliest attempts at understanding the importance of a convulsion in ECT focused on terminating the ECT-induced seizure with lidocaine to determine if the length of a seizure correlated with the efficacy of the treatment (12). The initial finding was that an ECT seizure had to continue for at least 25 seconds to be therapeutic (13) and the patient had to accumulate a minimal number of seconds of EEG seizure time during a course of ECT (14).

A popular theory of the mechanism of action of ECT, the diencephalic hypothesis (15 ,16), assumed that the degree of response to ECT was correlated with stimulation of the deep brain structures that regulate the hypothalamic pituitary–endocrine end axis activity. Stimulation of this system resulted in the release of pituitary hormones such as adrenocorticotropin hormone (ACTH), thyrotropin, prolactin, oxytocin, and vasopressin. Research using rodents administered electroconvulsive shock (ECS) and examining the CSF of patients receiving ECT has supported a relationship between increases in neuropeptides during the convulsive stimulus (17). According to the diencephalic hypothesis, ECT seizures that have a longer duration, and ECT parameters that are more effective at stimulating the diencephalic structures (i.e., bilateral [BL] greater than unilateral [UL] and high-dose greater than low-dose ECT), therefore, would be more effective in treating depression.

Both of these assumptions have been questioned recently. Sackeim and colleagues were the first to demonstrate that the therapeutic benefit of the ECT seizure was dependent on the amount above the individual patient’s seizure threshold that the stimulus was administered and not simply the duration of the seizure (18). Although the acute release of neuroendocrine markers did correlate with the type of seizure administered and seizure duration, the expected correlation between the acute surge in plasma oxytocin, vasopressin (19), or prolactin (20), and clinical response to ECT was not shown in studies of depressed patients receiving a course of ECT.

Recent research on predicting a patient’s response to ECT have focused less on the quantitative analysis of seizure duration and more on the relationship between a qualitative analysis of the ictal and postictal seizure morphology to therapeutic response (21 ,22). ECT-induced seizures have a characteristic pattern of hypersynchronous neuronal discharge with excitation of cortical neurons during the initial tonic phase, followed by alternating excitatory and inhibitory effects in the clonic phase, and finally postictal suppression owing to inhibition and neuronal hypoexcitability.

A number of treatment-related factors affect seizure morphology, including electrode placement, the percentage above the seizure threshold that the stimulus is administered, and the stimulus waveform (23). A number of features of the ictal EEG seizure that demonstrate a more intense seizure predict clinical response to ECT. (See ref. 24 for review.) Seizure intensity is measured by increased ictal EEG amplitude (high-voltage spikes and waves), symmetry or coherence of ictal EEG amplitude between the right and left hemispheres, and weaker postictal hemispheric coherence, longer duration of stereotypic ictal EEG pattern, and greater postictal suppression or flattening of the EEG. These seizure characteristics have been used to predict the efficacy of an ECT course (22 ,25 ,26 and 27), or more precisely these variables can be used to predict when a seizure is not adequate. Inadequate EEG seizures have low-amplitude waves and are not symmetric, with no clear ending of the seizure in the postictal period.

Analysis of the EEG morphology has been used to determine seizure intensity (26). Clinicians can be trained to visually inspect the EEG strips during ECT and determine the adequacy of the seizure by evaluating the amplitude of the ictal EEG relative to baseline, symmetry of right and left hemispheric EEGs, distinct spike and wave pattern, and degree of postictal suppression (28). Both the Thymatron DGx ECT device (Somatics Inc., Pine Bluff, IL) and the MECTA 5000Q ECT device (MECTA Corp., Lake Oswego, OR) provide measures of the quality of the EEG. Although further testing of the clinical use of the computer-assisted EEG analysis provided with these machines is necessary, these devices may add to stimulus dosing, particularly in patients administered UL ECT, in determining if a seizure is adequate (24 ,27 ,29).

Another promising area of investigation into the mechanism of ECT is research correlating functional brain imaging with response to ECT. Studies have shown an increase in cerebral blood flow (CBF) up to 300% of baseline values with an accompanying increased permeability of the blood–brain barrier and increased cerebral metabolic rate (CMR) up to 200% during the ictal period (30). In contrast, CBF decreased to levels below baseline (31) or returned to baseline (32) and PET scans showed a marked decrease in CMR in the postictal period (33).

Although there have not been any clinical studies correlating the increase in CBF/CMR during the ictal period with clinical response, Nobler and colleagues (34) found a correlation between decreased CBF in the immediate postictal period and clinical response. This well-designed study included 54 depressed patients imaged using the Xenon inhalation technique. Patients showed a low baseline CBF compared to matched controls, and their response to ECT was correlated with the further decrease in CBF from baseline. These changes were greatest in the anterior cortical regions and the degree of change was correlated with clinical improvement on the Hamilton Depression Rating Scale. Moreover, these reductions in CBF persisted for the 2-month follow-up in responders, was correlated with improvement in depression scores and the nonresponders continued to have an increase in CBF compared to baseline. Nobler and Sackeim (35) point out that decreased CBF in the anterior cortex supports earlier findings by Max Fink (36 ,37) and their own group (38) of a relationship between frontal delta activity on EEG and response to ECT. There are additional data suggesting that the reductions in cerebral blood flow that occur immediately after ECT may persist for days (39) to months (40) after the treatments and the most dramatic reductions occurred in the frontal cortex.

Sackeim has unified many of these EEG, CBF, and CMR findings with preclinical research in the anticonvulsant hypothesis as the mechanism of action of ECT (40). During a course of ECT, the patient’s seizure threshold is increased and seizure duration decreases during the first several treatments (41 ,42). ECT seizures usually are limited to less than 1 minute and there is an active inhibitory process in the interictal and postictal states evident by the development of slow or delta waves and decreases in the CBF and metabolic uptake of glucose. The anticonvulsant properties of ECT are hypothesized to occur because of enhanced transmission of inhibitory neurotransmitters and neuropeptides (e.g., GABA and endogenous opioid concentrations) and are an essential element of the therapeutic effect of ECT in mania and depression.

The magnitude of the seizure threshold increase is greater in more effective methods of administering ECT (i.e., high-dose UL and low-dose BL versus low-dose UL) and is correlated with clinical response (18 ,43). Clinically, Sackeim cites unpublished data that the patients who return to an acute course of ECT after relapsing have the same seizure threshold that they had at the start of treatment. However, it is unclear whether the return of the seizure threshold to baseline occurs after an acute course of ECT in all patients or only in patients who relapse. The duration of the seizure is also decreased over a series of treatments and is another indication of the anticonvulsant effect of ECT. However, seizure duration is not related to efficacy unlike seizure threshold (43).

The EEG of the patient during and immediately following therapeutic ECT treatments indicate that there is an ongoing active process in which the brain is inhibiting the seizure process. Inhibitory processes include the early onset of high amplitude slow-wave activity after the tonic phase of the seizure and bioelectric postictal suppression processes (21 ,22 ,27 ,44 ,45 and 46). The efficacy of ECT has been correlated with the early onset of these inhibitory processes, a fact that supports the anticonvulsant hypothesis. Two elements of seizure expression, seizure strength and peak amplitude of slow-wave activity, were inversely correlated with seizure threshold and the third element, postictal bioelectric suppression, was not related to seizure threshold (40). Because the seizure threshold is increasing during the treatment course, two of the essential elements of a therapeutic seizure (seizure strength and peak amplitude of slow-wave activity) are deteriorating, thereby limiting the effectiveness of subsequent seizures. This finding provides the rationale for developing EEG algorithms (see the preceding), increasing the stimulus dosing or retitrating the seizure threshold during a course of ECT in patients who are not responding.

During a course of ECT, as in epilepsy, CBF/ CMR increase dramatically during the seizure and decrease below baseline in the interictal and postictal states (35). Patients responding to ECT show a more marked global decrease in CBF as well as specific reductions in the anterior frontal cortex (34). These changes were correlated with an increase in the seizure threshold. Finally, increasing slow-wave activity in the frontal cortical regions after ECT was also associated with clinical improvement (38). Both these finding support the anticonvulsant hypothesis.

The anticonvulsant hypothesis unifies many research

findings and provides important new leads that have the potential for improving clinical outcomes and predicting patients who are at risk of relapsing after ECT. The anticonvulsant properties of ECT related to clinical outcome include an increase in the seizure threshold during a course of ECT, early onset of slow-wave activity interictally, distinct postictal suppression, and decreases in CBF/CMR and increased slow-wave activity after a series of treatments.

An anticonvulsant mechanism for ECT would be unique when compared to the antidepressant medications (which are rarely associated with seizures) and anticonvulsant medications (e.g., valproic acid and carbamazepine), which have only moderate antidepressant efficacy (47). However, there is evidence that newer anticonvulsant medications, including lamotrigine, may be more effective in the depressed phase of bipolar illness (48). The mechanism by which the anticonvulsants exert their antidepressant effects is poorly understood and is hypothesized to occur through a number of neurotransmitters, including inhibiting the presynaptic release of excitatory amino acids (e.g., glutamate) and enhancing the effect of inhibitory neurotransmitters and neuropeptides.

New research should focus on testing the anticonvulsant hypothesis and determining the neurotransmitters essential for the antidepressant properties of ECT. Examining the relationship of the anticonvulsant effects of ECT to the efficacy of the treatments by blocking or augmenting the anticonvulsant properties of ECT can test this hypothesis. For example, CSF neuropeptides associated with the anticonvulsant effects of electroconvulsive shock (ECS) have been isolated in laboratory animals (49). These neuropeptides could be given in conjunction with ECS to determine if the coadministration of these neuropeptides would block the therapeutic efficacy of ECS (50). Although ethical considerations may limit this type of research in humans, studies could be designed to investigate the relationship of the acute rise in endogenous anticonvulsant substances (including GABAergic and endogenous opioids) in the CSF of ECT responders versus nonresponders.

Clinical research should continue to concentrate on developing algorithms to determine the relationship of ECT treatment variables (e.g., seizure threshold) to ECT response or the loss of seizure efficacy during a course of ECT. These algorithms can test the anticonvulsant hypothesis and guide clinicians in administering effective treatments. Treatment variables (e.g., diminished CBF in the anterior frontal lobes) may also be investigated to predict relapse.

OPTIMIZATION OF ACUTE ECT

Part of "76 - Electroconvulsive Therapy: Sixty Years of Progress and a Comparison with Transcranial Magnetic Stimulation and Vagal Nerve Stimulation "

ECT is widely cited to have an antidepressant efficacy of greater than 80% (51). More recently, the percent of patients achieving remission after an acute course of ECT is conservatively estimated at between 50% and 80%. The reason for this apparent decline in efficacy is the increasing resistance to treatment among the patients referred for ECT in the last 15 years. Prior to the development of the serotonin reuptake inhibitors (SSRIs), the most common reason for referral for ECT was intolerance of available antidepressant medications, chiefly tricyclic antidepressants (TCAs), and monoamine oxidase inhibitors (MAOIs). Intolerance to antidepressant pharmacotherapy was particularly important in the elderly who constitute the majority of patients referred for ECT. The elderly are also the patient group most susceptible to the side effects of TCAs and MAOIs. The advent of SSRIs, serotonin, and norepinephrine reuptake inhibitors (SNRIs), 5-HT_{2A} blockers, and other novel antidepressants in the last 15 years has radically changed the medication histories of the patients referred for ECT. These newer agents are remarkably well tolerated, and a majority of patients receiving ECT have had at least one complete trial of an antidepressant without improvement. These patients who are refractory to antidepressant medications are also more refractory to ECT. The ECT response rate in antidepressant medication-refractory patients is probably no better that 50%, whereas the response rate in medication naive patients is closer to the historically quoted 80% to 90% (52). The problem of decreased acute response to ECT in this growing population of medication-refractory patients has led to new interest in the technical factors that control the response to acute ECT. Among these factors are electrode placement, stimulus dose, and possibly concurrent medications.

Despite 60 years of clinical application, the ECT field has only recently come to appreciate the relative contributions of stimulus electrode placement and stimulus intensity to the therapeutic and adverse effects of ECT. As previously discussed, clinical wisdom prior to 1987 taught that as long as the EEG seizure during ECT was ≥25 seconds, then the treatment was maximally effective. This belief was refuted by Sackeim and colleagues' report that when ECT is delivered with right unilateral (RUL) electrode placement and a stimulus just barely above the patient's seizure threshold, then the antidepressant response rate was approximately 20%, despite seizure durations ≥25 seconds (18). Further work by this group clarified that the efficacy of right unilateral (RUL) ECT was exquisitely sensitive to the magnitude of the stimulus dose expressed as a multiple of a given patient's seizure threshold (53) (Table 76.1).

	Barely Suprathreshold	2.5-Times Threshold
RUL	17%	43%
BL	65%	63%

TABLE 76.1. ANTIDEPRESSANT RESPONSE RATE BY ELECTRODE PLACEMENT AND STIMULUS DOSE

This work demonstrated that, within the stimulus dose studied, the efficacy for RUL was sensitive to dose, whereas the efficacy of bilateral (BL) ECT was insensitive to dose. Also, RUL ECT appeared inferior to BL ECT at any dose. Subsequent work confirmed that the efficacy of RUL ECT is dose dependent and that RUL ECT administered at six times the initial seizure threshold is as effective as BL ECT with fewer cognitive side effects than BL ECT (54). McCall and colleagues found a dose–response relationship in patients receiving RUL ECT that extended to 12 times the seizure threshold and, as predicted, cognitive side effects were increased as the stimulus dose increased relative to the seizure threshold (55). The response rate for RUL ECT at eight to 12 times threshold was about 70%, approximately the rates typically quoted for BL ECT.

Based on this new information, it seems reasonable to recommend that ECT be delivered with either BL electrode placement at a stimulus dose just above threshold, or with RUL placement at a stimulus dose markedly above threshold. Less intensive strategies (i.e., RUL at 2.5 times threshold) should probably be avoided for routine use. Although it is clear that the lower intensity RUL strategies have less acute amnesia side effects, this advantage is probably offset by poorer efficacy and consequently poorer quality of life (QOL), because depression severity is among the best predictors of QOL in severely depressed patients (56 ,57).

There remain three important considerations in the routine use of titrated unilateral ECT. First, many psychiatrists are hesitant to determine the seizure threshold because they feel that the procedure is medically dangerous. There is a potential risk to stimulating the vagus nerve with subconvulsive stimuli without adequate compensatory adrenergic discharge from a seizure and the possibility of prolonged asystole. However, a controlled operative setting with cardiac monitoring decreases the possibility of brief periods of bradycardia causing any significant risk for a majority of patients.

Second, some would argue that the initial treatment in a series of titrated seizures is a “wasted” seizure, adding to costs and potential cognitive side effects without any significant therapeutic benefit to the patient. The unilateral seizure at or near the seizure threshold used during the initial treatment setting to determine seizure threshold probably adds little benefit. However, the potential advantages of determining the seizure threshold and adjusting the subsequent seizures to the threshold has advantages in maximizing benefit and decreasing the potential for future ineffective treatments (if the energy delivered is too low) and cognitive side effects (if the energy is too high).

Finally, fixed high dose RUL ECT is an effective treatment for depression (55 ,58) and this data could obviate the need to determine seizure threshold. Because the majority of patients treated with ECT are older and older patients have very high seizure thresholds, dose titrations at eight to ten times threshold are generally at or above the 400-mC range used by McCall and associates. In fact, in some older patients even a suprathreshold stimulus set at 400 mC may be too low to achieve antidepressant efficacy.

Continued support for the efficacy of suprathreshold RUL ECT has raised some concern about the fact that ECT machines in the United States are restricted in the amount of energy they can deliver per treatment (504 to 576 mC maximal output). Abrams argues that the FDA mandated maximum output for ECT machines used in this country often does not allow for the administration of effective suprathreshold treatments and has called for a reexamination of these guidelines (59).

The question of whether or not to continue, discontinue, or initiate antidepressant medication during a course of acute ECT is also pertinent to the issue of improving the response rate among patients with a history of antidepressant medication resistance. Clinically, physicians are divided in their practice regarding antidepressant medications during ECT, and there are no good data to support any position. One of the developments in ECT practice in the 1990s was the occurrence of SSRI-resistance in ECT patients, and the virtual lack of TCA trials in these same patients before coming to ECT. This is especially important because there are some data to suggest that TCAs (i.e., nortriptyline) may be more effective than SSRIs in the severely depressed or hospitalized elderly (60). Possibly, the addition of an antidepressant (i.e., nortriptyline) may improve the antidepressant response to ECT in patients with a history of novel-antidepressant resistance.

PREVENTION OF RELAPSE AFTER ECT

Part of "76 - Electroconvulsive Therapy: Sixty Years of Progress and a Comparison with Transcranial Magnetic Stimulation and Vagal Nerve Stimulation "

In general, patients who receive an acute course of ECT are either subsequently resistant or intolerant of antidepressant medications. Patients diagnosed with psychotic depression are particularly susceptible to relapse after an acute course of ECT. Two studies found a relapse rare of approximately 70% in 1 year for a total of 53 patients with a diagnosis of psychotic depression (61 ,62). These studies were retrospective and could not examine compliance rates or the adequacy of either the initial (pre-ECT) or continuation medication trial.

In a prospective study, Sackeim and co-workers (63) followed 58 patients for 1 year after ECT. They examined a number of clinical variables including a retrospective review of the adequacy of the pre-ECT medication trial. The most important factor in determining relapse on maintenance medication after an acute course of ECT was the adequacy of the pre-ECT medication trial. Patients (with and without psychotic features) who were rated as receiving a therapeutic medication trial(s) prior to their acute course of ECT relapsed at a rate that was twice the rate found in patients who did not receive an adequate pre-ECT medication trial (64% versus 32%). The maintenance medication was not standardized but the results indicated that the adequacy of

the post-ECT medication trial was only marginally related to the relapse rate and then primarily in patients who did not have an adequate pre-ECT medication trial. The patients who were not determined to be medication resistant prior to ECT had a lower relapse rate when they received an adequate maintenance medication trial. Sackeim and associates argue that many of these patients may have responded to antidepressant medication prior to ECT if they had received an adequate trial. The overall relapse rate remained very high (approximately 50%) and most of the patients who relapsed did so in the first 4 months of this 1-year follow-up study. This finding indicates that the efficacy of ECT may be relatively transient. Given the increasing medication resistance found in most ECT patient populations, the clinical challenge is increasingly to determine the most effective maintenance treatments and increasingly physicians are utilizing maintenance ECT.

The American Psychiatric Association's (64) clinical guidelines for continuation ECT (C-ECT) include patients who: (a) have recurrent depressive episodes responsive to ECT; (b) demonstrate resistance/intolerance or noncompliance with antidepressant medications; (c) can comply with the overall treatment plan including behavioral restrictions (i.e., limiting driving) and providing informed consent. Continuation and maintenance ECT strategies are being used increasingly in the treatment of patients with major depression who are felt to have a high-risk for relapse (65). The guidelines for the use of C-ECT have been actively discussed but there are little prospective data on which to base recommendations on frequency of treatments and how long they should be continued or the nature of the potential cognitive side effects. A majority of the studies are case reports and many predate antidepressant medication (66). More recent reports in patients with depression (66 ,67 ,68 ,69 ,70 ,71 ,72 ,73 and 74), mania (75 ,76), and schizophrenia (77) describe a marked decrease in the number of hospitalizations, hospital days, depressive symptoms, increased functional status, and stable cognitive functioning for the period of continuation ECT.

Theoretically, there are several potential theories that may explain the efficacy of maintenance ECT over maintenance medication. First, maintenance ECT may be effective because the ECT treatments are gradually tapered rather than abruptly discontinued. During this taper, most clinical protocols decrease the interval between the maintenance treatments if the patient shows signs of relapse. A tapering schedule over this period may be critical because most patients relapse within 3 months of stopping the treatments. In 1954, prior to the use of antidepressant medications as maintenance treatment, Bourne and Long (78) coined the term "convulsion dependence" to describe psychotic patients who relapsed unless they were tapered from their ECT treatments.

The second potential therapeutic benefit may be the fact that ECT has a different mechanism of action than the antidepressant medications. Increasingly patients are presenting for ECT after multiple failed medication trials and there may be little benefit from yet another trial of an SSRI. In fact the one medication regimen that has been shown to be effective in maintenance therapy is a combination of lithium and nortriptyline (discussed in the following). The benefit of this combination therapy may be owing to the fact that few patients had been given lithium augmentation prior to their acute course of ECT.

Finally, maintenance ECT is similar to depot haloperidol in the treatment of schizophrenia and may provide prophylactic benefit from improved compliance in patients who might otherwise not comply with their maintenance medication. Most studies of maintenance ECT only report patients who complied with the treatment regimen. The experience at the Emory University Outpatient ECT program is similar to the data reported by Clarke and colleagues (67). When patients do not complete the scheduled 6-month maintenance ECT program, we found that more than half of the patients relapsed.

In 1991, Monroe (79) discussed the need for increased research into continuation and maintenance ECT. There is clear evidence that these treatments are being used increasingly in clinical practice, yet there is a lack of guidelines to establish the optimal treatment frequency, the type of patient who would benefit from maintenance ECT versus medication, or an understanding of the potential long-term side effects. The NIMH is presently funding three studies that will add significantly to our understanding of maintenance ECT. Two multicenter trials are examining the efficacy of different maintenance strategies after an acute response to ECT. Sackeim and colleagues are comparing maintenance placebo, nortriptyline versus nortriptyline and lithium after an acute response to ECT. Preliminary results from this line of investigation show that nortriptyline provides only marginally greater protection against relapse during the post-ECT period than does placebo, with relapse rates of approximately 70% during the first year. The addition of lithium to nortriptyline resulted in a further significant reduction in relapse to approximately 40% during that interval. Charles Kellner is the principal investigator on a trial comparing maintenance medication and maintenance ECT. The authors are currently examining the cost effectiveness of maintenance medication compared to maintenance ECT in elderly patients with recurrent major depression. These last two trials do not yet have preliminary data available, but together they will provide prospective data on the relative effectiveness and costs of different maintenance strategies used after an acute course of ECT.

COGNITIVE PROBLEMS ASSOCIATED WITH ECT

Part of "76 - Electroconvulsive Therapy: Sixty Years of Progress and a Comparison with Transcranial Magnetic Stimulation and Vagal Nerve Stimulation "

The one significant remaining ECT-related morbidity is the potential for cognitive side effects. Although there is little

scientific literature supporting permanent brain damage after ECT (80 ,81 and 82), memory disturbances continue to be a serious side effect after an acute course of ECT. Clearly, there have been significant advances over the last 50 years. Delirium was a clinical goal in some early protocols (so called “regressive ECT”) that equated the development of delirium with therapeutic response. This technique provided no advantage over more conservative forms of ECT and has been abandoned. Replacement of sine wave stimuli with machines that provide a brief pulse stimuli, and the elucidation of the appropriate stimulus parameters that increase the efficacy of safer treatments (suprathreshold right unilateral versus threshold bilateral ECT) have both been important contributions to the decrease in the ECT associated memory loss over the past few decades. The potential development of ultrabrief pulse ECT and research into pharmacologic treatments such as physostigmine (83), naloxone (84), and thyrotropin releasing hormone (TRH) (85) all hold promise for further decreasing ECT-associated memory loss. Double-blind placebo controlled trials using with intranasal vasopressin (86 ,87), ACTH (88 ,89), dexamethasone (90), and nimodipine (91) have not shown the active drug to be more effective than placebo.

The frequency of ECT administration is yet another way of controlling ECT-related memory loss. Twice-weekly ECT is associated with an antidepressant response as good as thrice-weekly ECT, but with less adverse memory effects (and a slower rate of antidepressant response) (92 ,93). Recently, the issue of optimal electrode placement has been reopened with isolated enthusiasm for bifrontal stimulating electrode placement or an asymmetric placement (a right fronto-temporal electrode referenced to a left frontal electrode). Preliminary reports suggest that these novel electrode placements are associated with an antidepressant efficacy comparable to standard bilateral placement, with fewer cognitive side effects, but there are insufficient data thus far to recommend them as a replacement for standard BL or RUL placements (94 ,95).

NONCONVULSIVE STIMULI IN THE TREATMENT OF DEPRESSION

Part of "76 - Electroconvulsive Therapy: Sixty Years of Progress and a Comparison with Transcranial Magnetic Stimulation and Vagal Nerve Stimulation "

Repetitive transcranial magnetic stimulation (rTMS) and vagal nerve stimulation (VNS) are two new treatments for depression that, unlike ECT, use subconvulsive stimuli to treat depressive symptoms. Compared to ECT, these treatments have the potential for targeting specific brain regions and stimulating areas that are thought to be involved in depression while sparing areas such as the hippocampus and thus reducing potential cognitive side effects.

rTMS was first used in 1985 as a noninvasive method of stimulating brain neurons (96). rTMS produces pulses of electromagnetic currents conducted by the brain that have different effects on neuronal firing, depending on the frequency in which it is administered. In general, rTMS acts by inducing action potentials in neuronal elements, but at high frequency (5 Hz) the net effect of a stimulus train is excitatory (97); similarities have been drawn between the effects of fast rTMS and long-term potentiation (LTP) produced by high frequency electrical stimulation (98). At low frequencies (1 Hz) the net effect of a stimulus train is usually inhibitory (99 ,100). In animal studies, rTMS has been demonstrated to cause down-regulation of *B*-adrenoreceptors (101) and, as has been shown in ECS, rTMS up-regulates astroglial gene expression in the CNS (102). Preliminary data support rTMS in the treatment of a number of psychiatric disorders including depression, schizophrenia, obsessive-compulsive disorder, and posttraumatic stress disorder (103).

This chapter focuses on the use of rTMS in depression and compares rTMS to ECT. From the outset it should be stressed that the efficacy of rTMS in the treatment of depression is modest and much of the research has been focused narrowly on a relatively restricted group of treatment parameters. The majority of rTMS studies use set parameters: high frequency or fast stimulations (≥10 Hz) over the left dorsolateral prefrontal cortex (DLPFC) at or around the motor threshold (e.g., 80% to 110% MT). These parameters are based on PET data (104) and ECT data (34) demonstrating hypofunctioning of the left prefrontal cortex in depression as well as two pivotal early studies demonstrating an antidepressant effect of fast left DLPFC rTMS (105 ,106). Although one recent parallel group sham controlled study found no treatment effect (107), most open (105 ,108 ,109) and double-blind studies (106 ,110 ,111) have confirmed a relatively modest antidepressant response for fast left DLPFC. When directly compared to ECT, 4 weeks of rTMS appears to be as effective as ECT in nonpsychotic, but not psychotic, depression (112). In this study there may have been a bias for the ECT group because over half of the patients in the ECT group and none of the patients in the rTMS group remained on antipsychotics and/or antidepressants. Two weeks of either RUL ECT or one ECT treatment followed by four rTMs sessions were also shown to be equivalent in the treatment of 22 depressed outpatients (113).

To date there have been no seizures reported using fast rTMS within the established safety guidelines (114) and no cognitive side effects in patient populations (109). The most common side effects are pain at the treatment site and headaches usually relieved by acetaminophen.

Realizing the potential benefits of rTMS, however, is dependent on expanding the treatment parameters including research on the variable effects of slow versus fast stimulation. Although early studies using slow TMS demonstrated poor outcomes (115 ,116 and 117), and are often cited as rationale for using fast rTMS, the stimulation site was the vertex in these three studies. More recent trials of *slow* rTMS over the *right* DLPFC have shown benefit. Klein and colleagues (118)

randomized 71 depressed patients to 2 weeks of slow, active or sham treatment over the right prefrontal cortex and 41% of active-treatment subjects had a 50% or greater drop in Hamilton depression scores compared to only 17% of sham-treatment subjects. Similarly, Tormos and associates (119) showed a significant antidepressant response to *fast left* DLPFC stimulation and *slow right* DLPFC stimulation, but not fast right DLPFC stimulation or sham. Slow left stimulation was not administered. Trials of slow TMS over the left DLPFC have also shown promise. Padberg and colleagues (120) randomized 18 nonpsychotic patients to treatment over the left DLPFC using fast, slow, or sham treatments. They showed a statistically significant (but clinically insignificant) response to fast and slow stimulation compared to placebo. In two small studies, George and Nahas demonstrated that lower frequency stimulation (5 Hz) might be more effective at 20 Hz TMS. Patients who were administered 5 Hz rTMS over the left DLPFC had a higher response rate (50% decline in the HDRS) than those administered 5 Hz rTMS over the right DLPFC (6/10 versus 3/10 responders, respectively) and placebo (0/10 responders) (121 ,122). Slow TMS (<1 Hz) has never been associated with seizures or any other adverse consequences in neurologically normal individuals; therefore, it is potentially safer than fast stimulations (114).

There are two basic clinical problems associated with rTMS. First, although half the patients respond to the treatments (defined as a 50% improvement in the HDRS), a much smaller percentage obtains remission (HDRS ≤10). Second, and perhaps of more concern, is the fact that a majority of patients (up to 100% in some studies) relapse in the month after treatment. Both the antidepressant response (M. Szuba, personal communication) and relapse rate (109) are improved by increasing the number of weeks of treatments but, as with ECT, the most severely ill patients may respond partially and relapse quickly. Combination treatment strategies (slow right and fast left) and maintenance rTMS strategies are being employed to improve response and keep patients in remission.

Beyond simply stimulation of the right or left cortex, techniques are being developed to assist in focusing the magnetic impulse on specific cortical structures. The development of new more focal coils and neuroimaging techniques to guide the placement of the rTMS stimulation (123) hold promise on targeting specific brain regions.

Using these techniques, rTMS can help in elucidating the neuronal pathways involved in depression. Initial studies using functional neuroimaging and rTMS have shown that many of the effects of rTMS occur at brain regions distant from the site of stimulation including the caudate, orbitofrontal cortex bilaterally, and cerebellum (124). These studies have also called into question the hypothesis that fast rTMS increases neuronal excitability (125 ,126) and slow rTMS inhibits neuronal firing (127 ,128).

However, it may be possible to determine if rTMS is effective in given individuals by evaluating the functional neuroimaging before and after rTMS stimulation. Speer and associates have shown that patients with hypometabolism on baseline PET scans utilizing [^{18}F]-Fluorodeoxyglucose in the left prefrontal cortex responded preferentially to 2 weeks of fast rTMS (20 Hz) as compared with patients with hypermetabolism who responded at a higher rate to slow (1Hz) rTMS (129). Individual characteristics may be a key factor in determining treatment response.

Vagal nerve stimulation (VNS) is another new and promising treatment for major depression. VNS has been successfully used to treat patients with intractable seizures since 1994 and was noticed to have positive effects on mood that were not simply secondary to the decrease in seizure frequency (130). The VN has both parasympathetic efferent fibers to the heart and GI tract and sensory afferent fibers (approximately 20% and 80% of the fibers, respectively). The afferent fibers connect the nucleus tractus solitarius to the orbital and lateral frontal cortices, and parabrachial nucleus (PN) and locus ceruleus (LC). The fibers passing through the PN/LC (which are adjacent to one another) connect to the hypothalamus and thalamus and, central to the antidepressant properties of VNS, the bed nucleus of the stria terminalis and amygdala. George and associates (131) detail the rationale for the use of VNS in treatment-resistant depression, including these VN afferent connections to the limbic system as well as PET data showing activation of limbic structures (132) and increases in CNS monoamines with VNS (133 ,134 and 135).

The first open trial of VNS by Rush and colleagues included 30 nonpsychotic patients with treatment-resistant unipolar or bipolar depression (136). As in the treatment of epilepsy, the stimulator was attached to the left vagal nerve, which can be accessed peripherally in a procedure similar to implanting a cardiac pacemaker, and compared to the right VN has fewer afferent fibers to the autonomic system controlling cardiac and gastric physiologic functions (137). Twelve of 30 patients (40%) met criteria for treatment response (≥50% decrease in HDRS) and 5 patients had a final HDRS ≤10. None of the patients discontinued treatment because of adverse events. The most common adverse events (which were similar to the AE's in the epilepsy trials) were hoarseness (60%) and throat pain (27%). Ten percent of the patients had abnormal wound healing.

VNS may be an effective treatment in resistant depression. The two variables that predicted clinical response to VNS included previous response to ECT (only one of 19 patients who had received ECT had a sustained response to VNS) and decreased stimulator output. Encouragingly, of the ten responders with available follow-up data over 4 to 9 months, all have demonstrated continued response.

VNS has been shown to be safe in the treatment of over 6,000 patients with epilepsy and may also provide relief to the 10% to 20% of depressed patients who fail or have an inadequate response to available somatic treatments.

The adverse side effect profile and costs could be dramatically reduced if a method of stimulating the VN could be achieved without surgery. The cost of the device and electrodes is $9,200, and the additional cost of the surgical procedure raises the total costs to approximately $12,000 to $25,000 (131). These costs are comparable to what might be expected for acute and 1-year maintenance treatment for ECT; however, insurance coverage may depend on the results of the pending placebo-controlled study and FDA approval for the treatment of depression. VNS is approved for the treatment of epilepsy.

Some researchers have questioned the benefit of electrical stimulation, which does not produce a seizure (138), arguing that subconvulsive seizures in ECT have not been shown to provide any clinical benefit (139). However, the anticonvulsant hypothesis assumes that the beneficial effects from ECT derive not from the convulsion, but the anticonvulsant effects of the seizure. VNS has documented anticonvulsant effects. Slow rTMS dampens neuronal excitability (100) and theoretically may be useful in treating epilepsy (140). There is also research underway at Columbia University using fast rTMS to precipitate a convulsion in animal models to determine the efficacy of TMS seizures in depression. Further investigations using animal models could potentially cause focal convulsions of specific brain regions (e.g., limbic structures) and spare brain sensitive structures that cause side effects but are not integral to the therapeutic effect (e.g., hippocampus). Together rTMS and VNS have the potential of providing valuable insight into the pathophysiology of depression and may potentially add to the treatment of resistant depression.

Current and Emerging Treatments for Acute Mania and Long-Term Prophylaxis for Bipolar Disorder

Paul E. Keck Jr.

Husseini K. Manji

Paul E. Keck, Jr.: Department of Psychiatry, University of Cincinnati College of Medicine, Cincinnati, Ohio.

Husseini K. Manji: Laboratory of Molecular Pathophysiology, National Institute of Mental Health, Bethesda, Maryland.

The range of available medications for the acute treatment of bipolar mania and maintenance treatment of bipolar disorder (BD) has expanded rapidly in recent years. Data regarding medications with established antimanic efficacy are growing and a number of new agents with putative mood-stabilizing properties are under study. These developments are fortunate because recent studies also indicate that the long-term outcome of many patients with BD remains poor (43 ,45 ,100).

Data from randomized, controlled clinical trials supporting the efficacy of lithium, valproate (VPA), carbamazepine (CBZ), and typical antipsychotics as antimanic and mood-stabilizing agents are reviewed in the following. Studies of two other important drug classes under active study for patients with BD, atypical antipsychotics and novel antiepileptics, are also reviewed (62). Finally, the development of signal transduction modifiers and regulators of neuroplasticity and cellular resiliency as truly novel agents for the treatment of BD is discussed.

LITHIUM

Part of "77 - Current and Emerging Treatments for Acute Mania and Long-Term Prophylaxis for Bipolar Disorder "

Acute Mania

Lithium was superior to placebo in the treatment of acute mania in five controlled studies (8 ,31 ,55 ,85 ,93). Only one of these studies utilized a parallel design (8). The remaining four studies were crossover trials of varying duration (31 ,55 ,85 ,93). These crossover studies may have been vulnerable to carry-over, period, and abrupt treatment discontinuation effects, which may have deflated placebo response rates, and contamination of the study blind (16 ,49). In addition, two studies utilized nonrandom assignment (31 ,93). Finally, many of the early landmark lithium studies used diagnostic criteria to define BD that may not be comparable to those of DSM-III-R1 or DSM-IV (2 ,10 ,62). Although Bowden and associates used lithium as an active control (8), data from this parallel-design study are the most methodologically rigorous. In this study, 17 (49%) of 35 lithium-treated patients displayed more than 50% reduction in manic symptoms as measured by the Mania Rating Scale (MRS) total score from the Schedule for Affective Disorders and Schizophrenia (SADS-C) compared with 24% of placebo-treated patients at 3 weeks. The lithium-placebo effect size was a moderate 0.4 (48). Further analysis of data from this study revealed that mania characterized by predominantly elevated or elated mood was associated with lithium response, whereas depressive symptoms during mania and multiple prior affective episodes were associated with poor response to lithium (95 ,96). These findings are similar to those of earlier reports, which found that patients with mixed mania had a lower likelihood of lithium response compared with classic mania (64). In studies in which response of psychotic symptoms was also assessed, lithium also produced significant improvement in these symptoms (8 ,31 ,55 ,93).

Lithium has also been compared with standard antipsychotic agents in nine controlled trials in patients with acute mania (30 ,40 ,75 ,78 ,86 ,87 ,90 ,97). Of these studies, three found lithium to be comparable to chlorpromazine (40 ,90) or haloperidol (86) over treatment intervals ranging from 1 to 3 weeks; four found lithium superior to chlorpromazine (40 ,75 ,87 ,97) or haloperidol (86) over 1 to 5 weeks; and one study found haloperidol plus placebo and haloperidol plus lithium superior to lithium plus placebo after 1 and 2 weeks (30). In the largest and most rigorous study comparing

lithium and a typical antipsychotic in acute bipolar mania, Prien and colleagues (78) assessed the efficacy of lithium versus chlorpromazine in 225 patients divided into “highly active” or “mildly active” groups. In the mildly active group, both medications produced significant and comparable improvement. However, chlorpromazine-treated patients experienced more frequent and severe side effects. In contrast, chlorpromazine produced more rapid reduction in measures of agitation, grandiosity, hostility, and psychotic disorganization than lithium in the highly active group over the first week of treatment. In this latter group, dropouts were higher for lithium (38%) than chlorpromazine (8%). At the end of 3 weeks of treatment, both drugs were significantly and comparably effective.

In summary, the studies reviewed indicate that lithium is superior in efficacy to placebo and comparable or possibly superior to standard antipsychotics for the normalization of affective symptoms in mania. These studies also indicate that lithium exerts antipsychotic effects in patients with psychotic mania. On the other hand, standard antipsychotics appear to have a more rapid onset of action and, therefore, may be more effective initially, especially in severely manic or agitated patients.

Maintenance

The prevention of affective episodes is the essential goal of the maintenance treatment of patients with BD. Double-blind, placebo-controlled studies conducted during the late 1960s and 1970s demonstrated that lithium was superior to placebo in preventing recurrent affective episodes (3 ,19 ,21 ,25 ,27 ,38 ,41 ,67 ,79 ,83 ,92). A recent analysis of six parallel group, placebo-controlled lithium maintenance treatment trials in patients with bipolar I disorder found an odds ratio favoring relapse in patients receiving placebo of 4.1 (95% CI: 2.1, 7.7) at both 6 and 12 months of treatment (49). However, more recent data from five naturalistic long-term studies of patients maintained on lithium for greater than 1 year suggest that a substantial number of patients do not respond adequately to lithium prophylaxis (36 ,56 ,69 ,73 ,81). Baldessarini and Tondo recently reviewed 24 reports on long-term lithium treatment published between 1970 and 1996 and also analyzed its clinical efficacy in 360 patients at a single center who began lithium maintenance monotherapy after 1970 (4). There were no significant differences in lithium response, defined either as percentage of patients displaying more than 50% improvement or percentage episode-free, among patients treated in the 1970s, 1980s, or 1990s. The specific response rates are of clinical interest: Approximately 66% of patients displayed more than 50% improvement and only 33% were episode-free. Not surprisingly, patients with mixed episode, psychotic features or rapid cycling were less treatment responsive. Other studies also found that mixed mania or rapid cycling were associated with a poor lithium response (24 ,64).

VALPROATE

Part of "77 - Current and Emerging Treatments for Acute Mania and Long-Term Prophylaxis for Bipolar Disorder "

Acute Mania

The efficacy of VPA in the treatment of acute bipolar mania was established in six double-blind, randomized controlled trials (8 ,11 ,26 ,28 ,37 ,76). These studies include comparisons of VPA versus placebo in crossover trials (11 ,26) versus placebo in a parallel group trial in lithium-refractory or intolerant patients (76), versus placebo and lithium in a parallel group trial8 and against lithium in two parallel group trials (28 ,37), one of which also compared rapid loaded of divalproex (30 mg/kg per day) with gradual titration (37). Two of these trials led to approval by the United States Food and Drug Administration (USFDA) of divalproex for the treatment of manic episodes associated with BD (8 ,76). In these two studies, response to divalproex as defined by more than 50% reduction in total manic symptoms was comparable, with 53% (76) and 48% (8) of patients responding, respectively. Similarly, among responders in these two studies significant improvement was evident by day 7 and 10 of treatment, respectively, using a gradual divalproex titration schedule beginning with an initial dose of 750 mg per day. Divalproex exerted therapeutic effects on psychotic and manic symptoms in both studies. In the study by Bowden and colleagues (8), all patients with rapid cycling (n = 8) were randomly assigned to divalproex; four (50%) displayed at least 50% improvement on the MRS, which was comparable to the overall response of the divalproex-treated group. This finding is consistent with two other reports from open trials suggesting efficacy of divalproex in patients with rapid cycling (13 ,63). In a subsequent analysis of response according to several definitions of depressive (mixed) mania, Swann and associates found that the presence of even mild depressive symptoms was associated with a poor antimanic response to lithium, but had no significant effect on VPA response (95). Divalproex was well tolerated in this study and significantly more lithium-treated patients dropped out of this trial owing to side effects than patients receiving divalproex or placebo.

VPA and lithium were comparable in efficacy in two other head-to-head comparison trials, although the relatively small sample sizes in these trials makes them vulnerable to a type II error (28 ,37). As in the Bowden and colleagues study (8), Freeman and colleagues also found that the presence of depressive symptoms during mania was associated with a greater likelihood of VPA than lithium response (28). VPA was compared with haloperidol in an open randomized trial in patients with psychotic mania (65). In that study, 36 inpatients with bipolar I disorder in a manic or mixed episode with psychotic features received either divalproex rapid loading (20 mg/kg per day) or haloperidol (0.2 mg/kg per day) for 6 days. Divalproex and haloperidol were equally effective in reducing both manic and psychotic symptoms (8 ,76). The improvement in psychosis

with divalproex treatment was consistent with findings in two other studies and with improvement in manic psychosis produced by lithium in earlier studies (8 ,31 ,55 ,93). Several other studies investigated the efficacy and tolerability of divalproex rapid loading (20 to 30 mg/kg per day) (37 ,46 ,65) and one recent pilot 5-day trial explored intravenous VPA administration (1,200 to 1,800 mg per day) (35). Although all four studies reported rapid improvement (within 3 days) in manic symptoms among responders, only one of these studies was a double-blind, randomized trial (37). In this controlled trial, the study was designed to assess the tolerability of divalproex loading (30 mg/kg per day × 2 days, then 20 mg/kg per day) and was not powered sufficiently to detect differences in efficacy. VPA has also been compared against placebo as adjunctive therapy to standard antipsychotics in acute mania (68). In a multicenter, double-blind, parallel design, 3-week trial conducted in Europe, 136 patients receiving standard antipsychotics were randomized to VPA or placebo. By study termination, significantly more VPA-treated patients displayed a decrease in concomitant antipsychotic treatment. In summary, these studies suggest that VPA has a broad spectrum of efficacy in acute mania, mixed mania, and rapid cycling, and appears to be comparable to lithium and haloperidol in overall antimanic efficacy.

Maintenance

Open maintenance trials of VPA in patients with BD reported that approximately 45% to 50% of patients experienced a recurrent affective episode in follow-up periods ranging from 6 to 24 months (15 ,52 ,82). A randomized, open comparison of lithium and VPA found generally good efficacy for both drugs over an 18-month period (52). Bowden and associates recently reported the results of the largest, prospective, double-blind, randomized maintenance trial of pharmacological treatment in patients with BD using survival analysis to assess time to and rates of relapse (9). In this study, 38% of patients receiving placebo relapsed, compared with 31% on lithium and 24% on divalproex (differences not significant). It is instructive to compare the results of this study with those of the other large maintenance study that compared lithium to placebo (79). In this latter study, 68% of patients receiving placebo relapsed compared with 36% of patients on lithium by 1 year (79). Thus, the drug relapse rates were very similar between studies but the placebo relapse rate was much lower in the Bowden and co-worker study (9). This disparity in placebo relapse rates is probably owing to several factors. First, although both studies standardized enrollment by an index manic episode, it is likely that patients in the Bowden and associates study were less severely ill because only 18% had been hospitalized during the index episode, whereas all patients in the Prien and colleagues study had been hospitalized. Second, the definition of relapse differed between the studies. In the Prien and colleagues study (79), a relapse was an event that required hospitalization or supplemental drug treatment; in the Bowden and associates study (9), it was the occurrence of any affective episode. Finally, the Prien and colleagues study consisted of a more homogeneous sample of lithium responders diagnosed by more conservative diagnostic criteria (80).

As described, many patients with BD have symptomatic or syndromic recurrences on monotherapy with lithium or VPA. The addition of a second mood-stabilizer is a common strategy to enhance maintenance treatment efficacy. Unfortunately, only one controlled trial has examined this approach using the combination of lithium and divalproex in maintenance treatment (89). In this pilot study, 12 patients with bipolar I disorder receiving lithium plasma concentrations (0.8 to 1.0 mEq/L) were randomized to adjunctive maintenance treatment with divalproex (plasma concentrations 50 to 125 mg/L) or placebo and followed for 1 year. Patients who received the combination of lithium and divalproex were significantly less likely to experience a relapse but significantly more likely to suffer at least one moderate or severe adverse event. It is possible that adverse events might be reduced by using doses of lithium and/or divalproex at the lower end of the therapeutic range for each agent.

CARBAMAZEPINE

Part of "77 - Current and Emerging Treatments for Acute Mania and Long-Term Prophylaxis for Bipolar Disorder "

Acute Mania

Although 14 double-blind controlled studies have found CBZ to be effective in the treatment of acute mania, only five of these studies are not confounded by the use of concomitant agents with antimanic effects (reviewed in Keck and associates 1992) (44). In the only placebo-controlled trial, 19 patients were crossed over between CBZ or placebo (5). During CBZ treatment, 63% of patients displayed significant improvement on global nursing measures of mania, depression, anxiety, anger, and psychosis. Relapse typically occurred on placebo.

Two studies compared CBZ with lithium (53 ,88) In the first study, 34 inpatients were randomized to lithium or CBZ for up to 4 weeks (53). Twenty-eight patients (14 per treatment group) completed the study and were included in the data analysis. There were no significant differences in improvement between the two drugs on the BPRS and the Beigel-Murphy Manic State Rating Scale. However, lithium-treated patients showed significantly greater improvement in CGI change scores. In addition, only four (29%) of 14 CBZ-treated patients were considered responders, whereas 11 (79%) of 14 lithium-treated patients responded. In the second lithium comparison study (88) 70% of 52 hospitalized patients randomized to lithium or CBZ dropped out of the trial by 8 weeks owing to lack of efficacy.

Of the study completers, 36% who received CBZ and 37% who received lithium were rated as improved (defined as at least partial remission of manic symptoms). Two studies compared CBZ with chlorpromazine in the treatment of acute mania (34 ,71). In the first comparison trial, 60 acutely manic patients were randomized to either agent in a 6-week trial (71). There were no significant differences in efficacy between the two drugs, with moderate to marked improvement in 70% of the 32 patients treated with CBZ and 60% of 28 patients receiving chlorpromazine. In the second study (34 ,37) patients were randomized to CBZ (*n* = 15) or chlorpromazine (*n* = 19) in a 3-week trial. Response was assessed in 26 patients who completed the trial. Patients treated with CBZ (*n* = 15) or chlorpromazine (*n* = 11) had comparable improvement. In the CBZ group, 67% were rated as displaying at least moderate improvement and 59% for the chlorpromazine group. In summary, data from these five trials suggest that CBZ is superior to placebo and comparable to lithium and chlorpromazine in the treatment of acute bipolar mania.

Maintenance

The efficacy of CBZ in the prevention of recurrent affective episodes has been a matter of controversy (22 ,77). This controversy rests in part on the heterogeneity among the early controlled maintenance studies (22 ,54 ,74 ,101), and the availability of only one placebo-controlled maintenance trial (70). Interpretation of this latter study is also limited by the use of adjunctive rescue medications other than lithium and CBZ to treat breakthrough symptoms. The liberal use of these adjunctive treatments thus limits the degree to which relapse rate can be directly attributed to CBZ or placebo in this study.

Two recent large prospective, double-blind, long-term maintenance studies provide new data comparing the efficacy of CBZ with lithium (23 ,33). In the first study (33), 144 patients were randomized to lithium (*n* = 74; mean ±SD serum level, 0.6 ±1 mEq/L) or CBZ (*n* = 70; mean ±SD) dose, 621 ±186 mg per day) and followed for 2.5 years. Affective relapse, hospitalization, need for supplemental medication, and adverse events requiring treatment discontinuation were used to define treatment failure. Using survival analysis, there were no statistically significant differences between the two treatment groups in time to episode recurrence or hospitalization. However, significantly more patients receiving CBZ required supplemental medications for symptomatic recurrences and experienced adverse events requiring treatment discontinuation. In a secondary analysis of predictors or response, patients with classical features (bipolar I patients without mood-incongruent delusions and comorbidity) had a lower rehospitalization rate with lithium than with CBZ (32). For patients with nonclassical features (mixed states, bipolar II, and NOS) a trend in favor of CBZ was found.

In the second lithium comparison study, 52 outpatients with bipolar I and II disorder were randomly assigned for an initial year of treatment with lithium or CBZ, a crossover to the alternate drug in the second year, followed by a third year on the combination (23). Among evaluable patients, 13 (31%) of 42 lithium-treated patients relapsed within 1 year compared with 13 (37%) of 35 CBZ-treated patients. Seven (24%) of 29 remaining patients relapsed on combination therapy. As in the previous study, a higher percentage of patients receiving CBZ withdrew because of adverse events. The percentage of patients who had moderate or marked improvement on the CGI was not significantly different: 33% on lithium, 31% on CBZ, 55% on the combination; however, on a variety of measures of mania, lithium was more effective than CBZ. Finally, patients with a history of rapid cycling responded significantly better to the combination (56% response) compared with lithium (28%) or CBZ (19%).

STANDARD ANTIPSYCHOTICS

Part of "77 - Current and Emerging Treatments for Acute Mania and Long-Term Prophylaxis for Bipolar Disorder "

Acute Mania

There is one double-blind, placebo-controlled study of a standard antipsychotic in the treatment of acute bipolar mania (50). In that study, 13 patients were randomized to chlorpromazine (1,200 mg per day), imipramine (300 mg per day), or placebo for 7 weeks. Response was assessed using a global scale ranging from -9 to +9. Chlorpromazine was significantly superior to placebo and imipramine on global outcome (6.1 versus 2.0 and -2.8, respectively). Studies comparing standard antipsychotics with lithium, VPA, and CBZ are reviewed in the preceding.

Maintenance

There are no parallel group, double-blind randomized maintenance trials of standard antipsychotics in the maintenance treatment of patients with BD.

ATYPICAL ANTIPSYCHOTICS

Part of "77 - Current and Emerging Treatments for Acute Mania and Long-Term Prophylaxis for Bipolar Disorder "

Clozapine

Acute Mania

No double-blind, randomized controlled trials of clozapine in the treatment of acute bipolar mania have been published. Clozapine has been reported to be an effective antimanic agent in three open-label, prospective studies (6 ,14 ,18). The first two studies evaluated treatment-refractory bipolar patients. In the first (6), 13 (87%) of 15 acutely manic patients who had failed to respond to a minimum 6-week antipsychotic trial of 500 mg per day chlorpromazine-equivalents

in combination with lithium (mean serum level 0.8 mEq/L) were rated as moderate or marked responders to clozapine. In the second study (14), 25 acutely manic patients with bipolar or schizoaffective disorder, all of whom had failed to respond to or tolerate lithium, VPA, or CBZ, and at least two standard antipsychotics, received a 13-week trial of clozapine (mean ±SD, 194 ± 145 mg per day) following a 1-week washout. Eighteen (72%) patients displayed marked improvement on the YMRS and eight (32%) on the BPRS, defined as more than 50% reduction in total score on either scale. Bipolar patients compared with schizoaffective patients, and non-rapid cyclers compared with rapid cyclers, exhibited significantly greater improvement on the BPRS. In the third study (18), 30 hospitalized acutely manic patients were randomized to clozapine (mean 166 mg per day) or chlorpromazine (mean 310 mg per day) in a 3-week trial. Although clozapine-treated patients displayed significantly lower YMRS scores after 2 weeks, there were no significant differences between the two groups at the end of the trial.

Maintenance

There are no randomized double-blind controlled studies of clozapine in the maintenance treatment of BD. Suppes and co-workers randomized 85 patients with DSM-IV criteria for schizoaffective or BD with treatment-refractory illness to add-on clozapine or treatment as usual (94). After 1 year, patients receiving clozapine displayed significant reductions in measures of mania, psychosis, and global improvement compared with patients receiving treatment as usual. In addition, total medication use decreased significantly in the clozapine group. This open-label, randomized trial confirmed earlier reports suggesting that clozapine exerted long-term mood-stabilizing effects in patients with treatment-refractory BD (102).

Olanzapine

Acute Mania

The efficacy of olanzapine in the treatment of acute bipolar mania has been established in three double-blind, controlled trials (7 ,98 ,99). In the first of two placebo-controlled studies, 139 inpatients with bipolar I disorder were randomized to olanzapine (*n* = 70) or placebo (*n* = 69) for up to 3 weeks (99). Olanzapine was begun at 10 mg per day and adjusted by 5-mg per day increments within a range of 5 to 20 mg per day; the median modal dose was 15 mg per day. Concomitant lorazepam up to 4 mg per day was permitted for the first 7 days as needed for agitation; 2 mg per day was permitted for the subsequent 3 days. The olanzapine group displayed significant improvement on the YMRS, CGI-BP severity of mania, and the PANSS total and positive symptom scores compared with the placebo group. Olanzapine also produced a significantly higher response rate (defined as ≥50% improvement in YMRS score) of 49% compared with placebo at 24%. However, olanzapine did not separate from placebo on the YMRS until the third week of treatment.

In the second placebo-controlled trial, 115 bipolar I inpatients were randomized to olanzapine (*n* = 55) or placebo (*n* = 60) for up to 4 weeks (98). This study used a higher initial starting dose of olanzapine, 15 mg per day, and concomitant lorazepam use was further restricted to 2 mg per day for the first 10 days. The olanzapine group again displayed significant improvement on the YMRS, CGI-BP severity of mania, PANSS total and positive symptom scores compared with the placebo group. These differences were evident by week one (the time of the first rating) and sustained throughout the trial. Olanzapine-treated patients also exhibited significantly higher response (65% versus 43%, respectively) and remission (61% versus 36%, respectively) rates than placebo-treated patients. In addition, patients presenting with prominent depressive symptoms during mania (HamD-21 scores ≥ baseline) showed a significant reduction in HamD-21 total scores with olanzapine compared with placebo.

In the third controlled trial, 30 inpatients with acute mania were randomized to olanzapine (*n* = 15) or lithium (*n* = 15) for 4 weeks (7). Olanzapine was administered as a fixed dose of 10 mg per day and lithium at 400 mg BID (mean serum level 0.74 mEq/L). Concomitant lorazepam 4 to 12 mg per day was permitted throughout the 4-week trial. There were no significant differences between the two treatment groups on any of the primary outcome measures—the Mania Scale and BPRS total scores and the CGI improvement scale. However, olanzapine-treated patients displayed significantly greater improvement than lithium-treated patients on the CGI severity scale at the end of 4 weeks of treatment.

Maintenance

There are no controlled trials of olanzapine in the maintenance treatment of BD published to date. In an open-label 52-week extension trial following the initial placebo-controlled acute mania study, none of the 98 patients who participated developed tardive dyskinesia during long-term treatment (99).

Risperidone

Acute Mania

There are two double-blind randomized active comparator studies of risperidone in the treatment of acute bipolar mania (84 ,86). In the first study, 45 inpatients were randomized to risperidone 6 mg per day (*n* = 15), haloperidol 10 mg per day (*n* = 15), or lithium 800 to 1,200 mg per

day (with levels ranging from 0.6 to 1.2 mEq/L) (*n* = 15) for up to 4 weeks (86). There were no significant differences among the three treatment groups in reductions on the YMRS, BPRS, CGI, and GAF from baseline to endpoint (LOCF). In the second trial, 158 inpatients receiving lithium or VPA were randomized to adjunctive therapy with risperidone 1 to 6 mg per day (*n* = 52), haloperidol (*n* = 53), or placebo (*n* = 51) for up to 3 weeks (84). Patients receiving risperidone or haloperidol displayed significantly greater improvement at 1 week, 2 weeks, and at endpoint (LOCF), but not at 3 weeks of treatment on the YMRS compared with patients receiving placebo. There were no significant differences between the risperidone and placebo groups from baseline to endpoint in BPRS and HamD total scores. There are no controlled trials of risperidone in the maintenance treatment of patients with BD.

Ziprasidone

Acute Mania

Ziprasidone has been studied in placebo-controlled trials in the treatment of acute mania in patients with BD and schizoaffective disorder, bipolar type (42 ,47). In a 3-week acute treatment trial of inpatients with bipolar I disorder, manic or mixed, 199 patients were randomized to ziprasidone 80 to 160 mg per day or placebo (42). Ziprasidone produced significant reductions on the Manic Rating Scale (MRS) total score (from the SADS-C) at day two and throughout the remainder of the trial compared with placebo. Based on a ≥50% reduction in MRS total scores, significantly more ziprasidone-treated patients responded (50%) compared with placebo-treated patients (36%). This study confirmed the findings of an earlier study that found that ziprasidone produced significant reductions in manic symptoms compared with placebo in patients with schizoaffective disorder (47). There are no controlled maintenance trials yet published of ziprasidone in BD. Finally, there are no controlled trials of quetiapine in the acute or maintenance treatment of BD.

NEW ANTIEPILEPTICS

Part of "77 - Current and Emerging Treatments for Acute Mania and Long-Term Prophylaxis for Bipolar Disorder "

Four new antiepileptic agents, gabapentin, lamotrigine, topiramate, and tiagabine are being investigated as potential antimanic agents (62). To date, no controlled trials have been reported for topiramate or tiagabine. However, two controlled studies evaluated gabapentin in the treatment of bipolar mania (29 ,72). In the first study, 117 outpatients with bipolar I disorder who displayed breakthrough manic symptoms (defined as a YMRS total score ≥12), whereas on therapeutic doses of lithium, VPA, or the combination, were randomized to adjunctive treatment with gabapentin 600 to 3,600 mg per day (*n* = 55) or placebo (*n* = 59) (72). Patients receiving placebo exhibited significantly greater improvement in YMRS total scores compared with patients receiving gabapentin.

In the second controlled trial, 28 patients with bipolar I (*n* = 13) or bipolar II (*n* = 15) disorder received 6-week crossover trials of gabapentin, lamotrigine, or placebo (29) The reduction in manic symptoms as measured by the CGI-BP was not significantly different among the three treatments. However, manic symptoms were quite low at baseline, raising the possibility that meaningful differences among the three groups might not have been detected. Lamotrigine was also compared with lithium in a 4-week double-blind, randomized trial in 30 inpatients with bipolar I disorder (39). Patients received lithium 800 mg per day or lamotrigine 25 mg per day for the first week, 50 mg per day during the second, then 100 mg per day for the final 2 weeks of the trial. At the conclusion of the study, both agents produced significant reductions in mean Mania Rating Scale, BPRS, and CGI total scores from baseline to endpoint. There were no significant differences between the two treatment groups. The small sample size, low lithium dose, use of as needed lorazepam throughout the trial, and absence of a placebo control group limit the results of this trial.

Lamotrigine is the only new antiepileptic agent studied to date in a randomized controlled trial in the maintenance treatment of bipolar disorder (12). In this study, bipolar I (*n* = 130) and bipolar II (*n* = 52) patients who were stabilized on initial open-label lamotrigine monotherapy were randomized to lamotrigine or placebo in a 26-week prevention trial. There were no significant differences between the lamotrigine and placebo groups in time to drop out for any reason and time to need for additional medication among bipolar I patients. However, in bipolar II patients, treatment with lamotrigine was associated with significantly lower relapse rates on these measures compared with placebo.

THE RATIONAL DEVELOPMENT OF TRULY NOVEL TREATMENTS FOR BD

Part of "77 - Current and Emerging Treatments for Acute Mania and Long-Term Prophylaxis for Bipolar Disorder "

Signal Transduction Modifiers

Although the large number of anticonvulsants and atypical antipsychotic agents in the pharmacopeia has greatly enhanced our ability to treat patients with BD, there is still clearly a real need to develop truly novel agents to adequately treat this devastating illness, and modify the long-term outcome for millions of sufferers. A major impediment in the development of truly novel agents has been the dearth of knowledge pertaining to the underlying pathophysiology of the illness. A true understanding of the pathophysiology of an illness as complex as BD must clearly address its neurobiology at different physiologic levels (i.e., molecular, cellular, systems, and behavioral). Abnormalities in gene expression

undoubtedly underlie the neurobiology of the disorder at the molecular level; this will become evident as we identify the susceptibility and protective genes for BD in the coming years. Once this has been accomplished, however, the even more difficult work must begin to examine the impact of the faulty expression of these gene products (proteins) on integrated cell function. It is at these levels that critical signaling molecules recently have been identified as candidate targets for the development of truly novel agents for the treatment of BD.

Multicomponent, cellular signaling pathways interact at various levels, thereby forming complex signaling networks that allow the cell to receive, process, and respond to information (58). The high degree of complexity generated by these signaling provides neurons with the flexibility to generate the wide range of responses observed in the nervous system. These pathways are undoubtedly involved in regulating such diverse vegetative functions as mood, appetite, and wakefulness, as well as higher cognitive functions—systems that are all affected in BD—and thus represent attractive putative mediators of mood stabilization. Over the last decade, there have been major advances in our understanding of the critical role of the protein kinase C (PKC) signaling pathway as a therapeutically relevant target for the long-term actions of mood stabilizers (57 ,59). The preponderance of the data indicates that chronic lithium attenuates PKC responses and down-regulates specific PKC isozymes (57). Studies in rodents and cultured cells have demonstrated that chronic (but not acute) lithium produces an isozyme-selective reduction in PKC α and ε. Moreover, the structurally highly dissimilar antimanic agent VPA produces strikingly similar effects on the PKC signaling pathway, as does lithium (17 ,57). In view of the pivotal role of the PKC signaling pathway in the regulation of neuronal excitability, and neurotransmitter release (57), it was postulated that the attenuation of PKC activity might play a major role in the antimanic effects of lithium and VPA. There is currently only one relatively selective PKC inhibitor available for human use—tamoxifen (20). Tamoxifen, a synthetic nonsteroidal antiestrogen, is also a potent PKC inhibitor at therapeutically relevant concentrations (20). Therefore, a pilot study was initiated to investigate the efficacy of tamoxifen in the treatment of acute mania, and it was found that tamoxifen did indeed possess antimanic activity (57 ,58). Clearly, the results have to be considered preliminary owing to the small sample size thus far. Nevertheless, the significant (and in some cases rapid and striking) results that have observed are intriguing. In view of the preliminary data suggesting the involvement of the PKC signaling system in the pathophysiology of BD (17 ,57), these results suggest that PKC inhibitors may be very useful agents in the treatment of BD. Larger, double-blind placebo-controlled studies of tamoxifen and novel selective PKC inhibitors in the treatment of mania are clearly warranted.

In recent years, a hitherto completely unexpected target for the action of lithium has been identified. Klein and Melton (51) were the first to demonstrate that lithium, at therapeutically relevant concentrations, inhibits glycogen synthase kinase 3B (GSK3B). GSK3B is now known to play a critical role in the CNS, by regulating various cytoskeletal processes, synaptic plasticity, and long-term gene expression (51 ,59). Interestingly, VPA (but not CBZ) also concentration-dependently inhibits GSK-3B *in vitro*, with significant effects observed at concentrations of VPA similar to those attained clinically (17 ,60). Most recently, it has been demonstrated that the chronic (3- to 4-week) administration of lithium and VPA also increase B-catenin levels in rodent brain (Chen and Manji, unpublished observations), compatible with inhibition of GSK3B during chronic *in vivo* administration of the agents under therapeutic paradigms. Overall, GSK-3B appears to play a critical role in regulating neuroplastic events in the CNS, and there is considerable excitement about the possibility of developing novel GSK-3B modulators as potential new therapeutics for both BD and neurodegenerative diseases (60).

NEUROTROPHIC AND NEUROPROTECTIVE AGENTS FOR THE OPTIMAL LONG-TERM TREATMENT OF BD

Part of "77 - Current and Emerging Treatments for Acute Mania and Long-Term Prophylaxis for Bipolar Disorder "

Recent studies investigating potential structural brain changes in mood disorders have demonstrated reductions in regional CNS volume and cell numbers (both neurons and glia) in many patients (61). It is thus noteworthy that lithium and VPA have recently been demonstrated to robustly increase the expression of the cytoprotective protein bcl-2 in the CNS (59 ,61). Chronic lithium not only exerts neuroprotective effects in several preclinical paradigms, but also enhances hippocampal neurogenesis (61). VPA robustly promotes neurite outgrowth and activates the ERK MAP kinase pathway, a signaling pathway utilized by many endogenous neurotrophic factors (61). Consistent with its preclinical neurotrophic/neuroprotective effects, chronic lithium treatment of patients with BD increases brain N-acetylaspartate (NAA, a putative marker of neuronal viability and function) levels, effects that are localized almost exclusively to gray matter (61). To determine if lithium was producing neuropil increases, quantitative three-dimensional MRI studies were undertaken that revealed that chronic lithium significantly increases total gray matter volume in the human brain of patients with BD (61). The evidence demonstrating the neurotrophic effects of lithium, VPA, and antidepressants, the enhancement of hippocampal neurogenesis in the adult mammalian brain, as well as the growing appreciation that mood disorders are associated with cell loss and atrophy, suggest that these effects may be very relevant for the long-term treatment of mood disorders. It is perhaps useful to conceptualize the cell death and atrophy that occurs in mood disorders as arising from an impairment

of “cellular resiliency.” In this context, it is noteworthy that a variety of strategies to enhance cellular resiliency via effects on molecules involved in cell survival and cell death pathways are currently under investigation.

CONCLUDING REMARKS

Part of "77 - Current and Emerging Treatments for Acute Mania and Long-Term Prophylaxis for Bipolar Disorder "

The growing body of data implicating signaling pathways in the pathophysiology and treatment of BD suggests that compounds with potent effects distal to the receptor may represent truly novel treatments for BD. The rapid technologic advances in molecular and cellular biology have greatly enhanced our ability to understand the complexities of the regulation of neuronal function; these advances are leading to an increasing number of avenues to modulate transmembrane signaling pathways, and hold much promise for the development of truly novel and improved therapeutics. Emerging results from a variety of clinical and preclinical experimental and naturalistic paradigms also suggest that optimal long-term treatment of BD may only be achieved by the early use of agents with neurotrophic/neuroprotective effects, irrespective of the primary, symptomatic treatment. The development of new treatments that regulate molecules involved in cell survival and cell death pathways, such as CREB, BDNF, Bcl-2, and MAP kinases remains an exciting prospect for the future.

Cost-Effectiveness of the Newer Generation of Antidepressants

Scott W. Woods

C. Bruce Baker

Scott W. Woods and C. Bruce Baker: Department of Psychiatry, Yale University School of Medicine, New Haven, Connecticut.

In the last decade or so, several new antidepressants have been introduced into practice, including the selective serotonin reuptake inhibitors fluoxetine (1987), sertraline (1991), paroxetine (1992), and citalopram (1998), in addition to bupropion (1985), venlafaxine (1993), nefazodone (1994), and mirtazapine (1996). Two of these medications are available in delayed-release formulations: bupropion SR (1996) and venlafaxine XR (1997). Only one of these medications is currently available in a generic formulation (bupropion, 1999).

Each of these medications is more expensive in terms of acquisition costs than the older generation of tricyclics and heterocyclics and monoamine oxidase inhibitors. Together, the newer generations of antidepressants accounted for approximately $7.7 billion in retail sales in the United States in 1999 (1), and antidepressants are second only to antibiotics in prescription sales by drug category.

Prices are of course subject to variation, but Table 78.1 shows that the "average wholesale price" for most of these medications is more than $2 per day, according to the 2000 Drug Topics "Red Book" (2). Actual costs to health care systems or patients can be substantially lower or higher than the figures in Table 78.1 would indicate, depending on a number of factors. Certain health care systems are able to qualify for discounted prices for certain medications, and patients can sometimes receive medications free of charge via physician samples or indigent care programs. Acquisition costs are also lowered by patient noncompliance. In addition, some of the newer antidepressants are available as scored tablets (Table 78.1), so that patients taking lower doses have the opportunity to reduce costs substantially with only the modest inconvenience entailed by breaking the pills. However, higher doses of some medications lead to higher acquisition costs when more than one pill is required for a particular dose. Regardless of these caveats, it is clear that the newer generation of antidepressants is more expensive to purchase than are the older generations.

Antidepressant	Strength (mg)	Dosing	Average Wholesale Price ($)[a]	
			Brand	Generic
Fluoxetine	10[b]	QD	76.60	NA
	20		73.14	
	40		158.45	
Sertraline	25[b]	QD	65.99	NA
	50[b]		66.50	
	100[b]		67.73	
Paroxetine	10	QD	66.95	NA
	20[b]		56.97	
	30		71.95	
	40		76.00	
Citalopram	20[b]	QD	60.51	NA
	40[b]		63.14	
Bupropion	75	TID	65.97	64.87
	100		74.30	86.54
Bupropion SR	100	BID	85.51	NA
	150		91.64	
Venlafaxine	25[b]	BID/TID	70.00/104.99	NA
	37.5[b]		69.72/104.58	
	50[b]		74.24/111.36	
	75[b]		78.71/118.07	
	100[b]		83.43/125.14	
Venlafaxine XR	37.5	QD	62.18	NA
	75		69.65	
	150		75.86	
Nefazodone	50	BID	74.11	NA
	100[b]		74.00	
	150[b]		74.00	
	200		74.11	
	250		74.00	
Mirtazapine	15[b]	QD	69.72	NA
	30[b]		71.83	
	45		76.50	

BID, twice daily; NA, not applicable; QD, daily; TID, three times daily.
[a]Least expensive price across suppliers, including repackaging houses. For QD dosing, the lowest cost for 30 pills was used, and 60 pills for BID dosing and 90 pills for TID dosing. When few or no suppliers offered lots of 30, 60, or 90 pills, the lowest-price 100-pill lot was multiplied by 0.3, 0.6, or 0.9, respectively, or the lowest-price 30-pill lot was multiplied by 2 or 3, respectively, whichever was lower. Unit dosing price excluded.
[b]Scored.

TABLE 78.1. AVERAGE WHOLESALE PRICE FOR A 30-DAY SUPPLY OF NEWER ANTIDEPRESSANTS

Given their higher acquisition costs, it is important to determine whether these new, more expensive medications are cost-effective as first-line treatment in comparison with the older, less expensive antidepressants. In other words, in lay terms, are the newer medications worth the prices charged? Despite their higher acquisition costs, the newer antidepressants could be more cost-effective if they resulted in greater increases in quality of life and functioning, or in a reduction of the nonmedication costs of illness in comparison with the older antidepressants sufficient to offset their higher acquisition costs.

The impairments in quality of life and functioning and the nonmedication treatment costs associated with depression are large, and any improvements in these areas achieved with the newer antidepressants would clearly offset their higher purchase price. The World Health Organization has calculated that depression was the fourth leading cause of disease burden throughout the world in 1990, and projected that it would be the second leading cause by 2020 (3). The costs of depression to society as a result of productivity lost because of morbidity and mortality have been estimated at $14.2 billion (in 1980) (4) and $31.3 billion (in 1990) (5) in the United States. Moreover, direct treatment costs for depression, exclusive of medication acquisition costs, have been estimated at $2.0 billion (in 1980) (4) and $11.2 billion (in 1990) (5) in the United States. Most of these costs were related to hospitalization. The better tolerability of the newer versus the older antidepressants might well lead to reductions in these expensive treatment services.

A formal determination of whether the higher acquisition price of the newer antidepressants relative to the older antidepressants is offset by savings in other areas or increased benefits is traditionally conducted with a cost-effectiveness

analysis. Cost-effectiveness is represented as a ratio between direct costs, the numerator, and changes in health status, the denominator. The relative cost-effectiveness of newer versus older antidepressants is represented as the incremental or marginal difference between the cost-effectiveness ratios determined for the newer and older antidepressants.

A cost-effectiveness model depends on many parameters, such as the effectiveness of alternative initial treatments, effectiveness of switching to secondary treatments, postulated lengths of treatment, and costs and health effects included.

The following are the major potential categories of costs and health effects (6). Direct costs are the resources consumed in providing the intervention, in this case the treatment of depression, which includes dealing with side effects and other consequences. Direct costs are further subdivided into four major categories. The first category encompasses changes in the use of health care resources (e.g., the costs of medication acquisition, physicians and other personnel, laboratory and other services, and the appropriately apportioned capital costs of buildings and equipment). The second category of direct costs encompasses changes in the use of other resources (e.g., transportation costs). The final two categories encompass changes in the use of informal caregiver time and in the use of patient time for treatment.

Health effects are divided into two major categories. In

the first category, the intrinsic value of changes in health status, a value is placed on achieving or avoiding a specific health state. The health state may be characterized by using a single domain or multiple domains (e.g., changes in clinical status, functioning, and quality of life). The outcomes measured in any one of these domains can be intermediate (e.g., changes in the Hamilton Depression Scale) or distant (e.g., years of life gained). In practice, when intermediate outcomes are used, the health state and cost-effectiveness ratio is sometimes denoted simply in the native units of a single domain (e.g., cost per patient remitted from depression), and value weights are not assigned. In fuller analyses, weights are assigned to the benefits, and the weights are denominated in more comprehensive generic units that can be compared and combined across domains. The most common generic unit is the quality-adjusted life year (QALY).

The second category major category of health effects, indirect costs or productivity effects, refers to resource consumption attributable to changes in productivity caused by changes in morbidity or mortality.

In the most comprehensive cost-effectiveness analysis, these cost and health effects categories are applied to all sectors of health care, even if the specific intervention falls within a limited sector (e.g., treatment of depression within the mental health specialty sector). In more limited analyses, the categories are applied only in the specialty sector.

We should note that *costs* are not the same thing as *prices*. From an economic perspective, the term *costs* refers to the value of the resources consumed in providing/producing a service such as treatment of depression, most ideally calculated in terms of the consumed resources next-best use. The many types of *prices* that can be assigned to resources, and which are used in most studies, may or may not reflect the economic value of the resources consumed.

The conclusions suggested by any given cost-effectiveness analysis depend heavily on each of the factors we have listed: overall structure of the model, cost categories and specific cost values used, health effects categories, method of measuring health effects, and weights assigned to outcomes. The conclusions of the analysis also depend on its perspective—that is, for whom is the treatment cost-effective? The perspective determines which costs, benefits, and outcomes are potentially relevant and what weights are appropriate. Clarity about perspective is critical because in most contexts, various combinations of cost and benefits are borne by or accrue to different entities. For example, in a highly simplified and hypothetical case, if an HMO pays for prescriptions completely, and if the choice of a particular antidepressant results in higher total expenditures for drug purchase but allows patients to be less dependent on family members, the cost is borne by the HMO but the benefit is gained by the patient's family. In this case, the antidepressant might be cost-effective from the perspective of the patient's family or even from the broader perspective of society, but not from the perspective of the HMO.

Some of the perspectives commonly discussed or used include the following: patient or patient/family, employer/payer, individual health care institution (e.g., an HMO), national health care specialty sector (e.g., specialty mental health), national health care comprehensive system (i.e., including all health care sectors), and global societal (i.e., including *all* costs and *all* health effects) perspectives.

In considering whether the available studies suggest that newer antidepressants are cost-effective, we will limit ourselves to addressing the question from the two perspectives most commonly used in studies. First, we ask, "Are newer antidepressants cost-effective as first-line treatment from a health care system perspective?" In addressing this question with evidence from the available studies, one must appreciate that the studies to be reviewed have utilized multiple conceptualizations of cost-effectiveness. Some studies implicitly or explicitly assume equal effectiveness of newer and older antidepressants and ask whether the first-line use of newer antidepressants produces savings to the health care system in the direct treatment, nonmedication costs of treating depression that are sufficient to offset total direct treatment costs. Others model or measure clinical benefit and calculate average or incremental cost-effectiveness ratios. We report the authors' conclusions and discuss the limitations in design and methods. Most of the evidence regarding this first question is based on the perspective of a national health care comprehensive system, not merely of a mental health sector; consequently, the health care system perspective we address refers to all of health care, not just mental health care.

Second, we ask, "Are newer antidepressants cost-effective as first-line treatment from a global societal perspective?" Again, we review studies that utilize multiple conceptualizations of cost-effectiveness from this general perspective.

We also examine studies reporting relative rates of cost-effectiveness of the newer antidepressants.

To address our two major questions, we reviewed the recently published (July 1, 1995 to June 30, 2000) literature in English on antidepressants and cost analysis, focusing particularly on the newer antidepressants and updating our previous review (7). Relevant publications were identified by a search of Medline, Current Contents, and HealthSTAR computer databases and by manual bibliographic review. Studies available only as abstracts were not included. Other reviews of this topic have also been published recently (8 ,9 ,10 ,11 ,12 ,13 and 14).

The evidence most centrally relevant to the cost-effectiveness of antidepressants comes from studies that can be grouped into four methodologies: efficacy study metaanalyses, cost-effectiveness simulations, retrospective analysis of administrative databases, and prospective cost-effectiveness experiments. We review the data from each of these in turn. We also review briefly the data on whether a decrease in deaths from suicide is a benefit that favors the newer antidepressants.

EFFICACY AND TOLERABILITY METAANALYSES

Efficacy and tolerability studies provide information on expected percentages of responders and dropouts, which are central parameters in cost-effectiveness calculations, in addition to information on side effect burden. Cost-effectiveness simulations (see next section) often use data from efficacy metaanalyses.

Numerous metaanalyses of randomized short-term trials of selective serotonin reuptake inhibitors (SSRIs) versus tricyclic antidepressants (TCAs) are now available (Table 78.2), as are several metaanalyses of trials comparing non-SSRI newer antidepressants with older, control antidepressants (Table 78.3). These metaanalyses include several monumental efforts with careful attention to the unbiased inclusion of studies and minimization of publication bias. To simplify the presentation, Table 78.2 shows the original authors' conclusions about the identified principal efficacy and tolerability measures. These authors often considered treatment continuation as an efficacy measure, and treatment discontinuation for side effects as a tolerability measure. A metaanalysis of placebo-controlled comparisons in 49 studies from 1966 through 1995 that included an investigational antidepressant and a reference antidepressant (15) and two other metaanalyses (16 ,17) are not included in Table 78.2 because it is not clear whether the reported effect sizes for TCAs and SSRIs are restricted to the trials internally comparing TCAs with SSRIs. The results of the metaanalyses in Table 78.2 are remarkably consistent. Perhaps the consistency is not surprising given that the articles report on highly overlapping sets of clinical trials. The metaanalyses almost uniformly conclude that these two classes of antidepressant are quite similar in regard to efficacy. Only one analysis found evidence of greater efficacy for the SSRIs in comparison with a subgroup of older TCAs; another found

evidence for greater efficacy of TCAs when attention was restricted to inpatients, and the other eight metaanalyses reported similar efficacy for TCAs and SSRIs.

[d]Includes venlafaxine, mirtazapine, and milnacipran.

TABLE 78.3. METAANALYSES OF STUDIES COMPARING NON-SSRI NEWER ANTIDEPRESSANTS WITH OLDER CONTROL ANTIDEPRESSANTS FOR MAJOR DEPRESSION

The metaanalyses also conclude almost uniformly that the SSRIs have a small but consistent tolerability advantage over the TCAs in these short-term randomized trials. Nine of ten studies investigating tolerability found evidence of greater tolerability for the newer agents, but in general, the magnitude of the effect was relatively small. For example, dropout rates attributed to side effects were 15.4% versus 18.8% (18), 14.9% versus 19.0% (19), and 14.4% versus 18.8% (20) for SSRIs versus TCAs in three of the early metaanalyses.

The small size of the SSRI acceptability advantage in the efficacy studies is surprising, given the widespread entry of the SSRIs into clinical practice. Studies of antidepressant use in naturalistic practice often find a more pronounced tolerability advantage (21 ,22 ,23 ,24 ,25 and 26). Alternative explanations for this discrepancy are possible. Studies suggest that patients who enroll in randomized trials may differ from the general clinical population (27 ,28), and it is possible that patients who enroll in clinical trials are more tolerant of side effects than average. On the other hand, because these naturalistic studies are not double-blinded, patients in clinical practice could be influenced by expectancy effects.

COST-EFFECTIVENESS SIMULATIONS

Part of "78 - Cost-Effectiveness of the Newer Generation of Antidepressants "

Cost-effectiveness simulations most commonly construct mathematical models of clinical practice based on decision analysis. Usually, pathways of branching alternative treatment options and outcomes are created. Costs, probabilities, and in some cases value weights or utilities for outcomes are assigned to the alternatives. Typically, the values for these parameters are derived from metaanalyses, literature reviews, administrative databases, or expert panels. In addition to medication acquisition costs, these models can include any subset of the costs we defined above.

A substantial number of simulations have been published. Table 78.4 shows data from 19 published simulations comparing SSRIs with older control antidepressants. Table 78.5 shows data from nine simulations comparing newer non-SSRI antidepressants with controls. For each study, Table 78.4 and Table 78.5 show the medications compared, duration of the simulation, authors' apparent principal cost-effectiveness outcomes, authors' conclusions about relative cost-effectiveness, and a brief summary of methodologic limitations. Two additional mirtazapine simulations from U.K. and Swedish health care system perspectives are described in a review (11). Results were similar to those of the French and Austrian simulations (Table 78.4 and Table 78.5).

Legend: see Table 78.4.

TABLE 78.5. COST-EFFECTIVENESS SIMULATION STUDIES COMPARING NEWER NON-SSRI WITH CONTROL ANTIDEPRESSANTS

A simple “vote counting” across studies in Table 78.4 shows that most of the simulations concluded that SSRIs are more cost-effective than TCAs (10 favor SSRIs, six favor TCAs, and two are ties). Table 78.5 shows that eight of nine simulations favor the cost-effectiveness of newer non-SSRI antidepressants over older agents. Simple vote counting is problematic because it ignores numerous methodologic limitations of the individual studies. At least equally as problematic is the fact that the methodologic problems may far exceed those that are apparent; often, the published models are not “transparent,” meaning that they fail to specify

clearly the inputs to the model and exactly how the computations were made. This is critical because, as we noted above, the results of any simulation are depend entirely on the many details of the model. When these details are not stated, it is not possible for the reader independently to look for errors in critical assumptions or independently to conduct “sensitivity analyses” of the values of input parameters to evaluate the resulting impact on the models’ conclusions.

Other concerns arise about the simulations as a consequence of their sensitivity analyses. Generally, these studies report that results are not sensitive to any of the variations that they show in inputs. This raises concerns because if a simulation is properly designed, and if it contains no calculation errors, it ought to be sensitive to at least extreme variations in some inputs. One approach is to show what input values would be required for the medications to “break even” (29). The reader can then come to an opinion about whether the break-even inputs are reasonable possibilities or not.

The input values required to reverse the cost-effectiveness conclusion may be unreasonably high or low, but demonstration that the model is sensitive to input variation increases confidence in the integrity of the model and in the reported lack of sensitivity to less extreme variations. For example, if it is not possible to demonstrate the cost-effectiveness of TCAs when the acquisition cost of SSRIs is increased 1,000-fold, something is wrong with the model. In many of the decision analytic simulations concluding that the newer antidepressants are more cost-effective (30 ,31 ,32 and 33), the design and assumptions were very similar to those in an early model of SSRIs versus TCAs (34 ,35). This simulation was reported very explicitly and so is transparent and could be replicated by others. When the model was replicated, a design flaw was discovered and unrealistic assumptions were identified that drove the results (29). Correction of the design flaw and substitution of longer treatment lengths recommended by practice guidelines reversed the findings and yielded a cost-effectiveness advantage in favor of the TCAs. These same corrections could be applied to the other simulations that depended on the early example. The Australian Pharmaceutical Benefits Scheme reported similar significant problems with 67% of the pharmacoeconomic simulations it received in support of efforts to meet regulatory requirements for registration of new drugs in that country (36).

This limitation of short time horizons for the simulations is relatively common in the studies shown in Table 78.4 and Table 78.5 . In general, the longer treatment with antidepressants is continued, the less cost-effective the newer antidepressants as first-line treatment are likely to be. A longer treatment period progressively increases the medication acquisition costs associated with newer antidepressants. By contrast, much of the greater cost of treatment delivery of the older drugs is expended early in treatment, in visits for dose titration and management of side effects. Longer treatment periods progressively dilute this early cost over time. Of the only two simulations in which sensitivity analysis of treatment length was performed (29 ,37), both showed cost-effectiveness advantages for the inexpensive drug as length of treatment length increased, and one simulation utilizing intermediate treatment lengths favored the TCAs (38).

Given the subtle but powerful effect of the many details of cost-effectiveness simulations, many have expressed concern that these simulations may harbor critical biases that are difficult to expose. For example, one leading journal has taken the stance that cost-effectiveness simulations are more vulnerable to conflict of interest than other types of research, and it declines to publish any cost-effectiveness simulations (39).

In this regard, it may be noted that all the 15 simulations funded by industry shown in Tables 78.4 and 78.5 reported their own products to be more cost-effective than older control antidepressants. Of the studies sponsored by companies manufacturing newer non-SSRI antidepressants, four of six found the SSRIs to be less cost-effective than or tied with older antidepressants, and four of six found their own products to be more cost-effective than SSRIs. In both of the two studies funded by government, the SSRIs were less cost-effective than the TCAs when provisions were made for patients intolerant to TCAs to switch. The source of funding was not identified in three studies.

RETROSPECTIVE ANALYSES OF ADMINISTRATIVE DATABASES

Retrospective administrative database studies are a source of data on antidepressant costs and efficacy in actual clinical practices. In these studies, computerized pharmacy and service utilization records are used to analyze cost outcomes as a function of clinical assignment to antidepressant. Retrospective studies are less expensive than prospective trials and can be conducted more quickly. However, they are much more vulnerable to questions about the interpretation of results for several reasons. These studies are vulnerable to “selection bias.” Patients are not randomly assigned to treatment; therefore, it is likely that the constructed groups may not be comparable in some important way at baseline. They are also vulnerable to “cohort effects.” The retrospective groups may be drawn from different time frames. Apparent differences between treatments may in fact be a consequence of changing trends in practice over time (40).

Database studies generally lack any direct measure of clinical outcome. As a result, they generally assume a worst case of equivalent outcomes for the newer antidepressants and the older antidepressants and then defined the more cost-effective care as the treatment associated with lower overall costs of health care. A newer antidepressant can be

associated with lower overall costs of health care if the higher acquisition costs are more than offset by lower costs for other services. This type of cost-effectiveness analysis is known as *cost minimization*.

A few of the administrative database studies have constructed proxy outcome measures based on pharmacy refill data, such as "number of prescriptions refilled" (41). For example, one study used pharmacy claims to determine the duration of antidepressant treatment and then held that longer care is likely to be more beneficial. This study found fluoxetine to be associated with longer continuation on medication and costs similar to those of the comparison groups. The authors concluded that fluoxetine is cost-effective because adherence to treatment guidelines is better with no increment in cost. Other retrospective analyses have reported similar natural course of therapy findings but base a judgment of cost-effectiveness on finding a reduction in overall "depression-related" health care costs (42 ,43).

We briefly review the designs and results of available retrospective administrative database studies in Table 78.6 , Table 78.7 , and Table 78.8 . Table 78.6 lists studies comparing SSRIs with older antidepressants. Table 78.7 lists studies making comparisons among SSRIs, and Table 78.8 presents one study comparing a newer non-SSRI with control antidepressants. These tables indicate for each study the sample size in the administrative database, the time interval over which data were sampled, the type of patient population, the newer and control antidepressants analyzed, the stated principal economic outcome measure, the overall results on that outcome measure as interpreted by the authors, and a brief discussion of methodologic limitations. One small pilot study is not included in Table 78.6 (44), and a published retrospective database study not included in Table 78.6 reportedly found fluoxetine to be cost-effective in comparison with TCAs (Skaer et al., 1996; cited in ref. 12).

TABLE 78.8. RETROSPECTIVE COST-EFFECTIVENESS ANALYSES OF ADMINISTRATIVE DATABASES: NON-SSRIs VERSUS CONTROL ANTIDEPRESSANTS

Simple vote counting across the studies in Table 78.6 shows that the majority have concluded that SSRIs are more cost-effective than TCAs (seven favor at least one of the studied SSRIs, none favor TCAs, and five are ties). Again, simple vote counting is unsatisfactory because these studies are subject to numerous methodologic limitations.

The most important limitation of the studies in Table 78.6 is a possible cohort effect; the distribution of starts of different antidepressants may have changed during the study interval (40 ,45). During this time period, important influences on clinical practice totally unrelated to which antidepressant was used may have changed, so that the influence of starts on one type of antidepressant versus another may have been confounded with the effect of changes in clinical influences. For example, during the period encompassed by the first study in Table 78.6 , fluoxetine progressively gained market share, while at the same time health care organizations independently reduced expenditures through tighter management. Thus, a higher proportion of TCA starts may have occurred early in the study period, when care was not so firmly managed, and a higher proportion of fluoxetine starts may have occurred later in the study period, when visits and hospitalizations were more carefully scrutinized. Thus, cost savings in later years could erroneously be attributed to fluoxetine that are really a consequence of tighter management. The distribution of fluoxetine and TCA starts within the study period was not reported.

In relation to the problem of cohort effects, recent studies have included time of the antidepressant start within the study interval as an explanatory variable in the analysis, but they appear to have restricted attention primarily to its effect on initial selection of antidepressant. No study presents data indicating whether health care costs associated with antidepressant starts were increasing or decreasing during the study interval, or how a secular cost trend, if present, may have interacted with the distribution of starts of individual antidepressants during the study interval.

Other important limitations in the studies in Table 78.6 include a tendency not to adjust the analysis for baseline costs in some of them.

Table 78.7 shows the results of administrative database studies comparing cost-effectiveness among SSRIs. The first three studies, which sampled data from 1989 to 1994, found fluoxetine to be more cost-effective than sertraline or more cost-effective than sertraline and paroxetine. A type of selection bias that has been termed *launch bias* may have affected these findings (46). The time frames of these studies overlapped with the first year or two after launch of sertraline and paroxetine. It is possible that a new antidepressant is prescribed for a different type of patient in the early years after its launch than after it has been on the market for several years. Patients selected by their physicians to receive a brand-new antidepressant may generally be more severely ill than other patients. Recent analyses have attempted to control for initial severity. However, another possibility is that patients selected by their prescribers to receive a brand-new antidepressant may on average have been more resistant to previous treatment than other patients. Because treatment resistance correlates only partially with severity, adjustment for severity of illness may only partially correct a launch bias effect driven by treatment resistance. Most studies attempting to control for previous treatment eliminate patients who received antidepressants in the 4 to 6 months before the start of the index antidepressant. Although this exclusion is somewhat reassuring, it still does not prevent patients from being included in the analysis who were taking an antidepressant at the start of the study interval, then stopped antidepressant therapy for 4 to 6 months, perhaps because of ineffectiveness, then started a different, recently launched antidepressant identified as the index. Such patients would be predicted to be relatively unlikely to respond to treatment and relatively likely to incur treatment costs subsequent to the antidepressant start. To the extent that

such patients are included in an analysis, a launch bias may exist that is unfavorable to the second antidepressant.

In the first study in Table 78.7 , the sample was restricted to DSM-IV 296.2 “single-episode” depressed patients. This restriction was intended to reduce the possibility of a selection bias if the patients chosen to receive the newest medications were more refractory as a group than patients chosen to receive more established medications. This possibility may still have influenced the analysis because in subsequent studies, it was found that some patients with “single-episode” depression had had previous episodes that were treated with antidepressants (42 ,43).

The fourth study in Table 78.7 is consistent with a launch bias interpretation of the three earlier studies. In this study, the time horizon (1995 through 1996) was 3 to 4 years after the launch of sertraline and paroxetine. This study found the three SSRIs to be equally cost-effective. Limited retrospective data suggest that venlafaxine and other newer non-SSRI antidepressants are similar to SSRIs and TCAs in cost-effectiveness (Table 78.8).

The retrospective database method may be especially vulnerable to publication bias. Because the retrospective studies are inexpensive in comparison with prospective trials, and because the number of potential study sites is large, the possibility is greater with retrospective studies that multiple analyses are conducted but only a limited number published.

PROSPECTIVE COST-EFFECTIVENESS TRIALS

Part of "78 - Cost-Effectiveness of the Newer Generation of Antidepressants "

Prospective randomized cost-effectiveness experiments offer a potential “gold standard” methodology for investigating cost-effectiveness because of the internal validity arising from the randomization. In addition, they directly collect data on both outcomes and costs. The randomization permits the investigator to ascribe any observed differences in cost-effectiveness among treatment groups to the treatment itself and not to unmeasured baseline differences among the groups. The major difficulty with prospective randomized cost-effectiveness experiments, in addition to their expense and the time required to complete them, is the question of external validity. Are the patients who consent to random assignment representative of the entire group of patients in routine practice, or are they different in some important way? Relatively little attention has been paid to this issue in depression research, although in one study, the patients participating in a randomized trial of depression had significantly fewer comorbid diagnoses than did excluded patients and were more likely to have a single episode of depression (27).

At present, only two prospective pharmacoeconomic studies examining the cost-effectiveness of newer antidepressant treatment have been published. The initial report from the first study included data up to 6 months after randomization (4). Patients were followed for 2 years after randomization, and the long-term data were reported recently (26). Patients were enrolled from participating primary care clinics in a large HMO in the United States. Patient out-of-pocket copayment prescription expenses were waived. Patient identification depended on primary care physician referral. Physicians were asked to refer patients whom they were starting on an antidepressant for depression when both patient and physician were willing to consider random assignment. Of 621 patients referred, 579 (93%) were eligible, and 536 (93%) consented and were randomized. At baseline, 67% of randomized patients met DSM-III-R criteria for major depression; the remainder met criteria for either minor depression or dysthymia. The average score on the Hamilton Depression Scale at baseline was below 14. Patients were randomly assigned to receive fluoxetine (*N* = 173) or the commonly prescribed TCAs imipramine (*N* = 182) or desipramine (*N* = 181). After randomization, the patients were free to switch antidepressants. Evaluators but not patients or prescribing physicians were blinded to the initial treatment assignment. Randomized patients were evaluated at baseline and at 1, 3, 6, 9, 12, 18, and 24 months with measures of symptoms, quality of life, and service utilization.

At the 6-month follow-up, the proportion of patients continuing on the original antidepressant was nearly 60%

for fluoxetine, less than 40% for imipramine, and approximately 30% for desipramine. At the 24-month follow-up, the proportion of patients continuing on the original antidepressant was roughly 35% for fluoxetine and 10% to 15% for imipramine and desipramine. These data suggest a substantial acceptability advantage for the SSRI over the TCAs, at least when patients and prescribers are aware of the identity of the medication. However, the proportion of patients continuing to take any antidepressant medication was approximately equal at 6 months and at all the subsequent evaluations for the three groups. These data suggest that patients who find TCAs unacceptable generally agree to treatment with a second medication. Rates of symptoms and quality of life showed similar improvement at all time points, although some evidence was found at or near the trend level for the fluoxetine group to be slightly more improved at the 1-month time point only. These data indicate that the clinical outcomes in actual practice are essentially equivalent whether patients are initially assigned to an SSRI or a TCA. If average improvement is slightly faster when an SSRI is the initial choice, perhaps because fewer patients switch and start over, any difference is no longer apparent at 3 months or thereafter.

Among patients remaining on the initial antidepressant at 1 month, adverse effects were significantly lower in the group assigned to fluoxetine. The method of measurement of adverse effects is not described in detail. Differences in adverse events between the groups were not reflected in the measures of quality of life.

Cost-of-treatment data showed, as expected, that antidepressant medication costs were roughly double for the group initially assigned to fluoxetine ($217 vs. $97 for imipramine and $123 for desipramine during the first 6 months and $609 vs. $324 for imipramine and $376 for desipramine for the entire 24 months). Outpatient costs and inpatient medical and inpatient psychiatric costs were lower, although not significantly so, in the fluoxetine group ($1,750 vs. $2,008 for imipramine and $2,238 for desipramine during the first 6 months and $6,092 vs. $6,459 for imipramine and $6,381 for desipramine for the entire 24 months). These effects resulted in total direct costs across the groups that were not significantly different.

In this study, clinical outcomes were almost identical, whether patients were prescribed fluoxetine or a tricyclic first, when patients were permitted to switch medications freely. Patients who found tricyclics unacceptable generally agreed to treatment with a second medication and “caught up” in terms of clinical outcome. The newer medication “broke even” on costs, in that the higher acquisition costs of fluoxetine were balanced by the lower costs of other services, but did not result in an overall savings to the health care system. On the other hand, a formulary policy of requiring failure of a tricyclic before access to the newer medication was granted would not have saved money in this particular primary care practice. The authors concluded that the data provide no clear guidance in the initial selection of antidepressant medications and that patient and physician preference therefore provide an appropriate basis for treatment selection.

Interestingly, this group conducted a retrospective database analysis of patients during a similar period of time who did not participate in the randomized trial (47). Reassuringly, the cost-effectiveness results (Table 78.6) were very similar to those from the randomized study.

In the discussion, the authors point out that these conclusions may not apply to other practices. In particular, similar studies in psychiatric specialty practices are needed. The depression of patients in psychiatric specialty practices is generally more severe, and the consequences of delay in treatment response related to a need to switch medications and start over may be more worrisome.

The second randomized prospective antidepressant cost-effectiveness study was conducted in a primary care setting in France (2). Outpatients meeting DSM-IV criteria for major depression were randomized to sertraline (50 to 150 mg/d; *N* = 122) or fluoxetine (20 to 60 mg/d; *N* = 120) in double-blinded fashion for 6 months. Both groups improved significantly from baseline on measures of symptoms and quality of life, and analyses comparing the groups showed no significant differences; however, patients treated with fluoxetine utilized more medical resources. Analyses comparing groups in regard to work and productivity losses were not significant. Cost comparisons (converted to dollars) from the societal perspective favored sertraline over fluoxetine ($1,551 vs. $1,735), but neither the variability within groups nor statistical significance of the comparisons was reported.

COSTS OF AVERTING SUICIDE

Part of "78 - Cost-Effectiveness of the Newer Generation of Antidepressants "

Suicide is fortunately a fairly rare event, even in depressed patients (48 ,49). As a result, many cost-effectiveness studies have not included a consideration of suicide. We touch on the issue only briefly.

The relative safety of the newer antidepressants in overdose is well-known. The use of SSRIs is associated not only with fewer deaths from antidepressant overdose but also with reduced costs of treating overdose (50 ,51 and 52)

Despite clear reductions in mortality from overdoses with the newer medications in comparison with TCAs (53), controversial data from a general practice research database involving 4 million residents of the United Kingdom indicated the rate of death by suicide in patients receiving fluoxetine to be no lower than the rate of death by suicide in patients receiving TCAs (54). Fluoxetine-treated patients appeared to substitute violent methods or carbon monoxide poisoning for overdoses. Such complete method substitution would suggest that SSRIs do not save lives and that saving lives cannot therefore be used to justify their added

expense. These data, however, are based on only 11 suicides among a limited number of fluoxetine cases.

Freemantle et al. (55) modeled the cost per life year saved and cost per life saved that would result from the routine first-line use of SSRIs rather than TCAs in general practice in the U.K. in comparison with current U.K. practice patterns. This analysis produced a very wide range of estimates, primarily because of uncertainty regarding whether SSRI-treated patients would substitute other methods of suicide for overdoses. As part of a simulation, another study included suicide as part of the cost of treatment dropout (56). However, the expert panel estimates of suicide rates in this latter study were very high, and few costs were considered in the analysis.

Whether newer antidepressants do in fact save lives is crucial in a consideration of their cost-effectiveness. More data are needed about the extent to which patients, knowing that the pills are not lethal, might substitute methods of suicide that are even more deadly than TCA overdoses. However, recently emerging epidemiologic data appear to suggest that newer antidepressants may have a favorable impact on death by suicide when all methods, not just overdoses, are taken into account (57 ,58 ,59 and 60).

CONCLUSION

Part of "78 - Cost-Effectiveness of the Newer Generation of Antidepressants "

The available data that may be confidently brought to bear on the two cost-effectiveness questions posed in the introduction are surprisingly sparse. Only two prospective randomized studies have been carried out, both in primary care. More prospective studies are clearly needed. Most of the retrospective studies and the simulations contain methodologic limitations sufficient to generate significant concern about their conclusions. Additionally, the studies include diverse variations in almost all the elements of cost-effectiveness analysis, so that cross-comparisons and aggregate conclusions are very difficult to make. However, if we must draw conclusions from the current data, we would suggest the following tentative conclusions.

Based on the limited evidence available, the provisional summary from this review regarding our first question, “Are newer antidepressants cost-effective as first-line treatment from the health care system perspective?” is that first-line use of the newer antidepressants within primary care practice in the United States may be roughly equally effective and also cost-neutral in terms of direct medical resource costs to the health care system. The recently published long-term data from the only randomized study support this view (26), and the simulations and retrospective studies, with all their limitations, do not contradict it. However, because the data are sparse and contain multiple methodologic problems, health care organizations or systems feeling the pinch of the high acquisition costs of the newer medications would be well advised to conduct their own randomized studies. This is especially true for psychiatric practices and for practices in countries other than the United States.

The data for the primary care treatment of depression are sparse, but those for the cost-effectiveness of the newer antidepressants in psychiatric practice are even more scarce. No randomized studies have been published, and few of the simulations and none of the administrative database studies focus exclusively on psychiatric practice. Many features distinguish the treatment of depression in primary care from the treatment of depression in psychiatric practice, and these could potentially lead to different conclusions about cost-effectiveness. For example, the direct costs of treatment failure may be higher in psychiatric practice than in primary care (61), and this consideration would favor the cost-effectiveness advantages of the better tolerated newer agents. On the other hand, the tendency of psychiatrists to use higher and possibly more effective doses of TCAs than primary care prescribers do would likely favor the cost-effectiveness of TCAs over SSRIs in psychiatric practice. Similarly, it may be less likely in psychiatric practice than in primary care that the greater tolerability of SSRIs and the reduced requirement for dose titration would offset costs by decreasing the need for outpatient visits; for depressed patients in psychiatric practice, with relatively severe depression and higher levels of comorbidity, frequent visits may be necessary independently of these considerations to monitor for increased suicide risk. Prospective randomized cost-effectiveness experiments in psychiatric practice could address the substantially different environment of specialty mental health care.

Similarly, although the data on the treatment of depression in the United States are limited, those on the cost-effectiveness of the newer antidepressants in other countries, especially developing countries, are still more limited. No randomized studies outside the United States have compared newer and older antidepressants. Some of the simulations and none of the administrative database studies focus on other developed countries, such as Canada and the European nations. The many ways in which the treatment of depression differs across countries and economies could potentially lead to different conclusions about cost-effectiveness (62). Acquisition costs for the newer medications are generally lower in countries other than the United States (63). Nevertheless, price may still put the newer antidepressants out of reach for most of the population in some developing countries (64). The organization of health care systems varies greatly, and the potential of the newer antidepressants to offset costs could also vary greatly across countries. Prospective randomized cost-effectiveness experiments in countries other than the United States would make it possible to evaluate whether cost-effectiveness conclusions are widely applicable.

The second question we posed in the introduction was, “Are newer antidepressants cost-effective as first-line treatment from the global societal perspective?” This perspective

includes *all* costs and *all* health effects. Fewer studies have attempted to address societal indirect/productivity costs, and none of the studies is prospective. Indirect/productivity costs were not comprehensive in some studies, being limited to family burden or absence from work. In the studies reporting QALYs, the outcome rates were taken from expert opinion panels, or utility determinations were uncertain. Most of these studies have numerous other methodologic limitations. Better studies are needed, particularly on the substitution of suicide methods, enhancement of work productivity, and reduction of absenteeism and family burden. However, if the newer antidepressants are in fact health care resource cost-neutral in the health care system, the chance is significant that the newer antidepressants are cost-effective in society. Health care system health resource cost neutrality clearly suggests similar cost neutrality in total health resource costs to society because the total health care resource costs to society also are borne by the health care system. It is likely that society reaps benefits not seen from the health care system perspective, including decreased use of informal caregiver time, decreased use of patient time, and perhaps decreased use of resources other than health care resources, in addition to positive changes such as increased productivity.

Lastly, as newer antidepressants begin to come off patent, their cost eventually should go down as a result of generic competition. When this occurs, the cost-effectiveness of the newer medications will increase (45).

DISCLOSURE

Mechanism of Action of Antidepressants and Mood Stabilizers

Robert H. Lenox

Alan Frazer

Robert H. Lenox: Head CNS Group, Aventis Pharmaceuticals, Bridgewater, New Jersey.

Alan Frazer: Department of Pharmacology, University of Texas Health Science Center, San Antonio, Texas.

Bipolar disorder (BPD), the province of mood stabilizers, has long been considered a recurrent disorder. For more than 50 years, lithium, the prototypal mood stabilizer, has been known to be effective not only in acute mania but also in the prophylaxis of recurrent episodes of mania and depression. By contrast, the preponderance of past research in depression has focused on the major depressive episode and its acute treatment. It is only relatively recently that investigators have begun to address the recurrent nature of unipolar disorder (UPD) and the prophylactic use of long-term antidepressant treatment. Thus, it is timely that we address in a single chapter the most promising research relevant to the pharmacodynamics of both mood stabilizers and antidepressants.

As we have outlined in Fig. 79.1 , it is possible to characterize both the course and treatment of bipolar and unipolar disorder in a similar manner. Effective treatments exist for the acute phases of both disorders; maintaining both types of patients on such drugs on a long-term basis decreases the likelihood and intensity of recurrences. Further, because the drugs are given long-term, they produce a cascade of pharmacologic effects over time that are “triggered” by their acute effects. Both classes of psychotropic drugs incur a lag period for therapeutic onset of action, even in the acute phase; therefore, studies during the past two decades have focused on the delayed (subchronic) temporal effects of these drugs over days and weeks. Consequently, it is widely thought that the delayed pharmacologic effects of these drugs are relevant for either the *initiation* of behavioral improvement or the *progression* of improvement beyond that initiated by acute pharmacologic actions. The early realization that lithium is effective prophylactically in BPD and the more recent understanding that antidepressants share this property in UPD have focused research on long-term events, such as alterations in gene expression and neuroplasticity, that may play a significant role in stabilizing the clinical course of an illness. In our view, behavioral improvement and stabilization stem from the acute pharmacologic effects of antidepressants and mood stabilizers; thus, both the acute and longer-term pharmacologic effects of both classes of drugs are emphasized in this chapter.

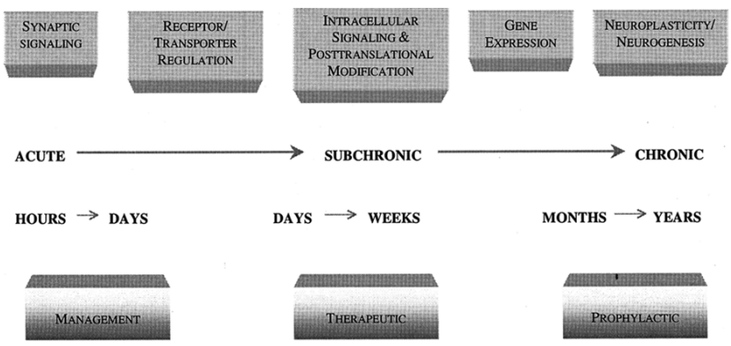

FIGURE 79.1. Mood stabilizers and antidepressant actions: short-term and long-term events. Lithium and antidepressants have acute effects on synaptic signaling that serve to trigger progressively longer-term events in signal transduction; these in turn lead to changes in gene expression and plastic changes in brain. The acute affects in critical regions of the brain result in changes in certain behavioral and physiologic symptomatology (e.g., activation, sleep, appetite) that facilitate the acute clinical management of mania or depression. Subchronic effects lead to amelioration of symptoms related directly to mood, whereas it is thought that the longer-term (chronic) effects underlie the prophylactic properties of these drugs to prevent recurrent affective episodes in both unipolar and bipolar disorders.

MOOD STABILIZERS

Part of "79 - Mechanism of Action of Antidepressants and Mood Stabilizers "

The term *mood stabilizer* within the clinical setting is commonly used to refer to a class of drugs that treat BPD. However, for the purpose of our discussion, it is important to differentiate the three clinical phases of BPD—acute mania, acute depression, and long-term prophylactic treatment for recurrent affective episodes. Although a variety of drugs are used to treat BPD (i.e., lithium, anticonvulsants, antidepressants, benzodiazepines, neuroleptics), we suggest that only a drug with properties of prophylaxis should be referred to as a mood stabilizer and included in this chapter. Significant evidence supports a therapeutic action for lithium, both in acute mania and prophylactically in a major subset of patients with BPD 1. However, the data for long-term prophylaxis with anticonvulsants (i.e., valproate, carbamazepine), although supported in part in clinical practice, remains less well established scientifically (see Chapter 77). In the absence of a suitable animal model, an experimental approach, used to ascribe *therapeutic relevance* to any observed biochemical finding, is the identification of shared biochemical targets that are modified by drugs belonging to the same therapeutic class (e.g., antimanic agents) but possessing distinct chemical structures (e.g., lithium and valproate). Although unlikely to act via identical mechanisms, such common targets may provide important clues

about molecular mechanisms underlying mood stabilization in the brain. Thus, in our discussion, we use studies of lithium as a prototypal mood stabilizer and cross-reference evidence for the anticonvulsants when the data are available. Furthermore, it is important to note that drugs that are useful in the treatment of acute mania or depression may not necessarily have prophylactic properties (1) and, as in the case of antidepressants that are effective in treating BPD, may actually serve to destabilize the illness. Although it is likely that the targets for lithium action early in treatment trigger its long-term properties of mood stabilization, to what extent the biological mechanisms underlying long-term lithium prophylaxis contribute to the efficacy of lithium in acute mania remain to be demonstrated.

Studies through the years have proposed multiple sites for the action of lithium in the brain, and such research has paralleled advances in the field of neuroscience and the experimental strategies developed during the past half-century. For the most part, proper interpretation of these data has at times been limited by experimental design, which has often ignored not only the clinically relevant therapeutic range of concentrations and onset of action of lithium, but also critical control studies defining its specificity of action in comparison with other monovalent cations and classes of psychopharmacologic agents. While the targets for the action of lithium have shifted from ion transport and presynaptic neurotransmitter-regulated release to postsynaptic receptor regulation, to signal transduction cascades, to gene expression and neuroplastic changes in the neuropil, the research strategy has evolved from a focus on a class of neurotransmitter to the ability of the monovalent cation to alter the pattern of signaling in critical regions of the brain in a unique manner. It is in this context that we highlight the most current thinking regarding putative sites for the therapeutic action of lithium in the brain, which is heuristic and sets the stage for future research directions.

Ion Transport

Ion-gated channels, which are driven by either adenosine triphosphate (ATP) or the net free energy of transmembrane concentration gradients, regulate the distribution of lithium across the cell membrane. These transport systems are critical for the regulation of resting lithium in the bulk cytoplasm in that they regulate steady-state intracellular ion concentrations that set the threshold for depolarization in excitable cells. Lithium exchanges readily with sodium; however, by virtue of its high energy of hydration, it can also substitute for the divalent cations calcium and magnesium, which may account for some of its major biochemical sites of action. Much of the anticonvulsant properties of valproate, carbamazepine, and lamotrigine have been attributed to their ability to inhibit sustained repetitive firing by prolonging the recovery of voltage-gated sodium channels from inactivation (2). However, it is important to note that anticonvulsant activity appears to be neither necessary nor sufficient for mood stabilization because lithium has proconvulsant properties outside its narrow therapeutic range.

Although some membrane transport systems specifically recognize lithium and regulate its transmembrane concentration (e.g., a gradient-dependent Na-Li exchange process) (3 ,4), it is likely that the primary regulation of lithium is affected by transport systems that accept the lithium ion as a substitute for their normal ionic substrates. The Na, K-ATPase pump has been extensively studied in relation to the membrane transport of lithium and the therapeutic effect of lithium (see refs. 5 and 6 for review). Based on measurements of lithium in peripheral neurons and synaptosomal membrane fractions from brain, long-term lithium treatment was found to decrease Na, K-ATPase activity, particularly in hippocampus (7). Various groups have studied Na, K-ATPase activity in patients with mood disorders and have reported alterations in the erythrocyte-to-plasma ratio of lithium in patients with BPD as a function of clinical state and genetic loading. Despite the fact that clinical studies through the years have been constrained by relatively small and often variable findings, evidence has been found that Na, K-ATPase activity may be reduced, especially in the depressed phase of both UPD and BPD, and is associated with an increase in sodium retention (see refs. 1 ,6 for review). Furthermore, long-term lithium treatment has been observed to result in an increased accumulation of lithium and activity of Na, K-ATPase in erythrocyte membranes, with concomitant reduction of sodium and calcium within erythrocytes in patients with BPD. Because the concentration of free calcium ion tends to parallel the concentration of free sodium ion, this finding may account for observations that intracellular calcium is increased in patients with BPD (8). Interestingly, when patients with BPD were treated with lithium, Na, K-ATPase activity was found to be increased, consistent with observations of reduced Ca^{2+} after treatment. However, such evidence from blood cells must be interpreted with caution; more recent data support the evolution of specific gene products for Na, K-ATPase expressed and uniquely regulated after translation, not only in neurons but in brain regions (9 ,10).

Although a balance of resting lithium conductance and net transport/efflux mechanisms regulates lithium homeostasis, the ligand gating of ion channels on the time scale of channel activity may play a more significant role in the regulation of intracellular lithium concentration within regulatory sites of an excitable cell such as the neuron. In the local environment of a dendritic spine, the surface area-to-volume ratio becomes relatively large, such that the lithium component of a synaptic current may result in significant (as much as fivefold to 10-fold) increases in intracellular lithium concentration following a train of synaptic stimuli (11). Such an activity-dependent mechanism for creating focal, albeit transient, increases of intracellular lithium at sites of high synaptic activity may play a role in the therapeutic specificity of lithium and its ability to regulate synaptic function in the brain.

Neurotransmitter Signaling/Circadian Rhythm

In search of a link between the mechanism of action of lithium and neurotransmission, the effect of lithium has been extensively studied in virtually every neurotransmitter system. Earlier studies focused on the modulation of presynaptic components, including the synthesis, release, turnover, and reuptake of neurotransmitters. In recent years, the focus has shifted to postsynaptic events, such as the regulation of signal transduction mechanisms (see refs. 12 ,13 and 14 for review). Despite the fact that some of the results of the presynaptic and postsynaptic investigations are not in full agreement, at present the evidence supports the action of lithium at multiple sites that modulate neurotransmission. Lithium appears to reduce presynaptic dopaminergic activity and acts postsynaptically to prevent the development of receptor up-regulation and supersensitivity. In the cholinergic system, lithium enhances receptor-mediated responses at neurochemical, electrophysiologic, and behavioral levels. Long-term lithium treatment increases GABAergic inhibition and has been shown to reduce excitatory glutamatergic neurotransmission. It is of interest that valproate has been shown to enhance γ-aminobutyric acid (GABA) signaling, and the anticonvulsant lamotrigine has been shown to reduce glutamatergic neurotransmission. (2). It is currently thought that the effect of lithium on the spectrum of neurotransmitter systems may be mediated through its action at intracellular sites, with the net effect of long-term lithium attributed to its ability to alter the balance among neurotransmitter/neuropeptide signaling pathways.

One of the unique and most robust properties of lithium is its ability to lengthen the circadian period across species—unicellular organisms, plants, invertebrates, and vertebrates (including primates)—so that a phase delay in the circadian cycle often results (see refs. 15 ,16 for review). These effects are noted following long-term but not acute exposure and occur within the range of concentrations used in humans to treat BPD (0.6 to 1.2 m*M*). It has long been recognized that a dysregulation of circadian rhythms is associated with the clinical manifestation of recurrent mood disorders in patient populations (see refs. 17 ,18 for review). In fact, it appears to be the interaction between the circadian pacemaker and the sleep–wake cycle that determines variations in sleepiness, alertness, cognitive performance, and mood (19 ,20 ,21 and 22). The early morning awakening, shortened latency in rapid-eye-movement (REM) sleep, and advances in hormonal and temperature regulation of many depressed patients, including those with BPD, are thought by some investigators to indicate a phase advance of the central pacemaker within the suprachiasmatic nucleus of the hypothalamus relative to other internal oscillators or external zeitgebers (23 ,24 ,25 ,26 and 27). Lithium may achieve its therapeutic and prophylactic effects by altering the balance of neurotransmitter signaling in critical regions of the brain, such as the

hypothalamus, and resynchronizing the physiologic systems underlying recurrent affective illness (1 ,28 ,29 and 30).

Signal Transduction

Phosphoinositide Cycle

Since it was discovered that lithium is a potent inhibitor of the intracellular enzyme inositol monophosphatase (IMPase) (K_i = 0.8 m*M*), which converts inositol monophosphate to inositol (31 ,32), receptor G protein-coupled phosphoinositide (PI) hydrolysis has been extensively investigated as a site for the action of lithium as a mood stabilizer (see ref. 33 for review) (Fig. 79.2). The "inositol-depletion hypothesis" posited that lithium produces its therapeutic effects via a depletion of neuronal *myo*-inositol levels. Furthermore, because the mode of enzyme inhibition of IMPase is uncompetitive, likely through interaction with Mg^{2+} binding sites (34), the preferential site of action for lithium was proposed to be on the most overactive receptor-mediated neuronal pathways undergoing the highest rate of phosphatidylinositol 4,5 bisphosphate (PIP_2) hydrolysis (35 ,36). It is also of interest that a number of structurally similar phosphomonoesterases that require magnesium have also been found to be inhibited by lithium at K_i values below 1 m*M* (37 ,38).

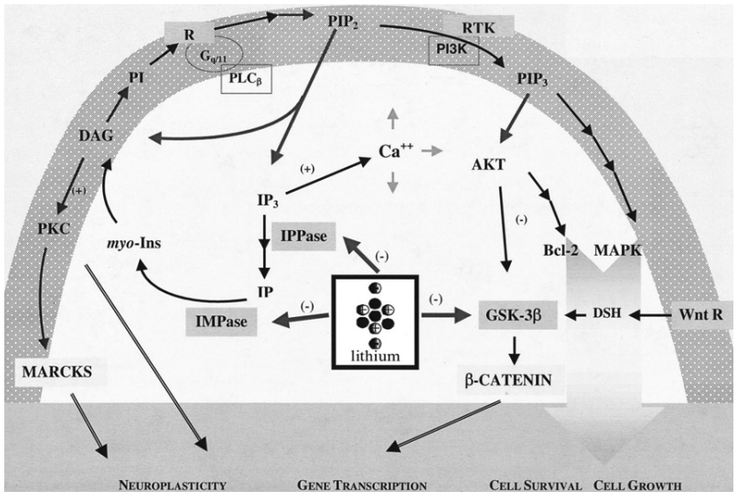

FIGURE 79.2. Molecular targets for lithium in phosphoinositide (PI) signaling. Pathways depicted within the figure are three major sites for an inhibitory action of lithium: inositol 1-monophosphatase (IMPase); inositol polyphosphate 1-phosphatase (IPPase); and glycogen synthase kinase 3ß (GSK-3ß). Inhibition of IMPase and IPPase can result in a reduction of *myo*-inositol (*myo*-Ins) and subsequent changes in the kinetics of receptor-activated phospholipase C (PLC) breakdown of phosphoinositide-4,5-bisphosphate to diacylglycerol (DAG) and inositol-1,4,5-trisphosphate. Alteration in the distribution of inositol phosphates can affect mechanisms mediating presynaptic release. DAG directly activates protein kinase C (PKC), and this activation results in downstream post-translational changes in proteins that affect receptor complexes and ion channel activity and in transcription factors that alter gene expression of proteins such as MARCKS (myristoylated alanine-rich C-kinase substrate), which are integral to long-term neuroplastic changes in cell function. Inhibition of GSK-3ß within the wnt-receptor (wnt-R) pathway alters gene transcription and neuroplastic events through an increased expression of downstream proteins such as ß-catenin. In addition, this inhibition can indirectly affect phosphoinositide 3 kinase pathways and intermediate factors (e.g., Bcl-2 and MAP kinases), which are thought to mediate cell growth and survival.

In cell systems and in cerebral cortical slices of chronically

treated rats, the effects of lithium on receptor-coupled PI signaling (39 ,40 ,41 and 42) and the down-regulation of myristoylated alanine-rich C-kinase substrate (MARCKS) protein (discussed below) can be prevented or reversed by a high concentration of *myo*-inositol. Recent genetic data from *Drosophila* indicate a role for the upstream inositol polyphosphatase (IPPase) as an additional target for lithium (43) (Fig. 79.2). *Drosophila* harboring a null mutation for the IPPase gene demonstrate aberrant firing of the neuromuscular junction, an effect that is mimicked by the treatment of wild-type flies with lithium. Although studies during the past several years have provided evidence that *myo*-inositol clearly plays a role in the action of lithium, it is evident that lithium-induced *myo*-inositol reduction may depend on cell type (39) and that sites other than PI signaling may be lithium targets, depending on the physiologic system under investigation. In studies examining the *in vivo* physiologic effects of lithium, such as polyuria or enhancement of cholinergically induced seizures, the addition of *myo*-inositol reduced but did not fully reverse the lithium-induced effects (44 ,45). Furthermore, the effect of long-term lithium on developmental polarity in the *Xenopus* embryo is rescued in the presence of *myo*-inositol (46), but this effect may not be totally attributable to a direct effect of lithium on IMPase (47) (see below).

Although the lithium-induced reduction in agonist-stimulated PIP_2 hydrolysis in rat brain slices has often been small and inconsistent, probably secondary to the size of the signaling-dependent PIP_2 pool (33 ,48), a recent study of patients with BPD in which proton magnetic resonance spectroscopy was used has demonstrated a significant lithium-induced reduction in *myo*-inositol levels in the right frontal lobe (49). However, the reduction in *myo*-inositol preceded the improvement in mood symptoms, indicating a temporal dissociation between changes in *myo*-inositol and clinical improvement. Consequently, these and other studies suggest that although inhibition of IMPase may represent an initial effect of lithium, reducing *myo*-inositol levels *per se* may be more important in the specificity of the cellular site of action for lithium than in the actual therapeutic response, which may be mediated by a cascade of downstream changes in signal transduction and gene expression (see below).

Adenylyl Cyclase

The other major receptor-coupled second-messenger system in which lithium has been shown to have significant effects is the adenylyl cyclase system. The cyclic AMP (cAMP) generating system plays a major role in the regulation of neuronal excitability and has been implicated in the pathophysiology of seizure disorders (50 ,51 and 52) and BPD (53). Studies in a variety of cell systems and in human brain have demonstrated that lithium attenuates receptor-coupled activation of the cAMP pathway at concentration that inhibits 50% (IC_{50}) values ranging from 1 to 5m*M* (see ref. 1 for review). Lithium *in vitro* inhibits adenylyl cyclase activity stimulated by guanosine triphosphate (GTP) or calcium/calmodulin, both of which interact directly with adenylyl cyclase (54 ,55 and 56). These inhibitory effects of lithium are antagonized by Mg^{2+}, which suggest that the action of lithium on the adenylyl cyclase system is mediated by direct competition with Mg^{2+} (55). However, attenuation of adenylyl cyclase activity following long-term lithium treatment in rat cortical membranes was not antagonized by Mg^{2+} alone but was reversed by increasing concentrations of GTP, which implies that the effect of long-term lithium treatment may be mediated at the level of G proteins (54 ,56).

Recent studies have examined the effects of valproate on components of the ß- adrenergic receptor (ßAR)-coupled cAMP generating system (57). Long-term valproate at a clinically relevant concentration has been shown to produce a significant alteration of the ßAR-coupled cAMP generating system in cultured cells *in vitro*. In contrast to long-term lithium (discussed above), long-term valproate was found to produce a significant reduction in the density of ßARs. Data generated during the past two decades reveal that carbamazepine inhibits basal and forskolin-stimulated activity of purified adenylyl cyclase and also basal and stimulated adenylyl cyclase in rodent brain and neural cells in culture (57 ,58 ,59 and 60). In addition, carbamazepine has been reported to reduce elevated cAMP in the cerebrospinal fluid (CSF) of manic patients (61). It appears that carbamazepine inhibits cAMP production by acting directly on adenylyl cyclase or through factor(s) that co-purify with adenylyl cyclase.

Lithium may have dual effects on the intracellular generation of cAMP. Whereas lithium decreases receptor-coupled stimulation of adenylyl cyclase, lithium increases basal levels of cAMP formation in rat brain (62 ,63). In addition, long-term lithium has been found to increase not only cAMP levels (64) but also levels of adenylyl cyclase type I and type II messenger RNA (mRNA) and protein levels in frontal cortex (65 ,66), which suggests that the net effect of lithium may derive from a direct inhibition of adenylyl cyclase, up-regulation of adenylyl cyclase subtypes, and effects on G proteins. Thus, it has been suggested that the action of lithium on the adenylyl cyclase system depends on state of activation; under basal conditions, in which tonic inhibition of cAMP formation through $G_{\alpha i}$ is predominant, levels of cAMP are increased, whereas during receptor activation of adenylyl cyclase mediated by $G_{\alpha s}$, cAMP formation is attenuated. It has been suggested that such a “bimodal model” for the mechanism of action of lithium may account for its therapeutic efficacy in both depression and mania (12). Although this would appear to be overly simplistic, it may bear clinical relevance to side effects of lithium, such as nephrogenic diabetes insipidus and subclinical hypothyroidism, which have generally been attributed to inhibition of vasopressin or thyrotropin-sensitive adenylyl cyclase.

G Proteins

As noted above, considerable evidence indicates that lithium attenuates receptor-mediated second-messenger generation in the absence of consistent changes in receptor density (see refs. 1 ,67 for review). Although lithium has been reported to reduce PI signaling via alteration in G-protein function in cell preparations (68 ,69 and 70), these data have not been replicated in rat or monkey brain (71 ,72). Although it appears that long-term lithium administration affects G-protein *function* (12 ,73), the preponderance of data suggest that lithium, at therapeutically relevant concentrations, does not have any direct effects on G proteins (1 ,74). A number of studies have reported modest changes in the *levels* of G-protein subunits; however, the effects of long-term lithium on signal transducing properties occur in the absence of changes in the levels of G-protein subunits *per se* (1 ,63 ,65 ,75). At the mRNA level, some evidence suggests that $G_{\alpha s}$, $G_{\alpha i1}$, and $G_{\alpha i2}$ may be down-regulated in rat cerebral cortex following long-term lithium (65 ,75 ,76). Again, however, these effects are small, and their physiologic significance is still unclear. Interestingly, the valproate-induced reduction in the density of ßARs (noted above) was accompanied by an even greater decrease in receptor- and post-receptor-mediated cAMP accumulation, which suggests that long-term valproate may exert effects at the ßAR/G_s interaction, or at post-receptor sites (e.g., G_s, adenylyl cyclase). A subsequent study has reported a reduction in the levels of $G_{\alpha s}$-45 but not in the levels of any of the other G-protein α subunits examined ($G_{\alpha s}$-52, $G_{\alpha i1/2}$, $G_{\alpha o}$, $G_{\alpha q/11}$) following long-term exposure to valproate (77).

Long-term lithium treatment has been shown to produce a significant increase in pertussis toxin-catalyzed [^{32}P]adenosine diphosphate (ADP)-ribosylation in rat frontal cortex and human platelets (1). Because pertussis toxin selectively ADP-ribosylates the undissociated, inactive Gαßγ heterotrimeric form of G_i, these data are consistent with a stabilization of G_i in the inactive conformation and an elevation in basal adenylyl cyclase activity. In this context, it is noteworthy that lithium appeared to increase the levels of endogenous ADP-ribosylation in C6 glioma cells and rat brain, whereas anticonvulsants either reduced ADP-ribosylation or had no effect (78 ,79). Currently, it is thought that the effects of long-term lithium may in part be mediated through post-translational modifications of G proteins that in turn may alter its coupling to receptor and second-messenger systems (1). However, given the relative abundance of G proteins, the physiologic impact of the level of post-translational changes induced by therapeutic levels of lithium on the balance of receptor-mediated signaling in brain is yet to be determined.

Protein Kinases and Protein Kinase Substrates

Based on the action of lithium in the PI signaling pathway, as discussed earlier, it was hypothesized that long-term prophylactic effects of lithium might be mediated via the diacylglycerol (DAG) arm of the PIP_2 hydrolytic pathway consequent to relative depletion of *myo*-inositol and subsequent DAG-mediated action on the regulation of protein kinase C (PKC) and specific phosphoprotein substrates (80 ,81) (Fig. 79.2). Studies during the past several years have provided evidence that PKC plays a crucial role in mediating the action of long-term lithium in a variety of cell systems, including primary and immortalized neurons in culture, and in rat brain (see refs. 12 ,33 ,81 ,82 for review). PKC represents a large family of at least 12 isozymes that are closely related in structure but differ in several ways—intracellular and regional distribution in the brain, second-messenger activators, specificity of association with the RACK (receptor for activated C-kinase) proteins, and substrate affinities—all of which suggest distinct cellular functions for these isozymes. PKC plays a major role in the regulation of neuronal excitability, neurotransmitter release, and long-term alterations in gene expression and plasticity. In fact, PKC activity has been implicated in processes underlying amygdala kindling and behavioral sensitization, putative animal models for BPD (83 ,84). PKC isozymes are highly expressed in the brain, with the γ isoform expressed exclusively, and are localized both presynaptically and postsynaptically. PKC is located in the cytoplasmic and membrane compartments of cells, and its activation requires translocation from the cytosol to RACK proteins within the membrane. Translocation from the cytosol to the membrane is most often associated with phosphorylation and activation of the enzyme, which is followed by autocatalysis and down-regulation of the enzyme on prolonged activation.

Studies of long-term lithium administration in the rat have demonstrated a reduction in membrane-associated PKC-α and PKC-ε in the subiculum and in CA1 regions of the hippocampus (85 ,86). In brain slices from lithium-treated rats exposed to phorbol ester, a known activator of PKC, a marked reduction was noted in the translocation of PKC activity from the cytoplasm to the membrane, and this was accompanied by a reduction in phorbol esterinduced serotonin release (87). Studies of long-term lithium in both C6 glioma cells and immortalized hippocampal cells in culture also demonstrate a reduction in the expression of these same PKC isozymes (see ref. 88 for review). This is interesting in light of data demonstrating an enhancement of PKC activity in platelets of patients during a manic episode (88). Moreover, administration of *myo*-inositol to rats was reported to reverse the down-regulation of PKC-ε in brain following long-term lithium, consistent with a role of *myo*-inositol in the downstream action of lithium on regulation of PKC by DAG. It is of note that valproate produces effects on the PKC signaling pathway similar to that reported for lithium (33 ,89). Long-term lithium and valproate appear to regulate PKC isozymes by distinct mechanisms, however, with the effects of valproate appearing to be largely independent of *myo*-inositol. These studies have

led to a pilot clinical study of the use of tamoxifen, a drug known to inhibit PKC *in vitro*, in the treatment of acute mania (90 ,91). Although the preliminary results appear consistent with the hypothesis, the sample size was small, and it is not known whether this drug *in vivo* inhibits PKC isozymes or whether its other properties (i.e., anti-estrogenic) play a role.

The activation of PKC results in the phosphorylation of a number of membrane-associated phosphoprotein substrates, the most prominent of which in brain is the MARCKS protein. Direct activation of PKC by phorbol esters in immortalized hippocampal cells effectively down-regulates the MARCKS protein (92). Long-term lithium administered to rats during a period of 4 weeks in clinically relevant concentrations dramatically reduces the expression of MARCKS protein in the hippocampus, and these findings have been replicated and extended in immortalized hippocampal cells in culture (39 ,93 ,94). Studies in hippocampal cells have demonstrated that the extent of down-regulation of MARCKS expression after long-term lithium exposure (1 m*M*) depends on both the inositol concentration and activation of receptor-coupled PI signaling, consistent with the hypothesis as stated above. Recent studies provide evidence for the regulation of transcription as a major site for the action of long-term lithium on MARCKS expression in brain (95). Moreover, this action of lithium in the brain and hippocampal cells is apparent only after *long-term* administration and persists beyond abrupt discontinuation of the drug for an extended period of time, paralleling the clinical time course of the therapeutic effects of lithium during initial treatment and discontinuation. Subsequent studies have discovered that this property of reducing the expression of MARCKS in hippocampal cells is shared by the anticonvulsant valproic acid, but not by other classes of psychotropic agents (96). Additionally, therapeutic concentrations of combined lithium and valproate have induced an additive reduction in MARCKS, also consistent with experimental findings that the two drugs work through different mechanisms on the PKC system and the clinical observation of the additivity of the two drugs in treatment responses (96). The altered expression of MARCKS further supports the role of PI signaling and PKC in the action of long-term lithium in the brain and may serve to provide insight regarding a role for neuroplasticity in the long-term treatment of BPD, as discussed below.

A crucial component of cAMP signaling is protein kinase A (PKA), which is a principal mediator of cAMP action in the central nervous system. Long-term lithium treatment has been shown to increase the regulatory and catalytic subunits of PKA in rat brains, an effect that appears to result in increased cAMP binding (97). Consistent with a lithium-induced increase in basal cAMP and adenylyl cyclase levels, a more recent study has reported that platelets from lithium-treated euthymic patients with BPD demonstrated an enhanced basal and the cAMP-stimulated phosphorylation of Rap1 (a PKA substrate) and a 38-kilodalton phosphoprotein not observed in healthy controls (98). The effects of lithium on the phosphorylation and activity of cAMP response element binding (CREB) protein, however, have been examined in rodent brain and in cultured human neuroblastoma cells, with somewhat conflicting results (99 ,100). Postmortem studies of brains of patients with BPD have shown changes in cAMP binding and in PKA activity in temporal cortex (101 ,102). These findings suggest that alterations in PKA activity may be associated with the action of lithium. It is of interest in this regard that carbamazepine attenuates forskolin-induced phosphorylation of CREB in C6 glioma cells (57).

It is well-known that lithium ion can have a significant effect on the development of a variety of organisms (103). In *Xenopus*, lithium significantly alters the ventral–dorsal axis of the developing embryo (104). One hypothesis regarding this action of lithium was based on its inhibition of IMPase and alteration in the dorsal–ventral balance of PI signaling in the embryo (105 ,106). Support for this hypothesis was derived from the observation that exposure to high concentrations of *myo*-inositol can reverse the effect of lithium (107). However, lithium ion has been shown to inhibit the activity of glycogen synthase kinase 3β (GSK-3β) (K_i = 2.1 m*M*) directly, thereby antagonizing the wnt signaling pathway, known to be instrumental in normal dorsal–ventral axis development in the *Xenopus* embryo (108 ,109 ,110 and 111). Furthermore, studies in which an embryo expressing a dominant negative form of GSK-3 was used have demonstrated that *myo*-inositol can reverse the resulting aberrant axis development in *Xenopus*, which suggests that *myo*-inositol reversal of dorsalization of the embryonic axis by lithium may be mediated, at least in part, by events independent of IMPase inhibition (47). Substrates for GSK-3β in cells include not only glycogen synthase but also β-catenin and microtubule-associated proteins (MAPs), both of which have been implicated in cytoskeletal restructuring; further, β-catenin is known to play a role in the expression of transcription factors [e.g., lymphoid enhancer factor (LEF) and T cell factor (TCF)]. Recent studies in human neuroblastoma cells have demonstrated that valproic acid also inhibits GSK-3β, after which levels of β-catenin increase (112). Thus, GSK-3β may contribute to our understanding of an action for long-term lithium observed in events associated with apoptosis and neuroplasticity, as discussed below.

Gene Expression

The clinical data indicating that onset of the therapeutic effect of lithium requires days to weeks of lag time and that reversal of the therapeutic effect on discontinuation occurs during a period of weeks to months suggest that the therapeutically relevant action of lithium in the brain involves long-term neuroplastic changes mediated by gene regulation. Evidence has accumulated that lithium can regulate

gene expression via nuclear transcriptional factors. One of the immediate early genes, c-*fos*, works as a master switch of gene regulation through interactions with *cis*-acting elements and other transcriptional factors. Lithium has been shown to alter the expression of c-*fos* in various cell systems (113) and in the brain (114 ,115 and 116); however, its effects have varied depending on brain region, cell type, and time course examined. (112 ,117 ,118 and 119).

It is known that c-*fos* interacts with *jun* family members to form activator protein 1 (AP-1), which binds to a common DNA site. Studies in both cell culture and rat brain following long-term lithium exposure *in vivo* demonstrate an enhancement of AP-1 DNA binding activity (99 ,120). Subsequent studies in cells with an AP-1-coupled reporter gene have confirmed a time- and concentration-dependent increase in transcriptional activity in the presence of lithium (121 ,122). These studies have also noted increases in the protein levels of c-*fos*, c-*jun*, and phosphorylated CREB. It is of interest that phosphorylation of c-*jun* inhibits DNA binding, whereas phosphorylation of CREB activates gene expression; both are substrates for GSK-3ß activity, which is inhibited by lithium. However, when AP-1 binding activity was measured following receptor activation, lithium treatment attenuated the induced AP-1 DNA binding activity (123 ,124). These seemingly contradictory findings suggest that the effect of lithium on gene transcription may depend on the activity level of the neurons. It has been suggested that by increasing AP-1 binding activity at the basal level, but decreasing it during stimulation, lithium can constrain the overall magnitude of fluctuations of gene expression as a function of neuronal activity (125). Valproic acid has been shown to have similar effects on the activity of AP-1 (120 ,122 ,126), which lends support to the possibility that gene regulation through AP-1 may represent a target for mood stabilizers. In addition, carbamazepine has been shown to inhibit forskolin-induced c-*fos* gene expression in cultured pheochromocytoma (PC12) cells (127). It must be kept in mind, however, that AP-1 binding activity is responsive to a multitude of signals and is unlikely to define the specific action underlying the therapeutic effect of lithium in BPD. Future studies may fruitfully examine a potential role for lithium in the regulation of newly discovered candidate genes linked to BPD (128), in addition to those implicated in its pathophysiology (129).
