FIGURE 29.3. Changes in effective connectivity predict learning. This graph shows the correlation between the temporal index of changes in effective connectivity and learning. The temporal index is defined as the time of a maximum increase in effective connectivity between posterior parietal cortex and posterior inferotemporal cortex. For example, a temporal index of 3 indicates that the maximum increase in effective connectivity occurred between the third and fourth blocks. The *numbers* denote the subject from which this temporal index of effective connectivity was obtained. Each subject was scanned during three independent learning sessions; therefore, each number appears three times. A negative slope means that the maximum increase in effective connectivity occurs earlier in fast learning. (From Büchel C, Coull JT, Friston KJ. The predictive value of changes in effective connectivity for human learning. *Science* 1999;283:1538–1541, with permission.)

Example: Attention

Electrophysiologic and neuroimaging studies have shown that attention to visual motion can increase the responsiveness of the motion-selective cortical area (*V5*) (23 ,24) and the PP (25). Increased or decreased activation in a cortical area is often attributed to attentional modulation of the cortical projections to that area. This leads to the notion that attention is associated with changes in connectivity.

Here we present fMRI data from an individual subject, scanned under identical visual motion stimulus conditions while only the attentional component of the tasks employed was changed. First, we identify regions that show differential activations in relation to attentional set. In the second stage,

changes in effective connectivity to these areas are assessed with structural equation modeling. Finally, we show how these attention-dependent changes in effective connectivity can be explained by the modulatory influence of parietal areas by using a nonlinear extension of structural equation modeling. The specific hypothesis we addressed was that parietal cortex could modulate the inputs from *V1* to *V5*.

The experiment was performed on a 2-T MRI system equipped with a head volume coil. fMRI images were obtained every 3.2 seconds with echo-planar imaging (32 slices in each volume). The subject was scanned during four different conditions: *fixation, attention, no attention*, and *stationary*. Each condition lasted 32 seconds to give 10 volumes per condition. We acquired a total of 360 images. During all conditions, the subjects looked at a fixation point in the middle of a screen. In this section, we are interested only in the two conditions with visual motion (*attention* and *no attention*), in which 250 small white dots moved radially from the fixation point, in random directions, toward the border of the screen at a constant speed of 4.7 degrees per second. The difference between *attention* and *no attention* lay in the explicit command given to the subject shortly before the condition: *just look* indicated *no attention*, and *detect changes* indicated the *attention* condition. Both visual motion conditions were interleaved with *fixation*. No response was required.

Regions of interest were defined by categoric comparisons with use of an output statistical image (*SPM{Z}*) comparing *attention* with *no attention* and comparing *no attention* with *fixation*. As predicted, given a stimulus consisting of radially moving dots, we found activation of the lateral geniculate nucleus, primary visual cortex (*V1*), motion-sensitive area (*V5*), and posterior parietal complex. For the subsequent analysis of effective connectivity, we defined regions of interest with a diameter of 8 mm centered around the most significant voxel as revealed by the categoric comparison. A single time series, representative of this region, was defined by the first eigenvector of all the voxels in the region of interest (15).

Our model of the dorsal visual stream included the lateral geniculate nucleus, *V1, V5*, and the PP. Although connections between regions are generally reciprocal, for simplicity we modeled only unidirectional paths.

To assess effective connectivity in a condition-specific fashion, we used time series that comprised observations during the condition in question. Path coefficients for both conditions (*attention* and *no attention*) were estimated by using a maximum likelihood function. To test for the impact of changes in effective connectivity between *attention* and *no attention*, we defined a free model (allowing different path coefficients between *V1* and *V5* for *attention* and *no attention*) and a constrained model (constraining the *V1* → *V5* coefficients to be equal). Figure 29.4 shows the free-model and estimated path coefficients. The connectivity between *V1* and *V5* increases significantly during attention. Note also a significant difference in connectivity between *V5* and the PP.

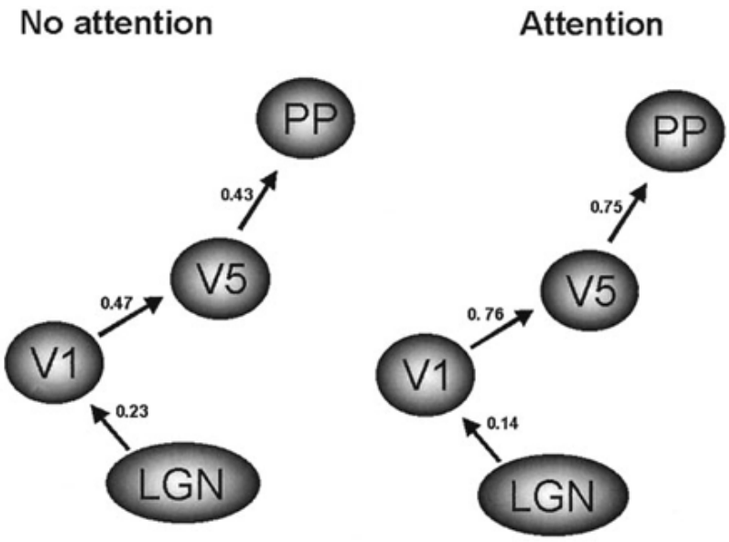

FIGURE 29.4. Structural equation model of the dorsal visual pathway, comparing *attention* and *no attention*. Connectivity between right primary visual cortex (*V1*) and motion-sensitive area (*V5*) is increased during *attention* relative to *no attention*. This is also shown for the connection between *V5* and the posterior parietal cortex. (From Büchel C, Friston KJ. Effective connectivity in functional brain imaging. *Neural Networks* 2000;13:871–882, with permission.)

The linear path model comparing *attention* and *no attention*

revealed increased effective connectivity in the dorsal visual pathway in relation to attention. The question that arises is, which part of the brain is capable of modulating this pathway? Based on lesion studies (26) and the system for directed attention described in ref. 27 , the PP is hypothesized to play such a modulatory role.

We extended our model accordingly to allow for nonlinear interactions, testing the hypothesis that the PP acts as a moderator of the connectivity between *V1* and *V5*. Assuming a nonlinear modulation of this connection, we constructed a new variable, *V1PP*, in our analysis. This variable, mediating the interaction, is simply the time series from region *V1* multiplied (element by element) by the time series of the right posterior parietal region.

The influence of this new variable on *V5* corresponds to the influence of the PP cortex on the connection between *V1* and *V5* (i.e., the influence of *V1* on *V5* is greater when activity in the PP is high). The model is shown in Fig. 29.5 . Because our nonlinear model could accommodate changes in connectivity between *attention* and *no attention*, the entire time series was analyzed (i.e., attention-specific changes are now explicitly modeled by the interaction term).

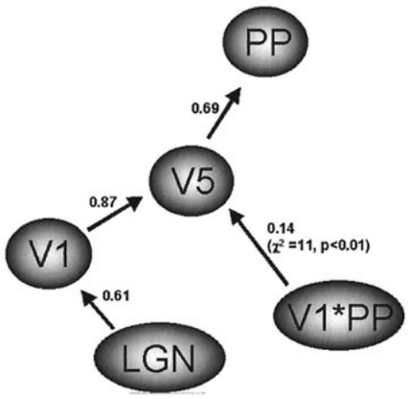

FIGURE 29.5. Structural equation model of the dorsal visual pathway incorporating the interaction effect of right posterior parietal cortex on the connection from right primary visual cortex (*V1*) to motion-sensitive area (*V5*). (From Büchel C, Friston KJ. Effective connectivity in functional brain imaging. *Neural Networks* 2000;13:871–882, with permission.)

As in the linear model, we tested for the significance of the interaction effect by comparing a restricted and a free model. In the restricted model, the interaction term (i.e., path from *V1PP* to *V5*) was set to zero. Omitting the interaction term led to a significantly reduced model fit ($p < .01$), which indicated the predictive value of the interaction term.

The presence of an interaction effect of the PP on the connection between *V1* and *V5* can also be illustrated by a simple regression analysis. If the PP shows a positive modulatory influence on the path between *V1* and *V5*, the influence of *V1* on *V5* should depend on the activity of the PP. This can be tested by splitting the observations into two sets, one containing observations in which the PP activity is high and another one in which the PP activity is low. It is now possible to perform separate regressions of *V5* on *V1* by using both sets. If the hypothesis of positive modulation is true, the slope of the regression of *V5* on *V1* should be steeper under high values of PP.

Variable Parameter Regression

As demonstrated in the previous sections, the basic linear model can be seen as a linear regression. The regression coefficient is then interpreted as a measure of the connectivity between areas. This interpretation of course implies that the influence is mediated by neural connections with an effective strength equal to the regression coefficient. Using this approach, one immediately makes the assumption that the effective connectivity does not change over observations because only a single regression coefficient for the whole time series is estimated. This is unsuitable for the assessment of effective connectivity in functional imaging because the goal in some experiments is to demonstrate changes in effective connectivity—for instance, as a function of different conditions (e.g., *attention* and *no attention*) or simply time itself. In the framework of regression analysis, there are three ways around this problem. Firstly, one can split the data in different groups according to the experimental condition (e.g., *attention* and *no attention*) and then test for the difference of the regression coefficients. However, we may not know *a priori* the time course of the changes that allow us to split the data in this way. A second, more general solution is to expand the explanatory variable in terms of a set of basis functions to account for changes in connectivity. Here, we present another alternative, variable parameter regression, that allows one to characterize the variation of the regression coefficient by using the framework of state–space models and the Kalman filter (28 ,29).

Mathematical Background

Consider the classic regression model

$$y = x\beta + u \qquad [2]$$

where *y* is the measured data vector, *x* is a vector of explanatory variables, and ß is the unknown parameter. Usually, ß is estimated as

$$\hat{\beta} = \text{pinv}(x)y \qquad [3]$$

However, ß can also be estimated recursively with the advantage that inversion of a smaller matrix is necessary. This approach is known as *recursive least squares* (30). This basic model is now extended to allow ß to evolve over time.

Variable parameter regression assumes *T*-ordered scalar observations (y_1,… y_T) generated by the following model:

$$y_t = x_t\beta_t + u_t,\ t = 1, \ldots, T, \qquad [4]$$

$$u_t \sim N(0, \sigma^2) \qquad [5]$$

where x_t is an *n*-dimensional row vector of known regressors and β_t is an *n*-dimensional column vector of unknown coefficients that corresponds to estimates of effective connectivity. u_t is drawn from a gaussian distribution. All observations are expressed as deviations from the mean.

A recursive algorithm known as the Kalman filter (29) can now be applied to estimate the state variable (β) at each point in time and also allows one to estimate the log-likelihood function of the model. A numeric optimization algorithm is then employed to maximize the likelihood function with respect to *P*. As the Kalman filter is a recursive procedure, the estimation of β_t is based on all observations up to time *t*. Therefore, the filtered estimates will be more accurate toward the end of the sample. This fact is corrected for with the Kalman smoothing algorithm, which is used *post hoc* and runs backward in time, taking account of the information made available after time *t*. Details of the Kalman filter and smoothing recursions can be found in standard textbooks of time series analysis and econometrics (31 ,32).

Example: Attention to Visual Motion

To illustrate variable parameter regression, we use the single-subject data set from the study of attention to visual motion. We concentrate on the effect of attention on the connection between the motion-sensitive area (*V5*) and the PP in the right hemisphere. Using structural equation modeling, we demonstrated that it is principally this connection, in the dorsal visual stream, that is modulated by attention (15). In the current analysis, we are interested in whether variable parameter regression is capable of reproducing these findings. We therefore have assessed the effective connectivity β_t by regressing PP on *V5*. An alternate direction search, numeric optimization, gave a x^2 statistic of 56.4. We therefore had to reject the null hypothesis of no variation at the 5% level. *P* was estimated to be 0.074 and σ^2 was 0.23. The ordinary regression coefficient β for the model $y = x\beta + u$ was estimated at 0.73. Figure 29.6 A,B shows the trajectories of the smoothed and filtered estimates β_t (T) together with the associated standard errors. It is clearly evident that β_t is higher during the *attention* conditions than during the *no attention* conditions. Figure 29.6D relates our technique to an ordinary regression. In this analysis, we constrained the variance term *P* to zero and reestimated β_t. The trajectory of β_t now converges to β, the ordinary regression coefficient of the model $y = x\beta + u$. As expected, the smoothed estimates are simply a constant (i.e., β = 0.73).

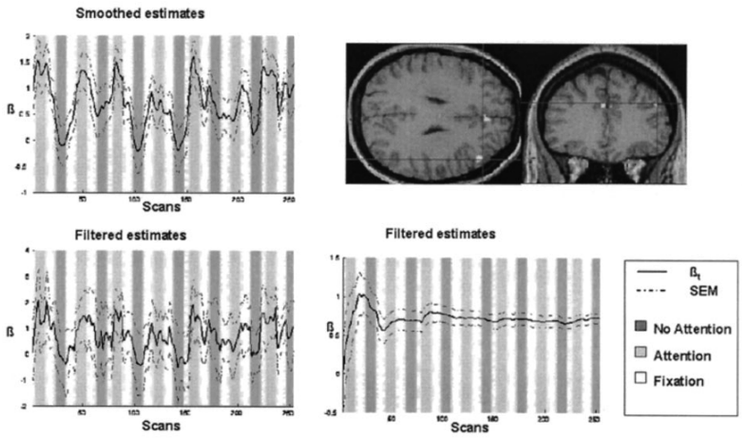

FIGURE 29.6. A,B: The trajectory of the smoothed and filtered estimates β_t (T) together with the associated standard errors for the variable parameter estimation of effective connectivity between motion-sensitive area (*V5*) and posterior parietal cortex (PP). It is evident that β_t (the dynamic regression coefficient) is higher during the *attention* conditions than during the *no attention* conditions. **C:** Areas that significantly covaried with the time-dependent measure of effective connectivity between *V5* and the PP [i.e., β_t (T)]. The output statistical image *SPM{Z{* thresholded at $p < .001$ (uncorrected) overlaid on coronal and axial slices of the subject's structural MRI. The maximum under the cross-hairs was at 45, 21, 39 mm, $Z = 4$. **D:** The relationship between our technique and an ordinary regression analysis. In this analysis, the variance term *P* was set to zero (i.e., fixed regression model). The trajectory of β_t now converges to β (= 0.73), the regression coefficient of the model $y = x\beta + u$. (From Büchel C, Friston KJ. Dynamic changes in effective connectivity characterized by variable parameter regression and Kalman filtering. *Hum Brain Mapping* 1998;6:403–408, with permission.)

We interpret β_t as an index of effective connectivity between area *V5* and the PP. In our example, the connection between *V5* and the PP resembles the *site* of attention modulation. This leads to an interesting extension, in which one might hypothesize that a third region is responsible for the observed variation in effective connectivity indicated by the trajectory of β_t (T). In other words, after specifying the *site* and nature of attentional modulation, we now want to know the location of the *source*. We addressed this by using β_t (T) as an explanatory variable in an ordinary regression analysis to identify voxels that covaried with this measure of effective connectivity. Figure 29.6C shows the result of this analysis. Among areas with statistically significant ($p < .001$, uncorrected) positive covariation were the dorsolateral prefrontal cortex and the anterior cingulate cortex. This result confirms the putative modulatory role of the dorsolateral prefrontal cortex in attention to visual motion, as suggested by previous analyses (15).

Effective Connectivity versus Categorical Comparisons

One obvious advantage of the assessment of effective connectivity is that it allows one to test hypotheses about the integration of cortical areas. For example, in the presence of modulation, the categoric comparison between *attention* and *no attention* might reveal prestriate, parietal, and frontal activations. However, the only statement possible is that these areas show higher cortical activity during the *attention* condition as opposed to the *no attention* condition. The analysis of effective connectivity revealed two additional results. Firstly, attention affects the pathway from *V1* to *V5* and from *V5* to PP. Secondly, the introduction of nonlinear interaction terms allowed us to test a hypothesis about how these modulations are mediated. The latter analysis suggested that the PP exerts a modulatory influence on area *V5*.

The measurements used in all examples in this chapter were *hemodynamic* in nature. This limits an interpretation at the level of *neuronal* interactions. However, the analogy between the form of the nonlinear interactions described above and voltage-dependent (i.e., modulatory) connections is a strong one. It is possible that the modulatory impact of PP on *V5* is mediated by predominantly voltage-dependent connections. We know of no direct electrophysiologic evidence to suggest that extrinsic backward PP to *V5* connections are voltage-dependent; however, our results are consistent with this. An alternative explanation for modulatory effects, which does not necessarily involve voltage-dependent connections, can be found in the work of Aertsen and Preissl (10). These authors show that effective connectivity varies strongly with, or is modulated by, background neuronal activity. The mechanism relates to the efficacy of subthreshold excitatory postsynaptic potentials in establishing dynamic interactions. This efficacy is a function of postsynaptic

depolarization, which in turn depends on the tonic background of activity.

CONCLUSIONS

Part of "29 - Interactions Among Neuronal Systems Assessed with Functional Neuroimaging "

This chapter has reviewed the basic concepts of effective connectivity in neuroimaging. We have introduced several methods to assess effective connectivity—multiple linear regression, covariance structural equation modeling, and variable parameter regression. In the first example, structural equation modeling was introduced as a device that allows one to combine observed changes in cortical activity and anatomic models. An application of this technique revealed changes in effective connectivity between the dorsal and the ventral stream over time in a paired-associates learning paradigm. The temporal pattern of these changes was highly correlated with individual learning performance, and therefore changes in effective connectivity predicted learning speed. The second example of structural equation modeling focused on backward modulatory influences of high-order areas on connections among lower-order areas. Both examples concentrated on changes in effective connectivity and allowed us to characterize the interacting areas of the network at a functional level. Variable parameter regression was then introduced as a flexible regression technique that allows the regression coefficient to vary smoothly over time. Again, we confirmed the backward modulatory effect of higher cortical areas on those areas situated lower in the cortical hierarchy. Although this field is less than mature, the approach to neuroimaging data and regional interactions discussed above is an exciting endeavor that is starting to attract more and more attention.

THE PROBLEM OF ATTRIBUTING CAUSALITY WITH OBSERVATIONAL FUNCTIONAL BRAIN IMAGING

Part of "30 - Measuring Brain Connectivity with Functional Imaging and Transcranial Magnetic Stimulation "

Developments in functional imaging during the past two decades have allowed for significant advances in understanding how the brain functions at a systems, circuit, or organ level. Positron emission tomography (PET), single-photon emission computed tomography (SPECT), and blood oxygen level-dependent (BOLD) functional magnetic resonance imaging (fMRI) now allow researchers to image brain activity (usually related to oxygen or glucose use) with crisp spatial and temporal resolution. For example, fMRI can spatially resolve structures as small as 1 to 2 mm and view brain activity in time blocks as brief as 2 to 3 seconds. Although this time resolution is crude relative to the speed of neuronal activity and information flow between brain regions (on the order of milliseconds), these tools are nevertheless able to demonstrate the activity of clusters of brain cells through a sustained time domain in association with a behavior or task. Unfortunately, these slow time frames cannot image the directional flow of information through the brain, although exciting research in this area is under way. Thus, functional imaging tools alone have been limited in their ability to demonstrate how brain regions work in a coordinated and connected fashion to modulate information and regulate and produce behavior.

Therefore, *a fundamental problem with conventional functional imaging to date has been the inability to probe and understand the causal relationship between regional brain activity and behavior*. For example, if a brain region uses more glucose (fluorodeoxyglucose PET, or FDG PET) or oxygen (^{15}O PET or BOLD fMRI) while a subject performs a behavioral act, one can safely say that this regional activity *correlates with* the behavior. Most functional imaging researchers have correctly and appropriately used the term *correlate*, rather than *cause*, knowing well that the exact causal relationship of the regional activity to the behavior remains unclear after even the most fastidious study. For example, is the region producing the behavior? Or is the region trying to inhibit or modulate the behavior? Or is the region only incidentally activated as part of the neural network?

A recent advance in this field involves combining functional imaging with transcranial magnetic stimulation (TMS), a new technology that noninvasively stimulates the cortex. Used alone without brain imaging, TMS has been useful as a crude mapping tool for motor functions (1). Recently, by combining TMS with functional imaging, researchers have begun to test directly theories about how information flows within the brain (i.e., the functional connectivity of different brain regions). Thus, with this new combination of imaging and noninvasive stimulation, the field can now move a step closer to making causal statements of brain function. In this chapter, we introduce the technology of TMS and describe some of the important issues involved in integrating TMS with imaging to address brain connectivity. We conclude by reviewing the most recent studies in this new field in which researchers have combined noninvasive brain stimulation (TMS) with functional brain imaging.

TRANSCRANIAL MAGNETIC STIMULATION

Part of "30 - Measuring Brain Connectivity with Functional Imaging and Transcranial Magnetic Stimulation "

Transcranial magnetic stimulation is a new method for noninvasively stimulating the brain (2 ,3). With TMS, a

brief but powerful electric current is passed through a small coil of wires held against the scalp. This generates a powerful local magnetic field, which passes unimpeded through the skull and induces a weaker and somewhat less focal electric current in the brain (4 ,5 and 6). The highly localized TMS magnetic field typically has a strength of about 1 to 1.5 tesla (T) [about 30,000 times the earth's magnetic field, or about the same intensity as the static magnetic field used in clinical magnetic resonance imaging (MRI)] (7). Although different coil designs allow for more focal or more diffuse stimulation, current technology limits the depth of direct stimulation to just below the skull in superficial cortex. The magnetic field declines exponentially with distance from the coil. MRI techniques have enabled researchers actually to *image the magnetic field* of the TMS coil (8). Unfortunately, the actual important physiologic effects are likely a consequence of the *electric current density* and the *induced electric field in the area of cortex* (Appendix I). Current theories hold that the induced electric fields cause neuronal depolarization or changes in neuronal activity, which result in information flow and neurotransmitter release. Newer MRI sequences in development may someday soon allow us to image the electric current density directly and, by applying this technology to high-resolution structural imaging, actually image the induced electric field (D. LeBihan, *personal communication; May, 1999*).

Transcranial magnetic stimulation can be performed in outpatient laboratory settings in awake alert subjects (Fig. 30.1) and does not intentionally cause a seizure, nor does it require anesthesia (9). Subjects usually notice no adverse effects except for occasional mild headache and temporary discomfort at the site of the stimulation. Repeated rhythmic stimulation is called repetitive TMS (rTMS). Recent technologic advances have led to the development of magnetic stimulators that can repeatedly stimulate faster than once per second (1 Hz). By convention, stimulation faster than 1 Hz is called *fast rTMS*, and stimulation slower than 1 Hz is *slow rTMS*. This distinction is important because some evidence from work in animals (10) and humans (11) suggests that stimulation at different frequencies may have divergent and even antagonistic effects on neuronal activity (12 ,13). Importantly also, the risk for seizures in healthy adults is virtually nil with slow rTMS, and so in the United States, research with slow rTMS does not require an investigational device exemption from the Food and Drug Administration (14).

FIGURE 30.1. The chain of events by which transcranial magnetic stimulation produces changes in the brain and resulting behavior. Transcranial Magnetic Stimulation (TMS): Time-varying electrical current in a coil produces ⇒ Focal 2 Tesla magnetic field passes unimpeded through skull ⇒ Induces current in neurons ⇒ Behavioral change.

Over primary motor cortex, a TMS pulse of sufficient intensity causes movement in the opposite arm or leg (an intensity called the *motor threshold*). Similarly, a single pulse of TMS over visual cortex can produce a subjective flash of light (or phosphene). Precisely timed pulses can also interfere with, or augment, other complex tasks (see ref. 1 for review). Thus, TMS alone without imaging has been used as a relatively spatially crude mapping technique, largely over the motor cortex. rTMS at frequencies of 4 Hz or higher applied over Broca's area can cause temporary speech arrest (15). This ability to block function temporarily is frequency-dependent. It is unclear which neurons are stimulated with TMS, and whether and how this varies as a function of intensity or frequency. It is also not known how TMS causes speech arrest—whether through synaptic tetany or activation of local inhibitory interneurons.

In summary, the ability to stimulate the cortex noninvasively with TMS in an awake, alert human is an important new tool and scientific advance. At present, knowledge is limited about the physiologic and pharmacologic actions of TMS, especially as they may vary as a function of frequency, intensity, or length, in different brain regions, and in disease states versus health. Coupling TMS with imaging will likely produce new knowledge in two different areas. First, it will probably advance understanding of how TMS affects brain and *thereby refine the clinical applications* and therapeutic uses of TMS in neuropsychiatry. More importantly, from the perspective of cognitive neuroscience, combining TMS with functional imaging *will open up new avenues for the investigation of brain circuits, connectivity, and the causal chain in brain–behavior relationships* and is thus a powerful new research tool.

BACKGROUND OF THE CONCEPT OF BRAIN CONNECTIVITY AND CIRCUITS

Current Approaches to Functional Imaging Analysis and Connectivity

The first step in functional imaging is to find out which areas of the brain show activity (based on increased blood flow) when a subject performs some mental or physical task, or mentally responds to a stimulus. Conceptually, this is simple—one compares images of the brain acquired during periods when it is responding to some well-defined test stimulus with images acquired when it is performing some well-defined control task. The assumption is that the differences in the two sets of images represent the differences in brain activity during the test stimulus and during the control task. However, these are fairly subtle effects. A small change in the signal can confound the data in unknown ways. The fMRI signal is inherently noisy and often changes because of instability of the instrumentation and environmental influences on the subject. For this reason, the problem of determining the areas of the brain that are being activated by the test stimulus and assigning a probability to that determination has been extensively studied, and the field has developed commonly accepted methodologies for processing PET and fMRI data (16 ,17 ,18 ,19 ,20 ,21 and 22).

Determination of Regional Activation

The concept of constructing an interpolated spatial map of a statistical parameter, *significance probability mapping*, was developed in the analysis of multichannel electrophysiologic (EEG) data (23 ,24). In early functional imaging with PET, Fox and Mintun (16) introduced what they called *change distribution analysis*, which consisted of a subtraction of subject-averaged PET images. Present fMRI-processing methodology draws on both these ideas. In its simplest form, a pixel-by-pixel *t* test is performed by comparing the distribution of activation values for two different conditions during the course of an experiment. This gives a *t* map (i.e., an image in which each pixel represents the Student's *t* statistic for the comparison of the test condition relative to the reference condition at that location). By using the associated *p* values and the number of degrees of freedom, the *t* values can be converted to *z* values (gaussian distribution: mean 0, variance 1) to obtain *z* maps. This is the basis for statistical parametric mapping (25), formally described as the construction of spatially extended statistical processes, or maps, to test a hypothesis (usually about neurophysiology) directly. Generally based on a linear and parametric model, statistical parametric maps (SPMs) are image processes with voxel values that are, under the null hypothesis, distributed according to a known probability density function, usually gaussian. In the same way that a *t* value is interpreted by reference to Student's *t* distribution, an SPM is interpreted by referring to the probabilistic behavior of stationary gaussian fields (26) and can be used to make statistical inferences about regionally specific findings (e.g., the probability of finding an activation focus by chance). In general, SPMs characterize experimentally elicited changes in terms of (multiple) activation foci. Regions of the SPM with high or low values are interpreted as regional activations. Thus, it is possible to locate areas of the brain that are “active” during the execution of some task (i.e., the signal in those areas has a time-varying pattern that correlates with the pattern of the conditions in the experiment) (17).

Functional and Effective Brain Connectivity

Intuitively, it is common to think of *brain functional connectivity* as two or more separate anatomic areas of the brain that influence each other in the performance of some mental or physical task (e.g., recalling a name or moving a finger), or to produce a mental state (e.g., sadness). This action or state of the brain, in turn, affects the body through the somatosensory system, the sympathetic and parasympathetic nervous system, and of course the brain's neuropharmacologic/neuroendocrine hypothalamic–pituitary–adrenal system. Both in electrophysiology and functional neuroimaging, connectivity of different areas of the brain has been based on the correlation between regions. In the case of electrophysiology, this means the EEG signal (24 ,27 ,28 ,29 ,30 ,31 and 32), and in functional neuroimaging, this means the time course of regional blood flow or glucose use (18 ,21 ,33 ,34)).

Friston et al. (19) emphasize the distinction between *functional connectivity*, the temporal correlations between remote neurophysiologic events, and *effective connectivity*, the influence of one neural system on another (i.e., a functional as opposed to a causal relationship). Viewed in this way, functional connectivity is simply the observed covariance among different brain systems. It is an operational definition and says nothing about the causal relations of the observed correlations. To characterize distributed brain systems, the functional connectivity (covariance) matrix, obtained from a time series of neurophysiologic measurements, is subjected to principal component analysis (PCA) (20 ,35) (Appendix II). The resulting eigenimages (principal components or spatial modes) each identify a spatially distributed system, comprising regions of the brain that are jointly implicated by virtue of their functional interactions (connectivity). This analysis of neuroimaging time series is predicated on established techniques in electrophysiology (both EEG and multiunit recordings). For example, in the analysis of multichannel EEG data, the underlying spatial modes that best characterize the observed spatiotemporal

dynamics are identified with a Karhunen–Loeve expansion. Commonly, this expansion is in terms of the eigenvectors of the covariance matrix associated with the time series. The spatial modes are then identical to the principal components identified with a PCA.

Structural Equation Modeling

Principal component analysis and factor analysis approaches attempt to integrate the spatially distributed activations found in SPMs into functional systems characterized by the eigenimages or spatial modes. However, one would like to go further and explore the influence of one area on another (effective connectivity), not just the correlation (functional connectivity). Many anatomic connections are reciprocal, and simple pairwise correlations cannot resolve asymmetric influences. Structural equation modeling is an attempt to address this problem.

In describing their neural structural equation models, McIntosh and Gonzalez-Lima (21) use the terms *anatomic model* and *functional model* (36). The *anatomic model* simply represents the discrete anatomic brain regions and the neuroanatomic connections between them used in the structural equation models. These anatomic models have been derived from the observation of patients with brain lesions and from animal studies, or inferred from neuroimaging studies and the analysis of SPMs. The interregional correlations of activity are used to assign numeric weights to the connections in the anatomic model, which leads to the functional model. A *functional model*, therefore, represents the influences of regions within the model on each other through the anatomic connections, and both the magnitude and the sign of the path coefficients can be estimated. In some respects, the functional model is close to the notion of effective connectivity (20 ,37) because it depicts the influence of one region on another. The difference is that the influences in the functional model, unlike effective connections, are explicitly depicted as direct and indirect effects through the anatomic model. Effective connectivity, as defined by Aertsen et al. (38), resembles most closely direct effects in that an effective connection is the influence of one neural element on another irrespective of direct or indirect influences. In structural equation modeling, effective connections, or total effects, are further decomposed into direct and indirect effects by use of the anatomic model. A similar distinction can be made in covariance analysis, which is often characterized as exploratory (objective) or confirmatory (theoretical) analysis. PCA and factor analysis are essentially exploratory techniques because no constraints are placed on how the variance in the system is expressed. Structural equation modeling is typically thought of as a confirmatory approach (confirmatory factor analysis) because a causal model is usually being confirmed or disconfirmed (39).

Transcranial Magnetic Stimulation as a Probe to Alter Connectivity Networks

Although the PCA and structural equation modeling techniques are well grounded statistically and quite powerful, they cannot eliminate the possibility that apparent interactions between two regions may be a consequence of other factors. The activity of two theoretically linked regions may be modulated, either directly or via changes in neurotransmitter release, by neurologic activity in a third region that is outside of the field of view of the imaging experiment, or has not been included in the structural equation anatomic model. The two regions may also be responding to different aspects of the test stimulus, either inherently because of the nature of the task, or because of engagement of the subject in performing the task.

Since it was first developed, TMS has been used to test nerve connections, nerve excitability, and nerve conduction times. One might think of this as two anatomic areas with a single connection. Paus et al. (34) and our laboratories at the National Institute of Mental Health (40 ,41) and the Medical University of South Carolina (42 ,43) demonstrated that TMS might be combined with neuroimaging to explore the connectivity of more complex three-dimensional networks in the brain to allow the direct assessment of neural connectivity without requiring the subject to engage in any specific behavior.

Because TMS seems to have a disruptive effect in most areas of the brain, its most likely use will be to suppress the activity of a region of the brain or disrupt communication between areas. This may be done by simply applying the TMS pulse at the moment the task is performed or the stimulus is applied, and noting the changed response pattern. It may also turn out that it will be possible to apply TMS after a precisely timed delay to modulate responses (44) and so investigate brain communications at time resolutions far greater than that of the hemodynamic response, approaching that of EEG. Thus, TMS provides a noninvasive means of perturbing brain circuits both spatially and at high temporal resolution. Because it is a noncognitive stimulus, its effects are less dependent on subject engagement (“attention and performance”), and because it is a more direct and quantifiable stimulus, it more closely relates to basic neurophysiologic parameters such as nerve excitability and conduction times.

INTEGRATING TRANSCRANIAL MAGNETIC STIMULATION WITH FUNCTIONAL IMAGING: PROBLEMS AND CHALLENGES

Part of "30 - Measuring Brain Connectivity with Functional Imaging and Transcranial Magnetic Stimulation "

Stimulating the brain with TMS while simultaneously imaging brain activity presents a host of unique technical problems, including (a) physically placing the coil in the scanner

and over the appropriate brain regions, (b) determining whether the TMS coil interferes with the functional image, and (c) integrating the brief time domains of TMS with the slower temporal resolution of most modern imaging tools. We discuss several of these issues and recent attempts at dealing with them.

Placement of the Coil—Structural or Functional Guidance

One of the most obvious problems in combining imaging and stimulation revolves around how to position the TMS coil over the skull. Most researchers have used either a structural or functional guidance system.

Structural Guidance

The shape of the coil determines the magnetic field in the brain, and thus the pattern of induced electric current (7 ,45). For circular coils, the magnetic field is most intense near the windings. When a circular coil is placed flat against the scalp, it induces a toroidal ring of electric current in the underlying cortex that is of the same size as the coil itself but more diffuse. The electric current distributions are assumed to be broad and the effects distributed. In contrast, with figure 8 coils, a focus at the intersection of the two loops is roughly twice as intense as that obtained with a circular coil and the same current (Fig. 30.2). Although the distribution of induced current is still fairly broad, stimulation over motor cortex demonstrates that it is sufficiently focal to cause movement in one location; moving the coil less than a centimeter or even slightly changing the angle results in no movement, or movement in different muscle groups.

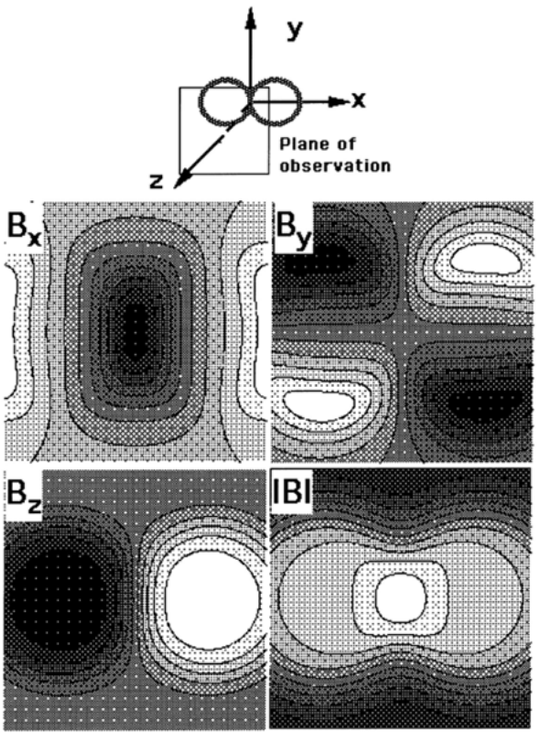

FIGURE 30.2. Magnetic field of single-turn figure 8 coil in plane parallel to and one-fourth diameter from the coil: *x, y, z* components and magnitude of field. (From Cohen LG, Roth BJ, Nilsson J, et al. Effects of coil design on delivery of focal magnetic stimulation. Technical considerations. *Electroencephalogr Clin Neurol* 1990;75:350–357, with permission.)

The coil can be positioned in several ways, based on the underlying brain structure. Perhaps the best method is to acquire a structural MRI scan of the head and then use image-guided systems to align the TMS coil precisely over a specific brain region. Several groups are exploring this option by using structural MRI and then integrating the TMS with PET (46 ,47). Performing the same mechanical alignment within an MRI scanner is more challenging because of the problems that arise when metal is used within a powerful magnetic field. An intermediate approach, employed by the McGill group (34), is to position the coil according to a probabilistic brain system keyed to landmarks on the subject being studied, rather than according to the subject's known anatomy as determined by MRI. This method is much easier and is adequate if one is planning on using only group statements for the statistical analysis (which requires spatially transforming the imaging data into a common brain atlas). Unfortunately, because the structural morphology of the brain and the functional location of behaviors vary greatly between individuals, the probabilistic method suffers from the problem that it is not certain *within an individual* whether the coil is positioned over the structure or region being studied.

The main difficulty with both image-based and structural localization is that unless one knows the exact relation of the induced currents relative to the position of the TMS coil, one really does not know where to stimulate most efficiently. The induced electric current is tissue-dependent, so it is not the same at different places on the scalp. Only if the currents had the same relation to the position of the coil, and one could use MR guidance to place the coil over the same sulcus or gyrus in a subject's brain, could one even be sure of stimulating the same structural area. However, brain conformation varies, so the induced currents might still impinge on the cerebral cortex at a different angle.

Paus and colleagues (34) approached this problem by obtaining an image volume with MR from each subject and

spatially transforming it into Talaraich space (a widely used common brain space) (48). After determining the Talairaich location shown by neuroimaging studies to correspond to a function, they performed the inverse transform back into the MR image space for each subject. Finally, using stereotactic guidance (49), they positioned the coil over this point, in effect ensuring that they were probably stimulating the functional location of the behavior in all subjects. Krings et al. (50) used a frameless stereotactic system to coregister TMS motor maps with fMRI data obtained during performance of a motor task. In two patients, they also performed direct cortical stimulation, finding good correspondence among all three methods. This probabilistic technique is more or less acceptable, depending on how consistently from one subject to the next a function is located within identifiable anatomic structures, and on how the shapes of those structures vary. Thus, this technique still entails the problem that function does not strictly map to the same location in different individuals.

Placement Based on Function

A different approach is to use TMS, electromyography, or functional imaging to determine the regions activated during a behavior and then position the coil directly over the functioning region. For behaviors like movement or phosphene production over visual cortex, one can bypass the imaging step, simply finding the scalp location with the desired behavioral effect and then keeping the TMS coil at this spot throughout an imaging study (*functional behavioral* approach to placement). Unfortunately, outside primary motor and vision areas, TMS does not produce easily viewed effects, so that this direct functional approach becomes impossible.

Despite its apparent simplicity, the *functional behavioral* approach of using elicited movement to guide coil placement to perform TMS over the motor cortex is associated with certain problems. The movement elicited by the TMS is a reassuring, if somewhat imprecise, way of being certain that one is in the correct area. However, even with comparable visible movement, one can be on one side or the other of the target area, and it is difficult to know how much or how little additional stimulation is occurring. Because this method reliably causes activation in large corticospinal circuits, we have used the functional behavioral approach for initial studies of interleaved TMS/fMRI effects over motor cortex (51 ,52).

Whichever method of locating the site of stimulation is used, it is important that the TMS coil be positioned accurately and repeatably, and then held securely in place so that its position relative to the brain is maintained throughout the stimulation. Each group seems to have developed its own mounting systems. We have developed a system for accurately and repeatably positioning the TMS coil within an MRI scanner (53). Both structural and functionally guided techniques have their place, and eventually systems will likely be developed for relating the two.

Interaction of the Transcranial Magnetic Stimulation Coil and Image Acquisition

Yet a different technologic problem in this new area revolves around whether and to what extent the TMS coil interferes with the functional image acquisition. Because of this concern, the early combinational studies used imaging techniques in which TMS was delivered in a location other than that where the actual brain imaging was performed (54 ,55). Both FDG PET and perfusion SPECT allow one to administer TMS and deliver the radiopharmaceutical agent away from the scanner. The tracer crosses the blood–brain barrier and then settles into active regions. The subject can then be transported to the scanner for image acquisition.

Because of radiation dose limits and slow time resolution, neither of these techniques (FDG PET and perfusion SPECT) is suited for thoroughly examining circuits and behavior with the combination of TMS and imaging. For this purpose, it is much better to have the TMS coil directly within the scanner. However, one then has to understand to what extent, if any, the TMS coil interferes with the acquisition of the functional images.

In PET, groups can perform an initial transmission scan before the functional image and then subtract the minor reduction in tracer counts caused by the TMS coil. Obviously, solid core coils are not suited for this type of combinational imaging. With fMRI, the TMS coil can produce both static and dynamic artifacts. Although it may be possible to correct for the static effects, as in PET, some groups are so concerned about static artifacts that they have developed systems that quickly lift the TMS coil 2 to 3 cm from the scalp during the actual MR image acquisition following a train of pulses (56). Both mechanical and pneumatic systems have been developed to do this. Although it minimizes the potential impact of the artifact, mechanically moving the TMS coil produces shimming and alignment issues on its own and does not allow for true interleaved imaging in real time. The dynamic artifacts produced by TMS within an fMRI scanner are both more complicated and more difficult to account for (see Fig. 30.3 and ref. 53 for a full discussion). Substantial progress has been made, so that this is not a major concern.

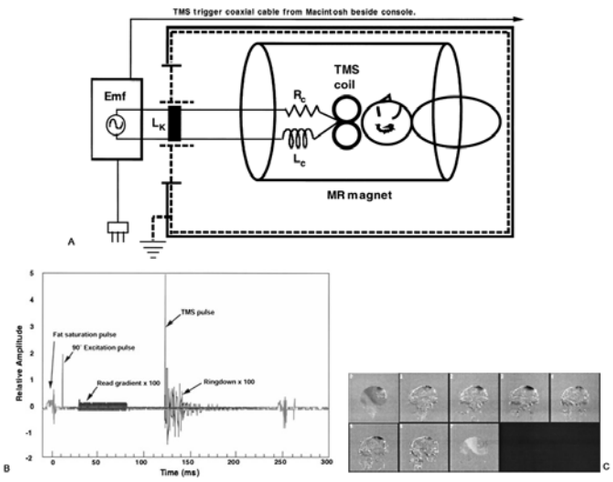

FIGURE 30.3. Researchers at the Medical University of South Carolina have recently developed the technique of performing transcranial magnetic stimulation (TMS) within the bore of a conventional 1.5-T magnetic resonance imaging scanner, the setup of which is depicted in **(A)**. This process produces dynamic TMS-induced eddy currents **(B)** and static TMS-induced eddy currents **(C)**. As seen in **(B)**, these dynamic eddy currents are approximately twice as strong as the read gradient for about 20 milliseconds, and then drop to approximately the same size as the read gradient for another 20 milliseconds. Although the major eddy currents have died out by 40 to 50 milliseconds after the TMS pulse, some longer, low-level currents are still present that cause significant image artifact **(C)**.

Integration of Temporal Domains of the Scanner and Transcranial Magnetic Stimulation

The final picture produced by each of the functional imaging tools represents summed brain activity over a measure

of time. The averaged time domain ranges from 20 to 30 minutes for FDG PET, to 40 to 60 seconds for ^{15}O PET and perfusion SPECT, to 2 to 3 seconds for BOLD fMRI, to milliseconds for EEG and electromyography. The actual TMS pulse is very brief, on the order of 300 microseconds. Thus, it is important in all combined imaging studies to understand the relationship between the TMS activity and the summed functional image. Moreover, because of the concerns of potentially causing a seizure with long trains of high-intensity, high-frequency TMS, only certain TMS parameters can be used constantly over the time domains of some forms of imaging. Unfortunately, some TMS effects, such as speech arrest, occur only with high-intensity and high-frequency stimulation.

Steady State

In this model, researchers perform TMS throughout an entire scan and then compare results with those of another scan in which all conditions are the same except for the TMS. Even with this design, and stimulation frequencies of approximately 1/s (1 Hz), most of the imaging is performed with the actual TMS machine off as a function of time.

Block Design

A different model is to scan in blocks in which periods of TMS are separated by periods of rest. An example of this is shown in Fig. 30.4 , which describes the interleaved TMS/fMRI

setup. Figure 30.5 portrays results of a recent study in which TMS was administered over motor cortex. This study showed that TMS at intensities slightly greater than motor threshold (110%) activates approximately the same number of pixels in the same region as does a volition movement (Fig. 30.5C). This study also revealed the relative magnitude of the TMS effect and the temporal relationship to changes in blood flow.

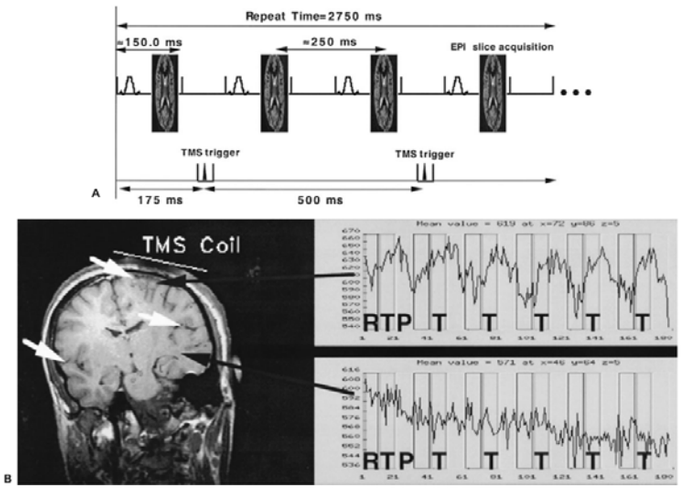

FIGURE 30.4. To perform interleaved transcranial magnetic stimulation/magnetic resonance imaging (TMS/fMRI), one must coordinate the TMS pulses with the MRI signal acquisition and interleave the two. **A:** An example of this process for a TMS rate of 1 to 2 Hz. **B:** An example of serial blood flow changes underneath the TMS coil (over left motor cortex) and in a control region. Note the increase from rest, *r*, in absolute blood oxygenation-dependent (BOLD) activity underneath the coil when it discharges at 1 Hz (task, *T*), and how it decreases afterward (post, *P*).

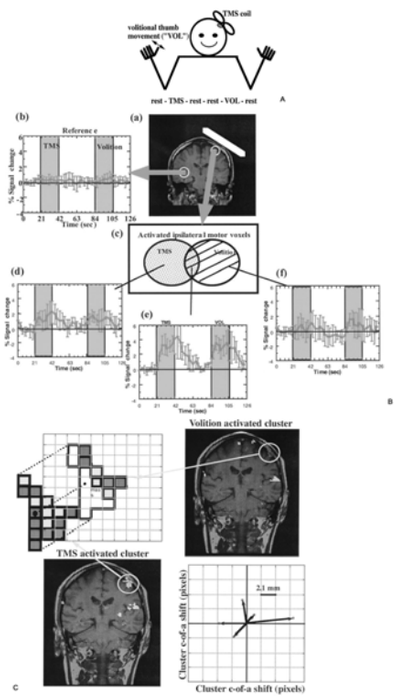

FIGURE 30.5. One of the first studies in which this interleaved technique was used attempted to detect differences between volitional and transcranial magnetic stimulation (TMS)-induced movement of the thumb. In **(A)**, the TMS device was placed over the left motor cortex of subjects, who alternately had TMS move their thumb *(TMS)* and then volitionally moved their thumb in response to a tone *(VOL)*. In **(B)** are averaged group time series of brain activity during TMS, volition, or a noise control region *(upper left)*. Note that for voxels that were activated in both tasks, the percentage rise in blood oxygenation-dependent (BOLD) activity does not differ from baseline. Thus, TMS produced BOLD changes that are dynamically similar to those of regular movement. In **(C)**, the center of mass of the BOLD signal is virtually the same for both TMS and volition, within the limit of resolution of the magnetic resonance imaging scanner (2 mm).

Single-Event fMRI

The method that is currently closest to the actual timing of TMS and brain events is single-event fMRI, or averaged-single-trials fMRI. With this method of scanning, images are steadily acquired at a rapid rate while the performance of a single event is rapidly interspersed. One can image the brain activity associated with a single TMS pulse by repeating the event many times and averaging the images acquired at similar times after the events, much as electrophysiologists have done with evoked responses (57). Although the BOLD response is relatively sluggish (on the order of 2 to 3 seconds), some groups are experimenting with the initial slope of the response to attempt to increase time resolution (Fig. 30.6). Applying TMS pulses to different brain regions with different interpulse interval times (milliseconds) may represent a unique way of improving the temporal resolution

of BOLD fMRI and of studying information flow within circuits. With further refinement, the combination of single-pulse and paired-pulse TMS and averaged-single-trials fMRI will probably be of considerable interest in *in vivo* neurophysiology.

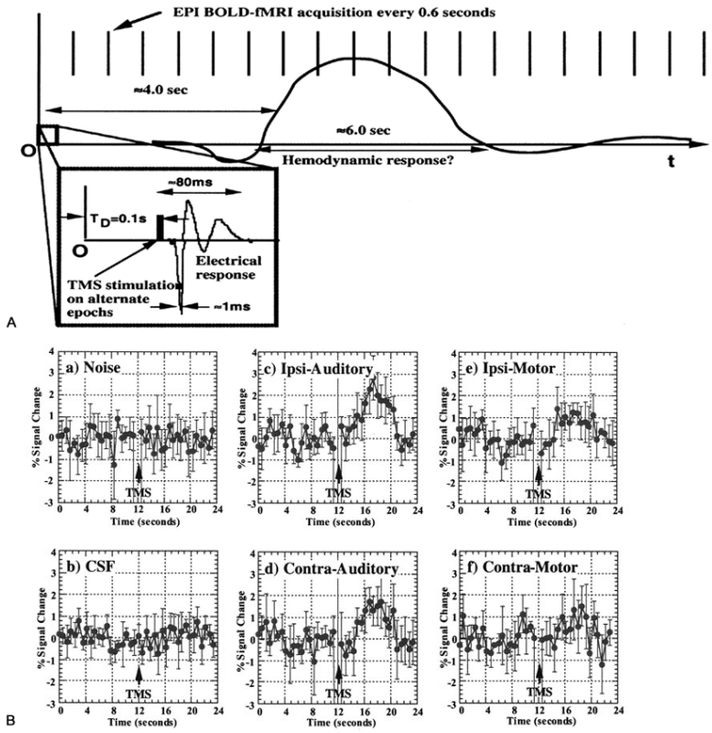

FIGURE 30.6. One can also use an averaged-single-trials approach of transcranial magnetic stimulation (TMS) and functional magnetic resonance imaging (fMRI)—that is, one can discharge a single TMS pulse and then measure the blood oxygenation-dependent (BOLD) response *(top)*. The time series above show the BOLD response in a control region, for the auditory cortex, and in motor cortex. Note that a single pulse of TMS over motor cortex sufficient to cause the opposite thumb to move produces more blood flow changes in auditory cortex (caused by noise) than it does in the motor cortex under the coil.

REVIEW OF TRANSCRANIAL MAGNETIC STIMULATION FUNCTIONAL IMAGING STUDIES TO DATE

Part of "30 - Measuring Brain Connectivity with Functional Imaging and Transcranial Magnetic Stimulation "

Transcranial Magnetic Stimulation Interleaved

Fluorodeoxyglucose PET

The first published combination of TMS and functional neuroimaging in real time was performed with FDG PET in a patient before and after rTMS treatment for refractory depression (54). At a separate time, these investigators also injected the glucose while the patient was intermittently stimulated at 20Hz over the left prefrontal cortex for 20 minutes. In comparison with her depressed scan at baseline, her total brain metabolism rose following weeks of TMS treatment. Also, the scan that was taken during left prefrontal TMS showed marked increases in activity, especially over the prefrontal cortex. Conclusions from this single case study are limited.

Complexity of the Issues as Demonstrated by Initial Simple Studies over Motor Cortex

A basic question for TMS and functional imaging is what happens to blood flow or activity in motor cortex while TMS is stimulating the thumb. A straightforward hypothesis would be that TMS increases blood flow in a manner similar to that produced by volitional movement. Confusion ensued when an early and still unpublished study of 1-Hz stimulation over the motor cortex for thumb showed decreased glucose uptake at the putative site of stimulation and in the contralateral motor cortex (40). Stimulation was performed at 1 Hz because FDG takes 20 minutes to settle into neurons and is thus a composite picture of brain activity over 20 minutes. This paradoxical decrease in localized brain activity both under the coil and at the mirror or contralateral site during TMS was surprising, but findings of decreased brain activity like this had been found in some electrophysiologic studies (12). The final image was a summed picture of 20 minutes of brain activity. It is likely that TMS has multiple different effects during that time—increased activity immediately with stimulation, decreases during the rest time between TMS pulses, and dynamic changes across the 20 minutes. Peter Fox and one of the chapter authors (MSG) (58) next sought to test this finding directly by using ^{15}O PET rather than FDG PET, with the TMS coil directly in the scanner. ^{15}O PET has a shorter time frame (approximately 1 minute for tracer uptake) than ^{18}FDG PET (20 to 30 minutes). Therefore, imaging with ^{15}O PET during stimulation requires that the TMS coil be placed inside the PET gantry. Using the exact same design as in the FDG study, but scanning every 10 minutes for 1 minute, we found that slow (1-Hz) rTMS over the motor cortex caused an *increase* in cerebral blood flow, although this was noted in only four subjects (58). Both of these studies used a functional behavioral placement

of the TMS coil over the optimal position for movement of the thumb and stimulated at or near the motor threshold with visual confirmation that the TMS was producing activity in the motor circuit. Thus, the results of these two initial studies were confusing and frankly contradictory.

To add even more confusion, Paus et al. (34) in the same year published a study combining ^{15}O PET and TMS. In this study, intermittent fast (10-Hz) rTMS over the frontal eye fields for 1 minute caused dose-dependent *increases* in blood flow at the stimulation site and in visual cortex. In other words, when they increased the number of 10-Hz trains within the minute, blood flow increased. Surprisingly, when the same investigators used the same rTMS parameters in the same subjects but shifted the coil to motor cortex, they found a *dose-dependent reduction in cerebral blood flow* (59). Importantly, they positioned the coil based on a probabilistic brain, and they also stimulated below motor threshold. No thumb movement occurred in these subjects.

Thus, the initial dream of using TMS and imaging to address connectivity problems in the brain has been hindered by a lack of consensus about basic imaging and TMS questions. Using yet a different technology, BOLD fMRI, our group in several studies consistently found that over much shorter time domains (7 to 30 seconds), TMS at motor threshold or above, positioned by a functional behavioral approach, consistently produced increases in blood flow at the stimulation site and in connected regions, such as the contralateral motor cortex and cerebellum (51 ,52). The issue now appears to be settled; the same National Institutes of Health group that found decreases with FDG PET has recently completed a more fastidious ^{15}O PET study. In this study, Speer and colleagues found dose-dependent *increases in blood flow* in motor cortex with 1-Hz TMS, as was noted in the study of Fox et al. (58) and confirmed with the BOLD fMRI technique by our laboratory (A. Speer, *personal communication; May, 2000*).

There is now a small consensus in the existing literature that blood flow increases under the motor cortex in a dose-dependent manner when the TMS coil is positioned by finding the appropriate spot for optimal thumb movement (functional behavioral technique) and stimulation is above motor threshold (and activates large excitatory neurons). When the TMS coil is positioned in this same region by a probabilistic approach, dose-dependent decreases have sometimes been found. Thus, some of the discrepancy in the literature can be explained not only by differing time domains of the imaging technologies, but also by potential differential effects caused by the method of coil placement. In this vein, using an identical study paradigm as their most recent TMS motor study, the National Institutes of Health group (Speer and colleagues) stimulated the same subjects over the prefrontal cortex, defined simply as a certain distance from the motor area (a very crude probabilistic approach, such as has been employed in many of the TMS challenge and clinical studies). Paradoxically, this group found in these same subjects *dose-dependent decreases* in blood flow over prefrontal cortex. In earlier work at 80% motor threshold, we found similar decreases in eight healthy adults when we used perfusion SPECT, with a tracer uptake time of 30 to 40 seconds, to image cerebral blood flow during fast (20-Hz) left dorsolateral prefrontal cortex rTMS (60). In comparison with a control scan with sham TMS, we found relative decreases under the coil site and in the anterior cingulate and orbitofrontal cortex. In contrast, a recent BOLD fMRI study over prefrontal cortex by our group found increases in blood flow at 120% motor threshold (61). With fMRI, one can examine individual differences, and a great deal of heterogeneity of response was noted across subjects. We are currently performing repeatability studies within subjects over time to address the inherent noise in this scanning system and the question of whether repeated TMS/fMRI studies yield consistent results.

The two most likely explanations for the opposite findings over motor and prefrontal cortex are that different brain regions react differently, or that the method of TMS coil placement matters, and that the effects of clear stimulation of large corticospinal neurons may be different from those of nonspecific stimulation of local inhibitory neurons with only probabilistic positioning. Obviously, a series of studies is needed to settle this most important issue. For example, an important next study would be to test directly the issue of blood flow as a function of functional behavioral versus probabilistic coil placement and see if functional positioning produces increases in blood flow and probabilistic placement decreases, presumably secondary to differential stimulation of excitatory versus inhibitory neurons.

BOLD fMRI

As mentioned above, the most promising, but also the most technically challenging, TMS imaging modality is a combination of TMS and fMRI. Bohning et al. (51) first demonstrated the capability of interleaving TMS and BOLD fMRI with good spatial and temporal resolution. This technique was initially thought impossible by many because of concerns about introducing a focal TMS magnetic field (1 to 2 T) inside a clinical MRI scanner of 1.5 T. Our group has found that this technique, with the right precautions, is both feasible and safe. Considerable progress has been made in devising a system for interleaving TMS with fMRI (53). Figure 30.4 shows one subject's brain with areas of TMS-induced activation superimposed in color. The time–activity curve shows the changes in BOLD signal over the course of the experiment as the TMS machine is alternately triggered at 1 Hz for 18 seconds and then turned off.

Work to date with this technique has shown that it is sensitive enough to detect subtle differences in brain blood flow response that result from minor changes in TMS intensity (52).

Additionally, direct comparisons of blood flow changes in motor cortex caused by TMS or volition show a surprising similarity between TMS-induced changes and those associated with normal movement (71). For example, the location of the peak blood flow change is the same for TMS and normal movement (within 2 mm). Also, stimulating at around 1 Hz and just at motor threshold activates roughly the same amount of brain tissue, and to the same degree. Thus, although many have the perception that TMS is causing supraphysiologic changes in the brain, these data imply that TMS at these parameters is acting remarkably like normal physiology.

Using Interleaved TMS/fMRI to Address Issues of Connectivity: An Initial Study

Several electrophysiologic studies have suggested that 1-Hz TMS over time domains of 3 minutes or more is inhibitory (12). To test whether this inhibitory effect occurs at time domains of several seconds, we performed TMS within an fMRI scanner and measured blood flow with the interleaved TMS/fMRI BOLD technique. Within a 1.5-T MRI scanner, five adults were stimulated by applying a figure 8 TMS coil over the left motor cortex at the optimal spot for producing movement in the contralateral (right) thumb (abductor pollicis brevis). In 21-second epochs, subjects alternated between rest and a sequential finger opposition task in their left (nondominant) hand. In alternating-movement trials, TMS was applied either at 120% motor threshold or 10% of stimulator output (below the threshold for movement) (Fig. 30.7). Coronal echo-planar BOLD images were acquired continuously throughout, interleaved so that TMS occurred 100 milliseconds after every fourth image acquisition.

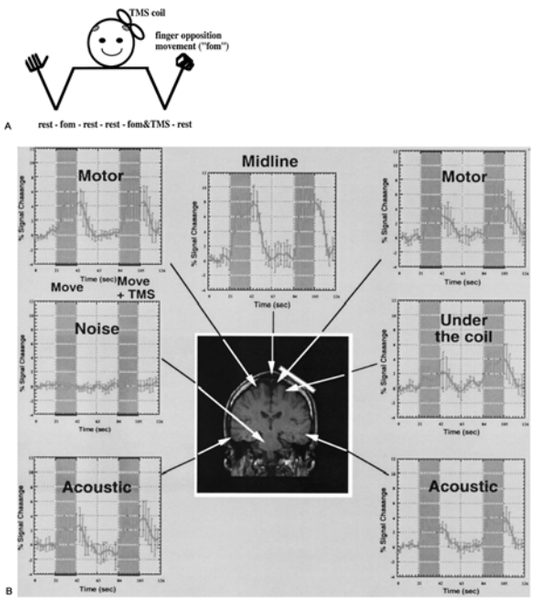

FIGURE 30.7. Several transcranial magnetic stimulation (TMS) electrophysiology studies have demonstrated that low-frequency TMS over one motor cortex can inhibit the opposite motor region. In this study, we applied TMS over the left motor cortex and had subjects perform a complex task with their nondominant (left) hand. TMS was applied on alternate epochs. We hypothesized that TMS would inhibit the blood oxygenation-dependent (BOLD) response in the right motor cortex. We did not see this. Interestingly, TMS produced an increase in BOLD response under the coil in an area of cortex that was already active. This simple study in which TMS was used to test connectivity highlights many of the issues raised in this chapter concerning how and where to apply TMS, and whether baseline activity in the underlying brain matters in terms of response.

With this technique and at these short time intervals, TMS did not inhibit the local or remote BOLD response during movement. In fact, TMS of the left hemisphere caused a local 1.5% increase in blood flow in addition to the 2.5% activation caused by the complex movement. We therefore concluded that the application of TMS over motor cortex for 21 seconds during a motor task-enhanced motor cortex activation does not inhibit the BOLD response. Actually imaging the remote inhibitory or modulatory effect of TMS at a different site remains for the future.

Averaged Single Trials

There is no doubt that a single TMS pulse applied to motor cortex is capable of causing a neuronal response because its consequences can be clearly seen in the form of an overt movement of the contralateral extremity. However, to date, the only functional neuroimaging technique in which the response to single-pulse TMS has been observed is EEG. Our laboratory recently sought to determine if interleaved TMS and fMRI could be used with an averaged-single-trials protocol to detect BOLD response to neuronal activation induced by a single TMS pulse, and to measure its time course.

The technique is important because it allows a comparison of different TMS events by means of their associated BOLD responses. For example, with a single-event technique. it might be possible to compare different TMS intensities, or coil orientations, or single versus paired stimulation (through one coil or possibly two different coils, one conditioning coil and one test coil). Such studies could provide a bridge between electrophysiology (variation of motor evoked potential amplitudes) and fMRI (variation of BOLD response). Moreover, combining TMS with precise timing relative to a behavior with the averaged-single-trials technique would likely make it possible to image the activity of brain circuits and their connections.

In an initial study in this area, five healthy volunteers were studied with interleaved TMS/fMRI and an averaged-single-trials protocol (57). The BOLD fMRI response to single TMS pulses over the motor cortex was detectable in both ipsilateral motor cortex under the TMS coil and contralateral motor cortex, and also bilaterally in auditory cortex. The associated BOLD signal increase showed the typical fMRI hemodynamic response time course. The response of the brain to a single TMS pulse over motor cortex at 120% of the level required to induce thumb movement (1.0% to 1.5% signal increase) was comparable in both level and duration with the auditory cortex response to the sound accompanying the TMS pulse (1.5% to 2.0% signal increase) (Fig. 30.5).

Thus, ultimately, TMS combined with fMRI may allow for more exact positioning of the TMS coil, with information obtained about the magnetic field produced and also about alterations in physiology and biochemistry. Refinements of the averaged-single-trials technique and precise timing of TMS offer the potential of increasing the temporal resolution of fMRI and promoting its evolution into a tool for assessing connectivity. Much background work is needed before this combined technique can achieve its potential.

Quantitative EEG

Ilmoniemi et al. (62) have combined high-resolution quantitative EEG (qEEG) with TMS and reported regional changes in spectral content that shifted over very brief episodes of time and corresponded with known regional connections with primary motor cortex. High-resolution EEG clearly has the best temporal window of all the techniques (in the millisecond range), although the spatial resolution is poor. Unfortunately, this group in Finland is the only one to date to be able to circumvent the technical problem of recording EEG immediately after TMS and so avoid the artifact produced by the TMS pulse. This area has not advanced as rapidly as expected in the last 3 years, perhaps because of the complexity of the technique.

Transcranial Magnetic Stimulation and Multimodal Integration

Lastly, several groups have now used TMS in a complementary way to address systems neuroscience questions. The TMS aspect of the study serves to confirm or validate a result from a purely functional imaging study. Two recent studies illustrate many of the important aspects of this type of work.

Kosslyn and colleagues (63) used TMS to investigate secondary visual cortex (area 17) and visual imagery. As a first part of this study, a traditional ^{15}O PET study was performed in subjects while they visually imagined a stimulus. As predicted from previous imaging studies in humans and animal studies, area 17 activated during this task. In a different cohort, with the use of probabilistic positioning, TMS over putative area 17 interrupted this visual imagery task. This study suffered in several respects, most notably in not knowing whether the TMS actually was applied over area 17. It nevertheless demonstrated the potential of using TMS as a convergent method of testing brain–behavior theories.

In a more elegant and rigorous application of this approach, Desmurget and colleagues (64) used TMS and imaging to test the role of the posterior parietal cortex in correcting the ongoing trajectory of movements (64). They scanned healthy subjects while they pointed to visual targets that either remained stationary or moved during saccadic eye movements. Then, using a functional image-based positioning system, they applied TMS over the left posterior parietal cortex during stimulus target presentation. The TMS disrupted the normal path corrections that occur in moving objects. Thus, in this study, TMS indicated the necessary and critical role of an area in the performance of a behavior and extended the traditional observational imaging approach.

CONCLUSIONS AND DIRECTIONS FOR FUTURE RESEARCH

Part of "30 - Measuring Brain Connectivity with Functional Imaging and Transcranial Magnetic Stimulation "

Transcranial magnetic stimulation combined with functional imaging offers the promise of a better understanding of brain circuits and the causal relationship between behaviors and activity in distributed brain regions. Several studies with a variety of imaging modalities have begun to use this approach. These studies have largely demonstrated that before the combination of TMS and imaging can be used fully, much more work is needed to improve methods. Very basic questions remain largely unexplored. These include how best to position the coil (functional behavioral versus probabilistic), how to adjust the intensity for nonmotor areas of cortex, and whether to account for differences in depth into the brain (e.g., atrophy). Additionally, a true understanding of TMS effects on the brain are still lacking, and this incomplete knowledge contributes to the lack of understanding of how best to use TMS to address systems neuroscience questions. For example, do different frequencies of stimulation produce varying effects on local metabolism, and if so, how? More complete knowledge of the local pharmacologic effects of TMS as a function of the many parameters of use would greatly advance our ability to apply TMS/imaging in neuroscience research. It is obvious that a great deal of systematic work is needed to understand this interesting tool.

However, although a better knowledge of TMS brain effects would expand and improve its use as a neuroscience tool, the ability to combine noninvasive stimulation of the brain with real-time functional imaging is an important new technique that will no doubt add to our ability to understand brain connectivity.

APPENDIX I

Determining The Appropriate Model For Calculating The Induced Electric Current In The Brain

Although, typically, the spherical model has been used, this assumes that the brain is a sphere with uniform conductivity inside spherical shells with different conductivities, corresponding to the skull and scalp. One group has gone so far as to use tissue segmentations based on MR images and estimates of gray and white matter and cerebrospinal fluid from the literature and the theoretic field of the TMS coil to perform finite element computations of the electric currents induced in individual brains (69). Unfortunately, these computations of the electric currents were performed with special field computation software and a supercomputer (69). Although the assumptions of most computational models that the brain is spherical and the cortex is an isotropic, homogeneous volume conductor are simplistic, some important observations have been made. The charge accumulation on the tissue surface tends to cancel the perpendicular component of the induced electric field, shielding the brain. This forces the resultant electric field to lie predominantly parallel to the tissue surface and fall rapidly with depth (65 ,66 ,67 and 68). These observations are also expected to be valid for models that more faithfully represent the actual shape and composition of the brain by treating it as a summation of finite elements. To take into account the inhomogeneous conductivity of the brain, Cerri et al. (69) used MR images to segment the brain into white matter, gray matter, and cerebrospinal fluid, and a conductivity versus gray level interpolation function derived from tissue conductivity data in the literature to obtain a three-dimensional conductivity map. They then divided the brain into discrete resistive cells (quasistatic approximation) and used a supercomputer to determine the current distribution that would be induced in the three-dimensional resistive network by

an external magnetic field pulse However, such methods are not generally available and are still an approximation. A means of imaging the induced electric field is what is really needed.

APPENDIX II

Principal Component Analysis And Singular Value Decomposition

Principal Component Analysis

Principal component analysis is a mathematical device that uses the intrinsic spatial and temporal properties of a set of fMRI data to reduce its dimensionality. PCA does not refer to a specific statistical model, entails few assumptions, and makes no comment on the significance of the resulting spatial modes. By orthogonalizing the covariance matrix, PCA extracts its important features in terms of principal components, or eigenvectors. These vectors are the linear combinations that account for independent or orthogonal amounts of variance in the observed data. In terms of functional connectivity, a principal component represents a spatially distributed brain system, comprising a subset of brain region, within which many temporal intercorrelations exist. Because any one principal component is orthogonal to the remaining principal components, these systems are functionally unconnected from each other, even though any single area may be implicated in more than one system. To perform PCA, a mathematical technique called *singular value decomposition* is usually used (70).

Singular Value Decomposition

Given a set of M linear algebraic equations relating a set of N unknowns, x_j, j = 1,2,...

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 + \cdots + a_{1N}x_N &= b_1 \\ a_{21}x_1 + a_{22}x_2 + \cdots + a_{2N}x_N &= b_2 \\ \cdots \qquad\qquad\qquad\qquad\qquad &\cdots \\ a_{M1}x_1 + a_{M2}x_2 + \cdots + a_{MN}x_N &= b_M \end{aligned}$$

or, in matrix form,

$$A \cdot x = b$$

where the as and bs are known. If $N = M$, there are as many equations as unknowns, and there is a good chance of finding a unique solution set of x_js.

If $M < N$ or $M = N$ but the equations are not all linearly independent, then there are effectively fewer equations than unknowns. In this case, either there is no solution, or else there is more than one solution vector x. In the latter event, the solution space consists of a particular solution x_p added to any linear combination of (typically) N-M vectors (which are said to be in the nullspace of the matrix A). The task of finding the solution space of A is called *singular value decomposition* of a matrix A.

Singular value decomposition explicitly constructs orthonormal bases for the nullspace (N-M dimensions) and the range (M dimensions) of the matrix, finding the least-squares best compromise solution.

In Vivo Molecular Imaging: Ligand Development and Research Applications

Masahiro Fumita

Robert B. Innis

Masahiro Fumita: Department of Psychiatry, Yale University School of Medicine, New Haven, Connecticut.

Robert B. Innis: Departments of Psychiatry and Pharmacology, Yale University School of Medicine, New Haven, Connecticut.

In positron emission tomography (PET) and single-photon emission computed tomography (SPECT), tracers labeled with radioactive isotopes are used to measure protein molecules (e.g., receptors, transporters, and enzymes). A major advantage of these two radiotracer techniques is extraordinarily high sensitivity (~ 10^{-9} to 10^{-12} *M*), many orders of magnitude greater than the sensitivities available with magnetic resonance imaging (MRI) (~ 10^{-4} *M*) or magnetic resonance spectroscopy (MRS) (~ 10^{-3} to 10^{-5} *M*). For example, MRI detection of gadolinium occurs at concentrations of approximately 10^{-4} *M* (1), and MRS measures brain levels of γ-aminobutyric acid (GABA) and glutamine at concentrations of approximately 10^{-3} *M* (2 ,3). In contrast, PET studies with [^{11}C]NNC 756 in which a conventional bismuth germanate-based scintillator is used can measure extrastriatal dopamine D1 receptors present at a concentration of approximately 10^{-9} *M* (4). Because many molecules of relevance to neuropsychiatric disorders are present at concentrations of less than 10^{-8} *M*, radiotracer imaging is the only currently available *in vivo* method capable of quantifying these molecular targets.

PET and SPECT quantify the distribution of radioactivities in the brain, the direct *in vivo* correlates of *in vitro* autoradiographic film techniques such as receptor autoradiography, Western blots, and Northern blots. Thus, the future possibilities of radiotracer imaging are broad and exciting—and include targets of receptors, signal transduction, and gene expression. From this broader perspective, PET and SPECT methodologies are described as "*in vivo* molecular imaging."

Although *in vivo* molecular imaging is a promising technique, several barriers— physical, monetary, and chemical—to its successful application in neuropsychiatric disorders must be addressed. Physical barriers include limited anatomic resolution and the need for even higher sensitivity. However, recent developments with improved detector crystals (e.g., lutetium oxyorthosilicate) and three-dimensional image acquisition have markedly enhanced both sensitivity and resolution. (5). Commercially available PET devices provide resolution of 2 to 2.5 mm (6 ,7). Furthermore, the relatively high cost of imaging with SPECT, and especially PET, can be partially subsidized by clinical use of the devices. Recent approval of U.S. government (i.e., Medicare) reimbursement of selected PET studies for patients with tumors, epilepsy, and cardiac disease has significantly enhanced the sales of PET cameras and their availability for partial use in research studies. Thus, the major barriers for the expanded use of PET are not physical or monetary, but rather chemical in nature. Simply stated, the major barrier to radiotracer imaging of molecular targets may well be the difficulties associated with developing the radiotracers themselves. Labeling the appropriate precursor typically is not the major impediment. Almost all candidate ligands contain carbon and hydrogen, and the positron-emitting nuclides ^{11}C and ^{18}F can usually be incorporated as an isotopic variant (^{11}C for ^{12}C) or an atomic substitute (^{18}F for ^{1}H). As described in the next section, the most common obstacle to the development of *in vivo* tracers is the relatively small window of appropriate combinations of lipophilicity, molecular weight, and affinity. For a molecule to pass the blood–brain barrier, relatively small molecular weights, less than 400 to 600 daltons (d), and moderate lipophilicity are required. However, in brain, relatively low lipophilicity and high affinity are required to achieve high ratios of specific to nonspecific binding. In contrast, the requirements for *in vitro* ligands are much less stringent because the blood–brain barrier can be removed by homogenization or tissue sectioning and most nonspecific binding washed away. The special requirements of *in vivo* probes (low molecular weight, high affinity, and just the right amount of lipophilicity) are discussed in the next section.

REQUIRED PROPERTIES OF AN *IN VIVO* TRACER

In addition to a high degree of affinity and selectivity, several other properties are required for useful *in vivo* tracers.

Combination of Small Molecular Weight, Appropriate Lipophilicity, and High Affinity

Tissue uptake of a drug (whether radioactive or not) is often analyzed within the theoretic framework of a *compartment*, which is defined as a space in which the concentration of a drug is uniform. Within brain tissue, the time-dependent concentration of drug is described for at least three compartments—free [$C_{2f}(t)$], nonspecifically bound [$C_{2ns}(t)$], and specifically bound [$C_3(t)$] radiotracer (Fig. 31.1). Free and nonspecifically bound ligand, $C_{2f}(t)$ and $C_{2ns}(t)$, cannot be washed away, the way they are in *in vitro* studies. Therefore, a high ratio of specific to nondisplaceable uptake in brain (C_3/C_2) is required to obtain reliable data; to reduce the number of unknown variables, $C_{2f}(t)$ and $C_{2ns}(t)$ are often combined in a single compartment and defined as a compartment, $C_2(t)$) (Fig. 31.2).

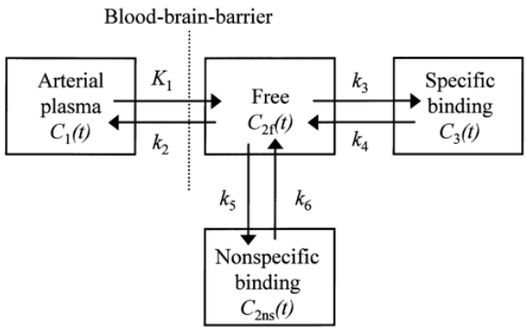

FIGURE 31.1. Compartmental description of radioactively labeled tracer

uptake in brain.

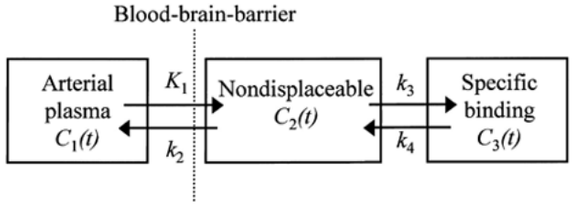

FIGURE 31.2. Three-compartment model (two tissues). To reduce the number of variables, $C_{2f}(t)$ and $C_{2ns}(t)$ in Fig. 31.1 are combined in a single compartment, $C_2(t)$.

Three major factors (i.e., lipophilicity, molecular weight, and affinity) determine the *in vivo* characteristics of a tracer. It is easy to understand that small molecular weight and a high degree of lipophilicity are required to pass the blood–brain barrier because it is composed of a lipid bilayer. However, lipophilicity has opposing effects on the brain uptake of a tracer. Increasing lipophilicity enhances the permeability of the compound, but it also tends to increase plasma protein binding, thereby decreasing the concentration of free drug available to cross the blood–brain barrier. From rat experiments in which 27 tracers of various chemical classes were used, Levin (8) obtained the following simple equation to derive a capillary permeability coefficient, P_c, from an octanol/water partition coefficient, P, and the molecular weight, M_r.

$$\text{Log } P_c = -4.605 + 0.4115 \bullet \log[P(M_r)^{-1/2}]$$

This equation was obtained for the tracers with molecular weights of less than 400 and relatively low lipophilicity (average log P, -0.34; standard deviation, 2.3). Because a higher lipophilicity is required for brain imaging tracers to be taken up adequately in brain, the equation only partially characterizes capillary permeability. High lipophilicity (higher value of log P) increases the binding to the plasma components (protein and cell membranes) (9) and reduces the capillary permeability coefficient expressed relative to the total plasma concentration of drug (10 ,11). Therefore, both low lipophilicity and high lipophilicity decrease the penetration of imaging agents across the blood–brain barrier, so that a parabolic curve is created (Fig. 31.3).

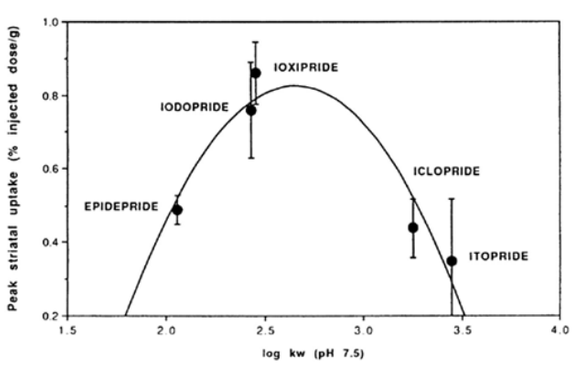

FIGURE 31.3. Relationship between apparent lipophilicity (log K_W) at pH 7.5 and peak striatal uptake (percentage of administered dose per gram of tissue in rat brain). Peak uptake occurred between log K_W of 2.4 and 2.8. Each point is the mean of four animals ± standard deviation. (From Kessler RM, Ansari MS, de Paulis T, et al. High-affinity dopamine D2 receptor radioligands. 1. Regional rat brain distribution of iodinated benzamides. *J Nucl Med* 1991;32:1593–1600, with permission.)

Although low lipophilicity decreases nonspecific binding in brain, it also decreases blood–brain barrier permeability (11). For any particular chemical series, optimal parameters

of affinity and lipophilicity generate a tracer with the best “signal-to-noise” ratio to measure the target molecule, as shown in Fig. 31.3 for a series of benzamide ligands for the dopamine D2 receptor. It should be noted that iodination for SPECT tracers usually increases lipophilicity in addition to molecular weight. Therefore, depending on the position in the optimization curve (Fig. 31.3), either an iodinated or a non-iodinated compound may show the most desirable *in vivo* properties.

Rapid Labeling of Precursor

The radionuclide must be incorporated quickly into appropriate precursor molecules because of the relatively short half-lives ($t_{1/2}$) of the isotopes (e.g., ^{11}C, 20.4 minutes; ^{18}F, 110 minutes; ^{123}I, 13.2 hours). Therefore, precursors must be available that allow quick labeling in one (but usually no more than two) synthetic steps just before the imaging study is performed.

Appropriate Clearance from Specific Binding Compartment

Following the bolus injection of radioactive tracer, the time–activity curve of an organ (e.g., brain) and its subcomponents (e.g., striatum) is characterized by uptake (rising) and washout (declining) phases. If the uptake phase is slow relative to the $t_{1/2}$ of the radionuclide, reasonably accurate data may be acquired only for the rising portion of the time–activity curve. Although parameters related to receptor density and affinity can be derived for selected targets with only the uptake portion, most quantitative methods calculate such parameters with both uptake and washout phases of the tissue time–activity curve. Thus, the tissue clearance of the tracer must typically be matched with the $t_{1/2}$ of the radionuclide. For example, ^{123}I can be used to quantify tracers with much slower tissue kinetics than ^{11}C. The rate of tissue clearance is in part determined by the affinity of the tracer, with ligands of higher affinity tending to “stick” longer to the target molecules. So, as with lipophilicity, the affinity of the candidate tracer should be high enough that significant tissue uptake occurs, but it should not be so high that washout is delayed beyond the usable measurement time of the radionuclide.

In summary, a low molecular weight is almost always mandatory, at least for tracers that cross the blood–brain barrier via passive diffusion. Lipophilicity should be high enough to allow adequate permeability of blood–brain barrier, but not so high as to cause unacceptable binding to plasma proteins or high levels of nonspecific binding in brain. Finally, the affinity of the tracer must balance the opposing goals of tight binding and fast washout from the brain. That is, a high affinity ligand is needed to provide high levels of tight binding of the ligand to the preceptor. However, if the binding is of such high affinity that the ligand shows negligible washout from the brain during the course of a typical study, then the washout rate cannot be determined and critical kinetic data are unavailable to calculate receptor levels in the brain. Such parameters are not required for therapeutic agents (in which fast uptake may not be even helpful) or for *in vitro* tracers (in which most nonspecific binding can be washed away). For example, the nondisplaceable uptake of [^{18}F]haloperidol (12) and [^{11}C]cocaine (13) is unacceptably high for optimal PET imaging of their molecular targets, dopamine D2 receptor and dopamine transporter, respectively, although they can provide valuable data about the disposition of the psychoactive drugs themselves. It should also be noted that desirable properties of radioactive tracers are usually different from those of therapeutic agents. For, example, slow clearance of haloperidol from brain (12 ,14) may maintain effective receptor occupancy for a long period of time. If the distribution in the nonspecific binding compartment [$C_{2ns}(t)$ in Fig. 31.1] is large, the compartment may act as a reservoir of the drug and provide stable levels in brain. The stringent requirements for an optimal radioactive tracer easily explain why only a tiny percentage of *in vitro* tracers and therapeutic agents are useful as *in vivo* imaging ligands.

Negligible Influence of Radioactively Labeled Lipophilic Metabolites

If the parent tracer generates lipophilic radioactive metabolites, they may enter the brain in significant concentration and confound the imaging study. If they do not bind to the molecular target (inactive metabolites), they will increase nonspecific binding [$C_{2ns}(t)$ in Fig. 31.1] and thereby decrease the signal-to-noise measurement of the target. On the other hand, if the radioactive metabolites are active (i.e., bind to the target), quantification is highly confounded because the measured signal represents undetermined proportions of parent tracer and metabolite, each of which may have a different affinity for the target. The problem of lipophilic radioactive metabolites may sometimes be avoided by appropriate selection of the labeling position. For example, a tracer for the serotonin 5-HT_{1A} receptor WAY 100635 can be labeled with ^{11}C at either an external (*O*-methyl) or internal (carbonyl) position. [*O*-methyl-^{11}C]WAY 100635 is rapidly metabolized in humans (15). The metabolic cleavage of WAY 100635 generates two moieties; the ^{11}C-containing methyl component is lipophilic and enters the brain, but the ^{11}C-containing carbonyl component is polar and does not enter the brain. The internal carbonyl labeling is more difficult than the external *O*-methyl labeling, but this clever radiochemistry has markedly improved the signal-to-noise measurement of 5-HT_{1A} receptors in brain (16).

Many tracers currently used for imaging studies produce at least somewhat lipophilic metabolites. However, the quantities produced or their kinetics in passing blood–brain barrier are such that they do not commonly confound the measurements. For example, if the uptake and washout of the parent tracer are fast relative to the production of radioactive

metabolites, then their component of the total measured activity may be negligible during the imaging study.

IN VIVO QUANTIFICATION OF TRACER UPTAKE

Part of "31 - Molecular Imaging: Ligand Development and Research Applications "

In vivo quantification of molecular targets with radiotracer imaging is much more complicated than *in vitro* measurements for several reasons: (a) For *in vivo* experiments, tracers are intravenously administered and not directly applied to the target tissue. Therefore, the delivery of a tracer to the target tissue is influenced by its peripheral clearance (i.e., metabolism and excretion). (b) Total tissue activity is measured, and the separate specifically bound, nonspecifically bound, and free components (Fig. 31.1) are usually estimated with relatively complicated mathematical analyses. (c) The spatial resolution of cameras is limited, and the activity in a region of interest is influenced by tracer uptake in adjacent areas. The details of *in vivo* quantification are beyond the scope of this chapter, and interested readers should refer to other sources (e.g., refs. 17 ,18). The following section provides a simplified overview of the typical parameters and methods of quantification used in radiotracer imaging.

Binding Potential

In addition to having appropriate chemical and physical characteristics, a useful ligand must provide imaging results that are "amenable to quantification" because analogue/visual images are likely to be of limited utility in neuropsychiatric research. The most commonly measured receptor parameter is the binding potential (*BP*), which equals the product of receptor density (B_{max}) and affinity ($1/K_d$, where K_d is the dissociation binding constant). Thus, increased uptake could reflect either an increased number of receptors or the same number of receptors, each of which has a higher affinity for the ligand. To measure both B_{max} and K_d separately, at least two experiments or two injections are necessary, in which formulations of the tracer with both high and low specific activity are used (19 ,20). Because the injection of a tracer with low specific activity (i.e., high mass dose) causes significant occupancy of the molecular target, the potential pharmacologic effects of the tracer must be both safe and acceptable within the experimental paradigm. If these studies are not performed, B_{max} and K_d cannot be measured separately, and only their ratio ($BP = B_{max}/K_d$) is used as the outcome measure (21).

Methods to Measure Binding Potential

In vivo quantification has followed the well-established Law of Mass Action applied to ligand–receptor interactions under equilibrium conditions:

$$\frac{B}{F} = \frac{B_{max}}{K_d + F} \qquad [1]$$

where *B* is the concentration of radiotracer bound to the receptor and *F* is the concentration of free radiotracer (i.e., not bound to proteins) in the vicinity of the receptor. Because radiotracer imaging typically involves the injection of a miniscule mass dose of ligand, the concentration of free radiotracer is quite low. That is, $F<<K_d$, with the result that

$$\frac{B}{F} = \frac{B_{max}}{K_d} \qquad [2]$$

Thus, *BP* can be simply estimated as the equilibrium ratio of bound (*B*) to free (*F*). With this fairly standard three-compartment model (i.e., two tissue compartments and one blood compartment; Fig. 31.2), *B* is denoted as C_3 and *F* as $f_1{*}C_1$. Thus, $B/F = C_3/(f_1{*}C_1)$. This equation makes the reasonable assumption for drugs that pass blood–brain barrier by passive diffusion that the concentration of free tracer in plasma ($f_1{*}C_1$) equals that in brain under equilibrium conditions. Note that Eqs. 1 and 2 refer to *equilibrium* binding conditions. Following the bolus injection of tracer, the ratio of receptor-bound tracer (*B*) and free tracer (*F*) changes dramatically and is not under equilibrium conditions. Figure 31.4 provides a schematic representation of radiotracer concentrations in brain and plasma following a bolus injection with Fig. 4A showing early time points and Fig. 4B showing the entire data. With use of the complete time–activity curves from brain (measured with a PET or a SPECT camera) and arterial plasma (directly sampled and measured in a gamma counter), the goal of compartmental modeling is to estimate the ratio of *B* and *F* under *equilibrium* conditions. In other words, if the free level could be maintained at a constant level, how many times higher than the free level (*F*) would the concentration of receptor-bound tracer (*B*) finally and stably be?

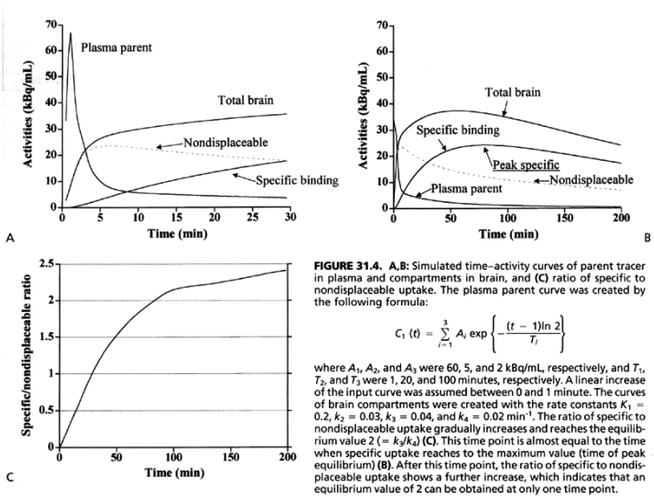

FIGURE 31.4. A,B: Simulated time–activity curves of parent tracer in plasma and compartments in brain, and **(C)** ratio of specific to nondisplaceable uptake. The plasma parent curve was created by the following formula:

$$C_1(t) = \sum_{i=1}^{3} A_i \exp\left\{-\frac{(t-1)\ln 2}{T_i}\right\}$$

where A_1, A_2, and A_3 were 60, 5, and 2 kBq/mL, respectively, and T_1, T_2, and T_3 were 1, 20, and 100 minutes, respectively. A linear increase of the input curve was assumed between 0 and 1 minute. The curves of brain compartments were created with the rate constants K_1 = 0.2, k_2 = 0.03, k_3 = 0.04, and k_4 = 0.02 min^{-1}. The ratio of specific to nondisplaceable uptake gradually increases and reaches the equilibrium value 2 (= k_3/k_4) **(C)**. This time point is almost equal to the time when specific uptake reaches to the maximum value (time of peak equilibrium) **(B)**. After this time point, the ratio of specific to nondisplaceable uptake shows a further increase, which indicates that an equilibrium value of 2 can be obtained at only one time point.

FIGURE 31.4. A,B: Simulated time–activity curves of parent tracer in plasma and compartments in brain, and **(C)** ratio of specific to nondisplaceable uptake. The plasma parent curve was created by the following formula:

$$C_1(t) = \sum_{i=1}^{3} A_i \exp\left\{-\frac{(t-1)\ln 2}{T_i}\right\}$$

where A_1, A_2, and A_3 were 60, 5, and 2 kBq/mL, respectively, and T_1, T_2, and T_3 were 1, 20, and 100 minutes, respectively. A linear increase of the input curve was assumed between 0 and 1 minute. The curves of brain compartments were created with the rate constants K_1 = 0.2, k_2 = 0.03, k_3 = 0.04, and k_4 = 0.02 min^{-1}. The ratio of specific to nondisplaceable uptake gradually increases and reaches the equilibrium value 2 (= k_3/k_4) **(C)**. This time point is almost equal to the time when specific uptake reaches to the maximum value (time of peak equilibrium) **(B)**. After this time point, the ratio of specific to nondisplaceable uptake shows a further increase, which indicates that an equilibrium value of 2 can be obtained at only one time point.

Several methods to estimate receptor parameters have been applied in radiotracer imaging and are briefly summarized below.

1. Compartmental modeling. Often viewed as the "gold standard," compartmental modeling typically requires concurrent and lengthy measurements of parent compound (separated from radioactively labeled metabolites) in plasma and of the brain time–activity curve. Kinetic parameters (K_1, k_2, k_3, k_4) are estimated from this so-called arterial input function (i.e., C_1) and the "impulse response function" of the brain (i.e., sum of C_2 and C_3). The goal of compartmental modeling is to determine the values of the rate constants between these compartments (Fig. 31.2), which when applied to the measured values of C_1 generate a brain time–activity curve similar to that actually measured with the PET or SPECT camera. The underlying concept is that the equilibrium ratio of *B* and *F* is equal to a ratio of kinetic rate constants.

$$BP = \frac{B_{max}}{K_d} = \frac{K_1 \bullet k_3}{k_2 \bullet k_4 \bullet f_1}$$

The major disadvantage of kinetic analysis of compartmental

modeling may often be logistic in nature because arterial sampling may be poorly tolerated, measurement of parent radiotracer in plasma may be technically difficult, and prolonged periods of data acquisition may be needed for both plasma and brain activities. The subsequent methods were developed in large part as “simpler” techniques to obtain receptor measurements that closely correlate with or directly equal those obtained in a complete compartmental analysis.

2. Peak equilibrium method. Based on good theoretic grounds, the “peak equilibrium method” [commonly attributed to Farde et al. (19) for radiotracer imaging] selects a unique equilibrium time as that when specific binding achieves its maximal level. Specific binding is operationally defined as activity in a target region (e.g., striatum) minus that in a background tissue region (e.g., cerebellum). From a practical perspective, a subject is continuously imaged for an hour or two following a bolus injection of tracer. Activities in target and background regions are plotted, and specific binding is calculated at each time point as the difference of the two curves (Fig. 31.4B). At the time of peak specific activity, a measure proportional to binding potential is calculated as specific/nondisplaceable = (target - background)/background, as in (striatum-cerebellum)/cerebellum for a D2 tracer.

One major advantage of the peak equilibrium method is that plasma measurements are not required. Its major limitations include the following:

(a) Background activity in brain is proportional but not equal to the free level of tracer (*F*). Thus, the outcome measure is not equal to *BP*; rather this ratio of specific to nondisplaceable uptake is proportional to *BP*.

(b) Nonspecific binding in the background region may not equal that in the target region, a situation that can be caused, for example, by different proportions of white and gray matter in the two regions. The assumption of equivalent nonspecific binding has been evaluated (usually in animals) with displacement of radiotracer binding by high doses of a nonradioactive drug that also binds to the site. The assumption would be supported by equivalent levels of residual activities in target and background regions with complete receptor blockade.

(c) The time curves of free levels in target and background regions would be predicted not to overlap exactly.

For example, during the uptake portion of the curve, the free level would be lower in the target region because both receptors and nonspecific sites bind the tracer. Thus, at the time of peak specific uptake, the free level in the target region would not be the same as that in the background region. Depending on the kinetics of specific and nonspecific binding, the resulting discrepancy might be significant.

3. Constant infusion methods. Stable levels of drugs, including radiotracers, can be achieved with constant (sometimes called *continuous*) intravenous infusion of the drug (Fig. 31.5A). At some point, typically referred to as *steady state*, the amount of drug entering the blood will equal that leaving the vascular compartment. The levels of both total and free drug in plasma will subsequently be stable. At a somewhat later time point, the amount of drug binding to a receptor in an organ will equal that coming off the receptor; the level of receptor-bound drug will subsequently be stable. In an analogy to *in vitro* receptor binding studies, this stable condition is a state of equilibrium receptor binding.

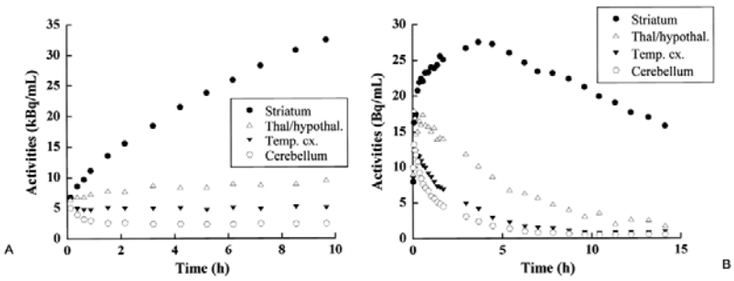

FIGURE 31.5. Brain time–activity curves in a bolus plus constant infusion/equilibrium **(A)** and a bolus/kinetic study **(B)** of [^{123}I]epidepride. **A:** [^{123}I]Epidepride was given as a bolus (145 MBq) followed by constant infusion with bolus/infusion ratio of 6.0 hours (the amount of the tracer given for 6 hours by constant infusion was equal to that of the bolus) in a 33-year-old man. Note that equilibrium was achieved only in low-density regions (thalamus/hypothalamus and temporal cortex), not in a high-density region (striatum), with this bolus/infusion ratio. To achieve equilibrium in all regions, including striatum, a higher bolus/infusion ratio and longer infusion are required. **B:** [^{123}I]Epidepride (371 MBq) was give as a bolus to a 24-year-old man. (Part **B** reprinted from Fujita M, et al. Kinetic and equilibrium analyses of [^{123}I]epidepride binding. *Synapse* 1999;34:290–304, with permission.)

The constant infusion (or so-called equilibrium) method is computationally much simpler than compartmental modeling and does not require extensive brain imaging or arterial plasma measurements. The concentration of receptor-bound tracer (*B*) can be estimated as target minus background. The level of free tracer in plasma (*F*) can be measured in either venous or arterial plasma because the body as a whole is in a condition of steady state. From a practical perspective, the subject is connected to an intravenous pump for several hours, and then a single image is acquired (e.g., 30-minute duration) and a single venous blood sample is obtained. The major disadvantage of this technique is that many hours of infusion may be required to achieve steady-state conditions in both plasma and brain. In addition, data are acquired during a relatively short interval (e.g., 30 minutes) of a long infusion period (e.g., 7 hours). Thus, activity measurements before and after the relatively brief acquisition are not used, and the resulting radiation exposure to the subject can be viewed as "wasteful." In contrast, "all" activity is measured and used in the analysis of a bolus/kinetic study (Fig. 31.5B). From a practical perspective, the total amount of injected activity is often fairly equivalent for a bolus/kinetic and a constant infusion/equilibrium study. However, the total activity in brain after many hours of decay may be quite low and cause statistical counting errors.

In summary, three basic methods can be used to estimate receptor binding potential: (a) compartmental analysis of a bolus/kinetic study, (b) peak equilibrium, and (c) equilibrium imaging following constant infusion of the tracer (with or without an initial bolus of tracer). For all three methods, the target parameter is typically B_{max}/K_d, which equals the equilibrium value of B/F under tracer occupancy conditions (i.e., < 10% of the receptor occupied by tracer). The "true" binding potential (B_{max}/K_d) can be calculated if the free concentration of tracer in plasma is measured with the assumption

that free concentration in plasma equals that in brain. In this case, the measurement of *BP* is the ratio of receptor-bound activity in brain to free plasma activity (*F*). Because a blood sample is not used in the peak equilibrium method, the true *BP* cannot be measured. An alternate outcome measure for each of these three methods uses the nondisplaceable activity in a background region of brain as a value proportional to free tracer concentration. This so-called poor man's binding potential is a ratio of activities in different regions of the brain (specific to nondisplaceable), and therefore plasma measurements are not required.

ESTIMATION OF ENDOGENOUS NEUROTRANSMITTER LEVELS

Part of "31 - Molecular Imaging: Ligand Development and Research Applications "

Molecular imaging probes can be used not only to measure a specific target but also, under appropriate conditions, to estimate concentrations of endogenous compounds that compete with the tracer for binding to the target. For example, a D2-receptor probe can be used not only to measure D2 receptors but also the extent of competition of this binding caused by endogenous dopamine. In fact, the most extensively studied indirect measurements have been the interaction of dopamine with D2-receptor ligands. These studies are briefly reviewed, and the special characteristic of a good ligand for such indirect measurements are discussed.

Tonic and Phasic Release of Dopamine

Dopamine transmission in striatum is thought to occur in two different modes, tonic and phasic (22 ,23). Tonic dopamine release represents the steady-state level of dopamine in the extracellular space, which is estimated to be in the nanomolar range. On the other hand, in phasic release, high extracellular concentrations of dopamine (millimolar range) are released within or near a synapse during an action potential. Close relationships have been proposed between abnormalities in phasic and tonic dopamine release and the symptoms of schizophrenia. Namely, excessive phasic release causes psychosis, and decreased tonic release causes cognitive deficits and negative symptoms (24).

Phasic release has typically been initiated by intravenous administration of a stimulant such as amphetamine or methylphenidate. These agents elevate synaptic dopamine concentrations either by releasing dopamine in a reverse manner via a dopamine transporter (amphetamine) or by blocking dopamine transporter-mediated reuptake of dopamine (methylphenidate). In an imaging study, the elevation of synaptic dopamine levels is estimated by the decrease in D2 radiotracer binding following stimulant administration in comparison with control conditions. Just as careful quantification is required for direct radiotracer binding to a molecular target, a similar if not even more rigorous approach is required for these indirect methods to ensure that measurements of both the tracer and the competing displacer represent “equilibrium” values and not just transient pharmacokinetic “artifacts.” To support the validity of these measurements, microdialysis studies have been performed in conjunction with D2-receptor imaging and a stimulant challenge (25 ,26). Although D2-ligand displacement correlated with the increase in extracellular dopamine measured with microdialysis, the relative increase in extracellular dopamine (1,000% to 4,000%) was much greater than the percentage of displacement of the ligand binding (5% to 15%). Thus, D2-receptor displacement is a “low-gain” monitor (i.e., underestimation) of the increase in extracellular dopamine. The reasons that the changes in binding are so much lower (although still, it is hoped, linear) relative to the increase in extracellular dopamine are unclear. This “low-gain” monitoring may reflect the fact that the imaging measurements cannot temporally track and therefore lag behind the chemical changes they are designed to measure. In other words, the displacement of radiotracer from the brain region occurs over a much slower time course than the relatively rapid changes in extracellular dopamine. Nevertheless, these stimulant-induced displacement studies appear to provide some reflection of changes in synaptic dopamine levels because they are relatively well correlated and because depletion of tissues levels of dopamine can block the effects of amphetamine (27).

The tonic release of dopamine has been estimated by the increase in D2-receptor binding induced by the depletion of endogenous dopamine. The removal of dopamine “unmasks” receptors, which then become available for radiotracer binding. The percentage of unmasking reflects the percentage of D2 receptors occupied by dopamine under basal or tonic conditions. Dopamine depletion has been induced in both animals and humans, with a resulting increase in D2 radiotracer binding (28 ,29). One limitation of these studies, especially in humans, is the difficulty of knowing whether depletion is essentially complete, so that the full extent of dopamine occupancy of the receptor has been measured. For example, if differences in unmasking are found in two subjects, does that reflect different levels of endogenous dopamine—or just different levels of dopamine depletion? A second limitation of this depletion paradigm is that increased receptor binding may not reflect “unmasking” but rather an up-regulation of D2-receptor levels, similar to that often found in denervation supersensitivity. One mechanism to minimize this potential confound is to perform the measurements as soon after dopamine depletion as possible. However, one clear advantage of the depletion paradigm in comparison with the stimulant-induced increase is that the depleted levels can typically be stably maintained during the scan. Thus, the relative slowness of the imaging measurements does not present a pharmacokinetic confound, as it does in studies with stimulant-induced release of dopamine.

Both stimulant and depletion studies have been performed in patients with schizophrenia. In general agreement

with the hypothesis of Grace, the “phasic” increase in synaptic dopamine (assessed following amphetamine administration) has been found to be elevated in drug-free schizophrenic patients, and the decrease in D2 radiotracer binding correlates with a transient increase in psychotic symptoms (30 ,31 and 32). In addition, stimulant depletion studies have found greater unmasking of striatal D2 receptors in patients with schizophrenia, which suggests that basal/tonic synaptic dopamine levels are higher in this disorder (33).

Affinity of Radiotracer

The relationship between affinity of the radiotracer and the sensitivity of its binding to endogenous dopamine is a source of confusion. Under *in vitro*equilibrium conditions and at tracer levels of radioactively labeled ligand, both the Michaelis–Menten and Cheng–Prusoff equations predict that the percentage of receptor occupancy by a competitive inhibitor (e.g., dopamine or other neurotransmitters) depends on the affinity of the inhibitor for the receptor and is independent of the affinity of the radioactively labeled ligand. However, such equilibrium binding conditions are achieved for neither the tracer nor the displacer if each is injected as a bolus. Even under these conditions, the sensitivity of radioligand binding to endogenous dopamine levels is theoretically (at least based on the *in vitro* theories) independent of the affinity of the radioactively labeled ligand when both the tracer and the displacer have achieved equilibrium binding conditions. However, if either the radiotracer (as in the bolus injection paradigm) or endogenous dopamine (as in stimulant-induced release) changes dynamically over time, the equilibrium condition is not achieved, and the apparent sensitivity of the radioligand to endogenous dopamine levels is determined by the kinetic properties of the radioligand (34 ,35). Equilibrium conditions can be achieved for both tracer and displacer in the dopamine depletion paradigm. For example, equilibrium can be achieved with bolus plus constant infusion of the radiotracer, and stable dopamine depletion with AMPT (α-methyl-*p*-tyrosine). The high-affinity D2 radioligand [^{123}I]epidepride provides an instructive example of the differences seen in kinetic and equilibrium studies. The kinetics of its uptake in brain are slow and do not show displacement by transiently increased dopamine levels induced with amphetamine (36). However, stable low levels of dopamine induced with AMPT show unmasking of D2 receptors (37).

In Vivo Confounding Factors

Although the displacement of radioligand binding by neurotransmitter can be simply described with *in vitro* tissue homogenates, several factors complicate the interpretation of *in vivo* experimental results. (a) The affinity states of some receptors for agonists, but not antagonists, is regulated by the receptor to guanyl nucleotide-binding proteins (38). Therefore, *in vivo* measurements are influenced by the affinity states and agonist or antagonist properties of the radiolabeled tracer, and results obtained with agonist and antagonist tracers may be different. (b) Agonist binding typically causes receptor internalization of G protein-coupled receptors (39 ,40). Thus, the endogenous agonist dopamine presumably facilitates the intracellular trafficking of D2 receptors (41), and radiotracers may differ in their affinity for the internalized versus membrane-bound receptor. (c) A significant proportion of D2 receptors are located extrasynaptically (42 ,43), where the concentration of dopamine is lower than in the synapse. Thus, neurotransmitters may occupy a smaller percentage of extrasynaptic receptors than of receptors within the synapse, and the *in vivo* measurement may not truly reflect synaptic neurotransmitter levels.

INTERACTION AMONG NEUROTRANSMISSION SYSTEMS

Part of "31 - Molecular Imaging: Ligand Development and Research Applications "

Abnormalities in psychiatric disorders likely represent the complex interaction of several neurotransmitter systems in the brain. PET imaging has recently been used to examine aspects of neurotransmitter interactions. For example, Dewy and colleagues (44 ,45 and 46) have pioneered studies on interactions among dopamine, GABA, and acetylcholine (ACh) systems in striatum. GABA neurons in the striatum have inhibitory effects on nigral dopamine neurons, nigral dopamine neurons have inhibitory effects on striatal ACh neurons, and striatal ACh neurons have facilitating effects on striatal GABA neurons. By estimating dopamine levels in striatum as described above, Dewey and collaborators showed in human or anesthetized nonhuman primates that the blockade of cholinergic transmission by benztropine (44) or scopolamine (45) decreased [^{11}C]raclopride binding (increase in dopamine levels) and that stimulation of GABAergic transmission by γ-vinyl-GABA (a suicide inhibitor of GABA transaminase) and lorazepam (a benzodiazepine agonist) increased [^{11}C]raclopride binding (decrease in dopamine levels) (46). In addition, they showed that a dopamine antagonist, *N*-methylspiroperidol, induced a decrease in [*N*-^{11}C-methyl]benztropine binding, indicating an increase in ACh levels (44).

Other interactions have also been studied with PET. In two human studies, an *N*-methyl-D-aspartate (NMDA) antagonist, ketamine, decreased [^{11}C]raclopride binding in striatum (47 ,48). In two human studies with similar techniques, the binding of [^{11}C]raclopride was decreased by stimulation of 5-hydroxytryptamine (5-HT) transmission with fenfluramine (a 5-HT releaser) (49) or psilocybin (a mixed 5-HT_{2A} and 5-HT_{1A} agonist) (50). However, these results are discordant with those of previous studies in baboon, in which citalopram (a 5-HT uptake inhibitor) increased [^{11}C]raclopride binding (51). Key aspects of the interaction between dopamine and 5-HT neurotransmitter

systems may well be mediated by glutamate. One significant limitation of these studies is that no useful glutamatergic PET probes have been developed to examine this important mediating neurotransmitter system. Furthermore, the linkage of pharmacologic challenges can be difficult to interpret. For example, if a disorder is associated with an abnormal dopamine outcome measured with PET in response to a 5-HT challenge, is the abnormal response caused by altered sensitivity of the dopamine or 5-HT system?

The results of these studies of interactions among neurotransmission systems have been interpreted under a simple assumption that the binding of [^{11}C]raclopride and other tracers is affected by synaptic neurotransmitter levels. This simple assumption has been questioned by elaborate studies by Tsukada et al. (52). They measured dopamine synthesis, dopamine transporter, and dopamine D2 receptor with L-[β-^{11}C]methyldopa (L-[β-^{11}C]DOPA), [^{11}C]β-CIT, and [^{11}C]raclopride, respectively, in combination with microdialysis in conscious rhesus monkeys. Scopolamine did not change extracellular dopamine levels in the striatum but increased [^{11}C]raclopride binding by decreasing its affinity at the dopamine D2 receptor (52) Furthermore, ketamine decreased [^{11}C]raclopride binding in the striatum without increasing extracellular dopamine levels, and it increased both dopamine synthesis and dopamine availability (53).

Although interpretation may be difficult, and although the pharmacokinetics of either the tracer or displacer and changes in the synthesis and reuptake of neurotransmitters and affinity of receptor binding may complicate the experiment, the authors feel that challenges linked with radiotracer imaging are likely to provide useful information to allow a better understanding of the pathophysiology of neuropsychiatric disorders.

USE OF RADIOTRACER IMAGING IN THERAPEUTIC DRUG DEVELOPMENT

Part of "31 - Molecular Imaging: Ligand Development and Research Applications "

Radiotracer imaging can provide useful information about molecules that are either the direct target of or indirect markers for the effects of therapeutic drugs. For example, if both the tracer and therapeutic drug competitively bind to the same target, then imaging can provide direct information on the extent and kinetics of receptor occupancy in the relevant tissue. In addition, the molecular target measured by the tracer (e.g., amyloid) can be used as a “surrogate” biological marker to assess the efficacy of the therapeutic agent (e.g., one designed to decrease amyloid deposition).

Measurement of Receptor Occupancy

Molecular imaging can provide useful guidance for two aspects of drug administration: dose and dosing interval. The dose is most easily chosen with a known target occupancy and accepted range. For example, typical antipsychotic agents occupy 50% to 80% of striatal D2 receptors (54). Thus, a new typical antipsychotic agent should show a reasonably acceptable side effect profile when given at doses that occupy this range of D2 receptors. With regard to dosing interval, the drug may be retained in tissue much longer than in plasma, and, therefore dosing intervals based on plasma pharmacokinetics may be too frequent. Such a situation has clearly been shown for antipsychotic agents, with which a high rate of receptor occupancy extends well beyond low plasma levels (55 ,56).

The measurement of receptor occupancy and pharmacokinetics in brain combined with the evaluation of adverse reactions in a small number of healthy subjects may provide valuable information for “go/no go” decisions at early stages of clinical drug development. If targeted receptor occupancy is achieved without causing adverse reactions, studies in patients are justified. If not, further studies may not be indicated. Even in the absence of a target level for receptor occupancy, it is reasonably safe to assume that doses associated with greater than 95% occupancy are unnecessarily high, and that those with less than 10% occupancy are unlikely to be efficacious.

The 5-HT$_{2A}$ antagonist M100907 may provide the best example of the use of PET receptor occupancy to provide useful information on dose and dosing interval. By measuring receptor occupancy with [^{11}C]*N*-methylspiperone in healthy human subjects, initially an appropriate amount of a single dose (57) and then an appropriate dose and dosing interval were determined (56). Further, a similar level of receptor occupancy was recently confirmed with [^{11}C]M100907 in a small number of patients with schizophrenia (58).

Dopamine Transporter Imaging as a Biological Marker in Parkinson Disease

Imaging of a biological marker may provide information that is useful either for diagnosis or as a monitor of disease progression. In Parkinson disease, the two most successful imaging targets used as biological markers are measures of dopamine synthesis with [^{18}F]FDOPA and of dopamine terminal innervation with ligands for dopamine transporter.

The symptoms of Parkinson disease are caused by the progressive loss of dopamine neurons in the nigrostriatal pathway. Therefore, a reasonable method of diagnosis would be to “count” the number of dopamine neurons noninvasively. Such measurements are possible with *in vivo* imaging tracers: [^{18}F]FDOPA and various SPECT/PET tracers for dopamine transporter. However, these tracers do not detect the same biological process. Whereas [^{18}F]FDOPA detects metabolic activities at dopamine nerve terminals, the tracers for dopamine transporter simply measure the density of the target protein. Because of this difference, the sensitivity to detect the decrease in dopamine neurons

may be different. In fact, both human and animal studies have indicated that the imaging of dopamine transporter is more sensitive to dopamine neuronal loss (59). Dopamine transporter can be quantified with SPECT tracers, which can be used with lower cost than can PET studies. Therefore, imaging of the dopamine transporter in movement disorders is widely performed in many developed countries.

It is clinically important but sometimes difficult to differentiate essential tremor and Parkinson disease. Dopamine transporter imaging clearly distinguishes these two groups, with only a small overlap (60 ,61). However, dopamine transporter imaging is not able to distinguish idiopathic Parkinson disease from other parkinsonian syndromes, such as multiple system atrophy (62). Further, these techniques have shown bilateral loss of dopamine transporter in hemi-Parkinson disease (i.e., the earliest stage of the disorder), which suggests that even preclinical disease may be detected (63).

Restoring dopamine levels with L-DOPA is still the core medication treatment of Parkinson disease. However, long-term treatment with L-DOPA frequently results in fading of the therapeutic effect and the development of serious motor and psychiatric side effects. Although palliative treatment with L-DOPA is clearly of significant clinical benefit, current drug development is oriented toward neuroprotective treatments designed to slow the loss of dopamine neurons and the consequent progression of symptoms. As a biological marker of dopamine terminal innervation of the striatum, dopamine transporter imaging may well be useful to monitor whether such new therapies actually slow the loss of dopamine neurons. In fact, SPECT imaging is sensitive to and can quantify dopamine transporter loss in longitudinal studies of patients with Parkinson patients treated with conventional therapies (64 ,65 and 66). Therefore, with appropriate sample sizes, this imaging technique can quantify a relevant biological marker as a surrogate measure of the efficacy of putative neuroprotective therapies.

IMAGING POST-RECEPTOR SIGNAL TRANSDUCTION

Part of "31 - Molecular Imaging: Ligand Development and Research Applications "

The majority of the imaging studies performed to date have focused on the synapse: transporters as presynaptic targets, receptors as postsynaptic targets, and indirect measurements of the transmitter as a type of “intrasynaptic” target. However, measurements of membrane receptors merely “scratch the surface” of the cell and ignore the multitude of important intracellular mechanisms required for biological effects. Therefore, two promising areas for expansion in the near future are post-receptor signal transduction and subsequent changes in gene expression. Abnormalities in second messenger systems have been postulated to play important pathophysiologic roles in many psychiatric illnesses, including mood disorders (67) and drug addiction (68). However, only a small number of PET and SPECT studies have been performed on these systems. Although tracers have been developed to image three major biochemical cascades [i.e., cyclic adenosine monophosphate (cAMP), phosphoinositide (PI), and arachidonate pathways], all existing ligands have moderate to significant technical limitations, and better ones are clearly needed. Some of these tracers are lipids, and their nonspecific binding is too high. In addition, because most of these tracers do not bind to a single type of protein but are metabolized by several enzymes, the interpretation of the results is not clear.

cAMP Cascade

Imaging of this signal transduction system was initially attempted by labeling its activator, forskolin, and a related analogue, 1-acetyl-7-deacetylforskolin, with ^{11}C (69 ,70). The binding of [^{11}C]forskolin may be correlated with the activation of adenylate cyclase (71). However, brain uptake of these tracers is very low (69).

Recently, imaging of this cascade was tried with an inhibitor of phosphodiesterase IV (PDE-IV), [^{11}C]rolipram (72). PDE-IV is the major subtype in brain of PDE, which hydrolyzes cAMP into 5′-AMP. PDE-IV is composed of four major enzyme subtypes, PDE-IV A, B, C, and D, and all four subtypes are found in human brain (73). Rolipram binds to and inhibits all four PDE-IV subtypes with high affinity. In one report of a rat *ex vivo* study, [^{11}C]rolipram was a promising tracer exhibiting high specific brain uptake (72). Further evaluation of the binding selectivity and kinetics must be performed in nonhuman primates and humans subjects.

Phosphoinositide System

Imahori and colleagues have studied the PI system *in vivo* using ^{11}C-labeled (74) and ^{123}I-labeled (75) 1,2-diacylglycerol. They showed specific incorporation of the tracer in the chemical components of the rat PI system, such as phosphatidic acid, phosphatidylinositol, phosphatidylinositol 4-phosphate, and phosphatidylinositol 4,5-*bis*-phosphate (74). Further, the tracer uptake was increased by an agonist at the muscarinic ACh receptor, which is known to be coupled with the PI system (74). However, absolute quantification of the tracer uptake is probably difficult because of the high lipophilicity. As explained above (“Required Properties of an *In Vivo* Tracer”), high lipophilicity causes a high level of binding to plasma components (protein and cell membranes), which reduces delivery of the tracer into brain. Under these circumstances, intersubject variability in the amount of tracer delivered to brain may be primarily determined by its binding to plasma components and not by neuronal activity of the PI system. If intersubject variability in f_1 (the free fraction of tracer in plasma) is noted, tracer

uptake cannot be compared among different subjects. Tracers with high lipophilicity and high binding to plasma components enter the brain slowly, and [^{11}C]diacylglycerol did indeed show such behavior (76). Further, whatever amount of a highly lipophilic tracer actually crosses the blood–brain barrier tends to exhibit a high rate of nonspecific binding. In summary, because of the difficulty in absolute quantification, the utility of this tracer as a quantitative measure may be significantly limited.

Arachidonate

The utility of [^{11}C]arachidonate to detect *in vivo* activity of phospholipase A_2 has been studied rigorously. After intravenous injection, [^{11}C]arachidonate is readily taken up (“pulse labeling”) and incorporated into cerebral phospholipids and other stable brain compartments (77). By stimulating receptors that are linked to phospholipase A_2, probably via the PI pathway, the labeled phospholipids are catalyzed to generate arachidonate, and the regionally localized enhancement of phospholipid turnover increases the uptake of [^{11}C]arachidonate. The cholinomimetic arecoline has been shown to increase [^{14}C]arachidonate levels, and this effect can be blocked with a muscarinic ACh-receptor antagonist (78). For the quantification of the activity of this signal transduction system, the measurement should not be affected by cerebral blood flow. Chang et al. (79) showed that the uptake of [^{11}C]arachidonate is relatively flow-independent in monkeys. As with radioactively labeled diacylglycerol, high lipophilicity may be a significant limitation in absolute quantification. The potential dependence of brain uptake on the plasma free fraction may preclude between-subject studies, although within-subject experimental designs may still be valid (e.g., before and after pharmacologic challenge).

IMAGING REGULATION OF GENE EXPRESSION

Part of "31 - Molecular Imaging: Ligand Development and Research Applications "

Signal transduction initiated with presynaptic firing does not terminate with the interaction of a transmitter with its receptors and consequent second messenger generation. Instead, signal transduction may extend to the nucleus with alterations in gene expression. A well-known example is the induction of the protooncogene c-*fos* by receptor–ligand interactions (80). In fact, oncogenes encoding growth factors, membrane receptors, cytoplasmic and membrane-associated protein kinases, guanosine triphosphate-binding proteins (GTP), and transcription factors play important roles in signal transduction and altered gene expression. These genes and their cognate proteins will be important future targets for brain imaging. Much of what we know about these proteins in the central nervous system is derived from studies of cancer biology. Thus, imaging oncogenes and their protein products is also an exciting target for nuclear oncologists, in part because they are pharmacophores for drug development. Several modalities are applied in cancer imaging, including (a) imaging oncogene products with radioactively labeled antibodies, (b) imaging messenger RNAs with labeled antisense oligonucleotides (81), (c) imaging reporter gene products with labeled reporter probes (82 ,83), and (d) applying conventional techniques with labeled small molecules that bind to particular oncogene products.

Because the blood–brain barrier presents a special obstacle in neuroimaging, most techniques successfully used in cancer imaging are difficult to apply in brain imaging. For this reason, the first approach with antibodies is not possible in brain imaging unless the integrity of the blood–brain barrier is disrupted, as in the case of brain tumors. The second approach, in which antisense oligonucleotides are used, is also difficult because these multiply charged compounds do not cross the blood–brain barrier in any appreciable amount. To make radioactively labeled oligonucleotide probes pass the blood–brain barrier, complicated techniques are required, including the utilization of receptor-mediated transport (e.g., insulin and insulin-like growth factor) (84).

The third technique, the use of reporter probes, is being rigorously pursued, with possible applications in gene therapies. The best imaging example is the use of labeled thymidine analogues (e.g., 5-iodo-2′-fluoro-2′-deoxy-1-ß-D-arabino-furanosyl-uracil) in cells expressing herpes simplex thymidine kinase. The probe is phosphorylated by the viral but not by mammalian thymidine kinases and is thereby trapped within the cell, as in the brain uptake of 2-deoxyglucose analogues (85). The basic idea is that gene expression can be monitored by radiolabeled substrate (“reporter probe”), which is metabolized by a transfected gene (“reporter gene”) product and trapped in cells but not metabolized by endogenous enzymes of the host (82 ,83). A reporter gene can be different from a therapeutic gene as long as parallel levels of expression are expected by sharing a common promoter.

At the moment, imaging of reporter probes is used to detect expression only of exogenously introduced genes. Endogenous gene expression, which is interesting in psychiatric research, could be studied by using transgenes containing endogenous promoters fused to a reporter gene (83). A limitation of these techniques in brain imaging is that the widely used reporter probes, the radiolabeled substrates of herpes simplex type 1 thymidine kinase, do not show good permeability of the blood–brain barrier. This limitation can be overcome by using dopamine D2 receptor as a reporter gene and D2 ligands as reporter probes (86 ,87). Because the expression of functional D2 receptors may cause unwanted effects, further studies are being performed on the use of D2-receptor mutants, which are not coupled with intracellular signaling but still maintain binding affinity for D2 ligands.

Parkinson disease provides a useful example for gene therapy of a neuropsychiatric disorder (88). The concept of gene therapy for Parkinson disease has grown directly from the promising results obtained by grafting fetal dopamine-producing neurons. However, the limited availability and ethically controversial nature of the tissue source have restricted the utility of fetal grafts in this disorder. As an alternative, a relatively unlimited supply of homogenous, well-characterized viral vectors could theoretically be produced to deliver tyrosine hydroxylase, the rate-limiting enzyme in dopamine synthesis. Attempts have also been made in animal models to deliver neuroprotective or neurotrophic factors, such as superoxide dismutase and glial cell line-derived neurotrophic factor, to prevent continued degeneration of dopamine neurons. Similar techniques of gene therapy have been investigated in motor neuron degenerative diseases and Alzheimer disease. Reporter genes whose probes can cross the blood–brain barrier, such as D2 receptors, can monitor the expression of these transfected genes. On the other hand, dopamine release from the grafts could be monitored by a conventional technique utilizing competition of radioligand binding to D2 receptors, as described in the section on estimation of endogenous neurotransmitter levels. In fact, this technique of receptor displacement has been used to detect dopamine release in patients with embryonic nigral transplants (89).

The fourth approach, the relatively conventional one of imaging with small probes for relevant gene or oncogene protein products, is hampered by the development of useful and selective probes. As described in the section on the required properties of an *in vivo* tracer, it is difficult to fulfill all the requirements for a successful brain-imaging agent. However, once good imaging agents are developed, these targets can in general be imaged without the complicated techniques required in the other three modalities, described above. Many new anticancer agents are being developed, and a significant number of these agents target signal transduction systems, which may also play pathophysiologic roles in psychiatric disorders (90 ,91). For example, Ras farnesyltransferase is a target for cancer chemotherapy and potentially also for brain imaging. After post-translational modifications, including farnesylation, Ras binds to the cell membrane and transmits signals. Many inhibitors of Ras farnesyltransferase have been developed as anticancer medications (92). Among them, a recently developed agent has a high affinity (93) and may be used as a template from which brain imaging agents can be developed. In addition, a small molecule ligand for epidermal growth factor receptor has been labeled with ^{11}C and has shown brain uptake (94).

Rapid developments in molecular biology and the advent of gene-targeting techniques have enabled the study of individual genes in mice by means of *in vitro* experimental techniques. Recently developed animal-dedicated PET devices (e.g., “rat PET” and “microPET”) achieve high resolution of about 2 mm and can now image these animals*in vivo* (6). These imaging studies may make it possible to apply new findings in molecular biology to the study of patients with neuropsychiatric disorders in exciting ways.

CONCLUSIONS

Part of "31 - Molecular Imaging: Ligand Development and Research Applications "

Progress in molecular neurobiology has dramatically changed our understanding of psychiatric disorders. A significant proportion of these findings have been obtained from animal experiments and postmortem human studies. A major challenge for neuroimaging in future years will be to extended the application of these *in vitro* probes to *in vivo* imaging of patients. Radiotracer imaging with PET, and to a lesser extent with SPECT, is ideally suited for such *in vivo* applications because of its extraordinarily high sensitivity and improving anatomic resolution (now about 2 mm). This chapter has reviewed what is arguably the most difficult barrier to accomplishing *in vivo* molecular imaging—the development of useful and quantifiable tracers. The blood–brain barrier is a challenge to both the delivery of radiolabeled tracers and the quantification of brain uptake of the tracers. However, many successful tracers have been developed to date. These probes have largely been synthesized as analogues of agents active at synaptic transmission and have provided measures of presynaptic, postsynaptic, and even “intrasynaptic” targets. Relatively little progress has been made in measuring intracellular signal transduction or gene expression. These two areas are clearly important targets for future ligand development. By bridging new findings in molecular neuroscience and clinical studies, *in vivo* molecular imaging will likely contribute to a greater understanding of psychiatric pathophysiology and, it is hoped, enhance the development of improved pharmacotherapies.

Event-Related Potentials and Magnetic Fields in the Human Brain

Steven A. Hillyard

Marta Kutas

Steven A. Hillyard: Department of Neurosciences, University of California, San Diego, La Jolla, California.

Marta Kutas: Department of Cognitive Science, University of California, San Diego, La Jolla, California.

To uncover the neural bases of a cognitive process it is important both to identify the participating brain regions and determine the precise time course of information transmission within and among those regions. Although neuroimaging techniques based on cerebral blood flow or metabolism (e.g., positron emission tomography [PET] and functional magnetic resonance imaging [fMRI]) are providing increasingly detailed pictures of the anatomic regions activated during cognitive activity, these methods lack the temporal resolution to reveal the rapid-fire patterning of neuronal communication. Noninvasive recordings of the electrical and magnetic fields generated by active neuronal populations, however, can reveal the timing of brain activity related to cognition with a very high, msec-level resolution. This chapter gives an overview of how these temporally precise recording techniques have been used to analyze perceptual and cognitive mechanisms in the human brain.

The changes in field potentials that are time-locked to sensory, motor, or cognitive events are known as event-related potentials (ERPs) and the corresponding magnetic field changes are termed event-related fields (ERFs). Both ERPs and ERFs consist of precisely timed sequences of waves of varying field strength and polarity (Fig. 32.1). These observed peaks and troughs in the waveform are often referred to as “components.” Some authors, however, prefer to use the term component to refer to portions of the waveform that originate from particular neural structures, whereas others consider ERP/ERF components to be those waveform features that are associated with a particular cognitive process or manipulation (2). Both ERPs and ERFs are generated primarily by the flow of ionic currents in elongated nerve cells during synaptic activity. Whereas synaptic currents flowing across nerve cell membranes into the extracellular fluid produce ERPs, the flow of synaptic current through neuronal processes produce ERFs, thereby giving rise to concentric magnetic fields surrounding the cell. When a sufficient number of neurons having a similar anatomic configuration are synchronously active, their summated fields may be strong enough to be detectable at the scalp.

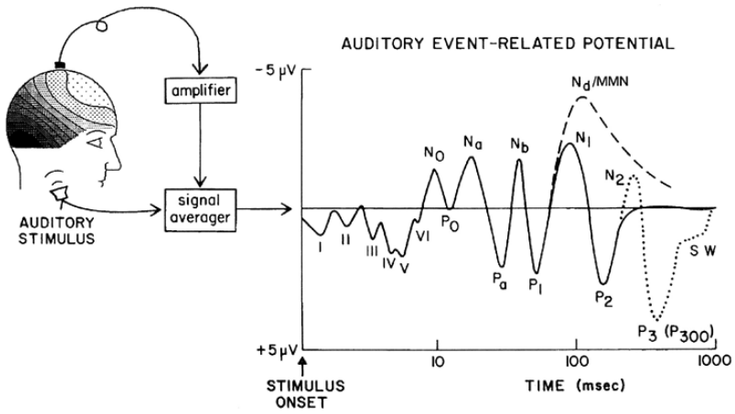

FIGURE 32.1. The characteristic waveform of the auditory event-related potential following a brief stimulus such as a click or tone. The individual components (peaks and troughs) are evoked with specific time delays (latencies) after stimulus onset. Note the logarithmic time base, which makes it possible to visualize the earliest waves (I–VI) generated in the auditory brainstem pathways. Longer latency negative (N) and positive (P) components are generated in different cortical areas. Dashed line shows increased negativity elicited by attended sounds (negative difference) or by deviant sounds (mismatch negativity), and dotted line shows N2 and P3 components to task-relevant target stimuli. Adapted from Münte TF, Schiltz K, Kutas M. When temporal terms belie conceptual order. *Nature* 1998;395:71–73.

When ERPs or ERFs are recorded from the surface of the head, the locations of the active neural generators can only be estimated rather than visualized directly. The calculation of generator locations from surface field distributions is known as the inverse problem, which typically has no unique solution. However, the validity of inverse source estimations can be considerably improved by using algorithms and models that take into account the geometry of the cortical surface, biophysical properties of the intervening tissues, constraints from neuroimaging data, and statistical likelihood of alternative source locations (3 ,4). In general, the localization of active neural populations is more straightforward with surface recordings of ERFs than with ERPs, because magnetic fields, unlike electrical fields, are minimally distorted by the physical properties of the intervening tissues.

ERP and ERF recordings have been used extensively to investigate the spatiotemporal patterns of brain activity associated with a variety of perceptual, cognitive, and linguistic processes. The general research strategy has been to discover the mapping between the components of the waveform and specific cognitive processes that are engaged by a particular task. When an ERP/ERF component can be shown to be a valid index of the neural activity underlying a cognitive operation, that component can yield valuable information about the presence or absence of that operation and its timing with respect to other cognitive events. In many cases, such data have been related to psychological models of the underlying processing operations and used to test alternative theoretical positions. In addition, by localizing the neural generators of such components, inferences can be made

about the participating anatomic circuits that can be interfaced with neuroimaging and neuropsychological data. This chapter describes recent advances made using this approach for analyzing the neural and cognitive mechanisms of preattentive sensory processing, selective attention, mental chronometry, memory storage and retrieval, and language comprehension and production. The use of ERP/ERF recordings to evaluate cognitive disorders associated with neurobehavioral and psychopathologic syndromes also is reviewed.

PREATTENTIVE SENSORY PROCESSING

Part of "32 - Event-Related Potentials and Magnetic Fields in the Human Brain "

Much of the early ERP waveform, and some later components as well, represent sensory-evoked neural activity in modality-specific cortical areas. These evoked components vary with the physical parameters of the stimuli and in many cases are associated with the preattentive encoding of stimulus features. In the visual modality, for example, the early C1 component (onset latency 50 to 60 msec) originates in retinotopically organized visual cortex (5) and varies in amplitude according to the spatial frequency of the stimulus (6). Similarly, the early auditory cortical components P50 and N100 (and their magnetic counterparts, M50 and M100) arise in part from generators in tonotopically organized supratemporal auditory cortex and reflect the encoding of perceived pitch (7).

In general, ERP amplitudes decrease when the time between successive stimulus presentations is made shorter than the refractory or recovery period of the component under study. Although the neural processes underlying ERP refractory effects are not well established, some candidate mechanisms include synaptic fatigue, active inhibition, and the persistence of sensory memory for the preceding stimulus. In line with this latter idea, the refractory period of the auditory M100 has been found to have a similar time course to that of sensory or “echoic” memory for stimulus loudness (8).

The P50 and Sensory Gating

The refractory properties of the auditory P50 (P1) component have been studied extensively over the past 20 years as a possible marker of abnormal sensory input control in schizophrenia (9 ,10 ,11 and 12). In the standard paradigm, pairs of auditory stimuli are presented with an ISI of 0.5 sec, and the amplitude ratio of the P50 evoked by the second stimulus (S2) relative to the first stimulus (S1) is calculated. In general, schizophrenic subjects do not show as large a reduction in the P50 amplitude to S2 relative to S1 as do normal controls. This refractory reduction of P50 amplitude to S2 has been interpreted as a sign of preattentive sensory gating, which occurs because the initial S1 automatically activates an inhibitory system that suppresses responsiveness to S2 (9 ,10). This inhibitory system presumably prevents irrelevant information from ascending to higher levels of cortical processing. The abnormally large S2/S1 amplitude ratio for P50 seen in schizophrenics was thus considered evidence for impaired sensory gating, which was suggested to be the principal sensory deficit of the disease process.

This pattern of more rapid P50 recovery in schizophrenia has been widely reported, but there have been some notable exceptions that raise questions about the exact conditions needed to produce the effect (13 ,14 and 15). A more serious question, however, is whether existing studies have, in fact, demonstrated a reliably abnormal S2/S1 ratio of the auditory P50 in schizophrenics. This concern stems from the way the

P50 has typically been measured—as the maximal positive amplitude within a time window (e.g., 40 to 80 msec) that encompasses the P50 peak. Such peak measures may be artificially inflated by increased levels of background noise in the EEG recordings, originating from either intracranial or extracranial sources. Thus, if a patient group has higher EEG noise levels, then the measured P50 amplitudes tend to be greater because the noise peaks are at times mistaken for the actual peak of the P50. This type of error is more pronounced when measuring the P50 to S2, because its amplitude is diminished relative to the noise owing to refractory effects. Reports of increased variability and lower reliability of P50 measures in schizophrenics (12 ,16) suggest that background noise levels are indeed higher in the patient groups. Several studies, however, have reported that the P50 evoked by S1 is smaller in schizophrenics (11 ,12 ,16), which suggests that overall response amplitudes may be lower and/or response latencies more variable in these patients. Further studies are needed to determine whether the actual S2/S1 amplitude ratio is reliably higher in schizophrenics, or whether this reported effect is a product of noise-sensitive measurement procedures.

Even if the S2/S1 ratio for P50 were determined to be greater in schizophrenia, there would still be some question about its functional interpretation. There is little evidence that refractory reductions of ERP amplitudes to stimuli repeated at 0.5 sec ISIs are associated with any reduction in the perceptual information reaching higher centers. Nor does it appear that the amplitude of P50 to S2 is reduced only when S2 is irrelevant (17), calling into question the hypothesis that the P50 refractory effect reflects the selective gating of irrelevant versus relevant sensory inputs. In addition, it has been reported that schizophrenic patients showing the most severe perceptual anomalies did not differ from normals in their P50 refractory effects (15). Thus, there seems to be scant evidence that reduced P50 refractoriness in schizophrenia, if such exists, is related to the selective gating or filtering of irrelevant sensory information in the auditory cortical pathways.

Auditory Feature Encoding

The preattentive coding of auditory features is indexed with considerable precision by the mismatch negativity (MMN) component and its magnetic counterpart, the MMNm. The MMN is a scalp-negative component with a latency of 120 to 250 msec that is specifically elicited by a deviant sound in a repetitive auditory sequence (18 ,19 and 20). The MMN can be triggered by any discernible change in the ongoing sounds, such as deviations in frequency, intensity, duration, rise-time, timing, and spatial location. MMNs also have been recorded to changes in more complex sound properties such as the phonetic structure of speech sounds and the patterning of tone sequences (20 ,21). Näätänen (22) has proposed that the MMN is generated by an automatic comparator process that contrasts current auditory input against a multidimensional trace of the previous repeating sound's features held in preperceptual sensory memory. This mismatch detection process may represent an early stage in the alerting and orienting of the organism toward novel and potentially important changes in the acoustic environment.

The MMN provides a window on auditory sensory or “echoic memory” because it is initiated by a mismatch with the memory traces of the preceding sounds (23). Indeed, the maximal interstimulus interval (ISI) at which the MMN can be maintained is of the order of 10 sec, corresponding well with behavioral estimates of the duration of echoic memory (19 ,20). The MMN also can be used to study more permanent auditory memory traces, such as those for the phonemic characteristics of one's native language (19) as they emerge during the first year of life (21).

It has been proposed that a supratemporal component of the MMN originating in auditory cortex reflects the preattentive sensory store and automatic change detection process, whereas a frontal component indexes the involuntary orienting of attention to the deviant event (24 ,25). For speech sounds, however, the MMN/MMNm appears to arise from sources in auditory cortex of the left hemisphere, in accordance with proposals that the left posterior temporal cortex is the locus of language-specific auditory traces (19).

Given that the MMN may be elicited with minimal cooperation from the subject, it has found wide applicability for the diagnosis and evaluation of a variety of neurobehavioral and psychiatric disorders (24 ,26). Schizophrenic patients have reduced or prolonged MMNs to pitch or duration deviants, with the degree of abnormality depending on the specific parameters of the stimulus deviance (24 ,27 ,28). These findings provide clear evidence for a deficit in preattentive auditory processing in schizophrenia, although there is some debate about whether the impairment is primarily in temporal processing (28) or auditory encoding and trace formation (27). A different pattern of abnormality has been observed in Alzheimer's disease, with MMN amplitude reductions becoming more prominent at longer ISIs (29), suggesting a more rapid decay of auditory sensory memory traces. MMN abnormalities indicative of auditory processing deficits have also been reported in cases of learning disorders, language and speech impairments, depression, autism, parkinsonism, and HIV infection. (See refs. 19 , 21 , 24 , and 29 for reviews.) Drugs that interfere with NMDA-receptor mediated neurotransmission also disrupt the MMN, which is consistent with models of schizophrenia that posit a disturbance in glutaminergic/NMDA functioning (27).

SELECTIVE ATTENTION

Part of "32 - Event-Related Potentials and Magnetic Fields in the Human Brain "

The brain's attentional systems include a central control network with projections to the sensory pathways of the different modalities that enable the selective modulation of

incoming information. A good deal of research on attention over the past few decades has been aimed at determining whether incoming sensory information is selected at “early” or “late” levels of processing—that is, before or after stimulus properties are fully analyzed (30). Current evidence from both behavioral and physiologic studies indicates that attention can select stimuli at different levels of the sensory pathways, depending on the features being attended and the task requirements.

Auditory Attention

In the auditory modality, ERPs have demonstrated that attentional selection occurs at early levels of cortical processing, but not in the brainstem pathways (31). In dichotic listening tasks with rapidly presented tones to the left and right ears, the earliest ERP component that is reliably influenced by paying attention selectively to one ear is a small positive wave with a latency of 20 to 50 msec (termed the P20–50), which has been localized using magnetoencephalography (MEG) to sources in or near primary auditory cortex. This short-latency modulation provides evidence for an attentional mechanism of sensory gain control at the earliest levels of cortical processing. A much stronger attentional modulation of auditory input takes place at 50 to 70 msec after stimulus onset in the form of a negative difference (Nd) potential that augments the amplitude of the evoked N1 wave to attended-channel sounds (Fig. 32.1). This N1/Nd attention effect also has been localized to auditory cortex by MEG recordings and is considered to be an index of further processing of attended sound information, or alternatively, of the closeness of match between incoming stimuli and the acoustic features that define the attended channel (30). These negative ERP modulations indicate the precise timing with which different auditory features are attended or rejected (32) and provide strong evidence for early selection theories of attention. Schizophrenic subjects reportedly show abnormally reduced Nd amplitudes when attending to multiple sound features, suggesting a deficit in their control functions for allocating attentional resources during selective listening (33).

In recent studies, auditory ERPs have been used to study how attention is allocated in a noisy environment with multiple, competing sound sources (34). When subjects listened selectively to sounds coming from one loudspeaker in a free-field array, the spatial focusing of auditory attention took place in two distinct stages: an early, broadly tuned input selection occurring over the first 80 to 180 msec (indexed by N1/Nd) was followed by a more sharply focused selection of target sounds that began at around 250 msec (indexed by the late positive P3 component). These findings indicate that auditory spatial attention is deployed as a sharply tuned gradient around an attended sound source in a noisy environment. Under these conditions congenitally blind persons were found to have sound localization capabilities superior to those of sighted control subjects (35). ERP data indicated that this enhanced capability of blind persons is mediated at least in part by an attentional tuning mechanism that operates within the first 100 msec after sound onset.

Visual Attention

Covertly directing attention to a specific location in the visual fields typically results in faster and more accurate detections or discriminations of stimuli at that location. Recordings of brain activity in both humans and animals have identified a number of sites along the visual pathways where afferent information is modulated under the influence of visual-spatial attention. Neurophysiologic studies in monkeys demonstrated strong influences of spatial attention on neural activity in extrastriate cortical regions, including retinotopic areas V2, V3A, and V4 and higher areas of both the ventral (inferior temporal lobe) and dorsal (area MT, posterior parietal lobe) processing streams (36). These findings are congruent with human ERP studies showing that stimuli at attended locations elicit enlarged P1 (70 to 130 msec) and N1 (150 to 190 msec) components (Fig. 32.2), which have been localized to generators in extrastriate visual cortex (37). This amplitude enhancement of the P1 and N1 waves occurs with little or no change of the component latencies, suggesting that spatial attention exerts a gain control or selective amplification of attended inputs within the visual-cortical pathways in the interval between 70 and 200 msec after stimulus onset (38).

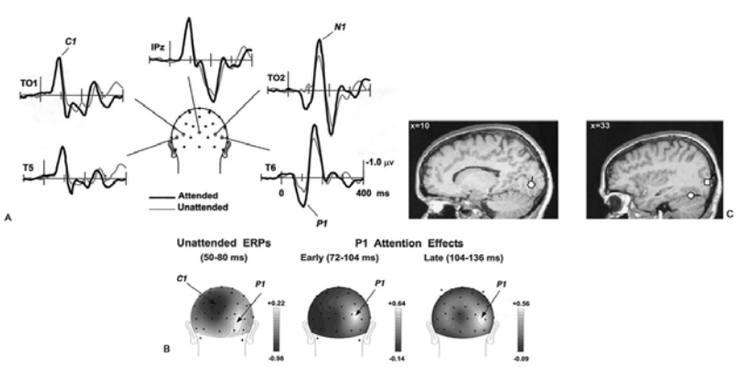

FIGURE 32.2. A: Visual event-related potential waveforms from several scalp sites in response to stimuli in left visual field in study by Martínez and colleagues (41). Subjects were required to attend to one field at a time while randomized stimulus sequences were presented concurrently to left and right fields. Note increased amplitude of P1 and N1 components when stimuli were attended and lack of change in C1 component. **B:** Voltage topographies of C1 component and of the P1 attention effect (increased positivity with attention) in two different time ranges. **C:** Locations of dipolar sources calculated for the C1 component (in primary cortex of calcarine fissure, *left*) and the early and late P1 attention effects (dorsal and ventral extrastriate cortex, respectively, *right*).

In experiments that combined PET neuroimaging and ERP recordings, the calculated dipolar sources of the P1 attention effect were found to correspond closely with regions of increased blood flow in retinotopically organized extrastriate areas, including areas V3/V4 and the posterior fusiform gyrus (37). Significantly, however, the earlier C1 component (onset at 50 msec), which appears to originate from generators in primary visual cortex (area V1), was found to remain invariant with changes in the direction of spatial attention. These findings suggest that spatial attention modulates the flow of visual information at a higher level than the primary cortex.

Recent studies in monkeys, however, reported that stimulus-evoked activity in area V1 may be affected by spatial attention when competing stimuli are present in the visual field (39). The participation of V1 in spatial attention has also been inferred from recent fMRI studies in humans (40). In a study combining fMRI with ERP recordings, Martínez and colleagues (41) observed focal increases in blood flow (BOLD signal) in area V1 as well as areas V2, V3/VP, and V4 at sites corresponding to the retinotopically mapped position of the attended stimulus; however, the amplitude of the C1 component again remained invariant (Fig. 32.2). The earliest influence of attention was on the P1 component (75 to 130 msec), which was localized through dipole modeling to dorsal and ventral extrastriate sources. It was suggested

that the attentional modulation of V1 activity revealed by fMRI may take place at a latency longer than the initial geniculo-striate response represented by the C1 and is consequent on delayed feedback of enhanced visual signals back to V1 from higher extrastriate areas. Such long-latency modulations in V1 have been observed in animals and may enhance figure/ground contrast in attended regions of the visual field (39).

The spatial allocation of attention has also been studied with the steady-state visual evoked potential (SSVEP), which is the oscillatory response of the visual cortex evoked by regularly repeating stimuli such as a light that flickers at a rate of 8 Hz or more (42). The amplitude of the SSVEP elicited by such a flickering stimulus is substantially increased in amplitude when attention is directed to its location, thereby indexing amplification of visual inputs within the spotlight of attention. The continuous nature of the SSVEP as a measure of cortical facilitation makes it suitable for measuring the time course of attention shifts among stimuli in the visual fields.

In contrast with spatial attention, when stimuli are selected on the basis of nonspatial features such as color, shape, or spatial frequency, a different pattern of ERP components is observed. Stimuli having the attended feature elicit a prominent “selection negativity” (SN) over the posterior scalp that begins at 120 to 220 msec and may extend for several hundreds of msec (37). The onset of the SN provides a precise measure of the time point at which a particular feature is discriminated and selectively processed, and localization of its neural generators points to the brain regions involved in the selection. When stimuli are selected on the basis of two or more features concurrently, recordings of the SN can indicate whether the features are selected independently or in an interactive, contingent manner (43).

MENTAL CHRONOMETRY

Part of "32 - Event-Related Potentials and Magnetic Fields in the Human Brain "

Motor preparation, execution, and evaluation are indexed by a series of electric (and magnetic) components both preceding and following movement onset. Prime among the ERPs indexing preparation is the readiness potential (RP), which is a slowly ramping negativity that starts about 1 s before the onset of a voluntary or self-paced movement and peaks around movement onset (44). The initial, bilaterally symmetric portion of the RP is generated in the supplementary

motor area (SMA). Approximately 200 to 500 msec before movement onset the RP becomes asymmetric, being maximal over central scalp contralateral to the active musculature. This lateralized portion of the RP has a somatotopic distribution over the motor cortex and has been localized to the primary motor cortex (45). This asymmetric portion of the RP can be seen in stimulus-locked averages (46) and serves as the basis for an index of differential motor preparation termed the lateralized readiness potential (LRP). Subtracting for each hand separately the activity over the ipsilateral from that over the contralateral central site, and then averaging the activity for the two hands together derive the LRP.

The LRP has proven especially useful in studies of mental chronometry aimed at answering questions about the dynamics of information processing. For example, LRP data have shown that whether a person responds quickly and accurately is in large part a function of whether he or she is prepared to do so before the stimulus appears. Appropriate preparation leads to fast and correct responses, whereas inappropriate preparation leads to fast but wrong responses, and no preparation at all leads to slow but accurate responses. More important, LRP data revealed that people develop biases that influence how they prepare to respond. (See refs. 47 and 48 for review.)

In a number of sensory-motor discrimination tasks, LRP recordings have provided strong support for “continuous flow” models that specify that transmission of perceptual information to the response system occurs continuously rather than in discrete, all-or-none stages. Such studies have revealed partial transmission of perceptual information (e.g., about letter identity) to the response system and have provided a means of tracking the time course of the extraction of various types of information. The LRP also has been used to determine the timing of “the point of no return;” that is, the time in the course of response preparation beyond which response execution cannot be stopped (47).

Readiness potentials have been examined in a number of patient populations. They are abnormal in a large majority of individuals with Parkinson's disease (PD), presumably because of abnormal activation of the SMA by the basal ganglia (49 ,50). Because the early part of the RP is sensitive to attention, it has been suggested that motor performance in PD patients might be improved by having them attend to movements that they might otherwise try to execute automatically (51). Individuals with tardive dyskinesia (TD) also show abnormal RPs that are larger in amplitude than those of normal controls and schizophrenic patients without TD (52). Unlike voluntary leg movements, involuntary myoclonic leg movements in patients with restless leg syndrome do not elicit an RP, suggesting that these involuntary movements have a subcortical or spinal origin (53).

Purposeful movements are generally monitored and evaluated so that remedial action may be taken if an error in committed. Performance monitoring of this sort is indexed by an ERP known as the error-related negativity (ERN), which peaks about 100 msec after the onset of the electromyographic activity associated with an erroneous response. ERN amplitude covaries with the perceived inaccuracy of a response (54) and is influenced by how similar the given response is to the correct one. An ERN is also elicited by a feedback stimulus that lets the subject know an error was made. ERN generators have been localized to the anterior cingulate gyrus and are modulated by lateral prefrontal cortex (55). Patients with lateral prefrontal cortical damage are impaired in correcting their behaviors and produce equal-sized ERNs for correct and incorrect responses. ERN amplitude is sensitive to mood and personality variables (56), especially when correct responses are rewarded and/or incorrect responses are punished (57).

MEMORY

Part of "32 - Event-Related Potentials and Magnetic Fields in the Human Brain "

Working Memory

Unexpected events typically require us to revise or update our current working mental model of the environment. Donchin and colleagues (58) proposed that this updating of the working memory (temporary, limited capacity) system is indexed by the P3 (also known as the P300 or P3b) component. (See refs. 59 and 60 for alternative views.) The P3b is a positive, broadly distributed component with a centro-parietal maximum and peak latency between 300 and 800 ms. It is elicited by infrequent target events in a sequence of higher probability nontarget events that are being attended, although irrelevant stimuli that draw attention may also trigger a P3. In general P3 amplitude grows with the relevance, salience, and utility of the target or “oddball” stimulus. The P3 can be elicited by many different simple and complex events, including the occasional absence of a predicted stimulus. (See ref. 61 for review.) The differences in the distribution and timing of P3s in various modalities are consistent with the proposal that there are multiple working memory stores.

P3 amplitude is inversely related to the overall probability of the target events, and varies with the fine structure of event sequences. The more difficult the categorization of the target events, the longer the P3 latency. P3 latency is not correlated with the variance in reaction time that is caused by response execution, thereby making it a rather pure measure of stimulus evaluation/categorization time. The combined sensitivity of the P3 to attention and stimulus evaluation makes it a good index of the availability and allocation of capacity-limited perceptual resources. Measurements of P3 latency and RT together can be used to pinpoint the processing locus of individual differences in performance, as was done, for example, to analyze cognitive slowing with normal aging (62). Similarly, P3 data have demonstrated that the prolongation of response time for the second of two decisions made in rapid succession (“psychological

refractory period") is owing to interference at a stage that follows perceptual categorization, presumably that of response selection (63).

Updating working memory has consequences for an individual's subsequent performance. For example, the relative amplitude of the P3 on a trial when a subject commits an error is predictive of the performance (accuracy and response speed) on the next trial; moreover, the larger the P3 to an item, the greater the likelihood that it will be remembered subsequently. (See ref. 64 for review.) Intracranial recordings in individuals with epilepsy have revealed P3-like potentials in the hippocampal region of the medial temporal lobe (65). The scalp-recorded P3, however, primarily reflects activity in a number of neocortical (frontal, central, parietal, temporal-parietal junction) and perhaps subcortical generators and is mediated by several neurotransmitter systems (66). Not surprisingly, therefore, many patient populations show abnormally small or delayed P3bs including schizophrenic patients, individuals at risk for alcoholism, patients with probable Alzheimer's dementia, and individuals with attention deficit and hyperactivity disorder, among others (61 ,66).

The storage of information in working memory may be modulated by attention and appears to be strongly suppressed during the "attentional blink" that follows detection of the first of two target stimuli presented in a rapid sequence. Luck and colleagues showed that the P3 was absent in response to targets that went undetected during the attentional blink, suggesting that no updating of working memory occurred. (See ref. 67 for review.) However, undetected target words did elicit late negative ERPs, indicating that they had been identified at the level of lexical/semantic processing. Thus, the ERP data provided strong evidence that the attentional blink acts at the postperceptual stage of working memory storage.

A frontally distributed late positivity (P3a) is elicited by rare and unexpected stimuli for which there is no memory template readily available. It appears to reflect an orienting response to stimulus novelty and is reduced in patients with prefrontal cortical injury (68). Maintenance of information in working memory is also reflected in sustained ERPs lasting on the order of seconds. These potentials vary in their scalp distribution as a function of the information being held in working memory, consistent with proposals of independent short-term buffers for verbal and nonverbal information, among others (69).

Long(er)-Term Memory

Encoding

Encoding processes (transforming sensory input into a lasting representation) are associated with an increased positivity between 200 and 800 msec that spans several components. Items that call for preferential processing because they stand out, for example, are better recalled and elicit larger P3 components (70). Likewise, the more deeply (semantically) an item is analyzed, the more likely it is to be remembered, and this is reflected in greater late positivity (71). Even among items that are all deeply processed, those that will in fact be remembered later elicit a larger positivity during encoding than those that will be forgotten (Fig. 32.3). These late components produced during encoding that are predictive of subsequent memory performance are collectively termed Dm effects (71).

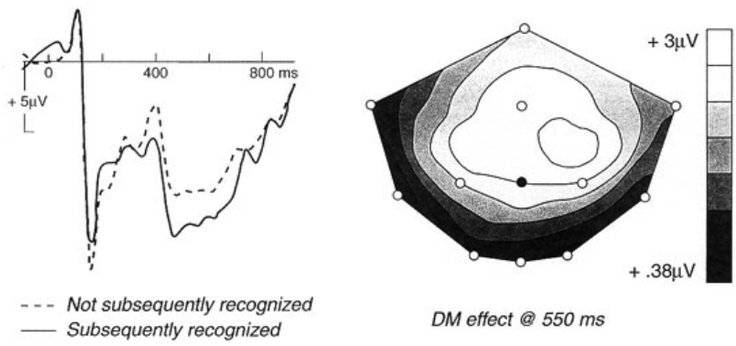

FIGURE 32.3. Averaged event-related potentials (ERPs) from midline parietal site *(filled in circle in map on the right)* sorted as a function of subsequent memory in a cued recall test. The responses to words subsequently recalled *(solid line)* are overlapped with those subsequently not recalled *(dashed line)*. Participants were presented the first three letters of a word and asked to use this stem as a clue for verbally recalling the words they had just studied. The voltage map of this difference related to memory (Dm) effect at 550 ms was computed by subtracting the ERPs to words subsequently not recalled to ERPs from those subsequently recalled. **A:** Semantically anomalous word. **B:** Unexpected word. Adapted from Paller KA. Recall and stem-completion priming have different electrophysiological correlates and are modified differentially by directed forgetting. *J Exp Psychol Learn Mem Cogn* 1990;16:1021–1032.

Dm effects are larger in semantic than in nonsemantic tasks and are not seen for items that have no preexisting representation in long-term memory. Van Petten and colleagues (73) suggested that this positivity indexes the richness of associative elaboration engendered by the to-beremembered event. Consistent with this proposal, the Dm effect varies with the encoding task and information retrieved from long-term memory and shows substantial variability in onset latency, duration, and scalp topography (74).

Retrieval

Retrieval processes are indexed by several ERP effects that vary with whether or not the rememberer is in a retrieval mode, whether memory is queried directly or indirectly, what aspect of the memory is being queried, and whether or not the retrieval attempt is successful (75 ,76). Retrieval itself is indexed by slow potentials sustained over several seconds with an amplitude determined by the difficulty of the retrieval and a scalp topography determined by the nature

of the information retrieved (77). These results fit with the notion that the brain areas involved in explicit memory are the same as those carrying out the initial encoding and perception and argue against the concept of a single, amodal memory store.

In a typical retrieval paradigm items are presented twice, and ERPs to the first and second (i.e., repetition) presentations are compared. When subjects are asked to recognize and detect the repeated items, the task is considered to probe memory directly or explicitly. By contrast, when the old or new distinction is irrelevant, as in tasks involving lexical decision, semantic judgment, or identification of visually degraded words, the stimuli may only tap memory indirectly or implicitly and may not produce actual recollection. In both implicit and explicit memory tasks, stimulus repetition produces large and reliable ERP effects. The first is a reduction in the amplitude of negativity between 250 and 500 msec (N400) that is associated with semantic processing (76). The N400 is reduced by repetition, whether or not the task explicitly calls for detection of repeated items, even in amnesic individuals with damage to the medial temporal lobes (78). Some authors have linked a frontal subcomponent of the N400 to repetition independent of recognition (79).

Another ERP consequence of word repetition is a change in the amplitude of a late positive component (LPC), which typically begins around 400 to 500 msec, and and is somewhat larger over the left than right scalp. There is mounting evidence that this LPC reflects conscious recollection. Factors that influence perceptual priming do not modulate LPC amplitude (80), whereas factors that influence recognition memory do. There is an LPC repetition effect whether memory is tested implicitly or explicitly. When participants are asked to indicate whether an item is old or new, correctly recognized old items elicit larger LPCs than do unrecognized old items or correctly recognized new items, although its distribution across the scalp varies somewhat with the materials (81). The LPC to correctly recognized old items is larger for confident than less confident decisions, and for items that participants actually “remember” (82).

When a subject attempts to remember some aspect of the context in which an item was studied or some attribute of the item that it shared with others in the study task, a large, late, frontally distributed (sometimes right lateralized) positivity is elicited (83). This large positivity over prefrontal sites occurs in addition to the standard LPC effect. The prefrontal locus of this ERP source retrieval effect fits with the known impairments that patients with frontal lobe damage have in retrieving source information about items that they recognize (84).

LANGUAGE

Part of "32 - Event-Related Potentials and Magnetic Fields in the Human Brain "

Semantic Analysis

The semantic analysis of verbal and nonverbal stimuli is indexed by the N400 component (85). The N400 is a broadly distributed component, with a negative-going peak over centroparietal sites often with a slightly right predominance; in young adults, it has an onset around 200 msec and a peak around 400 msec. The largest N400s are elicited by unexpected, semantically anomalous words in a sentence (Fig. 32.4). However, all *potentially* meaningful items (e.g., words and pseudowords, environmental sounds, pictures,

faces) can elicit some N400 activity with an amplitude that is determined by a variety of factors. With little or no contextual constraint, N400 amplitudes are inversely related to the frequency of the eliciting word in the language (86).

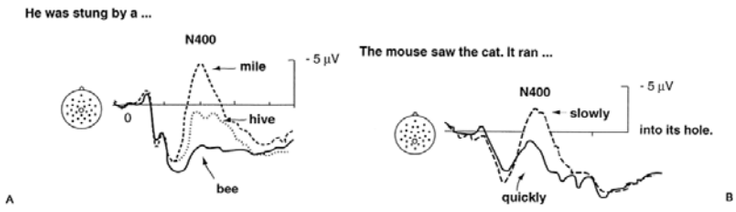

FIGURE 32.4. A: A prototypical N400 recorded at the vertex in response to a semantically anomalous word *(dashed line)* at the end of a sentence, compared with the ERP to the expected ending *(solid line)*, and an anomalous ending that is semantically related to the expected ending *(dotted line)*. Note reduced N400 for nonsensical ending ("hive") that is semantically related to expected ending. **B:** The N400 recorded at a midline parietal site elicited by a word that fits with the ongoing discourse context *(solid line)* versus that to a word that is less expected and does not fit as well with the ongoing discourse context *(dashed line)*. Data taken from van Berkum JJA, Hagoort P, Brown CM. Semantic integration in sentences and discourse: evidence from the N400. *J Cog Neurosci* 1999;11:657–671.

The N400 is typically considered an ERP index of semantic processing or contextual integration because its amplitude is modulated by its relation and fit to the ongoing context, be it a single word, a sentence, or a multisentence discourse. (See refs. 87 and 88 for review.) N400 amplitudes are enlarged to a word in unrelated word pair or in an incongruous or weak context relative to the response to the same word in a related pair or strong congruous sentence. The N400 in these cases is almost identical in timing and distribution over the head, indicating that by 400 msec at the latest, lexical, sentential, and discourse processes all converge to influence language comprehension in a similar manner. Visual half-field studies of the N400 show that the left hemisphere, in particular, uses the organization of semantic memory tapped by context words to aid in its online predictions, whereas the right hemisphere waits and integrates (89).

As would be expected of an index of semantic processing and contextual integration, N400 amplitude is greatly attenuated and its latency delayed in aphasic patients with moderate to severe comprehension deficits (90) N400 latency is also prolonged with normal aging and various dementias. Although ERP evidence for a differential organization of semantic memory in schizophrenia is equivocal, a delay in N400 latency has been reported. (See ref. 87 for review.) Intracranial recordings from patients with epilepsy show potentials functionally similar to the scalp N400 in the anterior fusiform gyrus (91).

Syntactic Analysis

The processing of language at a syntactic level is indexed by a several ERP components, both negative and positive. Many, although not all, syntactic violations elicit a late positivity variously called the P600 or the syntactic positive shift (SPS) (92 ,93 and 94). The P600 is typically elicited when some aspect of sentence structure violates the rules of the language—for example, if the subject of the sentence does not agree with its verb in number or if a word in a phrase is out of order. The P600 also may be elicited when processing difficulties arise at a structural level (87). Some researchers have proposed that the P600 belongs to the family of P3 waves (95). In addition to the P600, many syntactic violations also elicit a left anterior negativity (LAN), which some researchers have interpreted as an index of working memory usage (96 ,97).

The fact that an N400 or P600 is elicited shortly after a semantically anomalous or grammatically incorrect word, respectively, regardless of its ordinal position in a sentence, is most consistent with those models of sentence processing that emphasize the immediate and online nature of comprehension (98). That is, the language processing system seems to use all information as it becomes available, often to predict what words or ideas are likely to come next (89 ,99). That processing at a semantic and syntactic level yields different patterns of electrophysiologic activity suggests that the processes differ, if not the representations. Further, the presence of different ERP patterns to various syntactic violations indicates that syntax is not a unitary phenomenon mediated by a single neural generator. Many aspects of sentence processing at semantic, syntactic, referential, thematic, prosodic, and discourse levels are indexed by transient ERP effects and/or slow potentials that encompass the entire sentence (100 ,101). In short, the reported patterns of ERP effects are inconsistent with a view of language comprehension that gives syntactic analysis precedence over semantic analysis or a system wherein syntactic processes are isolated from all other processes. Instead, ERP data provide considerable evidence for parallel processing, interaction, and top-down effects during language processing. The brains of readers and listeners work very much online using all information as it becomes available to anticipate upcoming items, concepts, and schemas to achieve the aim of an efficient and error-free understanding of the incoming language (even if at times these predictions may lead to misunderstanding).

Language Production

As in language comprehension, many of the controversies in language production revolve around the issue of the relative timing of the different levels of processing that are engaged. Although there is a general consensus that producing a coherent utterance involves information at the levels of meaning, syntax, and phonetics there is no agreement as to whether meaning comes first and then phonologic form (i.e., a serial model), these processes overlap somewhat in time (i.e., a cascade model), or they unfold in parallel (102). Two ERP measures—the LRP and N200—can be used to track the time course of information availability as people prepare to speak, even if they never actually utter a word. In studies using a two choice go/no-go paradigm, subjects were shown a picture of an item on each trial about which they were asked to make two decisions (Fig. 32.5). Across experiments, decisions were based on semantic, syntactic, and phonologic aspects of the pictured item and its name. The timing of the N200 and LRP on no-go trials indicated that semantic information becomes available before syntactic information (by about 80 msec), which is in turn available before phonologic information (by about 40 msec) (103 ,104). Electrophysiologic data from the scalp thus support a serial model of speech production, indicating that people first figure out what they want to say and then choose exactly how to say it.

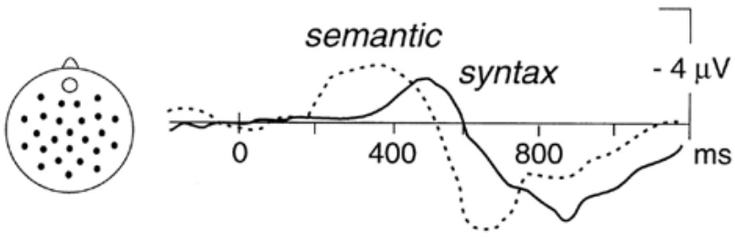

FIGURE 32.5. Overlapped are the N200 difference waves (no-go minus go event-related potentials) recorded at a midline prefrontal site *(as marked on head icon)* when the decision to respond or not (go/no-go) was contingent on a semantic *(dashed line)* versus a syntactic *(solid line)* attribute of the pictured object. Note that the N200 effect contingent on the semantic analysis peaks around 380 ms, whereas that contingent on syntax peaks around 500 ms. Data from Schmitt B, Münte TF, Kutas M. Electrophysiological estimates of the time course of semantic and phonological encoding during implicit picture naming. *Psychophysiology* 2000 Jul;37(4):473–484.

CONCLUSION

Specific components of ERPs and ERFs recorded from the surface of the head are sensitive to a wide range of sensory, perceptual, motor, mnemonic, and linguistic processes. It appears that many cognitive acts engender synchronous neural activity patterns that produce electrical and magnetic fields precisely time-locked to informational transactions in the brain. Recordings of ERPs/ERFs thus provide critical information about the timing and neural substrates of the processing stages that underlie cognitive activity. These physiologic data are being used increasingly to test alternative functional models and to constrain psychological theories (2 ,64 ,105).

Considerable progress has been made in demonstrating reliable associations between ERP/ERF components and a wide range of psychopathologic syndromes. In no case, however, is a single ERP/ERF component absent or abnormal in such a way as to be diagnostic. Rather, a given syndrome (e.g., schizophrenia) usually manifests abnormalities in one or more parameters of several different ERP components, and a given component (e.g., the P3) appears abnormal across a range of neurobehavioral syndromes. This is to be expected, except in the unlikely (and perhaps nonexistent) case in which the psychopathology would only affect a single, isolated cognitive subprocess that had a unique ERP/ERF marker. Thus, instead of seeking a single ERP marker, it seems more likely that various patient populations will be distinguished by different profiles of ERP effects across a number of different tasks (much like the approach taken in neuropsychological testing). Many of the same interpretational issues that are of concern with neuropsychological testing may become relevant for testing with an ERP battery, together with some that are specific to these physiologic measures. For example, the considerable synaptic plasticity of the neocortex suggests that even normal individuals' component amplitudes and latencies are likely to show considerable variability, depending on their life experiences. Such variability within the normal population clearly exacerbates the difficulty of uniquely identifying ERP/ERF markers of specific clinical syndromes. Further progress in achieving diagnostic specificity and sensitivity may require comparing ERPs/ERFs across multiple tasks in each patient to reveal reliable abnormalities that are related to specific cognitive manipulations. Such ERP/ERF abnormalities will become increasingly informative about the specific processing mechanisms that are dysfunctional in patient groups as the cognitive specificity of the distinctive components is sharpened through studies in normals and as better methods are developed for measuring and isolating those components. These developments should make it possible to incorporate ERP/ERF data into multimeasure diagnostic batteries to aid in classifying and subtyping psychopathologic syndromes.

Recent technical advances have made it possible to obtain more accurate information about the neural bases of ERPs/ERFs and their relationships with cognitive and behavioral variables. The neural generators of surface recorded ERP/ERF activity can be localized with increased precision using algorithms that exploit more accurate bioelectric models of the head and constrain the generators to lie within the cortical mantle as reconstructed from MRI scans. (See ref. 105 for review.) Source localizations can be further improved by incorporating functional imaging data (e.g., from fMRI) into the inverse calculations, thereby providing a more veridical picture of the spatiotemporal patterning of cognitive-related brain activity (3 ,4 ,106). New approaches also have been developed for decomposing these complex patterns of brain activity arising from multiple, concurrently active generators into functionally meaningful subcomponents. Among these, the technique of Independent Component Analysis (107) has shown considerable promise for decomposing ERP data sets from multiple task conditions into temporally independent and spatially localizable components that may be related to cognitive operations on the one hand and to fMRI activation patterns on the other. Newer spatiotemporal filtering procedures (e.g., wavelet filtering) have improved our ability to extract the ERP/ERF signal from ongoing brain activity and other background noise. (See ref. 105 for review.) These methods ultimately may allow reliable detection of event-related signals on a single-trial basis without relying on the usual computer averaging procedure. Single-trial analyses are important not only for achieving a closer correspondence between brain activity and behavioral performance but also for ascertaining the degree of trial-to-trial variability that may characterize different clinical syndromes. All of these techniques will substantially increase the utility of ERP/ERF recordings for analyzing the neural bases of both normal and disordered cognition.

Section IV
Drug Discovery and Evaluation

Herbert Y. Meltzer

Drug Discovery and Evaluation - Introduction

It is fitting to include in *Neuropsychopharmacology: The Fifth Generation of Progress* a group of chapters concerned with many of the important issues related to: (a) the development of new drugs (e.g., the role of preclinical models to develop and test targets for new drugs; (b) the role of biological markers and imaging studies to provide indices of drug action in humans or predict clinical response; (c) advances in clinical trial design; (d) the optimal utilization of existing drugs (e.g., pharmacokinetics); (e) pharmacogenomics in relation to drug metabolism, discovery, and development; (f) the ethical issues concerning clinical trials and neuropsychiatric research in general; (g) governmental (at least United States) regulation of the process of developing and utilizing new drugs; and (h) the evaluation of the impact of drug treatment on outcome of neuropsychiatric disorders from the perspectives of economics, clinical endpoints, and humanistic considerations. Although the majority of these issues are the same in many parts of the world where this book will be read, there are clear differences in ethical attitudes toward clinical research and governmental regulation of drug development and utilization around the world (despite the Declaration of Helsinki). It is beyond the scope of this volume to consider the worldwide variations in these issues. All the chapters that have preceded this section bear on the subject matter addressed here because new drug development depends so heavily on our understanding of the function of the brain in general, neurotransmitter and modulator receptors and elimination mechanisms, theories of the etiology of the major neuropsychiatric disorders, efficacy and side effects of existing treatments, and an understanding of the mechanism of action of existing drugs.

The process of new drug development has changed greatly in the few years since the last volume in this series and is likely to change even more rapidly in the immediate future. A great advance was the development of combinatorial chemistry and rapid, robotic characterization of the pharmacologic profile of the vast libraries of compounds produced by this shotgun approach, which, when successful, leads to the elegant and expensive custom syntheses of candidate compounds by sophisticated organic chemical procedures that are now often computer-derived or by methods involving cell and molecular biology to produce peptides or other organic substances. Together with greatly improved methods for analysis of structure-activity relationships, it has been possible to develop putative pharmaceuticals with the desired pharmacologic profile. The old cliché, beware what you desire because you may get it, is relevant here, because it much easier now to come up with the desired pharmacologic profile than it is to be certain that what is sought is what should be sought. There is not yet sufficient understanding of what is needed in the way of an optimal antidepressant, anxiolytic, antipsychotic, mood stabilizer, antidementia, or other type of drug, especially when a truly novel compound is sought.

The chapter by Geyer and Markou on the role of preclinical models in the development of psychotropic drugs mainly focuses on animal models for the major psychiatric disorders. These authors point out that this approach may seem somewhat old-fashioned compared to approaches such as high throughput screening and utilization of molecular biological techniques to develop targets based on gene expression and identification methods; however, they correctly state that preclinical models are *required* (emphasis added) to provide initial assessment of the functional effects of novel compounds in the integrated organism. We are not yet to the point where new chemical entities go directly into patients or even normal volunteers without some evidence that clinically relevant effects might be present. We

can expect major advances in the development of preclinical models as our knowledge of disease processes and our ability to alter the genome in laboratory animals increase. Knockout and knockin mouse models will increasingly guide drug discovery and testing. The importance of research designed to identify new drug targets based on the Human Genome Project and the ensuing effort to characterize the genes involved in neuropsychiatric disorders and the action of drugs used to treat neuropsychiatric illness is discussed in various chapters throughout this volume rather than in a single chapter in this section.

The use of biomarkers (i.e., natural history markers), biological activity marker, and surrogate markers is thoroughly explored by Wong and colleagues, who note that the importance of biomarkers as a means to reduce the cost of drug development, improve the ability to predict outcome, and expedite the identification of desired endpoints (e.g., no more than 80% occupancy of striatal $_2$ receptors in order to minimize the development of extrapyramidal side effects), is increasing all the time. The extraordinary development of a variety of brain imaging methods, including magnetic resonance imaging, functional magnetic resonance imaging, single photon emission computed tomography, and positron emission tomography, appears to be particularly suited for this purpose. Given the cost associated with a failed clinical trial, someday it may be possible to bring brain imaging into routine clinical practice to guide drug dosage and choice. However, more classical methods such as neuroendocrine testing or examining the effect of treatments on peripheral processes such as changes in saliva, serum, and blood cells still can be valuable at various stages of drug development.

Clinical trials abound in psychiatry. Good clinical trials are much more rare. Problems in trial design, identification of appropriate patients, recruitment, retention, and ethical issues surrounding the use of placebos are very much with us and show signs of becoming more rather than less intractable in the near future. The cost of clinical trials in Western countries has grown enormously, leading to fewer and smaller trials that are often market-driven rather than designed to answer the most important research questions. Kane describes a number of efforts that have been made to improve clinical trial design and to cope with the increasing limitations that current ethical viewpoints have placed on this process. It is a sign of progress that broader outcome measures other than global psychopathology are increasingly the focus of clinical trials. For example, the recognition that cognition may be a more important endpoint than the reduction of positive or negative symptoms in the evaluation of a new drug for schizophrenia is an enormous advance because it refocuses the goal of new drug development and allows for distinguishing between new and existing drugs on a much more meaningful basis.

Pharmacokinetics, pharmacodynamics, and drug disposition in relation to new drug development and their subsequent utilization have never been better summarized than they are in the chapter by Greenblatt and colleagues. Advances in this area yield the information needed to use drugs wisely. This area of research has matured to the point where the fundamental principles are well understood and can be readily incorporated into the processes of drug development and utilization. Information about drug interactions that affect efficacy, elimination, and toxicity are ever more essential in the current area of polypharmacy.

Özdemir and colleagues discuss pharmacogenetics, the field that explores individual differences in drug responses that depend on genetic factors and genetic-environmental interactions. A key part of this refers to genetic variations in the liver enzymes that metabolize drugs. Greenblatt and colleagues consider this as well as the genetic factors that determine pharmacodynamics, and thus directly impact on efficacy and side effects. It is clear that this is critically important to psychopharmacology and will become even more so with the completion of the Human Genome Project. They also consider how genomic research will play an increasingly important role in drug discovery and development, including the design of safer and more efficient clinical trials. Their term "personalized therapeutics" is provocative. Have doctors not tried to do this since time immemorial? Genetic information will aid the process to be more science than art (rather than the reverse).

Is medicine in need of new ethical compasses in clinical research? This would seem to be the view of the authors of the United States-based National Bioethics Advisory Commission (NBAC) or the newest version of the Declaration of Helsinki. NBAC, in particular, has singled out research on the mentally ill for more stringent regulation and unique standards. The chapter on ethical aspects of neuropsychiatric research by Pinals and Appelbaum thoughtfully analyzes these recommendations as well as the fundamental principles that should guide policy in this area. Professional societies such as the ACNP have developed guidelines for investigators in an effort to show that there is an awareness of the obligation to protect subjects who agree to research to the greatest possible extent with minimal diminution of the information to be gained from the study. A "safe" study from which we can learn little or nothing of use because of design flaws may be less ethical than others where the absolute risk may be greater, but still within acceptable limits, whereas the potential gain in knowledge is far higher. Institutional review boards (IRB) are becoming increasingly restrictive around clinical research with the mentally ill, based in part on a poor understanding of the intactness of their decisional capacities. It is imperative that methods to assure competence to give consent that meets the legitimate concerns of IRBs are employed in all trials.

Paul Leber, formerly head of the Division of Psychopharmacology of the United States Food and Drug Administration (FDA), explicates the policies of his former employer with the oratorical flourish he is renowned for now transmuted into the written word with equal elegance. This chapter

explains what was (and probably still is) guiding the policies of the regulators of the FDA, which has worldwide influence directly and indirectly. This chapter can serve as a primer on getting a new drug application approved by that agency.

Mahmoud and colleagues succinctly and clearly describe the process of evaluating treatment outcomes utilizing the Economic, Clinical, Humanistic outcomes (ECHO) model. These three perspectives on outcome are intimately intertwined. Trouble arises when any one of the aspects is overemphasized to the neglect of the others. There has been increasing awareness of the need for societal consensus on the importance of outcomes as the cost of achieving the best outcomes now possible has risen greatly as a percentage of gross national product in both developing and developed countries. Advances in medical research will surely suffer if there is insufficient attention to demonstrating that new therapies are more cost-effective, not just more effective, than previous methods. The critical issue of distinguishing between efficacy and effectiveness research and the need for both are thoroughly discussed.

In conclusion, this section on new drug development and clinical research issues should be of great importance to any reader who is interested in the broader picture of alleviating neuropsychiatric disease burden through psychopharmacology.

The Role of Preclinical Models in the Development of Psychotropic Drugs

Mark A. Geyer

Athina Markou

Mark A. Geyer: Department of Psychiatry, School of Medicine, University of California, San Diego, La Jolla, California.

Athina Markou: Department of Neuropharmacology, The Scripps Research Institute, La Jolla, California.

This chapter critically discusses how preclinical models, primarily animal models, can be used in neurobiological research to promote the development of psychotropic drugs as therapeutics for psychiatric disorders. The authors' previous chapter in *Neuropsychopharmacology: The Fourth Generation of Progress* (1) extensively discussed the process of developing, validating, and working with animal models relevant to psychiatric disorders. Various approaches to model development and validation criteria for animal models were defined and evaluated. These basic principles of model development and validation were further elaborated in the context of reviewing animal models of depression and schizophrenia. The present chapter is intended as a continuation and addition to the previous chapter. Thus, assuming the fundamental principles of model development and validation established in the previous chapter and briefly reviewed here, the present chapter focuses on additional aspects of model development, validation, and use that need to be taken into consideration when using models as aids to the development of *therapeutic approaches* for psychiatric disorders. These principles are clarified further by discussing a few exemplary issues relating to animal models used in the study of depression, schizophrenia, and anxiety. Although the development of pharmacologic treatments for psychiatric disorders is typically the major focus, the same basic principles of model use also can be applied in the development of nonpharmacologic therapeutics for these disorders.

DEFINITION OF A PRECLINICAL MODEL

Part of "33 - The Role of Preclinical Models in the Development of Psychotropic Drugs "

A model is defined as any experimental preparation developed for the purpose of studying a condition in the same or different species. A model is comprised of both the independent variable (i.e., inducing manipulation) and the dependent variable (i.e., the measure[s] used to assess the effects of the manipulation). The choice of the inducing manipulation is usually based on hypotheses about the etiology of the disorder of interest or nontheoretic exploratory attempts to induce the abnormality (as reflected in the dependent measures) that is considered relevant to the psychiatric disorder of interest. Pathologies having homology with those in humans can be induced in animals more readily if the etiology of the disease is known. Unfortunately, the etiologies of psychiatric diseases are largely unknown, making the choice of the independent variable particularly difficult. The choice of the dependent measures is usually based on operational definitions of abnormalities believed to be pathognomonic, or at least symptomatic, of the disorder of interest. As with the inducing manipulations, the selection of diagnostic criteria and determination of the core features of a psychiatric disorder are also debatable. Thus, the selection of both the inducing manipulations and dependent measures that comprise a model of a psychiatric disorder are based largely on theoretic arguments regarding both the etiology and core aspects of the disorder. The choice of dependent variables is somewhat easier than the choice of the inducing manipulation because it can be based on operational definitions of observable aspects of the disease, even if the chosen measure is not a core symptom of the disorder.

Preclinical models could involve either human or nonhuman experimental preparations. Typically, models are nonhuman animal preparations that attempt to mimic a human condition, including human psychopathology. Nevertheless, as implied in the definition of a model provided above, preclinical models could also be human experimental preparations. Whether a human or a nonhuman model should be used depends largely on the purpose of the model and the experimental question of interest (see the following). The vast majority of preclinical models in use are nonhuman because such models provide two distinct advantages over

human preclinical models. First, nonhuman models enable the investigation of the neurobiology of the phenomena of interest using invasive techniques that cannot be used in humans. Second, if used properly, nonhuman animal models can significantly reduce the cost of drug development by increasing (or decreasing) the degree of confidence in a particular pharmacologic approach before undertaking expensive and time-consuming clinical trials in the psychiatric population of interest. Nevertheless, it should be clarified that human preclinical models can also contribute importantly to this latter goal, if used properly (see the following).

PURPOSES OF A PRECLINICAL MODEL

Part of "33 - The Role of Preclinical Models in the Development of Psychotropic Drugs "

In developing and assessing an animal model, it is imperative to consider the *explicit* purpose intended for the model (2), because the intended purpose determines the criteria that the model must satisfy to establish its validity and utility. For example, is the purpose of the experimental system to model specific signs and symptoms or to model the entire diagnostic syndrome? Is the purpose of the model to promote our basic understanding of the neurobiological, genetic, environmental, and other factors that contribute to a mental disorder or the development of therapeutic agents for this disorder? Is the purpose of the model to rapidly and efficiently screen compounds to identify drugs that may have similar therapeutic properties to an existing class of compounds, or the identification of therapeutic targets that may lead to the development of compounds having novel mechanisms of action? The preceding are just a few general examples of the various purposes that a model may be intended to fulfill. Such purposes and uses explicitly guide the development and validation process for a particular model. Following, the necessary and sufficient criteria for evaluating preclinical models are reviewed briefly. (See refs. 1 and 3 ,4 ,5 ,6 and 7 for more extensive discussions.) Then, some general issues about preclinical models are discussed that also relate to the premise that the intended purpose of a model determines the validation criteria that the model must satisfy.

NECESSARY AND SUFFICIENT CRITERIA FOR EVALUATING PRECLINICAL MODELS

Part of "33 - The Role of Preclinical Models in the Development of Psychotropic Drugs "

The validity of a model refers to the extent to which a model is useful for a given purpose. Thus, depending on the desired purpose of the test that one wishes to validate, different types of validity are relevant. Further, in considering the validity of a model, both the independent and dependent variables need to be evaluated. The reliability and predictive validity of the model system are relevant to both the independent variable and dependent measures and are the most important criteria to satisfy. (See refs. 1 and 8 ,9 and 10 for definitions of the various types of validity.) The additional criteria relevant to the independent variable (i.e., inducing manipulation) include etiologic, construct, and face validity, with etiologic validity being the most relevant. The criteria relevant to the dependent variable include construct, convergent, discriminant, and face validity. Undoubtedly, the more types of validity a model satisfies, the greater its value, utility, and relevance to the human condition. Nevertheless, it could be considered circular logic if a model was required to satisfy all types of validity before being considered useful. Hence, it has been argued previously that predictive validity and reliability are the only *necessary and sufficient* criteria for the *initial* evaluation of any animal model (1).

Predictive validity of a model is broadly defined as the ability to make accurate predictions about the human phenomenon of interest based on the performance of the model (1 ,9). In reference to animal models of human psychopathology, the term predictive validity is often used in a narrow sense to refer to the model's ability to identify drugs with potential therapeutic value in humans (i.e., pharmacologic isomorphism) (2). Although correct, this use of the term is limited because it ignores other important ways in which a model can lead to successful predictions (7). For example, the identification of any variables that have similar influences in both the experimental preparation and modeled phenomenon can demonstrate predictive value of the experimental preparation and enhance one's understanding of the phenomenon.

Reliability refers to the consistency and stability with which the variables of interest are observed, and is relevant to both the independent and dependent variables (1 ,5).

APPROACHES AND ISSUES RELATED TO MODEL DEVELOPMENT

Part of "33 - The Role of Preclinical Models in the Development of Psychotropic Drugs "

Modeling Specific Signs or Symptoms Versus Modeling Diagnostic Syndromes

As discussed previously (1), early attempts at model development focused on reproducing in animals a psychiatric syndrome in its entirety. Such an approach, although useful in advancing the field at the time, has been largely abandoned because of increasing awareness that such an approach is typically impractical, unrealistic, and fruitless for the following reasons. (a) The defining symptoms of psychiatric disorders and even the diagnostic categories themselves are being revised and redefined continuously. (b) One would not expect homology on *all* aspects of a disorder between two species (e.g., one would not expect a rodent to exhibit a complete schizophrenia syndrome). (c) Modeling a syndrome in its entirety would require the validation of multiple endpoints. (d) There is considerable heterogeneity within each of the major diagnostic categories of psychiatric disorders. (e) The validation process for such a model needs to be extensive, thorough, and all-inclusive, and thus not different from the scientific process aimed at elucidating

the neurobiological and behavioral mechanisms mediating a psychiatric disorder.

Most recent approaches to the development of animal models rely on mimicking only specific signs or symptoms associated with psychopathologic conditions, rather than mimicking an entire syndrome. These specific signs or symptoms may be: (a) observables that have been identified in psychiatric populations that may or may not be pathognomonic for or even diagnostic symptoms of the disorder, but can be defined objectively and measured reliably; or (b) more theoretically based measures of psychological constructs that are believed to be relevant to the psychiatric disorder under investigation (2 ,7). The latter approach involves the definition of a hypothetical construct and subsequent establishment of operational definitions suitable for the experimental testing of the validity of the construct in both human and nonhuman animals. The narrow focus of this approach generally leads to pragmatic advantages in the conduct of mechanistic studies addressing the neurobiological substrates of the specific behavior under study. Furthermore, the study of putatively homologous behaviors in both human and nonhuman subjects effectively addresses and bypasses the nonconstructive criticism that complex mental disorders cannot possibly be modeled in nonhuman animals. (See ref. 1 for a more extensive discussion comparing these two approaches to modeling.)

An illustrative example of this approach is provided by some of the models now being used to identify antipsychotic drugs, based on the hypothesis that schizophrenia involves deficits in attentional filtering or gating (i.e., the psychological construct). Theoretically, schizophrenia patients suffer from impairments in filtering or gating of sensory stimuli that lead to an inundation of information and consequent cognitive fragmentation. The hypothetical construct of attentional filtering has been defined operationally and explored in multiple paradigms and in both human and animal studies. For example, numerous studies of schizophrenia patients have demonstrated deficits in behavioral habituation, which is a prerequisite to selective attention, prepulse inhibition (PPI) of startle, a preattentional sensorimotor gating phenomenon, and the gating of auditory P50 event-related potentials (ERPs) (11 ,12 and 13) (see Chapter 51). Each of these operational measures is potentially relevant to the construct of deficient filtering of incoming information, hypothesized to be a common element in the schizophrenia disorders (14 ,15). Each of these operational measures is also amenable to cross-species studies of analogous or homologous behaviors. (See the following for a discussion of these terms.) The fact that schizophrenia patients exhibit deficits in all three measures provides converging support for the hypothesis that schizophrenia involves disturbances in the filtering of sensory and cognitive information (i.e., construct validity). Nevertheless, a recent study explicitly testing the convergent validity of this hypothetical construct has prompted some further refinements in our thinking. Specifically, in a group of normal subjects, P50 gating was strongly correlated with the amount of startle habituation and only weakly with PPI (16), despite the fact that P50 gating appears to be more similar phenomenologically to PPI than habituation. Similar findings have been reported in the parallel animal paradigms using the same operational measures (17). This situation illustrates how phenomenologic similarity (i.e., face validity) can sometimes lead to erroneous conclusions until further detailed behavioral investigations of the construct(s) are undertaken. Furthermore, as reviewed elsewhere (see Chapter 50), habituation, PPI, and P50 gating exhibit some differences as well as similarities in their sensitivity to pharmacologic manipulations used to mimic schizophrenia-like changes in animals. Of critical importance is the relationship, if any, between these experimental measures of filtering deficits and clinical complaints of sensory overload or signs of thought disorder that prompted the original hypothetical construct (i.e., extrapolation from animals to humans). Surprisingly, within a cohort of schizophrenia patients (19), those with deficient P50 sensory gating reported fewer complaints of sensory overload than did patients with normal P50 gating (i.e., the opposite of the predicted relationship). With regard to the PPI sensorimotor gating measure, however, significant correlations have been observed between deficient PPI, and both distractibility (20) and measures of thought disorder based on an abstract problem-solving task (21) in schizophrenia patients. Hence, it appears that the three main operational measures of deficient attentional filtering do not all measure the same hypothetical construct. Thus, in parallel with the heterogeneous group of schizophrenia-like disorders, the construct of deficient filtering may not be a unitary construct, although it could still represent a phenomenologically common outcome of differing etiologies in different forms of schizophrenia. It is important to recognize that each of these measures is demonstrably affected in (presumably heterogeneous) groups of schizophrenia patients and each has engendered animal models that have varying degrees of predictive validity for the identification of antipsychotic treatments. It remains to be seen whether different subgroups of schizophrenia patients will exhibit only one or another of these deficits. If so, the parsing of the original hypothetical construct may lead to empirical distinctions among patient subgroups that could have important implications for the application of specific treatment approaches.

Discovery of Novel Versus "Me-Too" Treatments

Another extreme approach to model development and use relates to the limited purpose of systematically and efficiently screening and identifying potential therapeutic treatments without explicitly assessing the mode of action that leads to the therapeutic effect. In such a case, the model may or may not mimic the actual psychiatric disorder.

Rather, the model is only intended to reflect the efficacy of known therapeutic agents, and consequently lead to the discovery of new pharmacotherapies. Thus, the principle guiding this approach has been termed “pharmacologic isomorphism” (2). As discussed elsewhere (2 ,7), the fact that such models are developed and validated by reference to the effects of known therapeutic drugs frequently limits their ability to identify new drugs having novel mechanisms of action. Accordingly, an inherent limitation of this approach is that it is not designed to identify new therapeutics that may treat either the symptoms of the disorder that are refractory to current treatments, or patient populations that are resistant to current treatments. An example of such a limitation is found in the use of drug-discrimination paradigms used to identify new treatment compounds. In these paradigms, the animal is trained to recognize the drug state induced by a prototypical drug. Typically, the animal is required to press either the right or left of two levers, depending on whether it had been treated with the vehicle or training drug. Potential new therapeutics are then identified by their ability to substitute for the prototypical drug on which the animal was trained. Because these paradigms rely only on the subjective drug-induced cue to which each animal responds and not on an endpoint that can be validated by reference to other behaviors in animals or humans, such procedures can only identify drugs having a similar effect on some unknowable dimension. If the screening involves several paradigms, the profile of the drug can be compared qualitatively and quantitatively to the profiles of known compounds. Such profiles, when combined with “a special kind of flair for the problem” (22), may lead to reasonable predictions about the potential of the compound in the clinic. The ability to rapidly and efficiently identify treatments that may be shown clinically to have some advantages over the older treatments is an advantage of this approach. Nevertheless, these screening paradigms do not provide ways to predict whether the “me-too” drug will have any clinical advantages (e.g., fewer side effects, treatment of refractory symptoms or patient populations) over the “prototypes,” other than in relation to potency.

Modeling Specific Aspects of Treatment Effects: Chronic Versus Acute Drug Treatments

Because both the etiologies and core features of psychiatric disorders are still poorly understood, much research addressing the neurobiology of these disorders has focused on the study of the mode of action of known therapeutics. The targets of clinically effective therapeutics have provided excellent starting points in the investigation of the neurobiology of psychiatric disorders. When taking this approach, it is important that specific aspects of the treatment effects are taken into consideration and incorporated into the paradigms used. For example, it is recognized that chronic treatment with antidepressants is required before a therapeutic effect is observed. This therapeutic delay is not only a severe limitation of current antidepressant treatments but also a hurdle in determining the mechanisms through which antidepressants produce their beneficial effects. Because of this delay in the emergence of the therapeutic effects, it is assumed that these effects are mediated by neuroadaptations that develop as a result of the chronic drug administration. Much research has focused on these neuroadaptations in order to understand the neurobiology of depression; because the therapeutic effect may be produced through “normalization” of the specific abnormalities characterizing depression. It is possible, however, that the therapeutic effect may be produced by separate systems or mechanisms that counteract the abnormalities that are etiologic in depression.

The preceding discussion is relevant, not only to approaches that may be taken in studying psychiatric disorders, but also to the question of whether animal paradigms that demonstrate positive results after acute administration of an established antidepressant are indeed valid models of depression rather than just screening paradigms. It could be argued that with acute drug administration the mechanisms leading to the reversal of the behavioral deficit are not the same as the ones leading to the clinical therapeutic effect. Such arguments certainly have merit. An animal paradigm that not only indicates therapeutic efficacy but also the time-course of such effects is a powerful tool for both neurobiological investigations and drug discovery. The vast majority of animal models of depression do not readily satisfy this criterion despite extensive efforts over decades. Thus, the question is how to best design and interpret data from paradigms that appear to reveal primarily acute therapeutic effects. In many of the animal studies, the acute drug doses are much higher than doses that would be tolerated by humans, especially on the first drug administration. Higher doses may be more likely to produce an acute effect. This argument is supported by data with the forced swim model where it was shown that either high doses of antidepressant drugs or chronic treatment with low doses of antidepressants, ineffective when administered acutely, reversed immobility in the swim test (23). Further, it has been argued that antidepressants may produce immediate improvement of *some* symptoms in humans, but this acute effect may be hard to detect statistically because the initial improvement may be small and seen only in some, but not all, symptoms (23 ,24). Thus, it is possible that reversal of a specific behavioral deficit in a model after acute treatment may indeed be consistent with the clinical reality about a specific symptom. This experimental question is an example of a case in which preclinical animal data could guide the design of clinical investigations that would help assess and improve animal models. Finally, animal models that can only detect acute effects, when guided by good working hypotheses, can be used for target identification by investigating the mechanisms

that lead to reversal or exacerbation of the deficit of interest.

Issues Regarding the Use of "Normal" (Healthy) Versus Perturbed Animals

Although most animal models rely on an explicit inducing manipulation, some models test the effects of putative therapeutic compounds under baseline conditions, that is, without first inducing a deficit in the subjects. Even if such an animal model has predictive validity, it may not be useful in furthering our understanding of the pathophysiology underlying the disorder if the effects of therapeutic treatments depend on an interaction with the underlying pathophysiology. Specifically, the mechanisms through which drugs produce their effects in "normal" versus perturbed animals may differ, even if the primary neurochemical effect may be the same (25 ,26). Indeed, antidepressant drugs have been shown in some studies to have no effects in "normal" human or nonhuman subjects, whereas inducing "therapeutic" effects in patients or perturbed subjects. For example, fluoxetine, a selective serotonin reuptake inhibitor (SSRI) with antidepressant properties, does not induce euphoria or elevate mood in nondepressed healthy individuals even after chronic treatment (27 ,28). Similarly, treatment with tricyclic antidepressants or SSRIs has no effect on behaviors assessing reward function in unperturbed animals. More specifically, treatments with desmethylimipramine, a tricyclic antidepressant, or low doses of fluoxetine typically have no effect on intracranial self-stimulation reward thresholds (29 ,30 ,31 ,32 ,33 ,34 ,35 ,36 and 37), whereas reversing reward deficits observed after drug withdrawal or during chronic mild stress (31 ,32 ,38). Moreover, recent findings indicated that the coadministration of fluoxetine together with a relatively selective serotonin 1A receptor antagonist had *opposite* effects in "normal" rats (i.e., decreased reward), whereas reversing reward deficits (i.e., increased reward) in perturbed animals in which a reward deficit had been induced (34). Recent clinical and preclinical findings have suggested that the coadministration of a SSRI together with a serotonin 1A receptor antagonist leads to accelerated or augmented antidepressant effects compared to those seen after treatment with the SSRI alone, presumably by enhancing serotonergic neurotransmission to levels above those seen with the SSRI alone (39 ,40 and 41). In conclusion, the study of animals that exhibit a deficit that is pathognomonic of depression, rather than "normal" healthy animals, may be critical to the study of both the underlying pathophysiology and its treatment.

In other situations, however, it may be advantageous to utilize animal models that examine baseline behaviors. For example, known antipsychotic drugs can be identified with reasonable predictive power using the conditioned avoidance response paradigm (42). The conditioned avoidance response paradigm has then been applied to the testing of potentially novel mechanisms that may have efficacy in the treatment of psychosis (43). Latent inhibition is another paradigm in which antipsychotics produce changes in baseline behavior that are relevant to schizophrenia. Acutely ill schizophrenia patients exhibit deficits in latent inhibition that are reduced by antipsychotic treatment (44). Similarly, when the appropriate testing parameters are used in the analogous animal paradigm, both typical and atypical antipsychotics improve measures of latent inhibition under baseline conditions (45). In contrast to pharmacologically induced models (see the following), models such as the conditioned avoidance response and latent inhibition, in which known antipsychotics influence behaviors under baseline conditions, may be more effective in identifying new therapeutic targets for antipsychotic effects. As discussed elsewhere (see Chapter 50), most of the schizophrenia animal models used historically to identify antipsychotic agents have relied on the induction of abnormal behaviors by the administration of a dopaminergic agonist and then define an antipsychotic as a drug that reverses the agonist effect. Hence, most such models are primarily and perhaps exclusively sensitive to drugs that block dopamine receptors and may not detect novel mechanisms that could have efficacy without involving dopamine receptor blockade. Ultimately, only further research with each class of psychiatric treatments will determine the relative utility of models that use an explicit inducing condition versus models that rely on changes in baseline behavior.

Inducing Conditions: Drug-Induced Versus Nonpharmacologic and Genetic Models

With the exception of paradigms assessing treatment effects in nonperturbed animals, the inducing manipulations constitute a critical aspect of a model. The selection of inducing conditions for animal models of psychiatric disorders is difficult because the etiologies of psychiatric disorders are generally unknown and are likely to be heterogeneous within each diagnostic category. Inducing conditions could be environmental manipulations, drug manipulations, lesions, genetic manipulations, or combinations of the preceding. Further, all of the preceding manipulations could be implemented during development or combined with developmental manipulations or factors. An inducing condition may be selected: (a) based on theoretic arguments about the environmental and/or neurobiological factors that lead to the disorder; (b) because it induces a deficit that is considered pathognomonic of the disorder of interest, even though no theoretic arguments are made about the etiology of the disorder; or (c) based on purely practical considerations about the predictive value of the model without theoretic arguments about either the etiology of the disorder or the relevance of the dependent measure to aspects of the symptomatology characterizing the disorder. The selection of

each inducing condition has advantages and disadvantages and is often based on the following considerations.

Acute or chronic drug manipulations have the advantage of probing the function of a specific receptor or neurotransmitter system that either is implicated in the etiology of the disorder or produces the desired deficit. The main disadvantage of an acute drug manipulation, and often of chronic drug manipulations, is that it readily leads to "receptor" or "neurotransmitter tautology." For example, a deficit induced by a specific receptor agonist is very likely to be reversed most effectively by a receptor antagonist at the same receptor, as in the case of dopamine agonist–antagonist interactions in most animal models of antipsychotic action. The same applies to neurotransmitter systems. Nevertheless, reversal of a drug-induced deficit by a compound acting on a different neurotransmitter system is a powerful indication of system interactions that may be relevant to the pathophysiology and/or treatment of the disorder. Chronic drug manipulations offer additional advantages and disadvantages. Chronic drug administration is likely to lead to compensatory adaptations to the acute effects of the drug that are likely to be longer lasting than the effects of a single drug administration and to involve additional systems that are not involved in the acute drug effects. Nevertheless, the resulting neuroadaptations may be irrelevant to the disorder unless there is a relationship between the deficits induced by the drug and etiology of the psychiatric symptoms.

An example of a pharmacologic model is the use of the reward deficits seen during withdrawal from a variety of drugs of abuse as a model of the core symptom of "diminished interest or pleasure" in rewarding stimuli that characterizes depression (46). In rats, converging evidence indicates that withdrawal from psychostimulant drugs is associated with reward deficits expressed as elevations in brain reward thresholds (33 ,47), decreased breaking-points under a progressive ratio schedule for a sucrose reinforcer (48), and decrements in motivation for sexual reinforcement (49). The advantage of this model is the induction of deficits in reward and motivational processes that are hypothesized to be, not only pathognomonic of depression, but also deficits expressed as negative symptoms of schizophrenia. Thus, these paradigms focus on the study of a hypothetical construct that may have relevance to core symptoms seen in multiple diagnostic categories. These deficits are most likely homologous to similar deficits seen in people abusing these drugs because the etiology of the deficit is the same in both the animal model and humans. Nevertheless, it is not known whether pharmacologically induced deficits in reward and motivational processes are homologous, or just analogous, to similar deficits seen in nondrug abusing psychiatric populations. That treatments with clinically effective antidepressants reverse the drug-induced reward deficits in both rats and humans suggests that the deficits may be homologous across species (32 ,34 ,38 ,50).

Environmental manipulations often induce only short-lasting deficits in healthy subjects because a healthy system is able to "bounce back" readily once the inducing conditions have been removed. Potential interactions, however, between the environmental manipulation and a genetic predisposition may lead to long-lasting behavioral or neurobiological changes having relevance to the disorder of interest. Finally, environmental manipulations are important to use and incorporate into animal models because it appears that psychiatric disorders often result from interactions between "nature" and "nurture" to a larger extent than most nonpsychiatric diseases. Another advantage of environmental manipulations is that such manipulations are likely to affect integrated brain functions rather than a single component of a system.

Lesion manipulations offer different advantages and disadvantages compared to environmental and drug manipulations. An advantage of lesion manipulations over chronic drug manipulations is that lesions may lead to deficits and/or neuroadaptations in a variety of brain systems rather than just the one or few affected by a drug. A disadvantage of traditional lesion manipulations is that the initial lesion manipulation in most cases is a rather large insult to a specific brain site. Thus, the circuitry affected is dependent on the interconnections of this specific brain site. Nevertheless, recent advances in genetic techniques are allowing very precise "lesions" (knockouts) or increased expression (knockins) of specific proteins in selected brain sites in adult animals. Such technological advances, when combined with more traditional behavioral and pharmacologic aspects of well-developed models, are likely to advance our understanding of psychiatric disorders.

Developmental manipulations are gaining in popularity primarily because there is increased awareness that many psychiatric disorders develop gradually through childhood and adolescence and are lifelong. In some cases, investigators combine one of the previously discussed inducing manipulations with a developmental manipulation (e.g., applying the inducing manipulations during development or in a genetically altered animal). For example, decreases in PPI of startle, an operational measure of sensorimotor gating deficits that are evident in patients with schizophrenia, have been demonstrated to result from socially isolating rats from weaning until after puberty (51). Social isolation of rats in early stages of development has been used to produce a variety of behavioral abnormalities that have been related to both schizophrenia and depression. Recent studies have shown that 6 to 8 weeks of social isolation during development, but not during adulthood (52), produces deficits in PPI that are at least partially reversible by the administration of neuroleptic dopamine antagonists (51) or by clinically effective atypical antipsychotics having antagonist activity at multiple receptors (53 ,54). Furthermore, postweaning isolation rearing of rats also results in deficits in the gating of the N40 event-related potential, that are analogous to the deficits in P50 gating observed in schizophrenia (55).

Because schizophrenia commonly emerges in early adulthood, developmental factors have provided the basis for some etiologic hypotheses (56 ,57). Hence, further study of the gating deficits produced by isolation rearing of rats may establish a nonpharmacologic and developmentally relevant animal model of the gating deficits observed in patients with schizophrenia. Potentially, in contrast to the drug-induced models of gating deficits, such a model might have etiologic validity and might be sensitive to antipsychotic drugs having novel mechanisms of action.

Genetic manipulations are popular because of the recent surge of interest in genetic contributions to psychiatric disorders. Such interest promises to enable the development of a class of animal models based on hypothesized etiologic validity. As specific genes and gene products become linked to specific disorders, molecular biologists will be able to generate mutant or transgenic animals having genetic abnormalities that are potentially homologous to those seen in humans. Behavioral and pharmacologic studies of these genetically engineered animals will then be important in identifying the phenotypic changes associated with the mutation, testing hypotheses about the etiology of the disease, and exploring potential therapeutic treatments. The combination of genetic and molecular biological approaches with behavioral and pharmacologic approaches may well revitalize interest in etiologically based models of psychiatric disorders. It is important to recognize that genetic manipulations necessarily begin with the fetus and often lead to compensatory adaptations throughout the course of development. Hence, developmental factors must be taken into account and studied when working with such an early genetic alteration. The latter is an example of a case where a technological limitation can lead to new creative ways of studying the function of a system and how it may contribute to our understanding of the processes mediating a disease.

The increased use of strain differences and genetically engineered mutants in drug discovery programs will necessitate both practical and conceptual modifications to the development and validation of animal models. Among the most fundamental differences between these genetic models and most previous models involves the distinction between trait and state measures. Most of the traditional models used to explore psychiatric treatments have relied on relatively short-term changes in the state of the animal, as modified by inducing manipulations such as stressors or drugs. In contrast, by definition, genetically based models rely on traits rather than states. For example, it has become commonplace to use approach/avoidance conflict tests to examine the possibility that gene knockout mice exhibit alterations in what is called “anxiety.” Approach/avoidance conflict tests, such as the elevated plus-maze or the light/dark box, have been widely used in rodent studies of anxiolytic drugs. Anxiolytic drugs increase approach behavior in such paradigms, presumably because they reduce the anxiety that competes with the animal's tendency to explore novel stimuli and environments. Such an observation with an unknown drug could as readily be interpreted as an increase in novelty seeking (i.e., approach) rather than a decrease in anxiety (i.e., avoidance). The fact that known anxiolytic drugs increase approach behavior has provided substantive validation of approach/avoidance conflict tests for the identification of changes in state anxiety. Accordingly, such conflict tests are now being used widely in the characterization of mutant mice in attempts to identify changes in trait anxiety. It should be recognized, however, that the validation of a measure as predictive of a change in state may or may not validate the measure as reflective of a change in the conceptually related trait. That is, the observation of a shift in approach/avoidance behavior in a mutant mouse that is similar to that produced by an anxiolytic drug cannot readily support the conclusion that the mutant mouse exhibits low levels of trait anxiety rather than high levels of approach behavior, as in the trait of high novelty seeking. Only by examining approach/avoidance behavior across a range of contexts can one determine which pole of the approach/avoidance conflict is altered in the mutant animal (58).

Dependent Measures: Value of Analogous and Homologous Measures Across Species

As with the choice of inducing manipulations, the choice of dependent measures is not simple when developing animal models of psychiatric disorders, primarily because the major and core features of human psychopathology are still poorly understood and still debatable. Thus, what should be considered an adequate or appropriate endpoint for a model in psychiatry is not always clear. Whenever possible, it is preferable to work with homologous rather than analogous endpoints. The terms analogy and homology originated in comparative anatomy and refer to the morphology and function of a structure. Structures or behaviors across species that are similar in origin (i.e., neurosubstrates), form, and function are termed homologous, whereas structures or behaviors that have different origins or neurosubstrates, superficially similar form, and have similar function are termed analogous (59). Another term that has been used to refer to analogous endpoints is isomorphism (60). Thus, in some sense, the terms homology and analogy refer to both the symptomatology and the underlying substrates that relate to the etiology. Although homologous measures are preferable, they are rare. Fortunately, analogous measures can also be valuable. It is because of the assumption of homology, or at least analogy, among the physiological and behavioral characteristics of various species that extrapolations can be made from nonhuman animals to humans (61). The establishment of multiple forms of validation for a particular model provides convergent evidence in support of the postulate of cross-species homology.

When developing an animal model related to a psychiatric

disorder, it is important to determine what features of the disorder(s) the experimental preparation is intended to model. Investigators often begin by attempting to identify the core features of the particular disorder of interest. Nevertheless, it is clear that appreciable diversity of both etiologies and symptom profiles exists within each of the major psychiatric diagnostic categories. Furthermore, very few specific symptoms are unique to any specific diagnosis, but occur in multiple diagnostic categories. Hence, it is most productive to focus on specific features observed in patients as endpoints for use in the development of animal models, rather than on clusters of symptoms. A related implication of this reasoning is that multiple different animal models, in terms of the endpoint used, may all be useful in parallel. Thus, it is advantageous to utilize an array of models rather than rely too heavily on any one model. The endpoints used in such models could be *in vivo* behaviors, biological markers, or *in vitro* behaviors of biological systems or preparations. Operational definitions, especially of *in vivo* behavioral measures, assist in determining the theoretic relationship between the observable and the construct of interest (62 ,63). Finally, the observables should be measured objectively and reliably.

Human Preclinical Models: Relationship between Animal and Human Phenomena

Human preclinical models can also contribute significantly to drug development. Unfortunately, such human models appear to be underutilized, and relatively little effort is focused on the development of such human models. An advantage of using human preclinical models is that one would not have to be concerned about cross-species generalizations. Nevertheless, even with human models, questions regarding the etiology of the disorder or the relationship between the dependent measure and the symptoms still need to be addressed using the same principles as when extrapolating across species. Relative to animal models, human preclinical models are necessarily more constrained by the additional ethical considerations regarding the use of humans in research.

The most typical example of a human preclinical model is when a drug-induced state is used in healthy volunteers to mimic some aspects of a disorder of interest. For example, the glutamate antagonist ketamine is used to induce a state that mimics some aspects of acute schizophrenia in healthy volunteers (64 ,65). Then, using brain imaging, psychological assessments, and pharmacologic interactions, the neurobiology of this drug-induced state can be studied to gain insight into the possible substrates underlying the psychotic state in schizophrenia patients. Such a human preclinical model can also play an important role in assessing novel treatments. For example, it has been found that the atypical antipsychotic clozapine reduces the exacerbation of symptoms in schizophrenic patients given ketamine (66). In contrast, typical antipsychotics such as haloperidol are ineffective in treating psychotic episodes induced by drugs such as ketamine or phencyclidine (PCP). Hence, studies of ketamine effects in either human or animal preclinical models may aid in the identification of additional atypical antipsychotics having efficacy in the treatment of patients who are nonresponsive to typical antipsychotics. Indeed, in the PPI models of schizophrenia, the disruptive effects of glutamate antagonists on PPI of startle are reversed by atypical, but not by most typical, antipsychotics (67). Interestingly, this effect of clozapine-like antipsychotics is mimicked by the putative antipsychotic M100907, a selective serotonin-2A antagonist (68). In general, one goal of translational research is to utilize the knowledge gained from human preclinical and clinical studies to guide invasive neurobiological studies in animals, which in turn can be translated back to the human clinical studies. In the present example, this strategy would suggest that further studies could now determine whether M100907 reverses disruptions in PPI produced by ketamine in healthy human volunteers. Furthermore, clinical trials of the efficacy of M100907 in schizophrenia could be designed to test the hypothesis that only schizophrenic patients whose deficits in PPI are reversed acutely by M100907 would respond clinically to prolonged treatment with M100907. This admittedly speculative example illustrates some of the potential advantages derived from the use of homologous, or at least analogous, measures in animal and human preclinical models as well as in clinical trials. Such translational research is needed in the field of psychiatric disorders in order to guide both the refinement of the animal models and the development of new drugs.

DRUG DISCOVERY AND DEVELOPMENT: PRECLINICAL MODELS AND CLINICAL TRIALS

Part of "33 - The Role of Preclinical Models in the Development of Psychotropic Drugs "

An emerging belief is that animal preclinical models represent a bottleneck in psychotropic drug discovery (69). Compared to high-speed chemical synthesis, high-throughput screening of libraries of compounds, and rapid gene seeking and sequencing techniques, the use of preclinical models as screening techniques appears slow. Nevertheless, such preclinical models of human psychopathology are required to provide initial assessments of the functional effects of novel compounds in the integrated organism. Only such *in vivo* functional measures can confirm predictions about the potential effects of psychotropic drugs in patients. It is unrealistic to attempt to go from the “test tube” to the clinic when attempting to treat complex mental, cognitive, and emotional disturbances that do not yet have clearly defined neurobiological substrates, or even correlates. The “relative paucity of preclinical behavioral models predictive of clinical efficacy” (69) reflects the paucity of our quantitative measures of the human phenomena related to psychiatric

disorders, as well as the limited investment in the development of animal behavioral models over the past few decades. Despite the excitement in the field of neuroscience about the recent progress made in understanding brain function (70), there is also an appreciation of how little is known about the neurobiology of psychiatric disorders compared to advances in other fields of medicine (71). Given the rapidity of techniques available to target discovery and drug screening efforts relative to the limited state of our knowledge about psychiatric disorders, the role of *in vivo* preclinical models as the intermediary between these extremes needs to be considered carefully. Some preclinical models, such as the tail suspension or swim tests for antidepressants and the prepulse inhibition test for antipsychotics, are amenable to relatively rapid screening without knowledge or understanding of the compounds' mechanism of action. Paradigms that are far more laborious can be used in the identification of new targets through the investigation of the interacting systems that contribute to the disorder's symptomatology or the therapeutic effects of established drug treatments. After identification of such novel targets, drug development efforts can be focused in identifying a compound with the desired mechanism of action and other desired properties, such as no toxicity and limited actions at systems that would produce side effects. Converging evidence from other basic research efforts would be crucial in such an undertaking. Even though the previously described process is time consuming and requires well-integrated multidisciplinary research efforts, this process may lead to the breakthroughs in psychiatric drug development that have been long awaited.

After a candidate drug has been identified through the use of both animal and human preclinical models and safety issues have been addressed, then the therapeutic efficacy of the compound is tested in the clinical population. Unfortunately, such clinical trials often do not have sufficient power, in the statistical and experimental design meaning of the term, to detect potentially beneficial effects of novel candidate compounds. Because of the high cost of drug development, pharmaceutical companies are interested in pursuing drugs that have the potential to be used in a large market that is often a broadly defined diagnostic category. This situation is aggravated by the fact that diagnostic categories in psychiatry are still rather crudely defined by rating scales rather than by objective and quantitative measures. For example, it is often assumed, at least implicitly, that there is diagnostic homogeneity within a particular patient population. It is also assumed that the boundaries of psychiatric categories as currently defined are rather absolute. In fact, most psychiatric disorders do not have clear pathological or biological markers and are defined as constellations of symptoms that are on a continuum with normality (71). Even though such diagnostic issues are constantly discussed and debated among psychiatrists, such issues are often put aside in clinical trials. Typically, the main focus in clinical trials is on the global measures of remission that are acceptable to regulatory agencies. Unfortunately, the reliance on rating scales in clinical trials provides little specific information that is useful in guiding either human or animal preclinical studies. Although understandable in view of economic forces, the infrequent use of a selected battery of scientifically established objective measures even in the early phases of clinical trials limits the further development of translational research involving cross-species comparisons and model validation. Hence, clinical trials do not benefit sufficiently from the scientific information provided by academic research and seldom provide the kind of empiric measures that are needed to adequately validate related animal models. Emphasis on multiple biological or psychological measures of disease progression with or without treatment with the drug of interest could potentially provide valuable information about the mechanisms that underlie various aspects or symptoms of the disease and thus lead to pragmatic advances in our understanding of the neurobiology of psychiatric disorders. Communication from the clinic back to the preclinical behavioral laboratory will enable the refinement of established models and the creation of new ones. In turn, understanding of the disorder could benefit if clinical trials included measures suggested to be relevant from preclinical research in either human or animal models. Another situation that limits progress in drug development is a recent movement to discourage clinical trials that include a placebo control group. Instead, the new compounds are expected to show greater efficacy compared to established therapeutics for the particular disorder. Overall, this state of affairs significantly limits the potential to identify new drugs that may: (a) be more beneficial than established treatments to a subpopulation of patients; or (b) produce global improvement through amelioration of symptoms that are not adequately assessed by the established measures of efficacy. Thus, it is difficult to make real advances in the development of new drugs because the current system encourages a circular logic and approach.

Another limitation of clinical trials that contributes to this circular approach is the absence of use of well validated, objective, and reliable measures of psychopathology in addition to the available clinical measures. As with animal models, clinical trials also need to incorporate measures that objectively and reliably assess specific psychological constructs or processes that appear to be altered in the population of interest. The validation of any animal model can be only as sound as the information available in the relevant preclinical human literature and the clinical literature (7). It is very fruitful when conceptually related experiments are undertaken in both the relevant patient population and the putative preclinical human and animal models. That is, studies of appropriate patients are needed to establish the operational definitions of the hypothetical construct, and the construct's relevance to the particular disorder. In concert, parallel studies of the theoretically homologous construct,

process, or dimension are required to determine the similarity of the animal model to the human phenomenon. Development of animal models requires parallel development of clinical measures that allow meaningful comparisons. Clinical studies need to be informed by results from animal studies as much as the reverse is true. An important and advantageous aspect of the approach described herein is that the validation of the hypothetical construct and its cross-species homology can be established by studies of normal humans and animals, in addition to psychiatrically disordered patients or experimentally manipulated animals. Thus, this approach adds to and benefits from the psychological and neurobiological literature relevant to the hypothetical construct upon which the model is based. In a sense, this approach explicitly recognizes that the experimental study of the disorder in humans involves as much of a modeling process as does the study of the disorder in an animal model. Thus, more translational science is needed to relate animal findings to humans and vice versa.

William Z. Potter: Lilly Research Laboratories, Indianapolis, Indiana.

A drug developed for human use classically goes through a number of steps, including discovery, extensive preclinical studies for safety in experimental animals, and then human safety and efficacy studies. The Food and Drug Administration (FDA) requires successful completion of all the above tasks before approval for therapeutic use in human beings. The exciting advances in human genomics and combinatorial chemistry promise substantial applications to new drugs for human diseases; however, the time and expense associated with the processes necessary to bring a new drug to market are rising exponentially. Thus, there is a great need for functional models of disease progression, including animal models of human disease and biomarkers in human clinical trials.

BIOMARKERS AND SURROGATE MARKERS

Part of "34 - Proof of Concept: Functional Models for Drug Development in Humans "

The monitoring of biologic disease processes increasingly employs biomarkers (Table 34.1). At a recent National Institutes of Health (NIH) and FDA conference (1) biomarkers for clinical efficacy were divided into several groups including natural history markers, biological activity markers, and surrogate markers.

TABLE 34.1. ABBREVIATIONS FREQUENTLY ENCOUNTERED WITH BIOMARKERS AND SURROGATE MARKERS

5HIAA	5-Hydroxyindoleacetic acid	MAO	Monoamine oxidase
5HT	Serotonin	MAOI	Monoamine oxidase inhibitor
5HT2A	Serotonin type 2A	MCCP	Meta-chlorophenylpiperazine
5HTP	5-Hydroxy-L-tryptophan	MCV	Mean red cell volume
ACTH	Adrenocorticotropic hormone	MDL	MDL 100,907
AD	Alzheimer's disease	MHPG	3-Methoxy-4-hydroxyphenylglyco
Ag	Agonist	MOI	Medical optical imaging
AIDS	Acquired immunodeficiency virus	MOS	Medical optical spectroscopy
ALS	Amyotropic lateral sclerosis	MRI	Magnetic resonance imaging
AMP	Amphetamine	MRM	Magnetic resonance microscopy
An	Antagonist	MRS	Magnetic resonance spectroscopy
APOE	Apolipoprotein E	MTD	Maximum tolerated dose
CNS	Central nervous system	NE	Norepinephrine
CSF	Cerebrospinal fluid	NERI	Norepinephrine reuptake inhibitor
D_2	Dopamine type 2	NIH	National Institutes of Health
D2R	Dopamine type 2 receptor	NIOS	Near-infrared optical spectoscopy
DA	Dopamine	NIRI	Near-infrared imaging
DAT	Dopamine transporter	NMR	Nuclear magnetic resonance
ECD	Ethylenediylbis-L-cystein diethylester	NMSP	N-methyl-spiperone
EEG	Electroencephalogram	OCD	Obsessive-compulsive disorder
EPR	Electron paramagnetic resonance	OCT	Optical coherence tomography
FDA	Food and Drug Administration	P-EEG	Pharmaco-electroencephalogram
FDG	Fluorodeoxyglucose	PET	Positron emission tomography
fMRI	Functional magnetic resonance imaging	PK	Pharmacokinetic(s)
GABA	Gamma aminobutyric acid	PRE AMP	Before amphetamine
GBR	GBR 12909	PRL	Prolactin
GGT	Gamma-glutamyl transferase	rCBF	Regional cerebral blood flow
GH	Growth hormone	SPECT	Single photon emission computed tomography
HCFA	Health Care Financing Administration	SSRI	Selective serotonin reuptake inhibitor
HIV	Human immunodeficiency virus	SWS	Slow wave sleep
HMPAO	Hexamethylpropyleneamine oxime	V_h	Volume of distribution
HVA	Homovanillic acid		
IV	Intravenous		

A relevant issue in clinical trials is the selection of an appropriate endpoint. Endpoints that are less deleterious than death or onset of a disease are desirable. Surrogate markers or endpoints are events of a more intermediate nature. These typically replace the final endpoints such as mortality. A surrogate marker is defined statistically as a "response variable for which a test of the null hypothesis of no relationship to the treatment groups under comparison is also a valid test of the corresponding null hypothesis based on the true endpoint" (2). A good biomarker, in contrast, provides information on the possible mechanisms of action of medications or the pathophysiology involved in a disease process. Surrogate markers that are helpful in early drug development (e.g., FDA Phase I and II trials) provide a prognostic indication of a clinical endpoint relevant to FDA Phase III trials.

Accelerated approval, which has become more common in FDA clinical trials, may occur based on surrogate marker effects although completion of longer-term clinical outcome and clinical endpoints may eventually be required. Prentice (1989) suggested that a surrogate marker must be both prognostic of disease progression and affected by treatment (2); the effect of the treatment on the surrogate marker should mediate the effect of the treatment on the clinical outcome or true outcome measure. There are not yet any surrogates for neuropsychiatric disorders that fully meet these criteria.

ROLE OF SURROGATES FOR DRUG DEVELOPMENT

Part of "34 - Proof of Concept: Functional Models for Drug Development in Humans "

The value of surrogates and biomarkers for drug development is recognized by the pharmaceutical industry. The needs to reduce development costs, improve the practical attainment of predictive outcomes, and expedite these endpoints are motivations for growing interest in this area. We present in the following an overview of the current state-of-the art regarding utilization of various surrogate markers, in a much broader sense of the term, which includes biomarkers, in drug discovery and development. We start with the most basic steps pertinent to initial studies in humans.

The integration of preclinical science and assessment of therapeutic potential in humans is done primarily through quantification of drug and active metabolites in accessible specimens (blood, urine, and cerebrospinal fluid). This is an advance on the maximum tolerated dose (MTD) approach, which necessarily prevailed before sufficiently sensitive assay

methodology was available. In current drug development, upper doses for early human studies are based on toxicokinetic studies in at least two animal species (most often rat and dog) whereby one does not exceed some predetermined ratio between the exposure (i.e., plasma concentration) for the dose in humans and the exposure associated with toxicity in the most sensitive species (3). Thus, depending on the ratio selected, exposures in humans may produce few side effects and be below those achieved in the older MTD approach.

In practice, one often embarks on clinical studies with a constricted range of exposures and an inability to address the question of whether therapeutic (or biochemical) effects are greater at the MTD until much later in development (4). If a compound does not produce significant side effects within this original range, doses much higher than those used in initial Phase I studies can be tested depending on the nature of the toxicity observed in animals at the limiting exposure. Even if a limiting dose is identified in volunteer subjects, a greater dose may be tolerated in patients (5). Sramek and colleagues (1997) (6) have defined this transition from dosing in healthy volunteers to patients to be “bridging.” For instance, the difference in tolerated dose for schizophrenic patients compared with normal volunteers is often greater than 25-fold (5). Interestingly, before pharmacokinetic (PK) data were routinely used to limit exposure, one explored an MTD relatively early and concluded that if response was not achieved by that dose, one did not have a viable clinical candidate.

Most marketed and late in development psychopharmacologic agents do show limiting side effects above the recommended dose range, especially if such doses are given initially. Starting with three or more times the lowest standard dose of a selective serotonin reuptake inhibitor (SSRI) will produce far more marked nausea (and even vomiting) than after building up to the same dose over several weeks, as is done for the treatment of obsessive–compulsive disorder (OCD). This may seem simply common sense but the perceived market advantage of the starting and ultimate therapeutic dose being the same discourages exploration of higher doses that require some sort of titration over time in order to be well tolerated. For instance, even though it was appreciated early on that an antidepressant, venlafaxine, might be more efficacious at higher doses that were associated with

more marked side effects (7), it was marketed at target lower doses (37.5 mg b.i.d.), which only produce effects consistent with serotonin reuptake inhibitory activity. In the over 225 mg per day range (which requires some degree of titration to avoid unacceptable side effects), venlafaxine produces effects consistent with norepinephrine (NE) as well as serotonin (5HT) uptake inhibition (8 ,9) and is reported to be superior to SSRIs (10 ,11). Obviously, it would be beneficial if the relevant dose ranges of such compounds could be better understood earlier rather than later in the life of a drug.

In this particular example, if valid markers of 5HT and NE uptake inhibition in the brain were investigated as early in development as possible, then the doses necessary to achieve both effects and those achieving only one could have been systematically pursued from the outset. Such markers would be “surrogate” markers for clinical doses, allowing one to test the widely held hypothesis that in a big enough population of patients with depression, one will find those who respond better to combined NE/5HT uptake inhibitors than to SSRIs alone. Table 34.2 shows examples of biochemical markers that may serve as surrogates.

	Neurotransmitters and Metabolites[b]			Plasma Hormones			Physiologic	
Drug Class	**NE and MHPG**	**5HT, 5HIAA**	**HVA**	**PRL**	**GH**	**ACTH/Cortisol**	**Temperature**	**SWS**
Serotonergic								
SSRIs		↓5HT, ↓5HIAA		±↑				
Indirect-Ag				↑	↑			
$5HT_{1A}$-Ag				±↑	↑	↑	↓	
$5HT_{1B/D}$-Ag				↓	↑			
$5HT_{2C}$-Ag				↑		↑	↑	↑↓[c]
Noradrenergic								
NERI	↑NE, ↓MHPG				↑			
α2-Ag	↓NE				↑			
α2-An	↑NE							
Dopaminergic								
D2-An			↑↓[c]					
DA-Ag			↓					
Mixed								
Tricyclic antidepressants	↓MHPG	↓5HIAA						
MAOIs	↓MHPG	↓5HIAA	↓					
Atypical antipsychotics	±↑NE			=[d]				

5HIAA, 5-hydroxy indoleacetic acid; 5HT, serotonin; ACTH, adrenocorticotropic hormone; Ag, agonist; An, antagonist; GH, growth hormone; HVA, homovanillic acid; MAOI, monoamine oxidase inhibitor; MHPG, 3-methoxy-4-hydroxyphenylglycol; NE, norepinephrine; NERI, norepinephrine reuptake inhibitor; PRL, prolactin; SSRI, selective serotonin reuptake inhibitor; SWS, slow wave sleep.
[a]This table indicates the utilization of neurotransmitters and their metabolites, plasma hormones, and physiologic phenomena as surrogate markers for the biochemical effects produced by drugs on the indicated classes. Although the specified drug classes may affect other measures than those indicated (e.g. SSRIs also decrease MHPG), only those hypothesized to reflect a primary action are shown.
[b]In plasma, platelets, urine, and/or cerebrospinal fluid.
[c]Acute increase followed by decrease in responders.
[d]Equal sign (=) indicates no change.

TABLE 34.2. MEASURES THAT SERVE AS SURROGATES FOR PREDICTED BIOCHEMICAL EFFECT OF DRUGS TARGETED TO MONOAMINE NEUROTRANSMITTERS, TRANSPORTERS, RECEPTORS, AND DEGRADATIVE ENZYMES[a]

In the section that follows we briefly review how traditional surrogate markers (in the broadest sense), which antedate the application of brain imaging technology, are used.

PHARMACOKINETICS

Part of "34 - Proof of Concept: Functional Models for Drug Development in Humans "

Analytical technology, especially that provided by much simpler to operate equipment, allows for precise quantification of very low concentrations in blood so that rapid and accurate determination of a new compound’s pharmacokinetics (PK) is possible after much lower doses than required formerly. If a half-life is too short or long or if nonlinear pharmacokinetics are marked (e.g., half-life increases with doses in the expected therapeutic range), then development may go no further. Similarly, if a compound shows unacceptably wide variations in clearance because its metabolism is dependent on a highly polymorphic isozyme of cytochrome P-450 (e.g., CYP2D6), then it will be seen as of lower potential commercial value. Usually, *in vitro* tests using human hepatic microsomal preparations or P-450 isozyme specific cloned systems are used to screen for this possibility prior to human use, but these are not always

fully predictive. Thus, concentrations measured over time in Phase I studies serve, at this most basic level, as a surrogate of whether a compound has the potential to become a successful drug (12).

Drug interactions sometimes can constitute a serious safety risk (e.g., inhibition of terfenadine metabolism by CYP3A4 inhibitors leading to fatal QTc prolongation in genetically susceptible individuals) and, almost always, a marketing disadvantage. The same preclinical approaches referred to in the preceding are used to screen out compounds that depend for their metabolism on a problematic pathway. *In vivo* PK (and sometimes drug interaction data) are also obtained in animals, but more to set dose and frequency of administration to guarantee adequate concentrations for expensive chronic toxicology studies than to predict what the PK characterization will be in humans.

Low bioavailability (i.e., concentration after oral versus intravenous doses) is a special problem at this stage of preclinical development. First, for most compounds an oral form is seen as the ideal (if not only) option and low bioavailability almost always means very high variability in exposure to parent compound for a given dose. For instance, 2% to 10% bioavailability means an automatic fivefold range before individual variations seen in metabolic clearance after intravenous (IV) administration are taken into account versus 60% to 80% bioavailability, which only entails a 11/3-fold variation. High variability in exposure per unit dose makes clinical studies more difficult. Second, to reach the exposures required to define the concentration at which chronic toxicity is observed, low bioavailability means that much more compound will be necessary. This is actually a far more significant issue than is generally appreciated because amounts of material are limited early in development. It can be very costly to develop efficient synthetic schemes; one does not want to invest too much in syntheses until one is fairly sure that a compound is safe at pharmacologically active concentrations.

TOXICOKINETICS

Part of "34 - Proof of Concept: Functional Models for Drug Development in Humans "

This introduces the critical role of toxicokinetics, the goal of which is to establish in animals (usually rats and dogs) the ratio between the concentration that produces either unacceptable physiologic effects (e.g., QTc prolongation, seizures) or organ damage (e.g., liver, bone marrow) and the one that produces the targeted biochemical or behavioral effect, a ratio of at least 2 to 1. As the ratio approaches 1.0 it is increasingly unlikely that a compound will be taken into humans unless the observed unwanted effects are readily reversible and one is dealing with a condition for which existing therapies are poor or nonexistent (Alzheimer's disease [AD] or amyotrophic lateral sclerosis [ALS]). There are instances in which humans ultimately prove tolerant to drugs much more than would be predicted by these ratios, but this is only established after exposure to large numbers of subjects.

Although the ratios established in preclinical studies are interpreted as providing a reasonable estimate of any ultimate therapeutic index in humans, they are specific for both species and mechanism of action. In other words, the concentration necessary to achieve a behavioral or biochemical effect and produce toxicity can vary more than an order of magnitude across species. The relationship among *in vitro* biochemical effects, activity in some *in vivo* model, and undesired effects is poorly understood even at the preclinical level, particularly when one is investigating novel targets. Because efficacious *in vivo* concentrations in animals are based either on activity in an animal model (e.g., anticonflict activity to identify a potential anxiolytic) or biochemical changes (e.g., changes in brain serotonin) that are not measured in humans, we do not even have validation for existing drugs relating preclinical and clinical data (13). Not surprisingly, given the weakness of the link between an efficacious dose in rats and a therapeutic dose in humans, the clinical development of central nervous system (CNS) drugs is notoriously inefficient to identify therapeutic concentrations.

Measures of receptor occupancy or specific degree of enzyme inhibition do not drive the selection of an efficacious concentration. In other words, the basic preclinical work that underlies any test of a specific hypothesis such as "X% of inhibition produces effect Y" is rarely, if ever, done. Therefore, in toxicokinetic studies one hopes for very high ratios that provide a great deal of flexibility to study a extremely wide range of concentrations in humans, especially with novel compounds.

Phase I

Select starting doses for healthy volunteers based on findings from the preceding toxicokinetic studies, which is often one-tenth of the dose that produces a no-adverse-event level in the most sensitive species studied (4). Most marketed central nervous system (CNS) drugs produce some sufficiently unpleasant (but not dangerous) side effect that sets the dose range for subsequent studies, the so-called maximum tolerated dose (MTD). Multiple dose studies, administering various fixed doses over a 2- to 4-week period are also part of the Phase I protocols to get a general idea of safety and tolerability under likely clinical conditions (14). The observed steady-state concentration during repeated dosing, broadly speaking, is the first surrogate for the desired effect, the obvious but often incorrect assumption being that a certain value assures a certain biochemical effect in the brain based on extrapolations from preclinical data.

Once the initial safety studies are completed, there may be additional studies in healthy volunteers to assess efficacy. In the case of sedatives and hypnotics, healthy volunteers can be used reliably with a combination of subjective reports, objective measures of performance (looking for decrements), and the electroencephalogram (EEG) (15 ,16 ,17 ,18 and 19). These measures, however, are direct ones, of a desired or undesired effect, not surrogates. On the other hand, the so-called

pharmaco-EEG (P-EEG) is sometimes introduced as a surrogate measure of the therapeutic action a compound is likely to produce (20 ,21), but is probably more usefully viewed as a direct measure that a compound has produced some change in surface brain electrical activity. The P-EEG provides neither evidence of a direct effect in the brain nor proof of a hypothesized causative role of specific pharmacologic activity of the molecule (22).

In the majority of CNS Phase I studies, aside from measures of drug concentration, the only usual objective measures are targeted to the heart and other vital organs. Side effects are often simply recorded as spontaneous reports on a grid of prespecified subjective descriptors; sometimes a formal checklist is used. Thus, quantitative surrogate measures of drug effect are sparse.

Phase 1B/2A (Proof of Concept) Studies

There is wide variation in practice as to what is done, both with healthy volunteers and patient populations, before going on to full Phase II studies. These latter studies are powered to detect a clinically significant improvement, usually over placebo, often utilizing multiple dose arms (each with at least 50 or more patients) and multiple clinical sites. In the case of a compound acting on a novel target, the period before full Phase II trials is argued to be the phase during which exploratory work should be done (23). For instance, if one had an ampakine such as CX-516 that improved learning in rats, then one might show enhancement of some aspects of cognition in healthy volunteers after safe doses were established in Phase I studies (24). The improved performance in healthy subjects would then be a surrogate for improvement in AD to identify the appropriate dose.

In the more usual case of a variation on an existing mechanism (e.g., SSRIs), this is the period to verify which dose produces the desired biochemical effect so as to move as quickly as possible into Phase II trials with doses that one is confident will work (25 ,26). In this latter instance, the direct accessible biochemical measure becomes a surrogate for an effect in brain that is hypothesized to produce the clinical benefit.

We briefly review a range of specific measures that have been used in enough instances over the last two decades to qualify as surrogate markers. There is no available literature as to the extent to which these measures actually drove decisions about what doses to use in Phase II trials, but one can assume that they must have been influential in some cases. What is certain is that at least in the United States, outside of polysomnography (for sleep-related disorders) and EEG (for seizures), the measures have had no acknowledged regulatory impact. Assessments of decrements in performance (especially ability to concentrate, recall, and carry out motor tasks) and measures of cognitive enhancement all seem to be better classified as direct measures of an intended or unintended drug effect rather than surrogates. This leaves mainly biochemical measures, which can be broadly classified as “neuroendocrine.”

Cerebrospinal Fluid

The monoamine hypotheses of depression and schizophrenia, which are, in turn, based on the pharmacology of antidepressants and antipsychotics, generated an interest in measures of norepinephrine (NE), serotonin (5HT), and dopamine (DA) in humans. In most instances these were initially studied in an attempt to distinguish patients from controls but came to be applied to validating predicted effects of psychotropic agents (27).

Thus, NE reuptake inhibitors (NERIs) decrease NE turnover as measured by NE and its metabolites in urine or cerebrospinal fluid (CSF) (28 ,29 ,30 and 31) and by increasing plasma NE (32) or, more precisely, its spillover rate (33 ,34). Another marker of NE reuptake inhibition is based on the need for exogenously infused tyramine to be taken up into NE nerve endings to exert its effects, the so-called tyramine pressor test (35) or, more recently, the dorsal hand vein constrictor test (36). These latter two procedures have been recently employed to establish the dose at which venlafaxine produces NE reuptake inhibition (8 ,9 ,36). Because NE metabolism varies according to whether it occurs inside or outside neurons (37), a more definitive and perhaps more sensitive measure would be the ratio of extraneuronal to intraneuronal metabolites before and after treatment in an integrated pool (e.g., a 24-hour urine) (38) as shown for desipramine (30). However, all of these measures reflect functional changes in the peripheral sympathetic nervous system; therefore, they are at best surrogates for effects in the brain.

Some of these same measures have been applied to study other compounds, which are predicted to affect NE function either following acute or chronic administration. These include bupropion, clozapine, alpha 2 antagonists, and monoamine oxidase inhibitors (MAOIs) (39 ,40 ,41 ,42 ,43 ,44 ,45 and 46). Interestingly, such studies are not yet available to support or refute claims that the relatively new antidepressant mirtazapine produces alpha 2 antagonism in humans.

Most, if not all, drugs classified as SSRIs have been shown to inhibit platelet uptake of 5HT, most simply determined by investigating 5HT depletion in platelets following chronic administration (25 ,47 ,48 ,49 and 50). Some of these studies were clearly done prior to Phase II trials so they can be inferred to have influenced the selection of dose. Doses of SSRIs known to inhibit platelet uptake in humans have also been shown to reduce the turnover of 5HT in the CNS as reflected by reductions of its major metabolite 5-hydroxyindoleacetic acid (5HIAA) in CSF (44 ,51). Similarly, MAOIs reduce both platelet MAO and 5-HIAA in CSF (51 ,52). There are not, however, systematic dose response studies to compare the sensitivity of the peripheral and central measures. Moreover, 5HIAA in CSF obtained by a lumbar puncture reflects a complicated process of all sources of formation and clearance of the metabolite.

DA has been studied almost exclusively in terms of its metabolite, homovanillic acid (HVA) in blood and CSF. There is a complex relationship among administration of a

dopamine type 2 (D_2) antagonist, duration of treatment, clinical state, and HVA in either compartment (53 ,54 ,55 ,56 ,57 and 58). Although changes usually can be explained as consistent with altered turnover as a function of receptor antagonism, time, and presence or lack of clinical response, measures of HVA are not really useful as a surrogate measure of D_2 antagonism. Decreased HVA in CSF can be expected after mixed Types A and B MAO inhibition in the brain (52) and might be relevant to assessing DA uptake inhibition. There is, however, no available positive control for the latter. Bupropion, the one compound studied in regard to possible DA uptake inhibition, did not decrease HVA in the CSF (40 ,44).

Prolactin

Prolactin has the potential to be used as a marker for drugs affecting these systems, because either DA or 5HT can affect this circulating hormone. In the simplest and most widespread instance, it has been used as an index of D_2 antagonism. Unlike typical neuroleptics, atypical neuroleptics produce no elevations of prolactin at therapeutic dosages (59 ,60). By extension, absence of prolactin elevation after antipsychotics could be considered a surrogate of low D_2 receptor occupancy in the striatum and, hence, imply low to absent motor side effects (61 ,62).

Prolactin is also elevated following various pharmacologic challenges such as: (a) those that are predicted to increase extracellular 5HT in the brain including fenfluramine, clomipramine, l-tryptophan, and 5hydroxytrytophan; and (b) those that stimulate various types of 5HT receptors, including meta-chlorophenylpiperazine (mCPP) and some, but not all, putatively selective $5HT_{1A}$ agonists (63 ,64 ,65 and 66). In all of these instances, prolactin increase becomes a surrogate of increased serotonergic transmission in one or more regions of the brain. Blockade of this effect by appropriate 5HT receptor specific antagonists could serve, in turn, as a surrogate of a compound's ability to functionally antagonize the specified receptor in human brain (67 ,68 ,69 and 70).

Growth Hormone

There was a period in which plasma growth hormone (GH) was used as a surrogate for increased noradrenergic transmission in human brain (presumably at the level of the hypothalamus) after, for instance, the α2 agonist, clonidine, or an NE uptake inhibitor (71 ,72). One could, in turn, infer α2 antagonism by a test compound if it blocked the effect.

More recently, stimulation of plasma GH has been considered evidence of activation of both $5HT_{1A}$ and $5HT_{1B/1D}$ receptors (see Table 34.2 on page 459) (63). Sumatriptan increases GH, apparently through activation of the $5HT_{1B/1D}$ receptors (73 ,74), with the most recent evidence using the more brain penetrant, zolmitriptan, implicating $5HT_{1D}$ postsynaptic receptors (75). It has been suggested that stimulation of the 1B/1D receptors inhibits somatostatin release (76); however, an increasing volume of experimental research indicates that 5HT can act directly on the adrenal gland and possibly on the anterior pituitary as well (77). This provides another example of the same measure serving as a surrogate for very different CNS effects, the interpretation of which depends on knowing the potential target for a compound in advance. It is doubtful that any substantial decisions concerning doses of compounds affecting either noradrenergic or GABAergic or serotonergic systems have ever been made based on GH release stimulation or inhibition.

ACTH/Cortisol

Stimulation of the hypothalamic–pituitary–adrenal axis as reflected by increases of ACTH and/or cortisol has also been used as a marker of drug action in the CNS. This approach has been most extensively applied to evaluation of putative 5HT agonists, sometimes coupled with pretreatment with whatever antagonists were available (e.g., ritanserin and pindolol) (63). Such studies can generate evidence of apparent selectivity in postsynaptic receptor responses to indirect and direct agonists. ACTH release induced by 5-hydroxy-L-tryptophan (5HTP) is argued to occur through indirect activation of 5HT2 receptors because it is antagonized by ritanserin (78), whereas the cortisol response is not affected by doses of pindolol expected to produce $5HT_{1A}$ antagonism (67). Pindolol does, however, antagonize ACTH responses to a variety of agents classified as partial to full $5HT_{1A}$ agonists (64 ,79 ,80). Again, given the complexities of the ACTH/cortical response and the imperfect selectivity of the pharmacologic agents, quantitative conclusions as to degree of specific receptor activation or antagonism are not possible.

Other Physiologic Measures

Sleep EEGs have already been referred to and may have utility as surrogates of, for instance, activation or antagonism of 5HT2C receptors as reflected by decreases or increases of slow wave sleep, respectively (81 ,82).

Temperature decreases are consistently observed following $5HT_{1A}$ agonists (63 ,83), and hence can serve as a surrogate marker of $5HT_{1A}$ agonist effects in the CNS. Evaluating the ability of a novel compound to antagonize the hypothermia produced by a $5HT_{1A}$ agonist may be the easiest way to see if it antagonizes $5HT_{1A}$ receptors in the human brain.

LIMITATIONS OF CURRENT SURROGATE MARKERS

Part of "34 - Proof of Concept: Functional Models for Drug Development in Humans "

As described, there is no validated link between the concentration of drug in blood (or even CSF) and a specific biochemical effect in human brain (not to mention a specific brain region). Thus, even in the case of SSRIs, the most

widely prescribed class of drugs in neuropsychopharmacology, we do not know how closely platelet 5HT depletion reflects 5HT uptake inhibition in brain. Although known therapeutic doses of SSRIs invariably have been shown to deplete platelet 5HT, the converse is not clear; that is, any dose that is effective in platelets will be therapeutic. Matters are even less certain when it comes to using available surrogates of NE uptake inhibition to establish the dose of a drug. And, as already noted, primary dosing decisions are not made on the basis of whether compounds affect prolactin, growth hormone, or ACTH/cortisol responses.

One could use the CSF concentration of a drug as a reasonable estimate of the free drug concentration in brain under true steady-state conditions (84 ,85 and 86), and infer from one's preclinical *in vitro* and *in vivo* studies that this will produce a specific effect (87). The problem is that even in the most refined *in vitro* system, as represented by cloned human receptors expressed in some vector, the relationship among receptor occupancy, drug effect, and free drug concentration may be extremely different from that observed *in vivo* in humans thanks to multiple uncontrollable differences among these systems (13). Furthermore, *in vivo* animal studies raise questions about species differences; therefore, how does one select the dose for clinical studies when testing a new compound that is well tolerated with a wide range of safe concentrations that are predicted to be pharmacologically active by one or more preclinical models? How does one know that the target in question has been blocked or stimulated so as be sure that one is testing the hypothesis that such an effect produces therapeutic benefit? The answer is, one does not know with the surrogates (discussed in the preceding). This brings us to a discussion of the promise of direct measures of drug effect in the brains of living humans.

IMAGING STUDIES

Part of "34 - Proof of Concept: Functional Models for Drug Development in Humans "

Measures of Substrate Metabolism

Regional cerebral blood flow (rCBF) is a well-established surrogate marker widely used for both clinical diagnostic procedures and new drug development. rCBF is commonly assessed utilizing estimates of cerebral perfusion, such as single photon emission computed tomography (SPECT) with radioligands labeled with ^{123}I or ^{99m}Tc; for example, [^{123}I]iodoamphetamine, [^{99m}Tc]ethylenediylbis-L-cystein diethylester (ECD), and [^{99m}Tc]hexamethylpropyleneamine oxime (HMPAO). Although repeated assessments with multiple radiotracer injections are usually impractical because of the long half-lives of both ^{123}I and ^{99m}Tc, linearization techniques have been developed to estimate sequential measurements (88). Furthermore, ^{99m}Tc is relatively available in practically every hospital with a radiology or nuclear medicine department worldwide; therefore, SPECT procedures can be performed widely on a clinical basis.

By contrast, positron emission tomography (PET), another procedure to estimate rCBF, requires an onsite cyclotron, so it is not available in many areas. Recent third-party camera reimbursement of some PET procedures (primarily [^{18}F]fluorodeoxyglucose (FDG)) are making PET cameras more available, but cyclotrons are still relatively scarce. The two most widely used radioisotopes used in PET are ^{11}C with a half-life of 20 minutes and ^{18}F with a half-life of 110 minutes. Additionally, ^{15}O, with a half-life of 2 minutes is primarily employed in brain perfusion studies. The most available PET radioligand is FDG, a tool to measure glucose metabolism. Its advantages include ease of use, availability from commercial cyclotrons throughout much of the world, and sensitivity to a number of studies to facilitate drug development and assess mechanism of action (89). Its disadvantage is lack of specificity.

An example of the value of PET studies to obtain potential surrogate markers for development of drugs for substance abuse is the dysfunction of regional glucose metabolism in the limbic system and areas of working memory in cocaine euphoria and cocaine craving (90). [^{15}O] PET studies demonstrate increases in rCBF in the limbic system and decreases in the basal ganglia as manifestations of craving for cocaine following exposure to videotapes suggesting cocaine use (91).

ESTIMATION OF DOPAMINE RECEPTOR OCCUPANCY BY ANTIPSYCHOTIC DRUGS

Part of "34 - Proof of Concept: Functional Models for Drug Development in Humans "

It has been hypothesized that positive symptoms of schizophrenia, such as hallucinations and delusions, result from increased stimulation of postsynaptic dopamine (DA) receptors by DA (92). This DA hypothesis of schizophrenia is substantiated by the observation that positive symptoms of schizophrenia abate when DA receptor blocking drugs, such as neuroleptics, occupy the postsynaptic DA receptors. In 1988, Farde and colleagues demonstrated the concept that effective neuroleptic dosages for schizophrenia correspond to 80% to 90% occupancy of DA type-2 receptors (D_2Rs) by the drug (95). Thus, occupancy of 80% to 90% of D_2Rs may constitute a surrogate marker for the dosage of a D_2 antagonist producing maximal beneficial effects with minimal adverse and toxic effects. Furthermore, clinically equivalent doses of neuroleptics are estimated by comparing proportions of receptors occupied by various psychotherapeutic agents (93 ,94). Several examples of this approach are given in the following.

Receptor Occupancy by Typical Neuroleptics

The occupancy of D_2Rs by neuroleptics has been extensively evaluated by PET and SPECT. Historically, this began with the study of typical neuroleptics, including haloperidol and

fluphenazine, in healthy normal control subjects and patients with schizophrenia utilizing [^{11}C]raclopride (95 ,96), spiperone derivatives, including [^{11}C]N-methyl-spiperone (NMSP) (97), [^{18}F], or ^{76}Br (98). This research has established that a therapeutic response corresponds to occupancy of 65% to 90% of the D_2Rs by the drug; however, occupancy of greater than 90% of the D_2Rs is not associated with a greater therapeutic effect. Therefore, occupancy of 65% to 90% of D_2R_2 is correlated with a therapeutic dose of typical neuroleptics as well as other clinical manifestations of pharmacologic efficacy. For example, patients with acute extrapyramidal side effects were found to have higher DA receptor occupancies (82%) than those without (74%) (99 ,100). Wolkin and colleagues (1989) found a comparable occupancy of haloperidol in responders versus nonresponders indicating that treatment nonresponse is not a function of insufficient CNS binding of the antipsychotic (100).

Kapur and colleagues recently confirmed that the D_2 occupancy is an important mediator of beneficial and adverse effects (101) in a study of first episode schizophrenia and haloperidol. Although the patients showed a wide range of D_2R occupancy (38% to 87%), the degree of D_2R occupancy predicted clinical improvement, hyperprolactinemia, and extrapyramidal side effects. Also, Daskalakis and associates (1998) (102) found a relationship between D_2R occupancy and hyperprolactinemia.

Receptor Occupancy by Atypical Neuroleptics

D_2R occupancy has been determined for humans treated with atypical neuroleptics. For example, receptors of people treated with clozapine exhibit low (20% to 65%) D_2R occupancy and high serotonin type 2A ($5HT_{2A}$) receptor occupancy (94 ,99 ,103). In studies directly comparing clozapine (450 mg/day) and haloperidol (5 mg/day), there was a reversal of receptor occupancy producing high D_2 blockade with haloperidol and high $5HT_{2A}$ blockade with clozapine. Indeed PET imaging has been an important approach for screening a number of new antipsychotics with an atypical profile. Risperidone has been shown to block 40% to 60% of D_2 receptors at only 1 mg (104) with even higher $5HT_{2A}$ receptor occupancy. Indeed, in patients with schizophrenia, only 4 mg/day is needed for 70% to 80% occupancy with minimal risk of extrapyramidal side effects (105). After an oral dose of 6 mg risperidone, 75% to 80% of D_2Rs and 78% to 88% of $5HT_{2A}$ receptors are occupied (106). Plasma levels of risperidone correlate with D_2R occupancy (107). The proportion of D_2R occupancy has been estimated for other atypical neuroleptics; for example, olanzapine, has been shown to have D_2 occupancy similar to risperidone and greater than clozapine (108). The usual clinical doses of olanzapine (10 to 20 mg/kg) produce 71% to 80% D_2R occupancy. These doses usually do not result in the adverse effects of dyskinesias and prolactin elevation. On the other hand, doses of greater than 30 mg/day olanzapine are associated with greater than 80% D_2R occupancy as well as dyskinesias and prolactin elevation. Olanzapine exhibits 59% to 63% D_2Rs occupancy after single 10-mg dosing. Furthermore, olanzapine shows a greater (68% to 84%) occupancy of D_2Rs than clozapine (20% to 67%) after 10 to 20 mg daily dosing in patients (60). These characteristics suggest that olanzapine differs from clozapine. Additionally, quetiapine is characterized by abatement of psychotic symptoms in association with a transient increase in D_2R occupancy (62).

Receptor Occupancy as a Surrogate Marker of Clinical Efficacy?

One of the most important questions about D_2R and $5HT_{2A}$ receptor occupancy is the prediction of doses yielding clinical efficacy. D_2R occupancy predicted the clinical improvement of 22 first episode schizophrenic patients randomly assigned to 1 or 2.5 mg/day of haloperidol for 2 weeks (101). Thus, D_2R occupancy is related to the clinical response to antipsychotics (99 ,109 ,110).

PET studies have helped demonstrate that high levels of D_2R occupancy occur at very low haloperidol doses (111). Kapur (1996) showed D_2R occupancy of 53% to 74% at only 2 mg haloperidol in first-episode patients (114). Kapur and colleagues (1997) also showed D_2 occupancies between of 53% to 88% for haloperidol doses of 1 to 5 mg. Thus, the conventional therapeutic practice of haloperidol doses of greater than 10 mg/day is too high for many schizophrenic patients because there is no increase in beneficial effect, whereas the risk of adverse effects increases in proportion to the dose (112). Nevertheless, Volavka and colleagues (113) (1995) showed that antipsychotic efficacy of haloperidol increases with plasma levels up to 12 ng/mL, plasma levels that would predict almost completely saturated D_2 receptors according to the Kapur and associates (1997) data (112). Similarly, Wolkin found D_2 receptor occupancy increasing with haloperidol plasma levels up to 15 ng/mL and almost complete D_2R occupancy saturation with haloperidol plasma levels above 15 to 20 ng/mL (100). Thus, Wolkin's (100) and Volavka's (113) findings confirm each other and contradict Kapur's (112 ,114) studies. These differences could be explained partly by the differences in radioligands and patient populations. Further research by other investigators with various populations is needed to resolve the controversy.

Another important implication of receptor occupancy with neuroleptics is the prediction of extrapyramidal side effects. The probability of acute dyskinesias is directly proportional to the proportion of D_2Rs occupied by the drug (99 ,110 ,115). Furthermore, receptor imaging demonstrates

a lower degree of D_2 receptor occupancy during treatment with atypical neuroleptics. For example, PET has been used to obtain the minimal effective dose of risperidone. The high D_2R occupancy associated with 6 mg or more risperidone daily suggests a high risk of acute dyskinesias. On the other hand, 4 mg risperidone daily results in 70% to 80% D_2R occupancy and a lesser risk of acute dyskinesias (116). An additional role for occupancy studies in drug development takes the form of the interpretation of the time course of receptor occupancy following a single drug dose. Such studies help determine the appropriate dosing regimen for future trials, such as once or twice a day dosing. For example, 70% to 90% of $5HT_{2A}$ receptors are occupied during the 24 hours after a single oral 20-mg dose of MDL100,907 (MDL), a selective serotonergic agent, whereas only 20% are occupied 24 hours after a 10-mg dose (117). These results suggest that a 20-mg dose may be administered once daily, whereas a 10-mg dose requires administration twice a day. Thus, occupancy studies constitute surrogate markers for the outcome variable and frequency of drug administration.

Another use of occupancy studies is the correlation of D_2R occupancy with plasma levels of neuroleptics. This approach has been successfully applied to estimate D_2R occupancy by haloperidol in patients with low doses of haloperidol (118). These preliminary results can be refined in future research with larger sample sizes.

In summary, receptor occupancies have helped establish the optimal dosage range of antipsychotic medications. These imaging methods also have a role to determine *in vivo* occupancy of new neuroleptics with multiple sites for D_2 and $5HT_{2A}$ binding. The studies probably have their greatest role in giving approximate dosage estimates for future clinical trials.

Other Roles for Neuroreceptor Imaging in Drug Development

Four major areas in which neuroreceptor imaging can assist in drug development are listed in Table 34.3 . The first and most well developed area is in helping target rational drug dosing as in the neuroleptic studies described in the preceding. The second is the elucidation of the biodistribution of the drug by radiolabeling the drug or a derivative of the drug. Examples of this application include the characterization of MDL, which is the first selective $5HT_{2A}$ antagonist developed primarily for schizophrenia. MDL has been radiolabeled with [^{11}C] in an isotopic form such that a stable carbon atom (atomic number ^{12}C) is substituted with a radioactive atom (^{11}C) without a change in the pharmacology or chemistry. This procedure facilitates characterization of the biodistribution and washout characteristics of the agent (117).

Rational drug dosing
Biodistribution of drug bound to radiolabels
^{11}C and ^{18}F for PET
^{123}I and ^{99m}Tc for SPECT
Therapeutic rationale for drug utilization
Mechanism of drug action

PET, positron emission tomography; SPECT, single photon emission computed tomography.

TABLE 34.3. COMPONENTS OF THE DRUG DEVELOPMENT PROCESS ACCOMPLISHED BY NEURORECEPTOR IMAGING

The third application of neuroreceptor imaging to drug development is to better understand the mechanism of action of drugs. One example of this is in the development of drugs for cocaine abuse. Unlike neuroleptics and antidepressants, drugs developed to inhibit the action of cocaine have failed clinical trials. Although cocaine has been shown to affect multiple neurotransmitter systems, current research efforts to develop effective treatment for cocaine dependence focus on the dopamine system. Cocaine is hypothesized to produce euphoria by increasing the intrasynaptic concentration of dopamine. Cocaine has high affinity for the dopamine transporter (DAT); therefore, contemporary research to treat cocaine dependence includes the development of noncompetitive inhibitors of cocaine at this site without affecting dopamine transport. One example of potential treatments for cocaine dependence is the development of GBR12909 (GBR), a potent DAT inhibitor. This pharmaceutical, originally developed in Europe as an antidepressant, has found a potential new application as a prototypical drug for cocaine abuse. Prior studies have shown that IV infusion of GBR to Rhesus monkeys selectively reduced (1 mg/kg) and eliminated (3 mg/kg) cocaine self-administration (119). Villemagne and colleagues (120) tested the hypothesis that doses of GBR, which reduce self-administration, also produce significant occupation of DAT. Doses of 1, 3, and 10 mg/kg demonstrated occupancy of 26%, 53%, and 72%, respectively, in *Papio anubis* baboons (Fig. 34.1 and Fig. 34.2). These data suggest that doses that suppress cocaine administration also provide high occupancy of the DAT. Preclinical research supports the hypothesis that elevations of mesolimbic DA mediate the addictive and reinforcing effects of methamphetamine and amphetamine. *In vivo* rodent microdialysis has demonstrated that GBR attenuates cocaine and amphetamine induced increases in mesolimbic DA. Utilizing PET scans of a continuous infusion of [^{11}C]raclopride in baboons, Villemagne and colleagues (120a) also showed that GBR attenuates amphetamine induced striatal DA release by 74% (Fig. 34.3 and Fig. 34.4). Thus, GBR is a potentially effective agent to treat cocaine and methamphetamine dependence. This experimental

model is also being utilized to evaluate other forms of GBR such as the long-acting decanoate derivative.

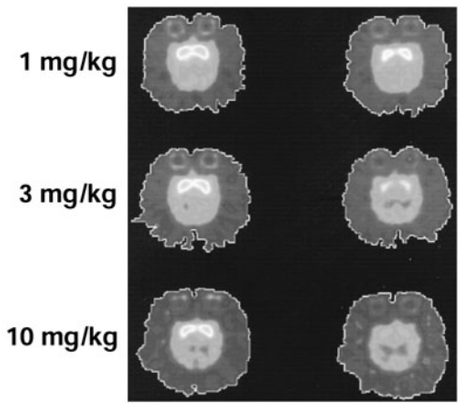

FIGURE 34.1. Reductions in dopamine transporter occupancy are shown in transaxial [^{11}C]WIN35,428 images in *Papio anubis* baboons before *(left)* and after *(right)* administration of three different doses of GBR. Each dose is given 90 minutes before [^{11}C]WIN35, 428 injection. The illustrations represent average PET images at midstriatal level between 70 and 90 minutes after the injection of the radiotracer normalized to the injected radioactivity. Modified from Villemagne V, Rothman RB, Yokoi F, et al. Doses of GBR12909 that suppress cocaine self-administration in non-human primates substantially occupy dopamine transporters as measured by [^{11}C]WIN35, 428 PET scans. *Synapse* 1999;32:44–50. Copyright © 1999, Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc. See color version of figure.

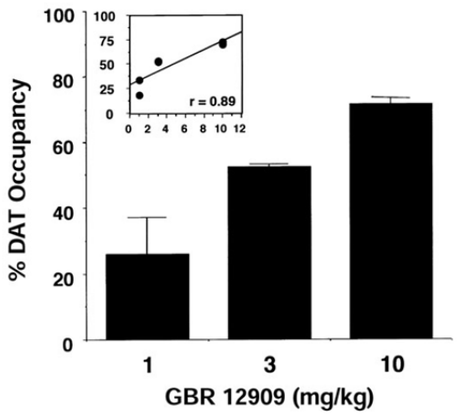

FIGURE 34.2. This histogram illustrates the percentage dopamine transporter (DAT) occupancy by GBR 12909 (GBR) as measured by positron emission tomography imaging with [^{11}C]WIN35, 428. DAT occupancy is represented as the percentage mean ± standard error of the mean differences between binding potentials at baseline and after GBR administration. Percentage occupancy is calculated by the formula as follows: [(Baseline binding potential - GBR binding potential)/Baseline binding potential] × 100. *Inset:* Relation between DAT occupancy and GBR dose (120). Modified from Villemagne V, Rothman RB, Yokoi F, Rice KC, Matecka D, Dannals RF, Wong DF. Doses of GBR12909 that suppress cocaine self-administration in nonhuman primates substantially occupy dopamine transporters as measured by [^{11}C]WIN35, 428 PET scans. *Synapse* 1999;32:44–50. Copyright © 1999, Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.

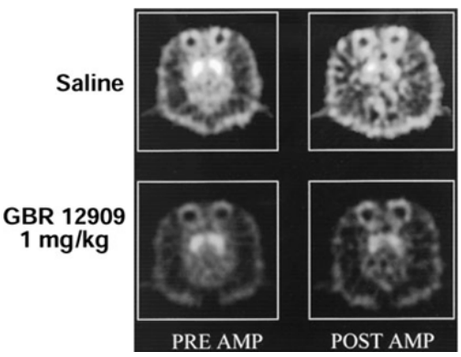

FIGURE 34.3. These images illustrate the binding of [^{11}C]raclopride to the basal ganglia of *Papio anubis* baboons treated with saline *(top row)* and GBR (1 mg/kg) *(bottom row)* after the administration of saline (3 mL/kg) (PRE AMP) *(left column)* or amphetamine (1 mg/kg) (POST AMP) *(right column)*. After the administration of saline (3 mg/kg) *(top row)* there is prominent binding of [^{11}C]raclopride to the basal ganglia at baseline (PRE AMP) *(upper left)* and significant reduction after the administration of amphetamine (1 mg/kg) (POST AMP) *(upper right)*. After the administration of GBR (1 mg/kg) *(bottom row)* there is reduced binding of [^{11}C]raclopride to the basal ganglia at baseline (PRE AMP) *(lower left)* and minimal reduction after the administration of amphetamine (1 mg/kg) (POST AMP) *(lower right)*. Modified from Villemagne VL, Wong DF, Yokoi F, Stephane M, Rice KC, Matecka D, Clough DJ, Dannals RF, Rothman RB. GBR12909 attenuates amphetamine-induced striatal dopamine release as measured by continuous infusion PET scans. *Synapse 1999;33:268–273*. Copyright © 1999, Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc. See color version of figure.

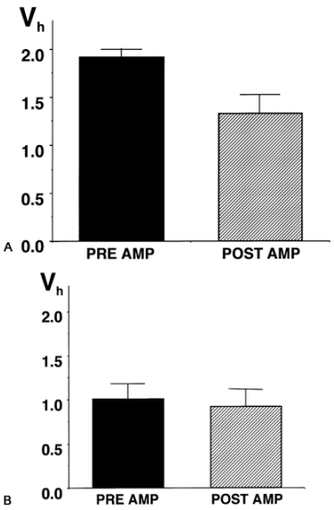

FIGURE 34.4. These histograms contrast the release of DA after administration of amphetamine (AMP) in *Papio anubis* baboons treated with saline *(left)* and GBR (1 mg/kg) *(right)*. For each histogram, the abscissa indicates the intravenous administration of saline (3 mL/kg) (PRE AMP) or amphetamine (1 mg/kg) (POST AMP) and the ordinate is the average volume of distribution (V_h) and the standard error of the mean. The left histogram illustrates a significant reduction in V_h consistent with the release of DA induced by amphetamine. The right histogram demonstrates a reduced baseline (PRE AMP) V_h after administration of GBR consistent with an increase in baseline extracellular intrasynaptic DA concentration (PRE AMP) and the absence of a significant change in V_h after the administration of amphetamine (POST AMP). Modified from Villemagne VL, Wong DF, Yokoi F, Stephane M, Rice KC, Matecka D, Clough DJ, Dannals RF, Rothman RB. GBR12909 attenuates amphetamine-induced striatal dopamine release as measured by [^{11}C]raclopride continuous infusion PET scans. *Synapse* 1999;33:268–273. Copyright © 1999, Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.

The fourth method in which neuroreceptor imaging can assist in drug development is the empirical evaluation of theories of disease, such as the DA hypothesis for schizophrenia. For example, Grace (1991) (121) proposed that schizophrenia is characterized by intrasynaptic concentrations of DA that are abnormally low in the basal tonic state and abnormally high in the simulated phasic state. This has been supported by numerous findings of elevated dopa decarboxylase measurements using [^{18}F]fluorodopa (122), elevated amphetamine induced dopamine release (123 ,124 and 125), and elevated D_2Rs (97 ,126). There is also some potential evidence that elevated intrasynaptic dopamine release is also found at baseline (126 ,127 and 128). In this example of the DA system, the combined strength of measuring presynaptic, postsynaptic, and intrasynaptic DA, for example, provides converging evidence to test this hypothesis. Development of additional ligands such as those for glutamate, glycine, and second messengers, will further expand the potential to evaluate the complex pathophysiology of schizophrenia.

MAGNETIC RESONANCE SPECTROSCOPY

Magnetic resonance spectroscopy (MRS) provides surrogate markers to determine clinical endpoints to evaluate new therapeutic interventions for specific diseases. For example, choline metabolites estimated through photon MRS function as surrogate markers of cognitive motor symptom severity in HIV-1 (129). Additionally, [^{19}F]MRS has been explicitly employed to examine the pharmacokinetics of psychotropic medications containing a fluorine group such as fluvoxamine (130). This allows direct comparison of brain and plasma concentrations, and brain elimination half-lives (131), although the sensitivity allows only micromolar measures in contrast to the nanomolar measures attained with PET. These methods have also been employed in animal models using [^{19}F]nuclear magnetic resonance (NMR) chemical shift imaging to study the cerebral distribution of general anesthetics *in vivo* (132).

MAGNETIC RESONANCE IMAGING

Part of "34 - Proof of Concept: Functional Models for Drug Development in Humans "

Magnetic resonance imaging (MRI) provides surrogate markers for disease progression to facilitate drug development. For example, T2-weighted cerebral MRI functions as a surrogate marker in early stages of demyelinating disease to predict disease progression and disability over the subsequent 10 years (132a and 132e).

Another example of the use of MRI as a surrogate marker for drug development is in the diagnosis and treatment of subjects with AD. Atrophy of the hippocampal formation has been correlated with memory and cognitive impairments. Reductions in the volume of the hippocampus have been predictive for the individuals who later develop memory impairments consistent with AD (133). Another marker of the vulnerability to develop AD is the measure of the apolipoprotein E (APOE) genotype. The relative risk for AD is increased for people with the gene (134). The APOE gene is associated with loss of hippocampal volume (135). Cross-sectional studies in 116 healthy volunteers, 59 to 85 years old, demonstrated significantly larger ventricular volumes and smaller gray and white matter volumes in older compared to younger individuals and in men compared to women over a period of only 1 year. An increase of over 1,500 mm^3 in ventricular volume was demonstrated during this time but no detectable change in the total or regional brain volumes. This suggests that determination of the pattern and rate of these changes longitudinally could be a future predictor of cognitive declines and dementia (136).

Functional MRI (fMRI), a technique in which subjects are asked to perform particular mental or physical tasks while the MRI is obtained, may provide biomarkers useful for drug development. For example, the rCBF of cocaine-dependent subjects administered intravenous cocaine exhibited increases in the nucleus accumbens, subcallosal cortex, and hippocampus and decreases in rCBF in the amygdala, temporal pole, and medial frontal cortex (137). Future studies utilizing this paradigm could additionally assess whether another compound administered before cocaine can antagonize or amplify its affects.

BIOMARKERS OF ALCOHOL ABUSE

Part of "34 - Proof of Concept: Functional Models for Drug Development in Humans "

The synergistic combination of carbohydrate-deficient transferrin (CDT), gamma-glutamyl transferase (GGT),

and mean red cell volume (MCV) functions as a possible biomarker for alcohol abuse (138).

NEWER MARKERS FOR DRUG DEVELOPMENT

Part of "34 - Proof of Concept: Functional Models for Drug Development in Humans "

Several techniques recently have been developed to provide the means to assess the efficacy of newly developed potential drugs. These procedures assist clinicians in both the (a) diagnosis of neuropsychiatric disorders, and (b) monitoring of the course of disease progression and the response to drug treatments and other therapeutic interventions. The application of the following novel procedures to drug development is the result of a collaborative effort jointly of the National Institutes of Health (NIH), the United States Food and Drug Administration (FDA), the Health Care Financing Administration (HCFA), and private industry (139). The protocols described in this section are likely to be instrumental in drug development for neuropsychiatric disorders in the future.

External Imaging of Internal Bioluminescent and Fluorescent Signals

Biological processes, such as the propagation of cancer cells, are studied in animal models by the detection of bioluminescent (140) and fluorescent signals recorded externally by means of sensitive photon detection systems (141). For example, optical imaging systems visualize near-infrared fluorescent molecular targets triggered by enzymes released by cancer in experimental animals (142). Other examples include the evaluation of potential agents to treat human cancer and infection by assessing the behavior of cells from patients in animals utilizing bioluminescent markers. The technique utilizes bioluminescent compounds bound to specific enzymes that signal the proliferation of cancers and bacteria. Human subjects with cancer or infection are treated with agents to alter the expression of genes that produce the enzymes needed for the growth of the cancer or bacteria. Then animals are injected with (a) cells from the previously cancerous or infected tissue of treated humans, and (b) bioluminescent markers that respond to the presence of the enzyme that was hopefully blocked in the humans. Detection of the bioluminescent markers in the animals indicates the proliferation of the enzyme to be blocked in the treated human and, therefore, the failure of the therapeutic attempt. This technique, which provides a surrogate for the clinical effects, is being applied to a variety of human diseases including cancer and infection (http://www.xenogen.com/). By analogy, this procedure could be applied to assess drugs developed to treat malignancy and infection of the CNS. For example, novel agents to alter the expression of the genes that code for the control of the production of enzymes required by cancer and infection of the CNS could be administered as therapeutic agents to suitable patients with malignancy and infection of the CNS. CSF from treated patients and bioluminescent compounds responsive to the presence of the enzyme that should be absent could then be injected into experimental animals. Detection of the bioluminescence in the experimental animal would then indicate failure of the new drug to prevent the growth of the tumor or infection. Thus, this technique offers the potential of surrogate markers to monitor the presence of CNS tumors and infections.

Simultaneous Optical and Magnetic Resonance Microscopy

Simultaneous optical and magnetic resonance imaging (MRI) is being developed in experimental animals. MRI contrast agents (143), such as fluorescently detectable magnetic resonance imaging agents, are utilized to permit light and magnetic resonance imaging microscopy at the same time (144). These compounds can be detected deep in tissue, not merely at the surface as with simple optical detection systems (e.g., for fluorescent dyes) (145). Although light microscopy can penetrate only 100 to 300 µm beneath the surface of organisms, MRI microscopy can penetrate 1 to 6 mm into an organism (144). For example, agents that can be simultaneously recognized by MRI microscopy and by fluorescent optical microscopy permit visualization of structures 1 to 6 mm below the surface of an organism approaching cellular resolution (i.e., 10 µm) (143 ,144).

Diffusion-Based Optical Imaging

Procedures to measure light emitted into opaque structures have been termed medical optical imaging (MOI), medical optical spectroscopy (MOS), near-infrared imaging (NIRI), and near-infrared optical spectroscopy (NIOS) (146). For example, three-dimensional optical coherence tomography (OCT) is a technique to image nontransparent biologic tissue by recording and analyzing light emitted into scattering media. OCT has been employed to visualize nerve fascicles in experimental animals for the microsurgical anastomoses of vessels and nerves (147). An example of diffusion-based optical imaging is the use of optical tomography to detect intraventricular hemorrhage in premature infants by external transmission of light emitted through the skull (146). These techniques may be utilized to develop treatments for human disease, including infections and malignancies (146). Hopefully, in the future they will be applied to CNS tumors and malignancies.

Magnetic Resonance Microscopy

Microscopic visualization of magnetic resonance images has detected transgene expression in experimental animals.

Identification of pathologic processes, including the proliferation of tumor cells in clinical settings (148), may be facilitated by this procedure. This technique offers the means to both detect the occurrence of malignancies and to monitor their growth (148). The application of this procedure to human CNS malignancy is a goal to be attained in the future.

Electron Paramagnetic Resonance

Electron paramagnetic resonance (EPR) (149) imaging and spectroscopy are procedures to spatially map parameters of physiologic importance by incorporating paramagnetic spin labels into the system of interest (150). This technique has been utilized to visualize oxygen concentration in the tissues of experimental animals (150) and to measure oxygen free radical generation in human endothelial cells exposed to anoxia and reoxygenation (151). EPR has been employed to estimate the production of nitric oxide in biological systems (152), a process vital to the measurement of the progression of pathologic processes (153), including cerebral ischemia (154) and malignancies.

CONCLUSION

Part of "34 - Proof of Concept: Functional Models for Drug Development in Humans "

Biomarkers and surrogate markers are tools currently utilized to develop new drugs. They provide evidence of the proof of concept required for successful Phase 1B/2A studies submitted to the FDA. Currently drugs are being developed by the use of neuroendocrine markers including CSF, prolactin, GH, ACTH, and cortisol. Imaging studies provide the means to estimate therapeutic dosages of new drugs. Surrogate markers include a variety of neuroimaging techniques including MRI, MRS, PET, and SPECT. Newer techniques for drug development are likely to include external imaging of internal bioluminescent and fluorescent signals, simultaneous optical and MRM, diffusion-based optical imaging, and EPR.

Ethical Aspects of Neuropsychiatric Research with Human Subjects

Debra A. Pinals

Paul S. Appelbaum

Debra A. Pinals and Paul S. Appelbaum: University of Massachusetts Medical School, Worcester, Massachusetts

Considerable world attention in the last century has focused on the ethics of clinical research with human subjects. Coming to the fore after World War II, with the Nuremberg War Crimes Trials, concerns were raised about the potential for abuse of nonvoluntary, uninformed subjects who might be utilized in questionable research. Out of the trials came the Nuremberg Code (1), which formalized ethical principles surrounding research with human subjects. When, in 1953, the United States opened the doors to the Clinical Center of the National Institutes of Health, guiding principles regarding human subject research at that institution were in place to greet the first subjects who enrolled in studies on site (2). By the following decade, in 1964, the World Medical Association developed the Declaration of Helsinki, which was an attempt to modify and expand upon the Nuremberg Code (1). This document classified research into clinical and nontherapeutic categories, and outlined the practice of consent that these types of research would require. The Declaration has since gone through multiple revisions and continues to be a significant guideline for research with human subjects, especially in Europe.

Despite these initial attempts to clarify the ethical principles and practices of human subject research, repeated abuses were widely publicized in the ensuing years: the Tuskegee syphilis study (3), studies involving injection of live cancerous cells in patients without their consent (4), and studies in which subjects were unknowingly exposed to radiation (5) among them. As each story was exposed, it inspired international review of the ethics of human subject research. Minority populations and those who may be vulnerable to exploitive research, such as the mentally ill, evoked particular concern. In the United States, federal commissions and agencies were created to address the concerns. Among the outcomes of these initiatives were regulations affording the government greater control over federally funded research. Institutions were required to develop Institutional Review Boards (IRBs) to review research protocols to protect human subjects and ensure an adequate consent process.

Beginning in the 1990s public concern again grew, as research with patients with mental illness became a focus of media attention (6 ,7 ,8 and 9). As an example, Hilts (6) in a widely publicized media report, described a study in which the use of methylphenidate in research subjects “threw 60 per cent of them into severe psychotic episodes.” Another exposé (8) described research at the University of California at Los Angeles (UCLA) involving outpatients with psychotic disorders who were withdrawn from active antipsychotic medications and observed for signs of relapse over time. One patient ultimately committed suicide more than a year after leaving the study, whereas a second had a significant exacerbation in psychotic symptoms, resulting in threats to kill his parents. In 1994 the federal Office of Protection from Research Risks (OPRR) investigated allegations that the UCLA study's research design and implementation had been unethical (10). Although the OPRR did not find unethical research practices, they questioned the adequacy of the informed consent process for this potentially high-risk study (11).

As a result of the controversy in the United States, federal and state agencies have begun to take a closer look at ethical issues raised in psychiatric research. One of the foci has been the process of informed consent in studies involving subjects who may have impairments in their abilities to make decisions, such as patients with severe mental illnesses. A 1995 report of the Advisory Committee on Human Radiation Experiments (ACHRE) found that approximately half of the studies it examined had “inadequate explanations of risks and discomforts in their consent material and paid no attention to the question of how to deal with subjects who might have impaired capacities to consent to research participation” (5).

In 1995, President Clinton appointed the National Bioethics Advisory Commission (NBAC), in part to address these concerns. In December of 1998, NBAC issued its report entitled *Research Involving Persons with Mental Disorders That May Affect Decision-making Capacity* (12). Among other things, the report recommended that an independent professional should assess a potential subject's capacity to provide informed consent for studies involving more than minimal risk. The report generated a swift and critical response from many psychiatric professionals who expressed concern that the recommendations reflected the misconception that all persons with mental illness have decision-making impairments. Thus, some considered the recommendations too restrictive and stigmatizing of persons with illnesses very much in need of study (13). Charney (14), however, wrote on behalf of the psychiatric research community that the NBAC report provided some valuable contributions to the ongoing debate, and acknowledged that “there is a crisis in confidence in the ethics of psychiatric research” that needed to be addressed. NBAC responded to the criticisms by stating that they envisioned their report as “part of a continuing societal conversation… about what regulations and guidelines should govern research involving persons with mental disorders that may affect their decision-making capacity” (15).

These developments highlighted numerous areas of ethical concern regarding research with human subjects with neuropsychiatric disorders, including subject recruitment, confidentiality, data access, and conflicting roles of investigators acting also as treaters. More recently, certain methodologic practices, such as placebo-controlled studies, drug withdrawal studies, and the so-called “challenge” studies, have attracted particular attention. Related to concerns about methodology, the ability of patients with mental illnesses to provide informed consent to research procedures has probably been one of the most controversial issues surrounding psychiatric clinical research, as highlighted in the NBAC report.

METHODOLOGIC CONTROVERSIES

Part of "35 - Ethical Aspects of Neuropsychiatric Research with Human Subjects "

Placebo Studies

In the mid-1990s, controversy over the use of placebos in research was rekindled; some commentators (16 ,17) contended that placebo use is unethical when standard effective treatments exist. Support for this limitation on the use of placebos stems, in part, from the Declaration of Helsinki (1), which declares that human research subjects have a right to therapeutically proven methods and treatments when available. Nevertheless, use of placebo agents is widespread throughout medical research (18 ,19).

Arguments in favor of the use of placebos in research, including psychiatric research, include the superior ability to assess accurately the efficacy of an experimental medication through the use of double-blind, randomized, placebo-controlled studies. In fact, this type of study design has been touted has “one of the major achievements of modern medicine” (20). The FDA, in considering what constitutes “adequate and well-controlled studies” (required for approval of new medications) states that the placebo-controlled experimental design has important scientific merit in establishing therapeutic efficacy as long as the objectives and the rationale for placebo use are clear (1). However, the FDA cautions that placebos should not be used “where existing treatment is life-prolonging” or if the placebo “exposes patients to a documented serious risk” (1).

Some authors have argued that findings of placebo research are misleading and deceptive (21), and that more or equally reliable findings could be had using active control agents (16 ,22). A central argument against the use of placebos in research on serious mental illnesses is that they are likely to contribute to a relapse of or failure to resolve psychiatric symptoms. One early report suggested that psychosis in and of itself may be biologically toxic to the brain (23), and may lead to short- and long-term adverse consequences. In addition to the potential risks associated with an exacerbation of primary symptoms, there are concerns about the psychosocial effects of relapse on patients. Specifically, prolonged periods of significant psychological distress may be associated with loss of interpersonal relationships, financial losses, and increased risk of suicide.

Despite the risks, by now it is relatively clear that the use of nonactive agents as a means of control has scientific merit when effective treatments for a particular illness are not yet known. When effective treatments do exist, a placebo comparison may still allow investigators to establish efficacy, learn more about the natural course of the illness, and compare side effect profiles of active agents against nonactive compounds. Studies examining the efficacy of a known medication and an experimental medication may—because of flaws in the studies’ design or implementation—not clearly differentiate between the two, and drugs with only minimal potential may be seen as more worthwhile than they are (24). Moreover, historic controls are not an adequate substitute for placebos because the apparent increase in the prevalence of experimental subjects who may already be resistant to treatment with standard medications (25 ,26). Thus, the analysis of the complexities of psychiatric illness and decisions regarding the risks and benefits of existing compounds compared with novel agents would be limited by only having the existing active comparison agent as a reference point (20 ,27). Furthermore, it has been argued that brief placebo periods may be conducted safely, particularly for inpatients (28), and do not appear to lead to long-term negative prognostic effects (29).

Drug Withdrawal Studies

Medication discontinuation studies in psychiatric research have become another point of ethical contention. The scientific rationale for drug discontinuation has included the desire to examine the pathophysiology and course of underlying illnesses when patients are in an unmedicated state. Furthermore, assessment of the clinical and neurochemical effects of medications in some cases can be more legitimately interpreted in a given individual after a period of drug washout, as the potential therapeutic or adverse effects of the initial treatment may present a confounding variable, making interpretation difficult (20 ,30).

However, significant concern about the use of this approach has been raised both in the scientific community and in the lay press. For example, recent literature suggests that chronic patients may have a poorer response to treatment or deleterious effects should they be taken off medication and experience relapses (31 ,32 and 33). In patients with bipolar disorder, concern has been raised that the clinical state following withdrawal of maintenance medication may actually be distinct from what it would have been had the natural course of the illness progressed without treatment at all (34). Furthermore, the risk of relapse itself has been of significant concern. In fact, a meta-analysis of the effects of drug discontinuation in schizophrenia demonstrated a relapse rate of 53% during an average 9.7-month follow-up (35) compared to a 16% relapse rate for those patients remaining on their medication. Despite the greater relapse risk, patients who experienced a worsening of their symptoms when off medications were able to return to baseline following reinitiation of treatment. Relapse risk may be particularly high when medications are discontinued abruptly (36 ,37). Questions have been raised about whether inconsistent use of neuroleptics may result in a higher risk of tardive dyskinesia (38 ,39).

Much as with placebos, the debate about the potential for neurotoxic damage as a result of experiencing psychosis itself (23 ,40) has raised further ethical questions about drug discontinuation studies. Although, the theoretic long- and short-term risks of psychosis have been widely cited, others have argued that the data on the risks of brief psychosis occurring during research studies are not clear (41 ,42). Furthermore, in the case of psychotic disorders, continuous treatment with neuroleptics is not without its own risks, including some risk of relapse and the risk of serious side effects (38). About 30% of patients will have no significant response to neuroleptics, and some patients can remain without relapse even after years of being off medications (43). The risks of ongoing treatment and potential adverse sequelae of withdrawing medications must be weighed in all psychiatric research. In this way, risks to human subjects may be minimized and drug withdrawal conducted when essential.

Challenge Studies

Another of the controversial research techniques that has undergone public scrutiny are provocation or “challenge” studies. These terms refer to experiments in which patients and sometimes healthy control subjects are exposed to drugs that exacerbate or create psychiatric symptoms. Provocation studies are not unique to psychiatry. In general clinical research, provocation studies have been conducted to induce pain, nausea and/or vomiting, bronchoconstriction, tachycardia, cognitive impairment, and even sepsis (44). These studies share the same basic goal of allowing investigators to learn more about symptom expression and potential therapeutic interventions. Although widely used in medical research, their use in studies examining psychiatric illnesses seems to have captured the interest of lay persons, advocacy groups, the media, and even policy makers. One theory is that these types of studies may be more common in neurobiological research, where less is known about the diseases being studied and animal models are sparse (45).

One of the hottest debates most recently has involved the use of ketamine, an NMDA receptor antagonist, and an approved anesthetic agent, to provoke psychotic symptom exacerbation in patients with schizophrenia and produce transient psychotic states in well control subjects. Tishler and Gordon (46) expressed concern that giving a healthy control or nonpsychotic person ketamine might present a risk of producing illness, given the “biological stressor of the experimental procedure and psychological stressor of psychosis [induced by the pharmacologic challenge].” In a review of all North American schizophrenia subjects who underwent ketamine challenge studies, Carpenter (47) concluded that the ketamine-induced increase in psychosis was mild to moderate and brief, any anxiety induced was mild and brief, and there was no evidence of ongoing negative consequences for subjects. It is noteworthy, as Carpenter points out, that the controversy surrounding the ketamine challenge study has been raised when results with fewer than 50 patients have been published. The media outcry against this type of study has led to trepidation to continue this novel avenue of scientific research. Yet, other authors have suggested that symptom provocation studies, beginning with early research involving amphetamine loading and including the more recent symptom induction studies, have contributed significantly to our understanding of psychiatric disease, at a cost of inducing only transient psychotic states with no long-term adverse effects (48 ,49) or evidence of altered disease course (50).

Although the data suggesting the safety of current challenge studies are encouraging, ethical implementation of such studies is complex because of the potential for negative consequences, even if transient or remote. It has been argued that these types of studies might be ethically justifiable if the underlying scientific principle is sound, if the effects are

not thought to be long-term or severe, and if subjects have the capacity to participate as “knowing, voluntary partners in the research enterprise” (49).

INFORMED CONSENT AND THE CAPACITY FOR CONSENT IN PERSONS WITH NEUROPSYCHIATRIC DISORDERS

Part of "35 - Ethical Aspects of Neuropsychiatric Research with Human Subjects "

Challenge, placebo, and drug withdrawal studies always raise questions of research ethics, but the controversy is heightened when the subjects involved suffer from mental illnesses. At the heart of the debate is the concern that these subjects, more than other human research subjects, have significant deficits in their abilities to provide informed consent, so that they may enter studies without full understanding of the inherent risks. Unfortunately, although this has become the focus of political and media attention, there is often a lack of understanding of what informed consent is, and what the literature shows regarding the capacity of mentally ill subjects to give informed consent.

The doctrine of informed consent is built from a complex interrelationship of medicolegal and ethical principles. Generally, informed consent, whether to research or treatment, is broken down into three parts: *voluntariness, disclosure*, and *competence* (51). Voluntariness implies that research subjects must be acting of their own free will when they agree to participate in research. Disclosure provides information on the basis of which potential subjects may make an informed choice. In research settings, disclosures must generally include such details as the nature and purpose of the study, as well as the potential risks and benefits involved in the study. Other information provided includes disclosure of the right to discontinue participation in the study, who will have access to the data, the differences between participation in research and routine treatment, and the availability of compensation should harm ensue as a result of the study.

Informed consent also requires task-specific competence. Competence consists of four separate elements (52). First, subjects must be able to *evidence a choice* regarding the decision at hand. The choice need not be expressed verbally, but subjects must be able to communicate their preference in some way. Also, the choice must be sustained over time. The inability to maintain a consistent choice over time might reflect significant mental status deficits such as those seen in psychotic ambivalence or delirious states.

Additionally, subjects must have a *factual understanding of the information* that has been presented to them. The degree of factual understanding required for competence is unclear, and there is no threshold value of how much information must be understood in order to be considered to have “enough” factual understanding. Furthermore, acceptable levels of understanding may vary depending on the risks involved in a proposed research study.

Subjects must also be able to *rationally manipulate the information* in a way that is not impaired by symptoms of their illness. They must demonstrate ability to reason through the information presented to come up with a logical decision, which need not be the decision that the person assessing competence would make. Patients with or without psychosis who have impairments in their reasoning, in addition to their primary symptoms (e.g., cognitive deficits, concrete thinking, or inability to abstract), might have difficulties in this regard.

Finally, subjects must have a *realistic appreciation of their situation*. Patients with schizophrenia, for example, who do not believe they are ill will have a limited appreciation of why they are being enrolled in a study examining that particular illness. The appreciation must include some awareness of the fact that the study involves research and not treatment, and so may be of no direct benefit to the individual.

Understanding of the capacities of persons with mental illnesses to consent to research has historically relied on data gathered from studies looking at competence to consent to treatment. Recent years have seen an expansion of the previously limited literature on competence to consent in research settings.

With regard to the ability to communicate a choice, although sometimes taken for granted, studies have shown that a proportion of patients will have difficulties in this area. In a study by Appelbaum, Mirkin, and Bateman, 9% of community mental health center patients who were contacted to participate in a study were found to be mute or catatonic (53). Eighteen percent of primarily depressed inpatients were unable to make a decision in vignettes that required some problem solving (54). The risk of simply excluding these persons from studies is that their inability to communicate a choice may reflect a degree of illness that is worthy of study, and their exclusion might skew the results of research based on altered group composition. Therefore, there may be value in considering whether proxy decision makers might in certain circumstances and with appropriate safeguards, enter into research those subjects who are unable to express a consistent choice.

Studies have also examined the capacity of patients to understand information. For example, Grossman and Summers (55) found that patients with schizophrenia understood only about half the information presented to them regarding the risks and benefits of a fictitious medication, and thus concluded that these patients may have difficulty providing true informed consent. The degree of psychopathology may affect learning of new information in schizophrenics (56). Kleinman and colleagues (57) suggested that a formalized informing process increased schizophrenic patient understanding of tardive dyskinesia. In a frequently cited study of 41 patients with affective disorders who were potential subjects of a sleep EEG study, Roth and colleagues (58) found that only about 50% of the subjects understood more than two-thirds of the information presented to them through a formal consent process, whereas a significant minority

of patients (about 25%) understood half or less of the information. Benson and associates (59) showed that patients with schizophrenia demonstrated greater impairment in understanding specific psychiatric research purposes and methodology in comparison to psychiatric patients with less severe psychopathology. Comparing the capacity of stable patients with schizophrenia and healthy volunteers to understand a low-risk study involving a magnetic resonance imaging test for research purposes, Pinals and co-workers (60) found no difference in understanding of consent forms between groups. Of note, neither group on average was able to correctly answer 100% of the questions on a brief questionnaire related to information on the consent form. Another study using a questionnaire relating to research protocols found that out of 49 patients with schizophrenia, 53% required a second trial at the questionnaire after re-education about the protocols to achieve a score of 100%, and 37% of subjects required three or more trials (61). The authors concluded that with an adequate informed consent process, research subjects with schizophrenia were able to comprehend consent form information.

Impairment of the ability to appreciate the nature of one's situation and potential consequences may have particular relevance in psychiatric disorders where insight into one's illness is often compromised. In a classic report, Soskis (62) found that 68% of schizophrenic subjects did not recognize the reason they were receiving treatment compared to 13% of medically ill patients. In an earlier study looking at patient appreciation of their participation in research, Appelbaum and associates (63) showed that more than half of the psychiatric patients interviewed failed to comprehend the research nature of some component of the methodology of the research in which they were participating. The authors called the subjects' tendency to view research as a therapeutic process, when in fact there may be no benefit to the subject at all, the "therapeutic misconception."

With regard to the ability of psychiatric patients to rationally manipulate information pertaining to research, Stanley and colleagues (64) reported that the degree of psychopathology in patients with mental illness did not appear to influence their willingness to participate in hypothetical research compared to nonpsychiatrically ill subjects. In that study, patients tended to agree to low-risk/high-benefit hypothetical studies more than high-risk/low-benefit studies. In a subsequent study, Stanley and associates (65) found that approximately one-third of patients with mixed psychiatric diagnoses refused low-risk/high-benefit hypothetical study enrollment, whereas about 40% of patients agreed to participate in a hypothetical study of high risk/low benefit. Garety and associates (66) found that subjects with schizophrenia or delusional disorder requested less information before reaching a decision and were quicker to change their estimates of the likelihood of an adverse event compared to nondelusional psychiatric patients and normal controls. In a study by Sachs and co-workers (67), persons with dementia were noted not to perform as well as nondemented elderly subjects in providing logical reasons for their decisions to participate in hypothetical research protocols.

Probably the most extensive data examining competency to make treatment decisions was reported by Grisso and Appelbaum (68 ,69) from the MacArthur Treatment Competence Study. This study utilized standardized instruments designed to assess capacities to make treatment decisions, and involved the assessment of multiple components of competence (understanding, appreciation, and reasoning) and the use of several subject groups. Deficits were most pronounced in patients with schizophrenia, and slightly more patients with depression were likely to have deficits than controls. Because the majority of all subjects performed well on measures of competence, the study underscored the notion that subjects cannot be presumed incompetent by virtue of mental illness alone.

Carpenter and associates (70) recently reported their findings examining how psychopathology and cognition affect decisional capacity. They used a modification of the MacArthur study instruments (MacCAT-CR: MacArthur Competency Assessment Tool-Clinical Research) (71) to examine making decision abilities relevant to research. In this study, 30 research subjects with schizophrenia did not perform as well as healthy controls in decision making, and performance was strongly related to cognitive impairments and somewhat related to symptomatology. However, the study found that a weeklong educational intervention that provided information regarding the hypothetical study led to improved decisional capacity such that scores of schizophrenic subjects were not significantly different from the well control group. In another recently published study, Appelbaum and associates (72) assessed the capacities of depressed patients to consent to research utilizing the MacCAT-CR. In this study, female outpatients with major depression did not show impairments in their decision-making capacities related to research. This study further demonstrated the utility of instruments such as the MacCAT-CR as a means of assessing decisional capacity as part of the broader informed consent process in an actual research study.

COMMENTARY

Part of "35 - Ethical Aspects of Neuropsychiatric Research with Human Subjects "

Although ethics in human subject research has long been the focus of attention, awareness of the ethical dilemmas has been heightened in recent years. Despite calls for a moratorium on all nontherapeutic, "high-risk" experiments, including drug washout and challenge studies (73), adverse events appear to be much less common than the public may have been led to believe. What can be gleaned from the current debate is that researchers must attend to the concerns raised, both to maintain public trust and ensure the

ethical integrity of research itself. As Bonnie (74) noted, the challenge is to create generally accepted guidelines on safeguards for subjects without compromising the pursuit of important knowledge or threatening the integral partnership of mental health advocates, persons with mental illness, and researchers.

The research community has made several efforts to tackle these issues. The American College of Neuropsychopharmacology (ACNP) has developed guidelines on ethical practices related to neuropsychopharmacologic research. Highlighted are the needs to: (a) ensure appropriateness of the study and its design; (b) minimize risk to subjects and maximize benefit to subjects or to the population of patients with the illnesses under study; (c) ensure informed consent, while paying particular attention to the needs of those subjects who may have decision-making impairments; and (d) protect confidentiality (75). The NIMH has established new rules for "high-risk" studies, including the creation of a special Human Subject Research Workgroup of the National Advisory Mental Health Council (NAMHC), which will review study protocols involving challenge methodology or drug withdrawal studies (76). After several meetings with representatives of the NIMH, in 1995 the National Alliance for the Mentally Ill (NAMI) adopted "Policies on Strengthened Standards for Protection of Individual with Severe Mental Illnesses who Participate in Human Subjects Research" (77). Among these policies are a recognition of the "critical necessity" of human subject research, and recommendations for protection of persons with cognitive impairments, clearer standards for consent protocols, and specialized training for members of IRBs that review studies involving neuropsychiatric disorders. Measures to ensure that ethical issues are addressed have been developed, including the Research Protocol Ethics Assessment Tool (RePEAT), which may assist in the planning of experimental protocols (78).

In addition to these efforts, there is a growing consensus on mechanisms for the ethical conduct of human subject research. It has been suggested that not pursuing placebo and drug withdrawal studies would be unethical, given all there is to learn from them regarding the pathophysiology, natural course, and treatment of severe mental illness (79). That said, it also is clear that specific approaches can be utilized in order to ensure that this research is conducted safely and ethically. For example, there may be some studies of pathophysiology in which subjects may be maintained on a low but effective neuroleptic dose, without interfering with the acquisition of valid data (38). For neuroleptic withdrawal in patients with schizophrenia, slow rather than abrupt tapering with careful ongoing monitoring may mitigate potential for bad outcomes (40). Drug-free phases may best be conducted while subjects are in an inpatient setting, or while they are very closely monitored as outpatients (38). In this way, if symptoms begin to re-emerge, subjects may be quickly and effectively treated before a bad outcome ensues. "Exit criteria" should be established *a priori* to determine when patients will be restarted on their medications (41). In addition, alternative treatments (such as adjuvant medications, psychotherapy, and rehabilitation treatments) during the placebo phase may be beneficial without compromising research design. Patients at known risk of catastrophic responses to relapse should be excluded from the subject pool. Finally, study subjects must be given the opportunity to provide informed consent, pose questions, and withdraw from study participation at any time. Those patients with initial decision-making deficits and those who may become decisionally impaired during the study will require special measures of protection, addressed in the following.

When challenge studies are proposed, again the scientific merit of the protocol must be weighed against its potential risks. Several suggestions have been made that may offer protections to subjects. For example, Tishler and Gordon (46) have suggested a careful recruitment process that would include detailed disclosure of the inherent risks, review of compensation for participation, and screening prospective normal subjects for the presence of or vulnerability to develop psychiatric illness. Miller and Rosenstein (49) indicated that: (a) the study should have clear scientific merit, (b) subjects with specific clinical vulnerabilities may need to be excluded from participation, (c) selected methods should minimize risks, (d) subjects should have access to careful monitoring and follow-up, and (e) informed consent disclosure should make clear that the challenge study is distinct from other studies in which the subject may be enrolled (80).

With regard to the consent process and the potential for decision-making impairments of mentally ill research subjects, existing literature provides only rudimentary guidance in identifying groups at high risk of impairment. A substantial number of persons with severe neuropsychiatric illnesses may have impairments in their decision-making ability related to research consent. Yet, the data also have shown that many of these persons will retain abilities to make decisions that affect their lives, and thus it is misleading to presume them incompetent by virtue of their diagnoses without adequate assessment.

Although policies will need to offer protection for those who may have decision-making impairments, excessive burdens must be avoided if advancement of knowledge is to continue. By thwarting attempts to conduct bold and novel studies, society runs the risk of limiting knowledge of the very populations who may be most in need of such research. The many subjects who have participated in neurobiological research willingly, even when the risk is high and the potential for benefit is low, testify to the desperation that some of these patients may feel regarding their illnesses. Brody has similarly commented on the justification for use of mentally infirm adults in nontherapeutic research, even if the research presents greater than minimal risk (1), because of the need

to study these complex illnesses. With these caveats, areas worthy of further consideration include disclosure practices, identification and assessment of subject competence, and questions of threshold levels of competence (81 ,82).

In all of these arenas, existing IRBs seem to be in a strong position to provide the scrutiny required. Unfortunately, many people believe that IRBs have become little more than clearinghouses for consent forms, rather than committees designed for careful review of all aspects of research ethics (83). In an attempt to deal with this concern, the NBAC report proposed the establishment of a special standing panel to review certain protocols that way present a greater risk to subjects (12). There are, of course, negative aspects of a shift from currently accepted local IRB authority to a federal agency far removed from where the study would take place (84). Regardless of the reviewing body, if the methodology appears questionable, persons with specialized knowledge in these areas should be consulted to address the questions raised. Attention to the minimization of potential risks of studies is also an important part of the mission of an IRB. With regard to the consent process, the IRB, in addition to reviewing consent forms, should be able to monitor investigator disclosure and determine the level of required subject competence based on a standardized evaluation of the risks and potential benefits involved in a proposed study.

Investigators may have other ways of advancing our current approaches to consent to research. For example, current literature has demonstrated that a modification of disclosure procedures may facilitate subject understanding and enhanced learning (57 ,59 ,60 ,70 ,85 ,86 ,87 ,88 and 89). Even with such efforts, however, there will always be potential subjects who will lack capacity, in one or more of its realms, to provide valid informed consent to participate in research. When patients are participating in studies of greater risk, a higher standard of competence should be required. The investigator and the IRB could work together to decide when formal capacity assessments are indicated (90).

After the inherent risks and competence needs are determined, a sliding scale of options regarding capacity assessment might be implemented. For example, in a low-risk study, one might consider a straightforward consent form and clinical assessment of competence, perhaps aided by a questionnaire specifically geared to the study at hand. As the stakes increase, formalized assessment instruments, such as the MacCAT-CR, might be adapted to the study in question. Oldham and colleagues (13), in their response to the NBAC report, suggested that “formal capacity assessments should be required for subjects when there is reason to believe that a mental or emotional state or a primary or secondary brain dysfunction may interfere with decision making.” They also suggest that, given the inherent potential for investigator bias, for research that presents more than a minor increase over minimal risk, independent evaluators, who function separately from the research team, could ascertain subject capacities. It is unclear at this time how feasible such an approach would be, but it may merit exploration.

Once subjects are identified who clearly lack capacity to consent or who may come to lack capacity as research progresses (such as patients with Alzheimer's disease or patients with schizophrenia enrolled in placebo-controlled studies), additional protections might be implemented to allow such persons to participate in research. Pursuit of a legal determination of incompetence and the appointment of a guardian to make decisions for the subject appears to be utilized rarely, in part because of the impracticalities and cost involved (51). The use of a durable power of attorney or advance directive might, however, allow a substitute decision maker to make decisions that the patient would have made during periods of greater competence (91 ,92 ,93 and 94).

Human subject research will always require careful scrutiny. Our history has shown that even well intentioned investigators may not be able to assess ethical aspects of the research they are undertaking objectively. Additionally, potential research subjects may enroll in studies for a variety of reasons, conscious and unconscious, without a full awareness or appreciation of the risks they are undertaking. Nevertheless, the current focus on ethical issues related to research should serve to heighten the awareness of the research team, including both investigators and subjects, regarding measures that can be taken to allow scientific advancement while protecting potentially vulnerable populations.

Regulatory Issues

Paul Leber

Paul Leber: Neuro-Pharm Group, LLC, Potomac, Maryland.

For over 60 years, the United States has relied primarily on a federal system of premarket drug product clearance to ensure the quality of the nation's drug supply. When the premarket clearance system was first introduced in 1938 in the aftermath of the Elixir of Sulfanilamide tragedy in which over a hundred patients needlessly died because of a drug manufacturer's carelessness (1), federal law required only that new drugs be tested and shown, prior to marketing, to be "safe for use." Since 1962, however, the law requires that new drug products also be shown to be "effective in use" under the conditions of use recommended in their proposed labeling.

This chapter considers how these two fundamental requirements of the Federal Food, Drug and Cosmetic Act (FFDCA), our national drug regulatory law, are currently interpreted and applied by the Food and Drug Administration (FDA) in its evaluation of new drug products. Issues that are singularly important to the evaluation of products intended for use in the management of psychiatric conditions are identified and explicated.

THE US FEDERAL DRUG REGULATORY SYSTEM: LEGAL BASIS, STRUCTURE, AND MODE OF OPERATION

Part of "36 - Regulatory Issues "

The basic structure and operation of the US federal drug regulatory system are established under the provisions of the FFDCA.

The FFDCA makes it unlawful "…to introduce or deliver for introduction into interstate commerce any new drug, unless an approval of an application… is effective with respect to such drug."

The application to which the Act refers is a New Drug Application (NDA). By law, authority to approve NDAs resides with the Secretary of the Department of Health and Human Services, but the Secretary delegates the actual authority to review and approve NDAs to the Food and Drug Administration (FDA, the agency).

The Act instructs anyone (i.e., a sponsor) seeking to market a new drug product to submit and gain FDA's approval of an NDA for the product prior to marketing it. Importantly, although it is not widely appreciated, NDAs are not approved for drug substances (i.e., chemical entities), *per se*, but for one or more specific "claimed" uses of a specific drug product (i.e., a specific formulation of the drug substance) under a specific set of conditions of use recommended (i.e., described) in the product's proposed labeling.

The Act describes, albeit in rather general terms, the information and reports that each NDA must contain. The details need not concern us, however. Suffice it to say that a sponsor's NDA is required to provide all the information necessary to allow the FDA to determine whether or not the drug product that is the subject of the application meets the standards set out in the Act for a lawfully marketed drug product. These standards address not only matters bearing on the product's safety and effectiveness in clinical use, but on its method of manufacture; chemical identity, purity, and strength; pharmaceutical performance; bioavailability; and proposed labeling.

The Act requires the FDA, in turn, to "file" (i.e., accept for review) any NDA that appears on initial inspection to provide, in a reasonably organized and coherent format, full reports of all the tests necessary to evaluate whether or not the drug product meets the requirements just cited.

Finally, the Act instructs the FDA to review and to approve a sponsor's NDA within 180 days of its submission, *unless*, on review, the agency determines that the reports it contains *fail* to establish that the drug product identified in the application fully complies with the Act's requirements.

THE INVESTIGATIONAL NEW DRUG APPLICATION

Part of "36 - Regulatory Issues "

Because the Act forbids the introduction into interstate commerce of new drugs unless they are the subjects of an approved NDA, the lawful clinical testing of unapproved new drug products would be a practical impossibility if the Act did not provide for an exemption to this ban.

The original FFDCA (1938), accordingly, provided for

precisely such an exemption, known then as a “Notice of Claimed Investigational Exemption for a New Drug.” The exemption is still available, but it is now officially known as an Investigational New Drug (IND) application.

Initially, an investigational exemption could be obtained largely for the asking. Between 1938 and 1963, the sponsor of an IND had only to agree to keep records and clearly label its new drug as to its status as an unapproved investigational new drug, but little else.

With the passage of the Kefauver and Harris amendments of 1962, however, the IND requirements were extensively revised and expanded. Congress was led to alter the requirements for investigational use because of yet another public health disaster involving a drug product. In this case, fortunately, the drug thalidomide, although widely marketed in Europe, was not marketed in the United States. However, the potent teratogen thalidomide was widely distributed under INDs in the United States; worse, when its teratogenicity was recognized and efforts were undertaken to recall the supplies of it that had been distributed, the extent of domestic distribution was not easily determined.

Although very few American women who had received thalidomide under an IND bore children with limb reduction defects, the episode raised substantial concerns about the safety of human research subjects (2 ,3). Thus, Congress amended the Act so as to give the FDA the authority to monitor and control the conduct of clinical drug research within the United States.

Under the 1962 amendments, the agency gained explicit authority not only to establish mandatory prerequisites for the granting of INDs, but also the power to prevent the initiation and/or suspend the conduct of a clinical investigation (i.e., impose a “clinical hold”) being carried out under an IND if and when the agency concludes that an investigation poses an unreasonable or unnecessary risk to human subjects. In 1997, with the passage of the Food and Drug Modernization Act (FDAMA), FDA’s authority under the Act’s IND provisions was clarified and explicated in more detail, but not substantively modified.

In sum, since 1962, the IND serves not only as a license sponsors must obtain to allow them lawfully to ship unapproved new drugs in interstate commerce, but also the device through which the agency monitors and maintains control over the way in which clinical research with new drugs is conducted within the United States.

WHAT AN APPROVABLE NDA MUST DEMONSTRATE

Part of "36 - Regulatory Issues "

The text of the Act, at least insofar as safety and effectiveness standards are concerned, speaks almost entirely to broad goals and generic principles. Responsibility for interpreting the Act and developing, revising, and promulgating the regulations and policies necessary to secure the aims Congress had in mind in drafting the Act are delegated to the FDA.

Safety

Insofar as safety is concerned, the Act demands that a sponsor provide full reports of all tests necessary to establish that its product will be safe for use. The Act instructs the agency to reject a sponsor’s application, if, on review, it determines that the drug has been inadequately tested, or, if tested adequately, the findings of the tests conducted are inadequate to show that the drug, as recommended for use, is safe for use, or show that the drug, again as recommended for use, is unsafe for use.

Efficacy

The Act instructs the FDA to approve an NDA *unless*, on review of the reports submitted, it concludes there is a lack of “substantial evidence” that the drug is effective as claimed in its proposed labeling.

HOW THE AGENCY INTERPRETS THE ACT’S GENERIC REQUIREMENTS

Part of "36 - Regulatory Issues "

Safety for Use

No pharmacologically active drug substance is ever likely to be entirely free of risk. Accordingly, the agency maintains that a regulatory determination that a drug is “safe for use” is, in actuality, a favorable “risk-benefit” determination (i.e., a conclusion, based on the information evaluated, that the risks imposed by the use of the drug are acceptable in light of the benefits it provides).

Risk-benefit assessments, however, are hardly straightforward undertakings. To begin, their reliability is in large part a function of the extent and quality of the information on which they are based. Unfortunately, the information ordinarily available to inform a regulatory risk-benefit assessment is limited in scope; a typical NDA, for example, is approved based on experience gained with a drug product in perhaps 1,000 to 2,000 human subjects *in toto*.

The information that is available, moreover, is in many respects marginal in regard to its aptness; the individuals who participate in drug development programs, although they are reasonably representative of the patient population to which the drug will be administered when marketed, are not fully representative of it. Accordingly, risks uniquely, or more likely to be, associated with the use of a drug in various subgroups of the population, particularly when those subgroups are rare and/or under-represented in the samples studied during the drug’s development, are almost never appreciated, let alone factored into the regulatory risk-benefit determination.

Data bearing on the risks of a drug are collected during premarket testing under conditions of use (e.g., dose, regimen of administration, duration of use, restricted use of concomitant medications, etc.) that vary substantively from those under which a marketed drug is likely to be used. This is of especial concern where duration of use is concerned.

Ordinarily, the bulk of premarketing data are obtained in relatively short-term clinical trials (weeks or months) although the product under development typically will be used, once marketed, over much longer intervals (months to years). As a consequence, a typical drug development program has little, if any, chance of detecting untoward effects of a drug that emerge only after an extended period of exposure.

Regulatory officials are well aware of these limitations, but for practical (i.e., a politic word for economic and political) reasons, must tolerate them. The International Conference on Harmonization (ICH) in which the US participates, for example, has issued a guideline (4) that states that it is ordinarily sufficient to evaluate a new drug, prior to marketing, in no more than 300 to 600 patients for 6 months and 100 patients for a year.

Anyone familiar with the arithmetic of risk estimation will recognize that an experience of “safe passage” on a drug gained in such limited numbers of patients is not very reassuring. The failure to see even one catastrophic or fatal event in a sample of 300 patients only reduces to 5% the chance that the drug investigated causes such unobserved events at a rate no greater than in one of every 100 patients exposed to it (5).

(The notion of “safe passage” in drug safety assessment is the author’s invention; it likens regulatory premarket clinical trials to journeys undertaken on uncharted waters. Much as early seafarers determined which of several routes between two points was safer by comparing the risks of one with another, society determines whether or not a new drug is safe for use from the proportion of patients exposed to it who enjoy safe passage.)

Whatever one’s personal sense of the size of such a risk, it is truly enormous from a public health perspective. Just imagine the horror if a new antidepressant drug product caused a fatality in one in every thousand patients exposed to it. Yet, our society, like those of other developed nations, is seemingly content to market drugs without being able to confidently exclude a 10-fold greater risk.

In recent years, highly publicized withdrawals of new drugs shortly after their approval for marketing because of previously unrecognized risks of use have focused public attention on the limitations of premarket drug safety assessment. Both the agency and regulated industry have, consequently, been urged to develop new and better methods and paradigms to predict the likelihood of new drugs to cause injury (6).

No doubt, both the agency and regulated industry would be delighted to do so if they could. It is somewhat difficult to fathom, however, what kinds of methods will make it possible to identify drug-induced injuries in advance of their occurrence caused by pathogenetic mechanisms that have yet to be recognized, let alone characterized.

On the other hand, it is difficult to deny that the systematic study of a drug product’s capacity to cause effects that have in the past been associated with an increased risk of untoward effects should sometimes be useful. The risk of pharmacokinetic interactions, for example, should be predictable if the major metabolic pathways involved in the elimination of a new drug, its metabolites, and the pathways of elimination of other drug products likely to be coadministered with the new drug are identified and adequately characterized. Knowledge of a drug product’s metabolism also makes it possible to identify individuals in the population that might be at unique risk of suffering injury because of their diminished capacity to metabolize the drug (e.g., 6% to 8% of the white population are “poor” metabolizers of drugs that are CYP 450 2D6 substrates). Presumably, as our knowledge of the human genome expands, our ability to predict drug-induced risks on such grounds will grow.

Efforts to screen drugs prior to marketing for specific properties that predict drug-associated harms are still largely in their infancy, however. Moreover, such approaches have inherent limitations. Their utility is typically predicated on the assumption that the indicator of risk employed (e.g., a capacity to prolong the QTc interval on the surface ECG) reliably and consistently predicts a drug’s capacity to cause harm. As is the case with almost all surrogate indicators, however, there is always a possibility that the association between the surrogate and harm found in one set of circumstances will not hold in another.

In contemplating the development of new approaches to premarket safety assessment, it is important to be mindful that many of our expectations may be unrealistic, even magical. Congress, for example, did not intend that premarket testing would successfully identify every unsafe or unfit drug product. If it had, it would not have authorized the agency (Section 505(e) of the FFDCA), to withdraw approval of any NDA for a drug if new information, not available at the time of approval, becomes available which shows the drug is unsafe for use as labeled. Moreover, it is evident that Congress not only anticipated that new risks would be recognized after a drug’s approval for marketing, but expected that postmarketing surveillance would detect them. Specifically, to ensure that adverse information and reports bearing on the safety of marketed drug products would be collected and made available for evaluation, the Act (Section 505(k)) requires the sponsors of marketed drugs “…to establish and maintain… records, and make… reports to the Secretary, of data relating to clinical experience and other data or information, received or otherwise obtained by [the sponsor]… with respect to… [its drug]… to enable the Secretary to determine, or facilitate a determination,

whether there is or may be ground for… [withdrawing approval of the NDA]."

In actuality, however, only a relatively small proportion of marketed drug products are withdrawn from the market on grounds of being unsafe. This fact is frequently overlooked in the midst of the sensationalist publicity and second-guessing that so often accompanies product withdrawals. In the vast majority of instances, in fact, after their evaluation, adverse reports received on a drug from postmarketing surveillance sources lead, at most, to revisions being made in the product's approved labeling.

The nature of the labeling changes made, and the publicity given to them, is a function of the severity, estimated frequency, potential reversibility, and likelihood of mitigation or avoidance of each newly appreciated risk. From a regulatory perspective, a labeling change is a sufficient legal remedy, even for relatively serious newly appreciated risks, provided it remains possible for the agency to sustain its earlier conclusion, albeit under the newly revised labeling, that the drug product is "safe for use" *as labeled*.

The foregoing discussion reveals just how subjective and tenuous drug safety assessments actually are. Indeed, even if the risks associated with the use of a drug product were known exhaustively and in detail, its risk-benefit assessment would likely remain arguable. Paradoxically, the crux of disputes about risk-benefit determinations less often concerns the seriousness of the harms a drug causes, than the value of the benefits its use provides.

There is good reason for this. Except in those few instances in medical therapeutics were the use of a drug can be shown to reduce the absolute incidence of death or a serious, otherwise irreversible, injury, a substantively meaningful numerical estimate of the value of the benefit provided by a drug lies beyond reach. This occurs because there is a substantive distinction between a drug with an effect and an effective drug treatment.

Given the proper choice of experimental design, an appropriate patient sample, and the use of validated outcome measures, a competently executed clinical experiment can, of course, generate a numerical estimate of the magnitude of a drug's effect on some assessment instrument or scale of measurement. What such a trial cannot do, at least in a way that can be understood in a public sense, is to provide a meaningful measure of the value of the drug's clinical benefit. Unfortunately, it is the clinical benefit provided, and *not* the numerical estimate of the magnitude of a drug's effect as measured on some rating instrument that must be considered in a substantively meaningful risk-benefit assessment.

Thus, in areas of medicine, like psychiatry, where the beneficial effects of a treatment are *not* ordinarily measured by counts of cures or numbers of actual deaths prevented, but in the degree of symptomatic relief afforded by treatment, it is ordinarily impossible to obtain a publicly meaningful, let alone quantitative, estimate of a drug's value.

It is to be acknowledged that there are statistical estimates of "effect size" available (7), but these are intended only to gauge the relative magnitudes of a measured effect and the natural variation of that measured effect among individuals in the population being investigated. Although such "effect size" estimates are necessary to make informed "guesses" about the numbers of patients that must be admitted to a controlled clinical trial to obtain a statistically significant result, they say nothing whatsoever about the value of the effect being measured.

In sum, although a regulatory risk-benefit determination is widely represented to be a reasonable and responsibly considered judgment that derives from a disinterested weighing of the gains and harms known to be associated with the use of a drug, it is much more accurately depicted as a gestalt informed by an inchoate process that mixes, in undetermined proportions, evidence, sentiment, and personal values.

Nonetheless, because the Act requires that marketed drugs be shown to be safe for use prior to marketing, the FDA must take the information and reports presented in a sponsor's NDA, and with the assistance of its consultants and advisors, determine whether a reasonably qualified and informed expert, in possession of the data that are available, could conclude, fairly and responsibly, that the drug is "safe for use" as labeled for use within the meaning of the Act.

Effectiveness in Use

Effectiveness determinations under the Act are, at least in comparison to those involving safety, relatively straightforward, provided, however, that a modicum of agreement exists within the community of qualified medical experts as to: (a) what constitutes a beneficial treatment effect in the area of therapeutics involved, and (b) how that therapeutic effect is to be measured.

Given agreement on these two matters, it is a relatively simple, although not always an easy or quick, task for a sponsor to procure the evidence necessary to meet the Act's substantial evidence standard, provided, of course, that the sponsor's product is truly an effective one. If controversies are extant within the community concerning the condition that is the target of treatment (e.g., its features, diagnostic boundaries, cardinal manifestations, etc.), as they often are in the field of psychiatry, the task of demonstrating a drug's effectiveness in use becomes considerably more complicated but still possible.

The key question that remains to be addressed in this section then, is what constitutes substantial evidence within the meaning of the Act.

Between 1962 and 1997, Section 505[d] of the Act offered the following definition of substantial evidence:

> … the term "substantial evidence" means evidence consisting of adequate and well-controlled investigations, including clinical

> investigations, by experts qualified by scientific training and experience to evaluate the effectiveness the drug involved, on the basis of which it could fairly and responsibly be concluded by such experts that the drug will have the effect it purports or is represented to have under the conditions of use prescribed, recommended, or suggested in the labeling or proposed labeling thereof.

A number of points about the agency's traditional interpretation of the substantial evidence standard are noteworthy.

The agency has long held that "substantial" evidence must derive, at least in part, from the findings of valid *clinical* experiments. This presumably reflects the view that the value of drugs intended for the treatment of a human disease or condition can only be evaluated meaningfully in tests conducted in human subjects actually afflicted with or at risk of developing that disease or condition.

Agency regulations make clear that for evidence to be deemed substantial, it must, in part, be adduced in scientifically valid experiments (i.e., adequate and well-controlled investigations). Inferences based on scientific theory alone, or on the findings of uncontrolled clinical studies or observations (e.g., case reports, case series, etc.) will not suffice (e.g., see 21 CFR 314.126 (e)).

Neither can clinical judgment or professional opinion, per se, contribute to the body of evidence required to meet the substantial evidence burden. In light of the importance seemingly given to expert opinion in the statutory definition of substantial evidence, this assertion may seem at odds with the Act's requirements. A careful reading of the statutory definition reveals, however, that substantial evidence does not include what experts believe. To the contrary, the reference to experts in the definition of substantial evidence serves only to describe the character of the evidence that can be deemed substantial. (The evidence must be of a kind, quality, and quantity that would allow a disinterested and informed *expert* to conclude, "fairly and responsibly," from the evidence that the drug will have the effect its sponsors claims it has.)

It is also important to be mindful that "substantial" is an arcane legal term. It is frequently, and incorrectly, taken to mean definitive, even compelling, but substantial does not have that connotation within the meaning of the Act. Authorities on the legislative history of the Act (8) note that Congress considered, but decided not to employ, a "preponderant" standard of evidence, choosing, instead, the legally less demanding "substantial" evidence standard. Congress concluded, evidently, that the public health would be better served if the Act allowed the marketing of a drug even if only a minority of qualified experts agreed that it had been shown to be effective. It may help, therefore, to think of substantial evidence as the quanta of evidence sufficient to persuade at least a sizable number, but by no means a majority, of disinterested experts that a drug has been shown to be effective as claimed.

Among all the agency's interpretations of the substantial evidence standard, none, perhaps, has caused more concern and enduring complaint than its determination that positive findings from *more than one* adequate and well-controlled clinical investigation are ordinarily required to establish a drug product's effectiveness in use.

Although the requirement that experimental findings be independently substantiated prior to their formal acceptance is fully consonant with common scientific practice and epistemological principle, the agency's interpretation of the statute in this fashion proved so controversial and so politically vexatious that it eventually led Congress (Food and Drug Administration Modernization Act of 1997 [FDAMA]) to add the following sentence to the Act's definition of substantial evidence.

> If the Secretary determines, based on relevant science, that data from one adequate and well-controlled clinical investigation and confirmatory evidence (obtained prior to or after such investigation) are sufficient to establish effectiveness, the Secretary may consider such data and evidence to constitute substantial evidence for purposes of the preceding sentence.

FDA authorities contend (circa 1999 to 2000) that the revised definition does no more than confirm FDA's long standing authority (its regulatory discretion) to interpret the Act's efficacy provision flexibly and responsibly so as to secure the "aims of Congress" and advance the interests of the public health. In fact, before the Act was amended in 1997, the agency had, on occasion, taken exception to its traditional interpretation of the effectiveness standard, approving an NDA on the basis of findings from but a single adequate and well-controlled clinical study (9).

Agency spokespersons assert, further, that in all but highly unusual circumstances corroborating positive findings from more than one adequate and well-controlled clinical investigation will continue to represent the minimal quanta of evidence sufficient to satisfy the Act's substantial evidence requirement.

Evidently, because Congress failed to explain clearly what it intended by the terms "relevant science" and "confirmatory evidence" in drafting FDAMA, agency officials seemingly enjoy a degree of latitude as to whether and when to rely on the findings of a single controlled clinical investigation. Whether FDA officials will elect to or be able to retain this flexibility in the long run is far from certain, however.

THE EVALUATION OF DRUG PRODUCTS INTENDED FOR USE IN THE MANAGEMENT OF PSYCHIATRIC CONDITIONS

Part of "36 - Regulatory Issues "

The Division of Neuropharmacological Drug Products (DNDP) is the organizational unit within the FDA's Center for Drug Evaluation and Research (CDER) that is responsible for the monitoring of INDs and the evaluation of NDAs for psychiatric drug products.

It is the Division's obligation to review an application, determine whether or not it meets the requirements of the FFDCA as interpreted under FDA's prevailing regulations and policies, and, based on that review, take appropriate regulatory action.

For IND issues, signatory authority on most matters is at the level of the Division Director. Signatory authority is divided where NDAs are concerned. NDAs for new chemical entities (NCEs) are approved or disapproved at the Office level (Office of Drug Evaluation 1); supplemental NDAs (those involving new claimed uses of already marketed drug products) are approved at the Division level.

It is important to be mindful that Divisional policies evolve over time. A reader who wishes to understand whether, and if so, how a particular policy applies to a specific problem or drug product would be prudent, therefore, to seek fresh guidance on the subject directly from an appropriate Division representative.

From a regulatory perspective, the fact that a drug product is intended for the management of a psychiatric, sign, symptom, condition, or disease presents no unique problem.

A drug claim can be advanced for virtually any effect on the structure or function of the body of humans, for the cure or management of a disease or condition, or relief of a sign or symptom. The Act makes no distinction between the value of symptomatic treatments and those that are advanced as cures for a disease. Almost any claim can be made, provided that it can be presented in product labeling in a way that does not make the product's labeling, "false or misleading" in any particular.

In psychiatry, as in most other therapeutic areas, the effectiveness of a new chemical entity will almost always have to be demonstrated in *more than one* adequate and well controlled clinical investigation. It is possible, however, when an application is submitted for a claim closely related to one for which the drug product is already marketed, that a single controlled clinical study with robust and internally consistent findings might suffice. Because reliance on a single study is an exception to ordinary practice, however, the decision whether or not to take this approach will invariably be made on an ad hoc basis.

The agency's regulations (21 CFR 314.126) enumerate five control conditions that may be suitable for the evaluation of the effectiveness of new drug products. In light of the variability in course and outcome among samples of patients assigned the same psychiatric diagnosis, it is highly unlikely that either the historic control or the no control designs would ever be deemed acceptable for the evaluation of a drug for a psychiatric indication.

A randomized controlled and blinded trial employing any one or combination of the three other enumerated control conditions (placebo, graded dose, and standard active drug), provided it produces a statistically significant ($P \leq 0.05$, two-tail) difference favoring the investigational drug over a control condition, will invariably serve as one source of evidence contributing toward the quanta required to establish substantial evidence of a psychiatric drug product's effectiveness in use.

Among all the designs conforming to the requirements enumerated in 21 CFR 314.126, however, one that includes both a placebo and a standard drug control is especially attractive. Not only does such a design allow an estimate of what might have been had no treatment been administered (i.e., the response among placebo-assigned subjects) (10), but it provides a test of the capacity of the sample of patients participating in the experiment to respond to a treatment of established effectiveness (i.e., the response among patients randomized to the active control)

The three- (or more) arm design just described provides an internal means to assess what Modell and Houde (11) describe as an experiment's "assay sensitivity," its capacity to discriminate an inert substance from placebo and one level of an active drug substance from another.

Knowledge of an experiment's "assay sensitivity," or lack thereof, is especially important in the evaluation of psychiatric drug products because a sizable proportion of psychiatric drug trials (e.g., close to 50% or so of antidepressant trials) (12–14) fail to discriminate between active and inert treatments. Obviously, the trial's failure can be discounted if the failure of a study to find a drug placebo difference is owing to the inability of the sample of patients randomized in the study to respond to drug. On the other hand, if the sample of patients enrolled can respond to standard treatment, but not the investigational drug, the trial must be viewed as a source of evidence that speaks against the effectiveness of the investigational drug.

Why the agency encourages the use of an active control arm in a placebo-controlled study, incidentally, is often misunderstood. It bears emphasis that the active control is not included to obtain an estimate of the standard drug's performance relative to that of the investigational drug, but solely to gauge whether or not the experiment has "assay sensitivity."

When an investigational drug appears to have a relatively low therapeutic ratio, the use of fixed-dose graded designs is advantageous because it provides the surest means to identify the dose or dose range most likely to be acceptable for a typical patient. The agency is mindful, of course, that a single dose is unlikely to be the best choice for all patients; nonetheless, for dose evaluation purposes, a fixed-dose design is more likely to be interpretable than a dose titration design. Clinicians often find this assertion counterintuitive, but designs allowing up-titration for therapeutic nonresponse commonly produce an inverted dose-response relationship (i.e., treatment resistant subjects who show poor response are given the highest doses of drug).

Another vexing issue regularly confronting regulators is how best to extrapolate the results of clinical investigations of new psychiatric drug products to labeling claims.

Although the agency's regulations require that the sample of patients evaluated in controlled effectiveness trials be "reasonably representative" of the population of patients for which a drug will be recommended for use, the patients recruited in typical commercially sponsored drug trials are never truly representative of the population, at least not in any formal statistical sampling sense. To the contrary, the choice of patient subject is almost always based on the sponsor's convenience and its desire to maximize the statistical efficiency of its study (15). This sampling strategy is not objectionable from a regulatory perspective when the primary goal of a clinical study is to establish that the investigational drug product has the effect claimed for it in at least some patients with the condition for which the treatment will be marketed.

What claimed uses should be granted to a sponsor of a drug based on the results of such studies is yet another arguable matter. During the author's tenure as DNDP's director, for example, clinical trials conducted in acutely exacerbated schizophrenic patients were deemed sufficient to support a claim for the use of a neuroleptic drug product in the "management of the manifestations of psychotic disorders." In a good faith attempt to adhere to the Act's requirement that product labeling not be false or misleading in any particular, the text of the Indications and Usage section also briefly described the clinical investigations that supported the "antipsychotic" claim, including the nature of the patient samples that had been employed in them and whether or not long-term maintenance trials had been conducted. The strategy employed was intended to reserve for practitioners the right to determine the extent to which the results of a sponsor's effectiveness trials applied to psychotic conditions other than schizophrenia. DNDP's current leadership takes a different view. At DNDP's annual morning session at the NIMH's annual NCDEU meeting (June 2, 2000) held in Boca Raton, Florida, Tom Laughren (group leader for DNDP's Psychopharmacology Unit) announced that henceforth claimed uses for psychiatric drug products would be more narrowly defined (i.e., ordinarily limited to the population of patients actually studied). Thus, drugs shown to be effective in studies enrolling schizophrenic patients will get claims for use in schizophrenia, not psychosis. Incidentally, the newly announced approach to product labeling is perfectly reasonable and certainly consistent with the requirements of law, although it is obviously not the one that the author prefers.

Difficulties arise in the extrapolation of study results in many other areas as well. Drugs are administered to individuals, not diagnoses. There is advantage in knowing, therefore, whether, and if so how and to what extent, various individual patient characteristics (sex, age, race, severity of illness, etc.) and the interactions among them affect response to a drug. Offsetting the interest in obtaining the data necessary to address these issues are the difficulties and costs (both time and money) encountered in obtaining them; recruiting representative patients from even the more important of the patient subpopulations (e.g., children, the elderly, the very ill, etc.) is often exceedingly difficult, and sometimes, just not feasible.

For decades, the FDA took a relatively passive stance in regard to the demands it made on the regulated industry for data that might better inform the use of prescription drug products in children. Groups interested in the welfare of children have lobbied long and hard for making the study of investigational drugs in children a premarket obligation. FDAMA attempted to encourage sponsors to conduct remedial pediatric studies by offering the incentive of a 6-month extension on the patent life of certain drug products. In 1998, however, the agency issued new regulations (21 CFR 314.55 and 21 CFR 201.23), asserting its authority to require sponsors to evaluate new drugs in clinical trials enrolling subjects of pediatric age.

It seems unlikely to the author that the agency would actually refuse to approve an otherwise safe and effective new psychiatric drug product on the grounds that the effects of the drug had not been adequately studied in children, unless, of course, the primary use of the product was likely to be in children (i.e., the drug is intended as a treatment for ADHD).

The fact that the official psychiatric nosology is continuously evolving further complicates the extrapolation of study results to product labeling claims. For example, prior to the promulgation of DSM-III in 1980, sedatives, as they were then known, were granted broad and nonspecific claims for anxiety, anxiety neurosis, etc. As a result of DSM-III, a distinction had to be made between generalized anxiety disorder and panic disorder. In recent years, claims have been further expanded to include not only long-established entities such as obsessive–compulsive disorder (OCD), but also new entities such as social anxiety.

On each occasion that the psychiatric nosology expands or changes, the agency is confronted with a set of new problems including not only how to evaluate claims for newly created entities, but how to conform existing drug product claims to fit with the revised nosology. In dealing with these issues, the agency has to consider whether or not already approved older claims subsume the new entities. (Is a new claim simply a re-expression of a previous one, a claim for a subset of the patients covered by the previously approved claimed use, or an entirely new claim for a previously nonexistent entity?)

The agency also must decide how broad a claim or set of related claims may be. For example, sponsors often seek to define a claimed use in a way that will allow the unique promotion of their drug product (i.e., distinguish their drug from others within the same therapeutic class). When a claim links some diagnostic entity or subtype of entity to a drug's effect and that linkage is irrelevant to the expression of the effect, the claim is considered, "pseudospecific." (The author early in his tenure as DNDP director coined the

term “pseudospecificity”; it was first applied in connection with claims advanced for the use of benzodiazepines in anxious patients suffering from specific medical conditions [e.g., the anxiety of heart disease, cancer, etc.].) Such claims, moreover, are misleading because they seek to promote a distinction without meaning; consequently, they can be rejected by the agency because they can be held to be a violation of the Act’s requirement that a product’s labeling not be false or misleading in any particular.

A claim that a marketed antibiotic is effective for the pneumonia of dementia, for example, even if based on empirical evidence that the drug is effective in curing pneumonias in patients with dementia, is pseudospecific because the linkage between the pneumonia and the diagnosis of the patients treated is of no pharmacologic or biological importance, existing solely because of the sponsor’s decision to select demented patients with pneumonia as subjects for study. A legitimate (i.e., nonpseudospecific) disease-related claim requires a demonstration that the effect of the drug is in some way conditioned on the presence of the diagnosis (i.e., the diagnosis of the disease controls to what extent, if any, the effect of the drug is expressed).

The distinction made by the Division between pseudospecific and legitimate disease-related claims has often proved to be both unpopular and a source of continuing controversy. Claims advanced by sponsors for the use of marketed antipsychotic drug products in the management of psychotic demented patients are a case in point. During the author’s tenure as Director of DNDP, these claims were regularly deemed to be pseudospecific, in the absence of evidence to prove the contrary.

Based on testimony and discussion at a Psychiatric Drug Products Advisory Committee (PDAC) held in March, 2000 on treatments for the management of behavior in dementia, however, it appears that the Division is now inclined to accept “the psychosis of Alzheimer’s disease” as a bona fide entity for which drug product claims may be made.

The seeming reversal in the Division’s prior position, as far as the author can determine, came about because the current membership of the PDAC endorsed the psychosis of Alzheimer’s disease as an entity *sui generis*. Support for the existence of this entity derived primarily from the testimony of psychiatrists who treat demented patients as to what they believe is the true state of nature. The fact that a diagnostic algorithm for the capture of patients with the “psychosis of Alzheimer’s disease” had been recently proposed, seemingly gave further support to the reality of the putative entity. Although there is little doubt that the algorithm endorsed by the PDAC does capture demented individuals who exhibit behaviors that can be deemed psychotic, the fact that it does so in no way establishes that there is, in nature, a unique psychosis of Alzheimer’s disease. Indeed, what the discourse at March meeting of the PDAC revealed is that when a diagnostic nosology is based on a taxonomic system controlled by authoritative figures (i.e., “opinion leaders” in the terminology of marketing departments within the regulated industry), the existence of a diagnostic entity may owe more to politics than biology.

Incidentally, the taxonomic nature of our official psychiatric nosology not only complicates the task of drafting of accurate product labeling, but also contributes to the high failure rate of studies intended to document the effectiveness of psychiatric drug products.

It bears note that DSM-III was developed, at least in part, in the hope that phenotypic similarities among patients would reduce within diagnostic category genotypic variability and, thereby, make psychiatric diagnoses more predictive of course, outcome, and treatment response than were the diagnostic categories based on the pseudoexplanatory, dynamic systems employed in DSM-II (16).

Unfortunately, this goal of DSM-III has yet to be achieved, in part, perhaps, because the effort to improve psychiatric nosology has been confounded by issues and interests that have little to do directly with biologic classification (e.g., a focus on new entities that expand the size of a drug’s potential market, or that advance a professional career, or a political interest, etc.).

Whatever the explanation may ultimately be, however, sample-to-sample variation in both drug and placebo response rates among samples of patients assigned identical psychiatric diagnoses documents that our current psychiatric nosology has poor predictive power, at least insofar as drug responsiveness is concerned. As a consequence, to demonstrate that their products are effective in use, sponsors have had little option but to conduct trials using relatively large sample sizes.

Some critics have complained that the FDA, by allowing sponsors to conduct these “overpowered” trials, has turned the drug regulatory system into an institution that certifies as valuable drug products that provide little, if any, more benefit than placebo (17). Perhaps there is some truth in these allegations, but, then again, who is to say what drug effect is so small as to be dismissible? As discussed, from a strictly regulatory perspective such criticisms are irrelevant. It is important to recall that Congress could have set out other and/or more demanding standards for establishing drug effectiveness, but it did not.

The agency does have an obligation under the law, however, to ensure that its effectiveness determinations are based on fair and reliable estimates of a drug’s measured effects. Accordingly, a large part of the effort expended in the review of an NDA is devoted to excluding the possibility that bias, rather than a true drug effect, accounts for the positive study reports submitted in the application.

Great pains are thus taken to ensure that a sponsor’s claims are supported by valid statistical analyses of outcome measures prospectively identified in each study’s protocol. Each study report is scrutinized for lapses in the execution of a study that might have introduced bias into the estimates

of drug effect it provides. Reviewers search for evidence that the randomization process failed, the treatment mask was penetrated, subjects failed to comply with protocol requirements, etc. The extent, pattern, and timing of premature discontinuations are carefully analyzed in an effort to determine whether the censoring process has created a biased estimate of the drug's effect.

The immediate goal of these efforts is to ensure that the comparison between the investigational and control treatments can be made "ceteris paribus" (all other things being equal).

The overarching aim is to determine whether or not the evidence submitted meets the Act's substantial standard fairly and responsibly.

THE FUTURE OF DRUG REGULATION

Part of "36 - Regulatory Issues "

These are, at once, the best of times and the worst of times for medical therapeutics. On one hand, we have access to more information about the function and body of humans than we have ever had; therefore, we have good reason to hold sanguine expectations for the future in regard to the discovery and development of effective new treatments. On the other hand, the armamentarium stands at increasing risk of being polluted by worthless, even unsafe drugs. Signs of this potential risk abound.

The public is gullible and uncritical where therapeutic claims are concerned, exhibiting not only unrealistic expectations for the countless potential treatments touted as promising by the medical establishment and the pharmaceutical industry, but a willingness to spend billions of dollars on unproved, perhaps unsafe, remedies and nostrums.

Although the FDA's substantive powers under the FFDCA to regulate the drug supply, even after the passage of FDAMA, have been constrained to only a relatively minor extent, FDA's mission has noticeably changed.

Today's agency is expected to work as a "partner" of the regulated industry in a joint effort to expedite the development of new and promising treatments, not merely to keep unfit drugs off the market. It is arguable whether such dual expectations truly advance the interests of the public health, however. As the former head of the FAA noted when she resigned in the wake the ValueJet crash in Florida's Everglades, it is difficult for a federal regulatory agency to serve simultaneously and well the interests of both the consumer and the industry it regulates.

Congress has limited FDA's authority in less obvious ways as well. An egregious and illuminating example of its behavior is the Dietary Supplement Health and Education Act (DSHEA) of 1994. DSHEA has, by fiat, simply removed whole classes of drugs from FDA's jurisdiction and oversight.

By what is as close to an Orwellian *1984*-like maneuver as one is likely to find, the Congress simply declared whole classes of drugs to be something else: nutriceuticals, botanicals, food supplements, etc. These substances escape the premarket drug clearance requirements of the FDDCA because they are deemed by DSHEA *not* to be drugs.

Some may consider the legerdemain of DSHEA to constitute a relatively minor threat to the public health. Vitamins, for example, have long escaped the premarket clearance requirements of the Act, and have not proved dangerous, except perhaps when some are taken at excessive doses. Subsumed within the ill-described mix of botanicals, nutriceuticals, food supplements, and other materials deemed to be "nondrugs" under DSHEA, however, are large numbers of incompletely characterized, pharmacologically active drug substances that have yet to be fully and reliably evaluated for their safety and efficacy.

The lack of data bearing on the safety and efficacy of these drug substances did not deter the Congressional Leadership, however; to the contrary, when Senator Orin Hatch, a sponsor of DSHEA, introduced the bill he asserted that…dietary supplements can help promote health and prevent certain diseases, a fact substantiated by an ever-growing body of scientific studies and other evidence. In my own state of Utah, healthy life-styles, coupled with common use of dietary supplements have made a real difference. Our state is one of the healthiest in the nation and we enjoy one of the lowest incidence rates for cancer and heart disease. In Utah, the use of herbs is a well-accepted practice that has passed from generation to generation (18).

What is chilling here is not Senator Hatch's espousal of his state's virtues and the benefits of herbs, but his seeming willingness to approach an important public health issue in his nonscientific manner. Even more alarming is the inference congressional passage of DSHEA allows about the general state of our society's respect for science and the scientific method. Evidently, a majority of our elected representatives believes the benefits of scientific progress are attainable without the use of sound scientific methods.

If the armamentarium is to be kept reasonably free of unsafe and ineffective drugs, the antidrug regulatory drift of our national politics must be reversed. The FDA has demonstrated that it can, with the limited authority it has under the FFDCA, serve as an effective guardian of the drug supply. It will continue to serve effectively in this role, however, only if it obtains the necessary political support.

Given the current antiregulatory political environment, and the unrealistic expectations of the body politic for near magical breakthroughs in therapeutics, that support will not be forthcoming without the full support of the medical, scientific, and health care communities.

The advances in molecular medicine are taking place at a hitherto unprecedented pace. Genetics has come of age and will greatly influence the future of health care and therapeutics in the twenty-first century, in much the same way the breakthroughs in quantum physics and chemistry shaped science and society during the early phases of the twentieth century.

The field of pharmacogenetics was introduced more than 40 years ago to emphasize the role of heredity in person-to-person differences in drug response (1 ,2). The focus of pharmacogenetic investigations has traditionally been unusual and extreme drug responses resulting from a single gene effect. Pharmacogenomics is a recently introduced concept that attempts to explain the hereditary basis of both monogenic as well as subtler and continuous variations in drug responses that are under multigenic control (3). Although the two terms are often used interchangeably, the scope of pharmacogenomic investigations follows a genome-wide approach and also aims to identify novel biological targets for drug discovery, with use of the new affordable high-throughput molecular genetic technologies (4). In theory, pharmacogenomics can assist in clinical decision making to choose the most appropriate medication and dose titration regimen for individual patients. Moreover, the principles of pharmacogenomics are not limited to therapeutics. They can be applied to understand the hereditary basis of differences in sensitivity or resistance to any foreign chemical (xenobiotics) or environmental factor including foodstuffs, pesticides, infectious diseases, and ionizing radiation (5 ,6 and 7).

The Human Genome Project has already provided a draft nucleotide sequence of the human genome by mid-2000 and the nearly complete sequence is projected to be available by 2003. In addition, nucleotide sequence variations among individuals, populations, and species will be available in the near future. It is clear that these advances will soon lead to identification of many genes causing common complex diseases, thereby creating numerous new potential drug targets. This will also present a bioinformatics and data analysis challenge for lead optimization among numerous new chemical entities (NCE) directed to such disease targets for therapeutic purposes. Pharmacogenomics is a hybrid research field that bridges the knowledge gained from the Human Genome Project with existing principles of population genetics, pharmacokinetics, pharmacodynamics, cell physiology, proteomics, and bioinformatics. It is expected that pharmacogenomics will importantly contribute to development of guidelines for rational and personalized drug treatment; it should also expedite the drug discovery, development, and approval process in the pharmaceutical industry (8).

The purpose of this chapter is to introduce pharmacogenomics to those from a clinical psychiatry perspective, and discuss the future research challenges for those who may have prior experience in the field.

HISTORICAL OVERVIEW AND CONCEPTUAL FRAMEWORK FOR PERSONALIZED THERAPEUTICS

Part of "37 - Pharmacogenomics and Personalized Therapeutics in Psychiatry "

The marked interindividual variability in psychotropic drug effects was recognized long ago (9 ,10). For example, the

same dose of an antidepressant medication may cause toxicity, efficacious treatment, lack of efficacy, or qualitatively different drug effects among patients and populations (11). Understanding the sources of such variability in dose–response relationships is central to individualized dosage and choice of drugs for therapeutic purposes (12). Interestingly, it has been a commonly held viewpoint that genetics is important mainly for the permanent characteristics of an individual (e.g., stature) or predisposition to certain diseases, rather than variations in drug effects (13). In 1932, Snyder documented one of the first known interactions between heredity and response to xenobiotics: the ability to sense the bitter taste of phenylthiourea, which is under strong genetic control (14). In 1962 Werner Kalow published the first monograph on pharmacogenetics (1). Some argue that the field of pharmacogenetic inquiry dates as early as 510 BC, when Pythagorus in Croton, southern Italy, warned about the "…dangers of some, but not other, individuals who eat the fava bean" (5). The molecular basis of this historic observation was later documented to be hemolytic anemia owing to glucose-6-phosphate dehydrogenase deficiency.

The interest in personalized therapeutics was further fueled by the thalidomide disaster in 1960s. Subsequent observational studies found that drug–drug interactions, and hepatic and renal insufficiency importantly contribute to the risk for adverse drug reactions (15). A series of studies in monozygotic and dizygotic twins firmly established that genetic factors play an important role in metabolism of many drugs, and not only in a few cases of unusual adverse

drug reactions (16). This led to the publication of systematic guidelines on individualization of drug therapy by the American College of Physicians, based on genetic, environmental, and disease-related determinants of person-to-person differences in dose–effect relationships (17).

The pharmacologic drug response is a complex trait and is likely under polygenic control, rather than simple monogenic regulation (18). However, in comparison to disease-related complex traits, there is a well-established theoretic working model describing the relationship between the prescribed drug dosage and clinical drug effects (19). The conceptual framework developed by the seminal works of Sheiner and others allows one to target candidate genes with potential mechanistic relevance to partition the variability in any drug effect into pharmacokinetic and pharmacodynamic components (Fig. 37.1) (20 ,21 ,22 ,23 ,24 and 25).

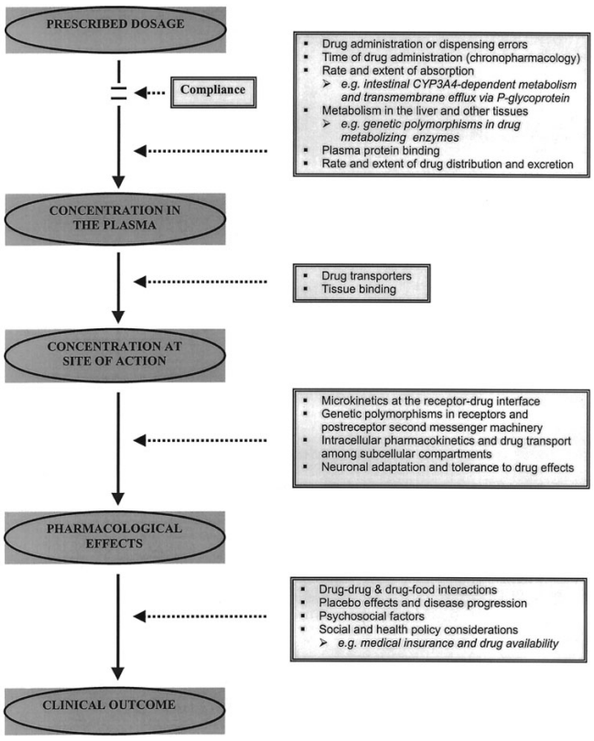

FIGURE 37.1. Pharmacological cascade describing the dose: clinical outcome relationship. Modified from Koch-Weser J. Drug therapy. Serum drug concentrations as therapeutic guides. *N Engl J Med* 1972;287:227–231.

The term pharmacokinetics describes the “drug concentration versus time” relationships in an organism by mathematical formulations of drug absorption from the site of administration, distribution, and elimination by metabolism and/or excretion (25). The pharmacodynamics explains the “drug concentration versus response” relationships and the related biological covariates (e.g., receptors, second messenger systems) (25). At present, pharmacogenomics is extending the early pharmacogenetic studies of drug metabolism to a broader context, to dissect the genetic control at multiple levels of the pharmacokinetic and pharmacodynamic pharmacologic cascade, from drug absorption and transport to drug–receptor interface and beyond. The progress made by pharmacogenomics, in many ways, is akin to developments in the computer industry. The potential benefits of high speed and efficient computing was self-evident early in the days of cumbersome mainframe computers, but it was not until the development of low-cost and proficient microcomputers that computerized information processing could be applied in daily life (analogous to contemporary ultrahigh throughput microarray genotyping technologies).

HUMAN GENETIC VARIATION AND SINGLE NUCLEOTIDE POLYMORPHISMS

Part of "37 - Pharmacogenomics and Personalized Therapeutics in Psychiatry "

The biallelic single nucleotide polymorphisms (SNPs) represent the most common DNA sequence variation in the human genome. It is thought that the complete human sequence including the coding regions, introns, and promoters will contain approximately one million SNPs (26). SNPs often result in predictable changes in amino acid sequence and contribute to diversity in protein function. SNPs are valuable biomarkers to elucidate the genetic basis of common complex diseases and pharmacologic traits. In the near term, the new genomic technologies will allow large-scale genetic association studies between numerous SNPs and drug response phenotype(s) in large samples of patients during routine drug treatment and clinical trials.

A pharmacogenetic polymorphism refers to a “…Mendelian or monogenic trait that exists in the population in at least two phenotypes (and presumably at least two genotypes), neither of which is rare; that is, neither of which occurs with a frequency of less than 1 to 2%…” (27). The definition of the minimum frequency threshold (i.e., 1% to 2%) is arbitrary and aims to emphasize that pharmacogenetic polymorphisms are *not* rare and different from those owing to recurrent spontaneous mutations occurring at much lower frequencies. A characteristic feature of pharmacogenetic polymorphisms is that they are usually biologically silent and do not present an evolutionary disadvantage or result in disease. This allows the maintenance of the less frequent phenotype at or above the 1% to 2% frequency level. Their clinical manifestations occur only when exposed to drugs or other xenobiotics, which target the polymorphic gene products.

Evident in the definition of pharmacogenetic polymorphism described in the preceding is the emphasis on phenotype (14). Alternative definitions of pharmacogenetic polymorphisms based on allele frequency also have been suggested (28 ,29). For example, Harris (1980) proposed that a genetic polymorphism occurs if the “…commonest identifiable allele (p) has a frequency no greater than 0.99…” (29). It was pointed out earlier that if the goal of pharmacogenetic studies is to investigate the clinical relevance of pharmacogenetic polymorphisms, phenotype-based definition of polymorphisms might be more applicable (28). On the other hand, if the goal is to use genetic polymorphisms as anthropological tools to study the evolution of the species and differences in response to xenobiotics between populations, a definition incorporating both allelic variations and phenotype may be more appropriate to allow understanding at a molecular and mechanistic level (28).

GENETIC VARIABILITY IN DRUG METABOLISM: CONTRIBUTION TO PHARMACOKINETIC VARIABILITY

Part of "37 - Pharmacogenomics and Personalized Therapeutics in Psychiatry "

Drug metabolism is one of the pivotal factors, which contribute to variability in pharmacokinetics. Drug metabolism is generally divided into two phases. Phase 1 reactions involve oxidative, reductive, and hydrolytic reactions, which unmask or introduce a functional group (e.g., a hydroxyl-moiety) to the parent compound. This often results in an increase in polarity of the drug. Phase 2 reactions involve conjugation (e.g., with glucuronic acid) of the metabolite produced in phase 1 reactions, or the parent compound, to more hydrophilic metabolites (30). Although drug metabolism is necessary for the elimination of lipophilic drugs (e.g., psychotropics), it may also be crucial for activation of prodrugs (e.g., codeine).

Phase 1 reactions are mediated, to a large extent, by the CYP enzymes that are mostly found attached to the smooth endoplasmic reticulum of the hepatocytes and other drug metabolizing cells (e.g., enterocyte in the gut) (31). A recent analysis of over 300 drugs from diverse therapeutic classes such as psychotropics, analgesics, and anti-infectious agents found that 56% of them primarily depend on CYPs for their metabolic clearance (32). Among CYPs, the largest contributions are made by CYP3A4 (50%), CYP2D6 (20%), CYP2C9, and CYP2C19 (15%) (32). Some of the drug metabolizing enzymes (e.g., CYP1A2 and CYP2D6) are also expressed in the brain and may potentially play a role in local disposition of psychotropics at the site of action (33 ,34).

CYTOCHROME P450 2D6 GENETIC POLYMORPHISM: A COMMON AND CLASSICAL EXAMPLE OF A MONOGENIC VARIATION IN DRUG METABOLISM

Part of "37 - Pharmacogenomics and Personalized Therapeutics in Psychiatry "

CYP2D6 genetic polymorphism is one of the most intensively studied autosomal recessive monogenic defects in drug metabolism. Many psychotropics, including most typical (e.g., perphenazine) and some atypical antipsychotics (e.g., risperidone), tricyclic antidepressants (e.g., nortriptyline), drugs of abuse, some of the serotonin reuptake inhibitors (SSRIs) (e.g., paroxetine), and codeine are metabolized by CYP2D6 (35 ,36 and 37).

Among Whites, approximately 7% of the population are poor metabolizers (PMs), whereas the rest are extensive metabolizers (EMs) for CYP2D6 substrates (35). The prevalence of PMs and the distribution of enzyme activity appear to be fairly consistent across the Western European and North American Whites. On the other hand, the frequency and type of *CYP2D6* alleles vary considerably among different ethnic groups. In Asians, the prevalence of PMs is only 1%, owing to almost complete absence of the nonfunctional alleles (e.g., *CYP2D6*4*) found in Whites (35). However, an often overlooked point in comparisons of pharmacogenetic polymorphisms between populations (e.g., Asians *versus* Whites) is that the key dependent variable is not only the prevalence of PMs but also the distribution of enzyme activity *within* EMs (36). Asian EMs (i.e., 99% of the population) display a significant shift in the distribution of CYP2D6 activity toward lower levels. The molecular basis of a lower CYP2D6 activity in Asian EMs is owing to a $C^{188}\rightarrow T$ base change in exon 1 which leads to $Pro^{34}\rightarrow Ser$ amino acid substitution in a highly conserved region (Pro-Pro-Gly-Pro) characteristic of CYP1 and CYP2 families (37). This allele was named *CYP2D6*10* (51% allele frequency in Chinese) and leads to a 10-fold decrease in activity *in vivo* (35). Thus, there may be discrete interindividual differences in disposition and therapeutic/adverse effects of psychotropics *within* Asians, depending on the gene-dose for the *CYP2D6*10* allele.

Another novel allele with reduced catalytic function, *CYP2D6*17*, occurs at high frequency in many black African populations and African-Americans. However, there appears to be considerable heterogeneity in the *CYP2D6* locus in Black populations. For example, in Ethiopia, only 1.8% were PMs of debrisoquine, 16% carried the *CYP2D6*10B* allele characteristic of Asian populations, and the *CYP2D6*17* was present in 18% of the subjects (38). Importantly, 29% of the Ethiopians carried alleles with duplicated and multiduplicated CYP2D6 genes associated with ultrarapid metabolism of substrates (38). Also, a high percentage of gene duplication and ultrarapid metabolism was found in Saudi Arabia and Spain, presumably owing to the genetic admixture during the earlier Islamic migration originating from some of the North African populations with ultrarapid CYP2D6 activity (36 ,37). The clinical significance of reduced catalytic function associated with the *CYP2D6*17* allele requires further research in patients with African ancestry.

At present, more than 50 *CYP2D6* alleles were described that encode an enzyme with inactive, decreased, increased, or normal catalytic function. The number of functional *CYP2D6* genes correlates with drug and metabolite concentrations in the plasma, as aptly documented using nortriptyline as a model substrate (Fig. 37.2) (39). In general, PMs are at risk for drug toxicity on treatment with medications predominantly inactivated by metabolism via CYP2D6. On the other hand, in prodrugs, which need to be converted to their active form by CYP2D6, opposite clinical consequences may occur in PMs. For example, codeine does not produce analgesic effects in PMs or after treatment of EMs with CYP2D6 inhibitors such as quinidine. Among EMs, those with duplicated or multiduplicated CYP2D6 genes and ultrarapid metabolism may develop subtherapeutic plasma concentrations and inadequate clinical response (40). Although high doses would be necessary in such patients, an alternative strategy would be to use low subtherapeutic doses of the CYP2D6 inhibitor quinidine, especially for drugs with high acquisition costs, to attain therapeutic plasma concentrations (41). Overall, routine genotyping for *CYP2D6* may be useful to avoid drug toxicity in PMs, to ascertain the pharmacokinetic mechanism of resistance to some psychotropics, as well as for differential diagnosis of noncompliance versus ultrarapid CYP2D6 activity. In addition, the markedly increased metabolite formation in patients with multiduplicated *CYP2D6* genes may potentially lead to qualitatively different and unexpected drug effects and toxicity (40).

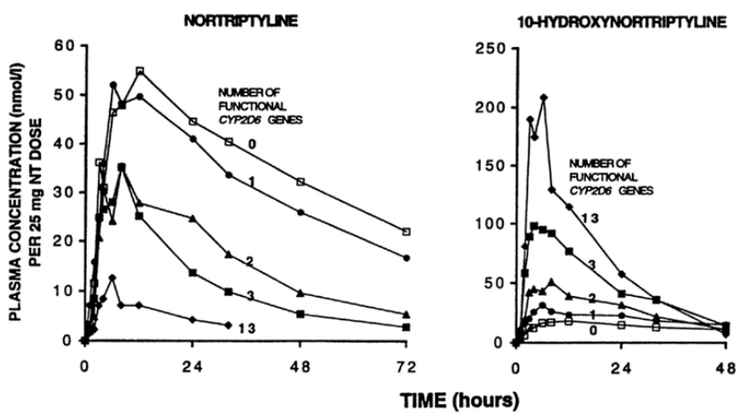

FIGURE 37.2. Average plasma concentrations of nortriptyline and 10-hydroxynortriptyline after a 25-mg single oral dose in White healthy volunteers with 0, 1, 2, 3, and 13 functional copies of the CYP2D6 gene. Note that the concentration of nortriptyline and its metabolite 10-hydroxynortriptyline are inversely affected by the number of functional CYP2D6 gene. Reprinted with permission from Dalén P, Dahl ML, Ruiz ML et al. 10-Hydroxylation of nortriptyline in white persons with 0, 1, 2, 3, and 13 functional CYP2D6 genes. *Clin Pharmacol Ther* 1998;63:444–452.

It is noteworthy that CYP2D6 with identical pharmacologic and molecular properties was identified in microsomal fractions in the brain. Hence, CYP2D6 may potentially contribute to local clearance of psychotropics at the site of action (42). Moreover, CYP2D6 in the brain is functionally associated with the dopamine transporter and shares similarities

in substrates and inhibitors (e.g., d-amphetamine), suggesting a role in dopaminergic neurotransmission (42). Differences in personality traits between EMs and PMs were noted in both Swedish and Spanish healthy White subjects, also suggesting that there may be an endogenous substrate for CYP2D6 in the brain (42).

The common polymorphic drug metabolizing enzymes in humans and their major variant alleles are presented in Table 37.1 (37). A worldwide web page with detailed descriptions of new alleles, nomenclature and useful references can be found at (http://www.imm.ki.se/CYPalleles/).

Enzyme	Major Variant Alleles	Mutation	Consequences for Enzyme Function	Allele Frequencies (%)			
				Caucasians	Asians	Black Africans	Ethiopians and Saudi Arabians
CYP2A6	*CYP2A6*2*	Leu160His	Inactive enzyme	1–3	0	ND	ND
	*CYP2A6*del*	Gene deletion	No enzyme	1	15	ND	ND
CYP2C9	*CYP2C9*2*	Arg144Cys	Reduced affinity for P450 oxidoreductase	8–13	0	ND	ND
	*CYP2C9*3*	Ile359Leu	Altered substrate specificity	6–9	2–3	ND	ND
CYP2C19	*CYP2C19*2*	Aberrant splice site	Inactive enzyme	13	23–32	13	14–15
	*CYP2C19*3*	Premature stop codon	Inactive enzyme	0	6–10	ND	0–2
CYP2D6	*CYP2D6*2xN*	Gene duplication or multiduplication	Increased enzyme activity	1–5	0–2	2	10–16

TABLE 37.1. HUMAN POLYMORPHIC CYTOCHROME P450 ENZYMES AND THE GLOBAL DISTRIBUTION OF THEIR MAJOR VARIANT ALLELES

CYP3A4: A NONPOLYMORPHIC VARIATION IN DRUG METABOLISM

Part of "37 - Pharmacogenomics and Personalized Therapeutics in Psychiatry "

The term “polymorphic metabolism” is often perceived as an alarming indication of marked variability in drug disposition. Although this assertion is correct to a certain extent, it does not imply that a nonpolymorphic drug-metabolizing enzyme is associated with reduced variability. For example, CYP3A4 is the most abundant CYP isoform in the adult human liver with large interindividual variability in its expression. *In vivo*, CYP3A4 activity displays at least 20-fold

difference in the population (43). Yet, the distribution of CYP3A4 catalytic activity is unimodal and nonpolymorphic in many populations.

CYP3A4 contributes to disposition of more than 60 frequently prescribed therapeutic agents with diverse chemical structures including antilipidemics, benzodiazepines, HIV protease inhibitors, immunosuppressants, and macrolide antibiotics (43 ,44). CYP3A4 also plays an important role for the metabolism of endogenous steroids (e.g., testosterone) as well as activation of dietary mycotoxins (e.g., aflatoxin B1) (43). The prediction of CYP3A4-mediated drug metabolism is complicated by the presence of at least two distinct pools of the CYP3A4 protein, in the liver and intestine, whose expressions appear to be regulated independently. The appreciation of marked variability in CYP3A4 activity is critical for individualized treatment with CYP3A4 substrates, to forecast drug–drug interactions mediated by CYP3A4, and to identify the factors predisposing to long-term toxicity (e.g., prostate and liver cancer) associated with variable metabolism of steroid hormones and procarcinogens (44).

CYP3A4 expression can be markedly induced *in vivo* during chronic treatment with drugs such as the antibiotic rifampicin, anticonvulsant carbamazepine, and glucocorticoid dexamethasone (43). Conversely, CYP3A4 catalytic activity can be inhibited potently by commonly used drugs including the azole antifungal agents (e.g., ketoconazole) and the macrolide antibiotics (e.g., erythromycin), or by foodstuffs such as grapefruit juice (44). For example, excessive sedation or psychomotor impairment can occur after oral administration of benzodiazepines with a low bioavailability (e.g., triazolam) or some nonbenzodiazepine (e.g., buspirone) hypnosedatives together with grapefruit juice (44). Many patients with a mental health problem also use nonpsychotropic medications. In such cases, clinically significant hypotension may be observed during treatment with dihydropyridine calcium channel antagonists (e.g., nifedipine) and CYP3A4 inhibitors.

Studies in monozygotic and dizygotic twins indicate a high heritability (H_2 = 0.88) of CYP3A4 activity (45); however, there has been relatively little progress in identification of the molecular genetic underpinnings of heterogeneity in *CYP3A4* expression. Recently, a novel allele, *CYP3A4*2*, causing a Ser222Pro change was found in Whites at a frequency of 2.7%, but this allele was absent in Black and Chinese subjects (46). The *CYP3A4*2* displays a substrate-dependent diminished metabolic clearance; for instance, nifedipine (but not testosterone) intrinsic clearance is impaired (46). Because functional polymorphisms in the promoter or the coding region of CYP3A4 do not appear to be very common, it is likely that CYP3A4 activity represents a complex trait regulated by multiple interacting genetic loci in the genome (47).

GENETIC VARIABILITY IN RECEPTORS AND DRUG TRANSPORTERS: CONTRIBUTION TO PHARMACODYNAMIC VARIABILITY

Part of "37 - Pharmacogenomics and Personalized Therapeutics in Psychiatry "

Historically, the pharmacogenetic factors related to drug efficacy and safety were mainly studied in the context of drug metabolism (48). In the past decade, the increasing application of mathematical models for “concentration *versus* effect” relationships during routine drug development clearly documented the marked interindividual variability in pharmacodynamics (23). It is estimated that approximately 30,000 proteins with diverse structures are expressed in the human brain, many of which may serve as potential drug targets (49). Recent studies of SNPs in genes relevant for psychotropic pharmacodynamics indicate that human genetic variation in drug receptors and transporters may significantly contribute to overall variance in response to drugs.

Dopamine D3 receptor *(DRD3)* gene is expressed in the basal ganglia and is thought to play a role in locomotion. Three independent studies found that the Ser9Gly polymorphism in the N-terminal extracellular domain of the DRD3 is associated with an increased propensity to develop tardive dyskinesia in patients treated with typical antipsychotics (Fig. 37.3) (50 ,51 and 52). Pharmacogenetic polymorphisms in the dopamine D4 receptor *(DRD4)* gene, especially the hypervariable exon III 48 bp variable number of tandem repeat (VNTR), have been studied intensively in relation to antipsychotic response to clozapine (53). Although the exon III 48 bp VNTR in *DRD4* does not appear to be a major contributor to clinical outcome during clozapine treatment, it is possible that haplotype analyses incorporating several variants in different locations would be necessary before definitive conclusions can be drawn for the importance of *DRD4* in antipsychotic response. Moreover, studies involving the serotonin receptor gene polymorphisms suggest an association between the 5-HT2A receptor and response to clozapine (53 ,54 and 55). Other neurotransmitters such as norepinephrine, acetylcholine, and glutamate may also contribute to antipsychotic drug effects, but genetic variation in these receptors has not been investigated following a pharmacogenomic perspective (18). A detailed review of polymorphisms in dopamine and serotonin receptor genes, their relevance for response to clozapine and other atypical antipsychotics, and methodologic considerations for application of molecular approaches to psychiatric genetics are available elsewhere (53).

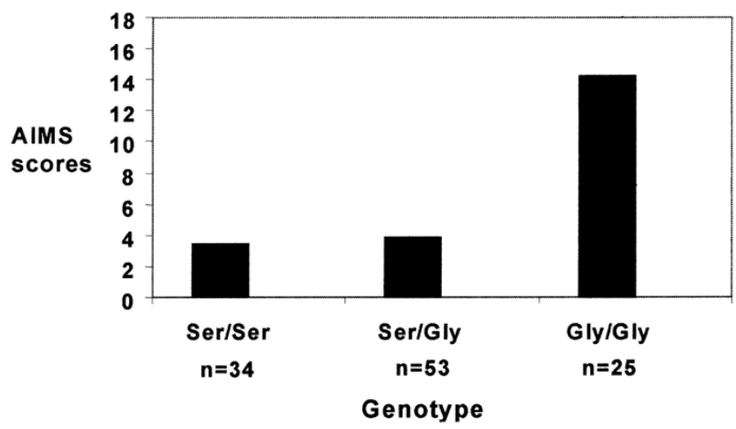

FIGURE 37.3. Average Abnormal Involuntary Movement Scale (AIMS) scores in 112 schizophrenic patients previously treated with typical antipsychotics and genotyped for the serine to glycine polymorphism in the N-terminal extracellular domain of the dopamine D3 (DRD3) receptor. A post hoc Student-Newman-Keuls test revealed a higher average AIMS score in patients homozygous for the glycine allele of the DRD3 gene, compared to those with a heterozygous or homozygous genotype for the serine allele. The analysis of variance results were corrected for age, gender, ethnicity and pairwise comparisons (F = 8.25, df = 2, P < 0.0005 [P < 0.0015, Bonferroni corrected]). Reprinted with permission from Basile VS, Masellis M, Badri F, et al. Association of the MscI polymorphism of the dopamine D3 receptor gene with tardive dyskinesia in schizophrenia. *Neuropsychopharmacology* 1999;21:17–27.

Because the first report more than 60 years ago on the use of amphetamine in children with attention deficit hyperactivity disorder (ADHD), it became clear that approximately 75% of ADHD cases show clinically significant improvement after d-amphetamine or methylphenidate treatment. Although the precise mechanism of action of these stimulant agents still remains elusive, their interaction with the dopamine transporter may contribute to their therapeutic

effects in ADHD. The VNTR polymorphism of the dopamine transporter gene appears to influence the response to methylphenidate, based on a preliminary study in 30 African-American children with ADHD (56). These limited data, however, do not allow generalizations on genetic determinants of response to pharmacologic interventions in ADHD at the present time.

The marked temporal delay in therapeutic effects is a well-known phenomenon with antidepressant agents. Therefore, it is advantageous to identify beforehand the subpopulation of patients who are unlikely to respond to a given medication so that various augmentation efforts can be initiated promptly. The high-affinity serotonin transporter (5-HTT) is a prime target for the serotonin reuptake inhibitor antidepressants (SSRIs). A functional polymorphic variant of the *5-HTT* gene characterized by a 44-bp insertion in its promoter region leads to differences in the amount of *5-HTT* transcript and the extent of 5-HT reuptake (57). Clinical studies suggest that the 44-bp insertion polymorphism of the *5-HTT* gene influences the antidepressant response to SSRIs including fluvoxamine and paroxetine (57). Further studies with other SSRIs and classical tricyclic antidepressants are called for to assess the overall clinical significance of *5-HTT* promotor polymorphism(s).

P-glycoprotein encoded by the *MDR1* gene is another drug transporter that affects transmembrane efflux and intracellular or tissue availability of numerous drugs. For example, amitriptyline (but not fluoxetine) can penetrate the brain more readily in knockout mice that do not express p-glycoprotein (58). Hence, differences in *MDR1* expression owing to genetic polymorphisms or secondary to chronic antidepressant treatment may explain treatment-resistance to amitriptyline in patients who otherwise attain therapeutic plasma drug concentrations.

The study of pharmacogenetic polymorphisms in drug targets is a relatively new but rapidly expanding research area. It is likely that molecular genetic profiling of patients for SNPs or other types of human genetic variation in both pharmacokinetic and pharmacodynamic targets will bring psychiatric genetics and clinical pharmacology one step closer to achieve the ultimate goal of individualized therapeutics.

PHARMACOGENOMICS AND DRUG DISCOVERY

Part of "37 - Pharmacogenomics and Personalized Therapeutics in Psychiatry "

The drug discovery in psychiatry was initially based on serendipity. The identification of lithium in 1949 and chlorpromazine in 1950s are two well-known examples where putative mechanisms of action were elucidated after the drugs were shown to be efficacious. The newer drug discovery paradigms have depended on the synthesis and identification of novel compounds through combinatorial chemistry

and screening for biological activity against known receptors or other biological targets with established endogenous ligands or substrates (59 ,60). With the Human Genome Project approaching to its completion, essentially all human genes will be available as potential drug targets. The challenge in drug discovery will then be to discern the function and therapeutic utility of these genes and their expressed products.

The experimental paradigms used by pharmacogenomics borrow substantially from the field of population genetics and the methodology used in earlier genetic studies of common complex diseases (60 ,61). For example, linkage and association studies are two well-known strategies to identify the genes causing a specific disease or variability in drug effects. The linkage design was traditionally used to test the relationship between inheritance of a complex disease phenotype within family members and microsatellite markers comprised of five or less short tandem repeats of DNA. The increasing availability of SNP markers and the ability to genotype the entire genome of large segments of patient populations with ultrahigh throughput methods such as the DNA microarrays, often referred to as “DNA chips,” now allow the application of genetic linkage or association designs to elucidate the genes responsible for variations in therapeutic response and toxicity. On the other hand, the obvious difficulties in administering drugs to different family members and obtaining relevant data on drug response phenotype may pose a constraint on application of linkage design to pharmacogenomics.

DNA microarray is an emerging powerful technological breakthrough that enables the study of global gene expression patterns and sequence variations at a genome level (62). In essence, DNA microarray is an extension of the Southern blot procedure and is comprised of different cDNAs or oligonucleotides etched systematically on a solid surface such as silica or glass plate. Each DNA species on the array represents a specific gene or expressed sequence tag, which is used to identify different SNPs or transcripts by hybridization and fluorescence detection. Microarrays with 10,000 or more genes are now available for use in clinical research or trials. An important application of microarrays is monitoring of temporal changes in gene expression during drug treatment or patients versus healthy individuals. The premise in these studies is that patterns of gene expression may serve as indirect clues about disease-causing genes or drug targets. Moreover, the effects of drugs with established efficacy on global gene expression patterns may provide a guidepost, or a “genetic signature,” against which the new drug candidates can be validated (63). Other new genomic technologies such as genotyping by mass spectrometry also are being developed. Collectively, pharmacogenomics adds another dimension to contemporary drug discovery efforts because it aims to identify novel drug targets in the *entire* human genome without *a priori* assumptions on disease pathogenesis or drug targets, thereby presenting an opportunity to unlock unprecedented novel mechanisms of drug action (4).

PHARMACOGENOMICS AND DRUG DEVELOPMENT

Part of "37 - Pharmacogenomics and Personalized Therapeutics in Psychiatry "

After the discovery of an NCE with therapeutic potential, the next step involves clinical testing in healthy volunteers and relevant target patient populations. For every clinician, an appreciation of the drug development process is important to make evidence-based choices among therapeutic alternatives and to be aware of the shortcomings of the data presented to support the efficacy and safety of new medications.

The drug discovery and development is a high-risk venture. Typically, it takes 8 to 12 years to introduce a new drug from discovery to clinical practice, with costs often approaching $100 to $300 million. On the other hand, it is estimated that approximately 90% or more of NCEs under development fail to meet the regulatory approval for clinical use (64). It is well known to most pharmaceutical scientists that the art of timely and cost-effective drug development rests on early identification and removal of drug candidates with poor efficacy and safety. It is conceivable that some of these NCEs may in fact have a favorable efficacy and safety profile in certain genetically determined subpopulations. Through proper design of clinical trials and using low-cost high-throughput genetic analyses, pharmacogenomics eventually can allow patenting of such “failed” NCEs in discrete patient populations and reinstate their market potential. In addition, a genetic test predicting drug effects would be considered another pharmaceutical product and an additional financial incentive for drug developers. For example, clozapine was recognized as a potential antipsychotic drug in early 1970s. The occurrence of agranulocytosis in several cases caused the termination of further development of clozapine in treatment-resistant patient populations until the late 1980s. The presence of genetic or other predictors of agranulocytosis would have expedited the development of clozapine and prevented the inconvenience of periodical hematologic monitoring.

Pharmacogenomics is also relevant for better use of medications that are already in routine clinical use (phase 4 drug development). A recent meta-analysis of prospective studies from 1966 to 1996 found that the incidence of serious and fatal adverse drug reactions in United States was 6.7% and 0.32%, respectively; ranking between the fourth to sixth leading cause of death, ahead of pneumonia and diabetes (65). Importantly, the adverse drug reactions in the latter study occurred during treatment with usual doses of drugs that already met the regulatory requirements for clinical use, and excluded cases owing to intentional or accidental overdose, errors in drug administration, or noncompliance.

It is likely that the proportion of such patients who are inadequately treated may further increase after accounting for therapeutic failures secondary to ultrarapid drug metabolism, for instance, and mismatches between the pharmacodynamic attributes of medications and drug targets in individual patients (23 ,37). Evidently, the existing pharmacotherapy system based on the traditional trial-and-error approach is unable to deliver personalized drug treatment and health care.

From the perspective of patients, healthcare providers, and managed care organizations, an increased probability of therapeutic response through genetic testing would reduce duration of inpatient hospital care, frequency and inconvenience of repeated physician visits owing to treatment resistance, and thus, easily offset the costs of pharmacogenomic-based drug development. For NCEs that readily meet the regulatory requirements with large efficacy margins (i.e., “blockbuster drugs”) over placebo or the existing standard treatment modalities, there may be less financial incentive—on the manufacturers’ part—to identify different subpopulations with differing drug effects, because this may potentially decrease the market share of their newly introduced medication. Therefore, although pharmacogenomics provides a clear rationale for improved drug discovery and personalized therapeutics, it will likely need enforcement by regulatory agencies before it can be utilized in routine clinical practice and pharmaceutical industry. This may in turn require amendments to existing regulatory policies for drug development. Also, as a result of the global harmonization attempts to standardize drug development and approval process, the settings of future clinical trials will not only be limited to Western society; therefore, it would be critical and advantageous to plan such policy amendments at a multinational level.

ETHICAL AND HEALTH POLICY CONSIDERATIONS

Part of "37 - Pharmacogenomics and Personalized Therapeutics in Psychiatry "

Pharmacogenomics arrived at the heels of the molecular biology revolution in 1980s and early 1990s. Although there is much optimism for a more efficient drug discovery and development process, there is also increasing concern about the implementation of genetic testing at various levels of the medical practice and its repercussions for health policy and managed care organizations. Confidentiality of the genetic test results is critical because it has important bearings on finding employment and obtaining life, health, or disability insurance. There is an urgent need to amend the existing medical curriculum to educate future clinical personnel for genetic counseling and fundamentals of molecular medicine. About 5% of the budget for the Human Genome Project is reserved to address these social and ethical issues.

CONCLUSION

Part of "37 - Pharmacogenomics and Personalized Therapeutics in Psychiatry "

Personalized therapeutics has been a preoccupation in clinical psychiatry for many decades. The traditional gene-by-gene approach to explain variability in drug response has been a mainstay in most pharmacogenetic investigations to date. However, the biological underpinnings of drug response are complex and often involve contributions by multiple genes, environmental factors, drug–drug and drug–food interactions, to mention a few (Fig. 37.4) (18 ,66 ,67 ,68 ,69 ,70 and 71). Clearly, a genome-wide approach will be an important advance in understanding the variability in drug efficacy and safety. To this end, sequence variations in the genome are only the first level of complexity. More intriguing and challenging is establishing the significance of differences in global gene expression patterns in relation to drug effects and targets. High throughput and genome-wide transcript profiling for differentially regulated mRNA species in disease, normal physiology, and after drug treatment offer an additional dynamic perspective for drug discovery. The development of protein chips may permit further explorations of functional genomics in the context of psychopharmacology. We may soon be surprised that the mechanism of action of some psychotropics may in fact rest on targets entirely different than what the conventional pharmacologic wisdom suggests (e.g., the monoamine hypothesis for antidepressant drug effects).

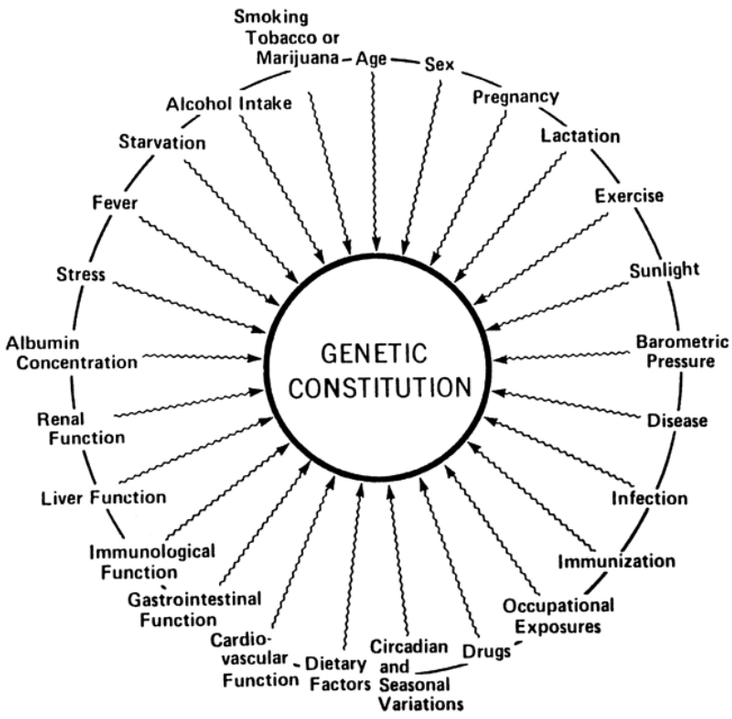

FIGURE 37.4. The interaction of genetic and environmental factors that may influence drug response in humans. Reprinted with permission from Vesell ES. On the significance of host factors that affect drug disposition. *Clin Pharmacol Ther* 1982;31:1–7.

At the present time, however, it is not clear whether and to what extent the genomic hypotheses can be tested within the framework of the available clinical trial methodology. For example, the sample size in most phase 3 clinical trials does not usually exceed 3,000 to 4,000 patients. Genome-wide association studies and statistical correction for multiple testing will require sample sizes well beyond the current resources of any single pharmaceutical company or an academic laboratory. Ideally, pharmacogenomics should be used for the prospective design of phase 3 clinical trials and not to salvage an NCE that proved to be ineffective or unsafe at the end of phase 3 investigations. Care should be taken for adequate representation of each subpopulation identified by genetic markers. The information obtained by genomic methods should ultimately be translated into discrete product labeling information. Otherwise, it is uncertain whether the off-label data available in the form of scientific publications will transform routine clinical practice and lead to personalized therapeutics. Also, genomic data are fundamentally different than the traditional covariates (e.g., weight, age) that have been used to explain variability in drug efficacy and safety, and thus require special considerations. Clear regulatory guidelines and new collaborations between academic institutions and the pharmaceutical industry, both at the level of basic and clinical research, are called for to implement pharmacogenomics in the drug development process and evaluate its significance for achieving drug safety, efficacy and effectiveness (72 ,73 and 74).

Pharmacogenomics emerged in late 1990s by coalescence of traditional methodologies used in human genetics, common complex diseases and pharmacogenetics, together with the impetus provided by novel genomic technologies developed as part of the Human Genome Project. The collection of genomic data is being more feasible by increasing accessibility and decreasing costs of molecular genetic analyses. Pharmacogenomics has far-reaching implications in medicine and biology and can be applied to various facets of therapeutics from drug discovery and neuroimaging to drug–drug and drug–food interactions (5 ,6 ,75). The road from pharmacogenomics to personalized therapeutics is arduous and challenging but the technology is now in place to validate the utility of pharmacogenomics in routine clinical practice and pharmacotherapy (76).

During the last decade, the application of pharmacokinetic and pharmacodynamic modeling techniques has become an increasingly important aspect of contemporary clinical psychopharmacology (1 ,2 ,3 ,4 and 5). These techniques have been applied during the process of development of new drug entities as well as for the improved understanding of the clinical actions of drugs that are already marketed. Techniques for the study of drug metabolism *in vitro* have advanced substantially during the last decade, and now are an integral component of preclinical drug development and the link to subsequent clinical studies of drug metabolism and disposition. Kinetic-dynamic modeling techniques have been combined with *in vitro* metabolism procedures and *in vitro–in vivo* mathematical scaling models to provide insight into the general problem of pharmacokinetic drug interactions in clinical psychopharmacology (6 ,7 ,8 and 9).

This chapter reviews some advances in pharmacokinetics, pharmacodynamics, and drug metabolism, along with methodologic applications to selected problems in clinical psychopharmacology.

POPULATION PHARMACOKINETICS

Part of "38 - Pharmacokinetics, Pharmacodynamics, and Drug Disposition "

Principles

Pharmacokinetic studies based on a traditional intensive-design model are usually conducted using carefully selected volunteer subjects, a controlled experimental design, and collection of multiple blood samples. After measurement of drug and metabolite concentrations in all samples, pharmacokinetic models are applied to determine parameters such as elimination half-life, volume of distribution, and clearance. During the new drug development process, a series of pharmacokinetic studies are conducted to determine the influence of major disease states or experimental conditions hypothesized to affect drug disposition. Such factors might include age, gender, body weight, ethnicity, hepatic and renal disease, coadministration of food, and various drug interactions. Classical pharmacokinetic studies can quantitate the effects of anticipated influences on drug disposition under controlled circumstances, but cannot identify the unexpected factors affecting pharmacokinetics. A number of examples of altered drug pharmacokinetics became apparent in the patient care setting only in the postmarketing phase of extensive clinical use. Examples include the digoxin-quinidine interaction, altered drug metabolism due to cimetidine, and the ketoconazole-terfenadine interaction.

Population pharmacokinetic methodology has developed as an approach to detect and quantify unexpected influences on drug pharmacokinetics (10 ,11 ,12 ,13 ,14 ,15 ,16 ,17 and 18). Population pharmacokinetic studies, in contrast to classical or traditional pharmacokinetic studies, focus on the central tendency of a pharmacokinetic parameter across an entire population, and identify deviations from that central tendency in a subgroup of individual patients. One software program widely applied to population pharmacokinetic problems is the nonlinear mixed-effects model (NONMEM). Analysis of clinical data using a population approach allows pharmacokinetic parameters to be determined directly in patient populations of interest and allows evaluation of the influence of various patient characteristics on pharmacokinetics. Because the number of blood samples that need to be collected per subject is small, this approach is often suitable for patient groups unable to participate in traditional pharmacokinetic studies requiring multiple blood samples (e.g., neonates,

children, critically ill patients, or individuals who are not able to provide informed consent) (19). In many cases the population approach has yielded pharmacokinetic parameter estimates similar to those delineated in classical pharmacokinetic studies of the same drug.

Application: Methylphenidate Pharmacokinetics

The population approach is illustrated in a study of methylphenidate (MP) pharmacokinetics in children (20). This is a patient group for whom the multiple-sample pharmacokinetic study design may not be appropriate for ethical and practical reasons. Participating subjects were 273 children aged 5 to 18 years having a primary diagnosis of attention-deficit/hyperactivity disorder (ADHD). They had been receiving MP at a fixed dosage level for at least 4 weeks, and were under treatment for at least 3 months. The treating physician for each patient judged MP to be clinically effective.

Children meeting the eligibility criteria had an initial screening visit, at which one parent or a legal guardian provided written informed consent, and the child provided assent. Demographic characteristics were recorded, including the dosage of MP, the usual times for individual doses, and the duration of treatment.

The second visit, which followed shortly, was a blood-sampling day. Each child, accompanied by parent or guardian, arrived at the investigator's office 30 to 60 minutes prior to blood sampling. The time and size of the last MP dose, and of any other medication received that day or during the prior 2 weeks, were recorded. A 5-mL whole blood sample was obtained by venipuncture. This sample was immediately centrifuged, and a 2-mL aliquot of plasma was removed for subsequent determination of MP concentrations by a liquid chromatography/mass spectroscopy/mass spectroscopy (LC/MS/MS) assay.

Analysis of Data

The identified independent variables were age, sex, body weight, size of each dose, and time of sample relative to the most recent dose. Since only single samples were available for all but 16 of these children, the contribution of within-subject variance to overall variability in outcome could not be assessed. The pharmacokinetic model was a one-compartment model with first-order absorption and first-order elimination, under the assumption that all subjects were at steady state (Fig. 38.1).

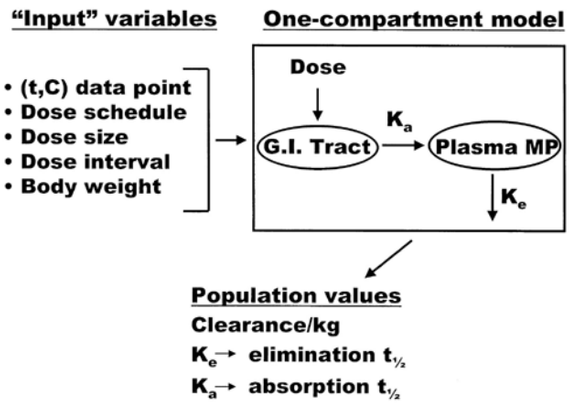

FIGURE 38.1. Population pharmacokinetic model for methylphenidate (MP). A series of data points, each consisting of the time (*t*) after the first dose of the day and the plasma MP concentration (*C*) at that time, was available from 273 subjects (one data point per subject). Each of these was linked to that subject's individual dose schedule, size of each dose, interval between doses, and body weight. These variables were entered into a one-compartment pharmacokinetic model with first-order absorption and first-order elimination, as shown. Using nonlinear regression, the process yielded "typical" population values of clearance per kilogram body weight, the elimination rate constant (K_e), and the absorption rate constant (K_a).

The overall model was specifically modified for each of the 273 subjects to incorporate the individually applicable independent variables, as well as the dosage schedule (b.i.d. or t.i.d.). Individual values of continuous variables (*t* = time sample taken relative to the first dose; *C* = plasma MP concentration) were fitted to a single set of iterated variables using unweighted nonlinear regression (Fig. 38.1). When the time between first and second doses, or between second and third doses, was not available, the mean value was assigned based on cases in which the data were available. For the b.i.d. dosage, the mean interval was 4.3 hours. For the t.i.d. dosage, the mean intervals were 4.1 and 3.7 hours, respectively. As is customary, clearance was assumed to be proportional to body weight.

Results

The total daily dose of MP was significantly lower in subjects receiving MP b.i.d. (n = 109) compared to subjects on a t.i.d. schedule (n = 164); the mean total daily dosages in the two groups were 25 and 39.3 mg, respectively (p <.001). Within each group, clinicians' choices of total daily dosages were influenced by body weight, as mean total daily dose increased significantly with higher body weights. However, the association of body weight with mean plasma concentration was not significant for the b.i.d. dosage group, and of only borderline significance (.05< p <.1) for the t.i.d group. This finding is consistent with the underlying assumption that clearance is proportional to body weight.

Age was significantly correlated with body weight (r^2 = 0.54, p <.001) and with height (r^2 = 0.77). Height and body weight also were significantly correlated (r^2 = 0.77).

An acceptable estimate of absorption rate constant could be derived only for the b.i.d. dosing data. The iterated parameter

estimate was 1.192/h, corresponding to an absorption half-life of 34.9 minutes. This estimate was then fixed, and the entire data set analyzed to determine clearance per kilogram of body weight, and the first-order elimination rate constant. The iterated estimates were 0.154/h for elimination rate constant, corresponding to an elimination half-life of 4.5 hours (relative standard error: 23%). For clearance, the estimate was 90.7 mL/min/kg (relative standard error: 9%). The overall *r*-square was 0.43 (Fig. 38.2). There were no evident differences in pharmacokinetics attributable to gender. Figure 38.3 shows predicted plasma MP concentration curves for b.i.d. and t.i.d. dosage schedules, based on the population estimates.

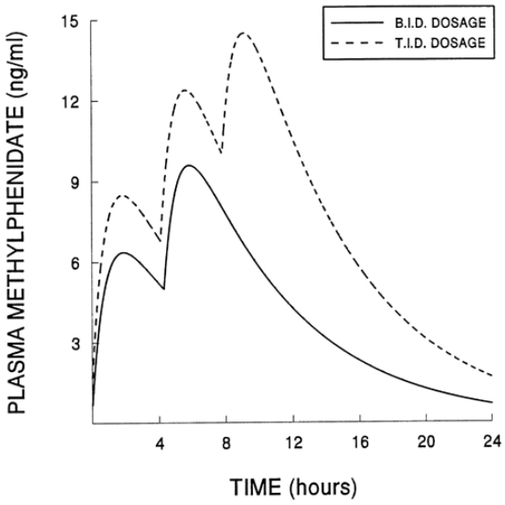

FIGURE 38.3. Predicted plasma methylphenidate concentration curves for b.i.d. and t.i.d. dosage schedules, based on parameter estimates from the population analysis, together with mean values of input variables (body weight, size of doses, intervals between doses). (From Shader RI, Harmatz JS, Oesterheld JR, et al. Population pharmacokinetics of methylphenidate in children with attention-deficit hyperactivity disorder. *J Clin Pharmacol* 1999;39:775–785, with permission).

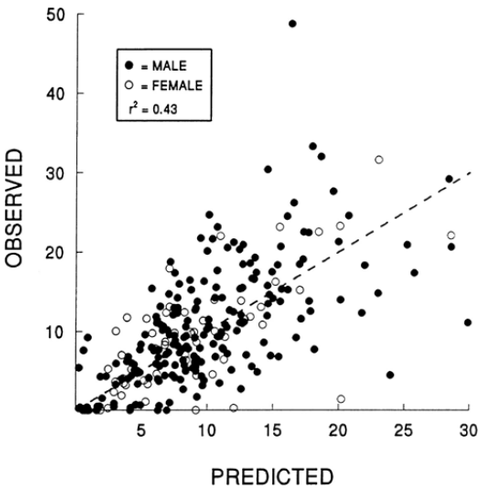

FIGURE 38.2. Overall relation of observed and predicted plasma methylphenidate concentrations (ng/ml). The *r*-square value of 0.43 indicates that the model accounts for 43% of the overall variance in plasma concentrations. (From Shader RI, Harmatz JS, Oesterheld JR, et al. Population pharmacokinetics of methylphenidate in children with attention-deficit hyperactivity disorder. *J Clin Pharmacol* 1999;39:775–785, with permission.)

Implications

Pharmacokinetically based approaches to the treatment of ADHD with MP are not clearly established (21 ,22 ,23 ,24 and 25). In the present study of prescribing patterns in particular clinical practices, the mean prescribed per dose amount for the whole study population was 0.335 mg/kg per dose (range = 0.044–0.568), and 36% of the children received between 0.25 and 0.35 mg/kg per dose. The mean total daily dose was 0.98 mg/kg/day for the entire sample, and increased significantly in association with larger body weight. This may reflect the clinicians' considering body weight in their choice of total daily dosage, or it may be that the dose was titrated according to response, which in turn was influenced by associations among concentration, clearance, and weight.

The pharmacokinetic model explained 43% of the variability in plasma MP concentrations during typical naturalistic therapy. The model fit equally well for both genders. Assuming that clearance is proportional to body weight in the context of intercorrelated age and weight allows age, weight, and daily dosage to be used to predict plasma concentrations of MP during clinical use in children. These findings support the value of prescribing MP on a weight-adjusted basis.

Our typical population value of elimination half-life was 4.5 hours, with a confidence interval of 3.1 to 8.1 hours. This estimate somewhat exceeds the usual range of half-life values reported in single-dose kinetic studies of MP (25 ,26). This could reflect the relatively small number of plasma samples from the terminal phase of the plasma concentration curve, upon which reliable estimates of beta are dependent. MP kinetics may also have a previously unrecognized dose-dependent component, in which estimated values of half-life are larger at steady state than following a single dose.

The single-sample approach described in this study allows relatively noninvasive assessment of pharmacokinetic parameters in a group of children and adolescents under naturalistic circumstances of usual clinical use, when blood sampling is not otherwise clinically indicated. This approach in general can be applied to other special populations such as neonates, the elderly, or individuals with serious medical disease.

KINETIC-DYNAMIC MODELING

Part of "38 - Pharmacokinetics, Pharmacodynamics, and Drug Disposition "

Principles

Pharmacokinetics is the discipline that applies mathematical models to describe and predict the time course of drug concentrations in body fluids, whereas pharmacodynamics refers to the time course and intensity of drug effects on the organism, whether human or experimental animal (Fig. 38.4). Both have evolved as the techniques for measuring drug concentrations, and drug effects have become more accurate and sensitive. Evolving in parallel is kinetic-dynamic modeling, in which the variable of time is incorporated into the relationship of effect to concentration (Fig. 38.4) (27 ,28 ,29 ,30 ,31 and 32). A concentration-effect relationship is, in principle, the most clinically relevant, because it potentially validates the clinical rationale for measuring drug concentrations in serum or plasma.

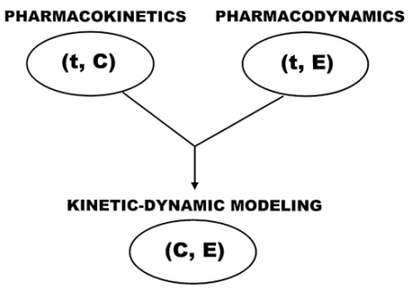

FIGURE 38.4. Schematic relation between pharmacokinetics, pharmacodynamics, and kinetic-dynamic modeling, based on the status of the variables of time (*t*), concentration (*C*), and effect (*E*). Note that kinetic-dynamic modeling incorporates both pharmacokinetics and pharmacodynamics, with time subsumed into the relation of concentration and effect.

A kinetic-dynamic study in clinical psychopharmacology typically involves medication administration (usually under placebo-controlled, double-blind laboratory conditions) followed by quantitation of both drug concentration and clinical effect at multiple times after dosing. Measures of effect necessarily depend on the type of drug under study. For sedative-anxiolytic drugs such as benzodiazepines, effects of interest may include subjective or observer ratings of sedation and mood; semiobjective measures of psychomotor performance, reaction time, or memory; or objective effect measures such as the EEG or saccadic eye movement velocity. The various measures differ substantially in their relevance to the principal therapeutic actions of the drug, the stability of the measure in terms of response to placebo or changes caused by practice or adaptation, the objective or subjective nature of the quantitative assessment, and the comparability of results across different investigators and different laboratories (Table 38.1). The extent to which the various pharmacodynamic measures provide unique information, as opposed to being overlapping or redundant, is not clearly established.

Classification (with Examples)	Relation to Primary Therapeutic Action	Effect of Placebo	Effect of Adaptation/Practice	Need for "Blind" Conditions	Approach to Quantitation
Subjective					
Global clinical ratings; targeted rating scales	Close	Yes	Yes	Yes	Transformation of ratings into numbers
Semi-objective					
Psychomotor function tests; memory tests	May be linked to adverse effect profile	Yes	Yes	Yes	Test outcomes are quantitative
Objective					
Electroencephalography	Not established	No	No	No	Fully objective computer-determined quantitation

GABA, γ-aminobutyric acid.

TABLE 38.1. PHARMACODYNAMIC ENDPOINTS APPLICABLE TO STUDIES OF GABA-BENZODIAZEPINE AGONISTS

Pharmacokinetic and pharmacodynamic relationships initially are evaluated separately, and the relationship of effect versus concentration at corresponding times is examined graphically and mathematically. Effect measures are usually expressed as change scores: the net effect (*E*) at postdosage time *t* is calculated as the absolute effect at this time (E_t) minus the predose baseline value (E_o), that is, $E = E_t - E_o$. Several mathematical relationships between effect and concentration (*E* versus *C*), often termed "link" models, are of theoretical and practical importance (5 ,32). The "sigmoid E_{max}" model, incorporates a value of E_{max}, the maximum pharmacodynamic effect, and EC_{50} is the "50% effective concentration," the concentration that is associated with half of the maximum effect (Fig. 38.5). The exponent *A* reflects the "steepness" of the concentration-response relationship in its ascending portion. The biological importance of *A* is not established.

Sigmoid E_{max}

$$E = \frac{E_{max} \cdot C^A}{C^A + EC_{50}{}^A}$$

Exponential

$$E = m \cdot C^A$$

Linear

$$E = m \cdot C$$

FIGURE 38.5. Three mathematical relationships between concentration (*C*) and change in pharmacodynamic effect (*E*) that are commonly applied in kinetic-dynamic modeling procedures. For the sigmoid E_{max} model, E_{max} is maximum pharmacodynamic effect, EC_{50} is the concentration producing a value of *E* equal to 50% of E_{max}, and *A* is an exponent. For the exponential and linear models, *m* is a slope factor.

A concentration-effect relationship that is consistent with the sigmoid E_{max} model may be of mechanistic importance, because drug-receptor interactions often fit the same model. The E_{max} and EC_{50} values allow inferences about questions such as the relative potency or efficacy of drugs producing the same clinical effect, individual differences in drug sensitivity, the mechanism of action of pharmacologic potentiators or antagonists, and the possible clinical role of new medications.

The sigmoid E_{max} model does not necessarily apply to all concentration-effect data (32). When experimental data are not consistent with the model, the corresponding misapplication of the sigmoid E_{max} relationship can lead to misleading conclusions about E_{max} and EC_{50}. Some data sets are consistent with less complex models, such as exponential or linear equations (Fig. 38.5); in these cases, the concepts of E_{max} and EC_{50} are not applicable. Kinetic-dynamic modeling is further complicated when drug concentrations measured in serum or plasma do not reflect the concentration at the site of action, which is sometimes termed the "effect site." This is illustrated by the data described below.

Application: Kinetics And Dynamics Of Intravenous Lorazepam

In this study the benzodiazepine derivative lorazepam was administered intravenously according to a complex bolus-infusion scheme (33). On the morning of the study day, a rapid intravenous dose of lorazepam, 2 mg, was administered into an antecubital vein, coincident with the start of a zero-order infusion at a rate of 2 µg/kg/h. The infusion continued for 4 hours and then was terminated. Venous blood samples were drawn from the arm contralateral to the site of the infusion prior to drug administration and at multiple time points during 24 hours after the start of lorazepam infusion. Samples were centrifuged, and the plasma separated and frozen until the time of assay. The EEG was used as the principal pharmacodynamic outcome measure (Table 38.1). The EEG was recorded prior to lorazepam administration, and at times corresponding to blood samples. EEG data were digitized over the power spectrum from 4 to 30 cycles per second (Hz), and analyzed by fast Fourier transform to determine amplitude in the total spectrum (4 to 30 Hz) and in the beta (12 to 30 Hz) frequency range (33 ,34 and 35). Concentrations of lorazepam in plasma samples were determined by gas-chromatography with electron-capture detection.

Analysis of Data

The relative EEG beta amplitudes (beta divided by total, expressed as percent) in the predose recordings were used as the baseline. All values after lorazepam administration were expressed as the increment or decrement over the mean predose baseline value, with values averaged across eight recording sites. The EEG change values were subsequently used as pharmacodynamic effect (*E*) measures in kinetic-dynamic modeling procedures described below. For pharmacokinetic modeling, the relation of plasma lorazepam concentration (*C*) to time (*t*) was assumed to be consistent with a two-compartment model (Fig. 38.6 and Fig. 38.7).

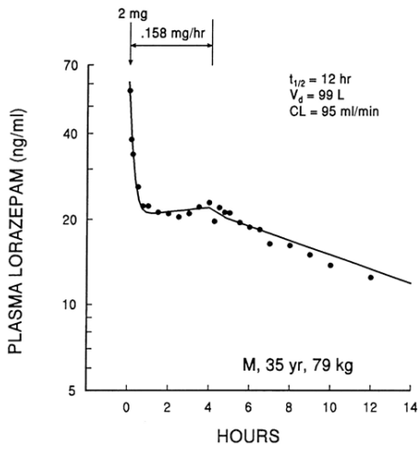

FIGURE 38.7. Plasma lorazepam concentrations (*solid circles*) together with the pharmacokinetic function determined by nonlinear regression (*solid line*), in a representative volunteer subject. Shown are the derived pharmacokinetic variables of elimination half-life ($t_{1/2}$), volume of distribution (V_d), and clearance (CL).

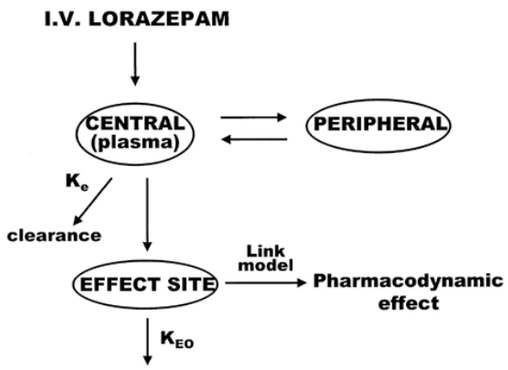

FIGURE 38.6. Schematic representation of the kinetic-dynamic model for the lorazepam study. Intravenous lorazepam was assumed to have kinetic behavior consistent with a two-compartment model: reversible distribution to a peripheral compartment, and first-order elimination (clearance) from the central compartment (rate constant: K_e). Lorazepam in plasma was postulated to equilibrate with a hypothetical effect site, from which the exit rate constant is K_{EO}. Finally, effect-site concentrations were presumed to be the principal determinant of pharmacodynamic effect, via a kinetic-dynamic link model as shown in Fig. 38.5.

Examination of plots of pharmacodynamic EEG effect versus plasma lorazepam concentration (*E* vs. *C*) indicated counterclockwise hysteresis (see below), suggesting a delay in equilibration of lorazepam between plasma and the site of pharmacodynamic action in brain. This equilibration effect has been described in previous clinical and experimental studies of lorazepam (34 ,36 ,37 ,38 and 39). Accordingly the relationship was modified to incorporate a distinct “effect site,” at which the hypothetical lorazepam concentration is C_E (Fig. 38.6). The apparent rate constant for drug disappearance from the effect compartment is k_{EO}; this rate constant determines the apparent half-life of drug equilibration between

plasma and effect site. Under these assumptions, the relation of E to C_E was postulated to be consistent with a sigmoid E_{max} model (Fig. 38.5).

Results

Kinetic variables for lorazepam were similar to those reported in previous single-dose studies of lorazepam pharmacokinetics (34 ,40 ,41 ,42 ,43 ,44 and 45). Overall mean values were volume of distribution, 1.7 L/kg; elimination half-life, 14 hours; clearance, 1.44 mL/min/kg. The bolus-infusion scheme rapidly produced mean plasma lorazepam concentrations in the range of 18 to 19 ng/mL, values close to the mean predicted value of 24 ng/mL.

Lorazepam infusion produced significant increases in EEG beta amplitude throughout the 24-hour duration of the study. The maximum change over baseline was measured at 0.25 to 0.75 hours after the initiation of lorazepam dosage, whereas the maximum plasma concentration was measured immediately after the loading dose (Fig. 38.8). The effect-site model eliminated the hysteresis, with a mean equilibration half-life of 8.8 minutes (Fig. 38.9).

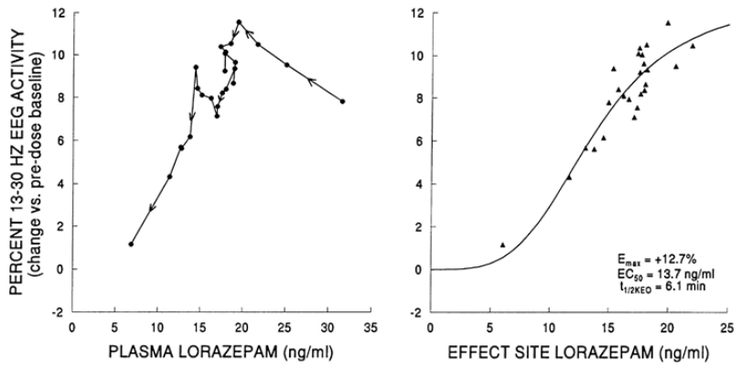

FIGURE 38.9. Left: Mean values of plasma lorazepam concentration versus pharmacodynamic EEG effect at corresponding times, with *arrows* indicating the direction of increasing time. As indicated in Fig. 38.8, the maximum EEG effect is delayed, and does not correspond in time to the maximum plasma concentration. *Right*: The scheme shown in Fig. 38.6 was applied to the data points, with the link model being the sigmoid E_{max} relationship shown in Fig. 38.5. The data points (*closed triangles*) are the hypothetical effect site concentrations and pharmacodynamic effect values at corresponding times. The *solid line* is the link model function determined by nonlinear regression, yielding the indicated values of E_{max} and EC_{50}. The overall mean equilibration half-life was 8.8 minutes.

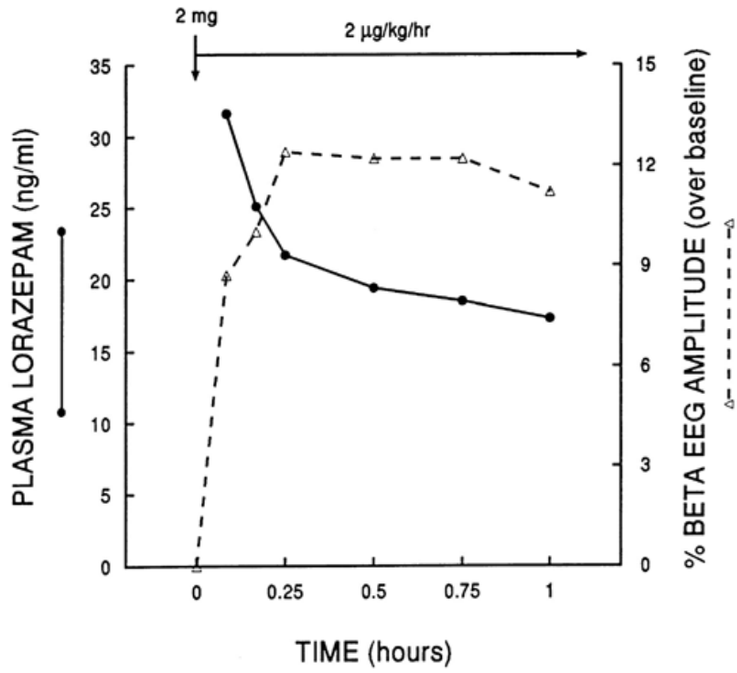

FIGURE 38.8. Mean values of plasma lorazepam concentration, and of EEG beta amplitude, during the first hour of the study. Note that pharmacodynamic EEG effects are delayed following the peak value of lorazepam in plasma.

Implications

Maximum EEG effects of lorazepam were significantly delayed following the initial intravenous bolus dose. Previous single-dose pharmacodynamic studies of lorazepam, using the EEG or other methods for quantitation of benzodiazepine

effect, consistently demonstrate a delay in attainment of maximum drug effect compared to attainment of peak concentrations in plasma (34 ,36 ,37). After rapid intravenous dosage, for example, maximum effects may be delayed for an average of 30 minutes after dosage. Experimental studies of the time-course of whole-brain concentrations of lorazepam, or of the degree of benzodiazepine receptor occupancy, indicate that the delay is attributable to the slow physical entry of lorazepam into brain tissue, probably because of the relatively low lipid solubility of lorazepam (34 ,38 ,39). The delay was mathematically consistent with a kinetic-dynamic model incorporating a hypothetical “effect site” distinct from the central compartment. The half-life for equilibration between plasma and the effect compartment was approximately 9 minutes. This matches clinical experience indicating that intravenous lorazepam cannot easily be used in situations requiring minute-to-minute titration of sedative or amnestic effects (40). Nonetheless, intravenous lorazepam can be used for the treatment of status epilepticus, although its onset of action may be somewhat slower than that of intravenous diazepam (46 ,47).

CYTOCHROMES P-450 IN PSYCHOPHARMACOLOGY: THE IMPORTANCE OF P-450-3A ISOFORMS

Part of "38 - Pharmacokinetics, Pharmacodynamics, and Drug Disposition "

The cytochrome P-450 (CYP) superfamily of drug metabolizing enzymes is now established as being of primary importance for the metabolism and clearance of most drugs used in psychopharmacology and in other areas of clinical therapeutics (6 ,7 ,8 and 9 ,48 ,49 ,50 ,51 ,52 ,53 ,54 and 55) (Fig. 38.10). For the CYP isoforms most relevant to human drug metabolism, each has its own distinct pattern of relative abundance, anatomic location, mechanism of regulation, substrate specificity, and susceptibility to inhibition and induction by other drugs or foreign chemicals (Table 38.2). The expression and *in vivo* function of at least two CYP isoforms (CYP2D6 and CYP2C19) are regulated by a genetic polymorphism, such that some members of a population fail to express “normal” levels of enzyme or expresses poorly functional protein (56 ,57 ,58 ,59 ,60 ,61 and 62). Individuals identified as “CYP2D6 poor metabolizers,” as an example, have very low clearance of drugs that are major substrates for biotransformation by CYP2D6 (such as desipramine, nortriptyline, venlafaxine, tramadol, and dextromethorphan). Such individuals are at risk for developing high and potentially toxic plasma concentrations of these

substrate drugs despite dosages in the usual therapeutic range.

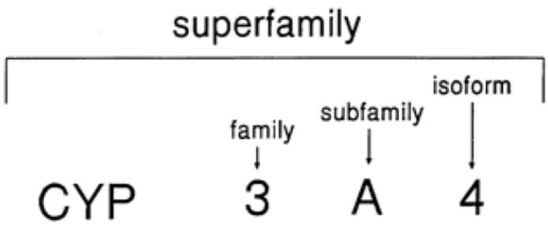

FIGURE 38.10. Nomenclature system for the cytochrome P-450 (CYP) superfamily of enzymes. Following the CYP designation, the number-letter-number sequence indicates the family, subfamily, and specific isoform.

CYP Isoform	Relative Hepatic Abundance	Genetic Polymorphism	Representative Substrates
1A2	13%	?	Caffeine, theophylline, tacrine
2B6	<1%	–	Bupropion, propofol
2C9	15%	+	S-warfarin, phenytoin, tolbutamide, NSAIDs
2C19	4%	+	S-mephenytoin, omeprazole (partial contributor to many others)
2D6	2%	+	Some psychotropic and cardiac drugs
2E1	7%	–	Chlorzoxazone, some inhaled anesthetics
3A4/5	29%[a]	–	Many (see also Table 38.3)

CYP, cytochrome P-450; NSAID, nonsteroidal antiinflammatory drug.
[a]Also present in gastrointestinal tract mucosa.

TABLE 38.2. OVERVIEW OF HUMAN CYTOCHROMES P-450

The CYP3A Isoforms

The overall importance of the CYP3A subfamily of drug-metabolizing enzymes, particularly in the field of psychopharmacology, has become increasingly evident over the last decade (6 ,7 ,8 and 9 ,63 ,64 ,65 ,66 ,67 ,68 and 69) (Table 38.3). The CYP3A isoforms are the most abundant of the CYPs, accounting on average for approximately 29% of identified cytochrome P-450 in liver (70) (Table 38.2). Within the CYP3A subfamily, CYP3A4 is the most important in the adult human, in terms of drug-metabolizing activity as well as quantitative dominance. CYP3A5, another CYP3A isoform, is also detected in varying amounts in some human livers and in esophagus, but quantities of CYP3A5 are less than quantities of CYP3A4. It is not established to what extent hepatic CYP3A5 is of clinical significance for drug-metabolizing activity. CYP3A7 is principally a fetal-specific isoform. The location and sequence of the genetic element responsible for CYP3A4 expression have been identified, as well as a regulatory segment located on the 5′ flanking region corresponding to the CYP3A gene.

Contribution of CYP3A to Net Clearance		
Complete or Nearly Complete	**Partial**	**Small**
Midazolam	Diazepam	Fluoxetine
Triazolam	Desmethyldiazepam	Sertraline
Alprazolam	Flunitrazepam	Nortriptyline
Bromazepam	Clonazepam	
Nefazodone	Zolpidem	
Trazodone	Citalopram	
Reboxetine	Haloperidol	
Buspirone	Clozapine	
Gepirone	Olanzapine	
Adinazolam	Mirtazapine	
Quetiapine	Amitriptyline	
Sildenafil	Imipramine	

TABLE 38.3. PSYCHOTROPIC DRUG SUBSTRATES FOR HUMAN CYP3A

CYP3A4 typically functions as a high-capacity, low-affinity enzyme. Its high substrate capacity is a consequence of both the relatively high value of maximum reaction velocity (V_{max}, expressed in nanomoles of product produced per unit time per milligram of protein) in a Michaelis-Menten relationship, as well as the high quantitative abundance of the protein in hepatic tissue. The low-affinity characteristic is reflected in the high K_m value (substrate concentration corresponding to 50% of V_{max}) in a Michaelis-Menten relationship. One consequence is that CYP3A-mediated metabolism usually is not “saturable” at substrate concentrations within the therapeutic range, because this range is likely to be far below the reaction K_m. Furthermore, in situations in which CYP3A is one of several cytochromes contributing to metabolism [e.g., amitriptyline *N*-demethylation (71), citalopram *N*-demethylation (72), or zolpidem hydroxylation (73)], the relative importance of CYP3A will increase at higher substrate concentrations. However, this is not invariably true. Nefazodone is a CYP3A substrate, but K_m values for production of the various metabolites are relatively low (74), and kinetics are nonlinear (75). Midazolam has a low K_m for the principal pathway (76 ,77), and there is evidence of nonlinear kinetics at higher concentrations in humans (78).

Significant quantities of CYP3A exist in gastrointestinal (GI) tract mucosa (65 ,69 ,79). The quantitative expression/

activity of GI tract CYP3A is not correlated with its expression/activity in liver, even though the expressed protein is identical at the two sites. For a number of moderate or high-clearance CYP3A substrates (e.g., midazolam and triazolam), GI tract metabolism contributes importantly to presystemic extraction (first-pass metabolism) after oral dosage (79 ,80 and 81); incomplete oral bioavailability therefore results from a combination of GI tract and hepatic presystemic extraction (Fig. 38.11). For low-clearance CYP3A substrates having oral bioavailability in the range of 80% to 90% or greater (e.g., alprazolam), the contribution of the GI tract is apparently small.

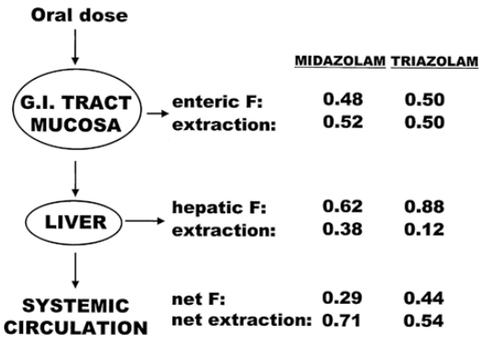

FIGURE 38.11. Relative contributions of CYP3A enzymes present in gastrointestinal (GI) tract mucosa, and in the liver, to net bioavailability (*F*) of orally administered midazolam and triazolam. Both of these compounds have net *F* values of less than 50% (29% for midazolam, 44% for triazolam). Both compounds undergo approximately 50% extraction during passage through the G.I. tract mucosa. However midazolam undergoes another 38% extraction across the liver, compared to only 12% for triazolam.

Inhibition and induction by other drugs or chemicals may modify CYP3A activity both *in vitro* and *in vivo* (Table 38.4). Identification of these compounds is of clear clinical importance, because it may allow anticipating of drug interactions that may be either potentially hazardous or of therapeutic benefit (6 ,7 ,8 and 9 ,65 ,69 ,79 ,80 ,81 ,82 ,83 ,84 and 85). Inhibiting drugs may also be used for investigating the relative contribution of CYP3A to net clearance, or for distinguishing the contribution of hepatic and GI tract CYP3A to overall presystemic extraction (81). Among the most potent CYP3A inhibitors are the azole antifungal agents (ketoconazole, itraconazole, fluconazole), the antidepressants nefazodone and fluvoxamine, and the calcium channel antagonists verapamil and diltiazem. These compounds produce “reversible” inhibition, by a competitive, noncompetitive, or mixed mechanism. Other potent inhibitors, such as the macrolide antimicrobials erythromycin and clarithromycin produce “mechanism-based” inhibition via a metabolic intermediate that complexes with and inactivates the CYP3A enzyme (86 ,87). The HIV protease inhibitor ritonavir and the nonnucleoside reverse transcriptase inhibitor delavirdine also are potent CYP3A inhibitors (88 ,89 ,90 and 91). A component of grapefruit juice inhibits CYP3A in the GI tract (92). Inducers of CYP3A include carbamazepine, rifampin, phenobarbital, nevirapine, dexamethasone, St. John’s wort, and possibly venlafaxine. Ritonavir is an inducer as well as an inhibitor, yielding a net effect on CYP3A metabolism that is difficult to predict (88 ,89 ,90 and 91 ,93 ,94 and 95).

Drug	Inhibition of:	Induction of:
Azole antifungals		
Ketoconazole	CYP3A	
Itraconazole	CYP3A	
Fluconazole	CYP3A, 2C9	
Terbinafine	CYP2D6

Cimetidine	CYP3A	
Omeprazole	CYP2C19	

TABLE 38.4. REPRESENTATIVE DRUGS HAVING CLINICALLY IMPORTANT EFFECTS ON THE HUMAN CYP ENZYMES

Variability among individuals in CYP3A activity is substantial, even when relatively homogeneous groups of healthy subjects are studied. A consistent finding in population studies of CYP3A activity is that distributions are unimodal, without evidence of genetic polymorphic regulation (96 ,97). However, several studies of CYP3A substrates have demonstrated a small number of individuals with unusually low clearance (96 ,98). The explanation for these observations is unclear, but the genomic determinants of such individual variations in clinical CYP3A activity have become

an active research topic. A number of genetic variants or single nucleotide polymorphisms in either the promoter or coding regions of the human CYP3A4 gene have recently been described (99 ,100 ,101 ,102 ,103 ,104 and 105). One of the promoter region polymorphisms, designated as CYP3A4*1B, is more prevalent in the African-American as opposed to the Caucasian populations. However, there is no evidence to indicate that any of the identified CYP3A4 variants accounts for individual variation in clearance of CYP3A substrates.

In Vitro Models of Drug Metabolism

In vitro systems now are extensively utilized to provide presumptive answers to fundamental clinical questions regarding drug metabolism and drug interactions, and to guide the planning of clinical pharmacokinetic studies (6 ,7 ,8 and 9 ,48 ,49 ,50 ,51 ,52 ,53 ,54 and 55 ,71 ,72 ,73 and 74 ,82 ,83 and 84). If drug X is biotransformed in humans to metabolite Y, two core questions occur: (a) What CYP isoform or isoforms mediate the biotransformation of X to Y? (b) What CYP isoforms do X or Y themselves either induce or inhibit?

Human liver microsomes generally are an important component of currently utilized *in vitro* systems. These preparations contain the various human CYPs in proportion to their abundance in human liver *in vivo*. If biotransformation of a specific substrate to its initial metabolite or metabolites can be replicated in microsomal preparations (Fig. 38.12), inhibition of that reaction by a relatively specific chemical inhibitor can be used as evidence supporting the contribution of the corresponding cytochrome. Chemical inhibitors can also be used in clinical studies, but the *in vitro* model has the advantages of lower cost, more rapid implementation, no risk of human drug exposure, the availability of a greater number of potential chemical inhibitors for research purposes, and the possibility of determining both the quantitative and qualitative contributions of specific cytochromes. Antibodies with relatively specific inhibitory activity against individual human cytochromes can also be used to support or confirm data from *in vitro* chemical inhibition studies (106 ,107). *In vitro* approaches have been strengthened with the availability of microsomes containing pure human cytochromes as expressed by cDNA-transfected human lymphoblastoid cells (108 ,109 and 110). These heterologously expressed pure cytochromes further support definitive identification of cytochromes mediating a specific reaction *in vivo*.

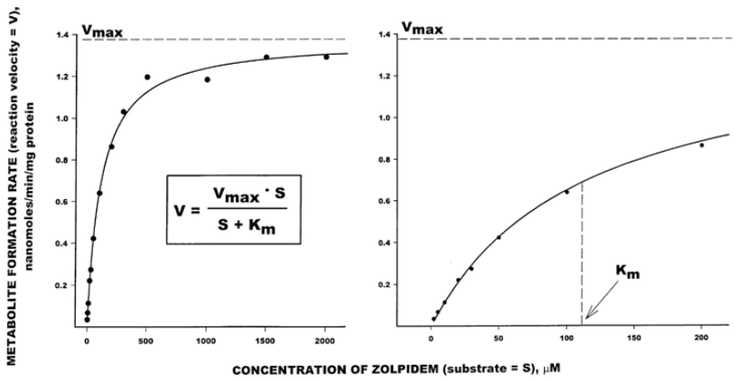

FIGURE 38.12. Example of an *in vitro* metabolism study using human liver microsomes (73). The substrate in this study was zolpidem, of which varying concentrations were incubated with liver microsomes and appropriate reaction cofactors. At each concentration of zolpidem, the rate of formation (*V*) of the principal metabolite of zolpidem (termed the M-3 metabolite) was determined. The relation between substrate concentration (*S*) and reaction velocity (*V*) was analyzed by nonlinear regression to determine the maximum reaction velocity (V_{max}) and the substrate concentration (K_m) producing a reaction velocity of 50% of V_{max}. **Left**: A substrate concentration range up to 2,000 μM. **Right**: The lower range of concentrations shown on an expanded scale.

The quantitative inhibitory potency of a series of drugs and their metabolites against specific index reactions can also be determined using human liver microsomes *in vitro* (6 ,7). The first of two general approaches uses fixed concentrations of the index substrate co-incubated with varying concentrations of the inhibitor in question. The relation of decrement in metabolite formation rate to inhibitor concentration is used to estimate a 50% inhibitory concentration (IC_{50}). This procedure is expeditious and relatively inexpensive, and the numbers can be used to compare the potency of a series of inhibitors (Fig. 38.13). IC_{50} values themselves are not dependent on knowledge of the specific biochemical mechanism of inhibition. However, IC_{50} values depend on substrate concentration when inhibition is competitive, and

can be applied to *in vitro–in vivo* scaling only when the mechanism of inhibition is noncompetitive (111 ,112). Inhibitory potency can also be estimated by determining the inhibition constant (K_i), a number that reflects inhibitory activity in reciprocal fashion. Estimation of K_i requires the study of multiple substrate concentrations and multiple inhibitor concentrations and therefore involves more work, time, and expense. The numerical value of K_i depends on the specific biochemical mechanism of inhibition, which may be unknown. Nonetheless, the inhibitor K_i, is independent of substrate concentration and can be used under some defined circumstances for quantitative *in vitro–in vivo* scaling of drug interactions. In general, K_i is always less than or equal to IC_{50}; K_i will be essentially equal to IC_{50} if inhibition is noncompetitive, or if inhibition is competitive and the substrate concentration is far below the reaction K_m. Both K_i and IC_{50} should provide similar or identical rank-order estimates of relative inhibitory potency for a series of inhibitors of a specific reaction. When the inhibition is purely competitive, K_i values for a specific inhibitor should theoretically be identical across different substrates metabolized by that particular CYP. However, this principle is not supported by experimental data, probably because of *in vitro* experimental artifacts, and because actual biochemical mechanisms of inhibition are not purely competitive. Therefore, absolute values of K_i or IC_{50} cannot be assumed to cross different substrates for the same cytochrome, although the relative rank order of inhibitory potency should be maintained.

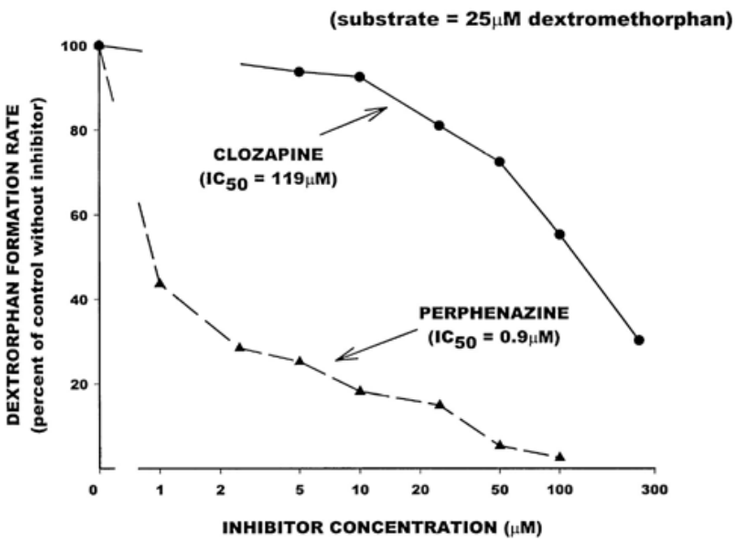

FIGURE 38.13. Example of an *in vitro* study of inhibition of CYP2D6 by two antipsychotic agents, perphenazine and clozapine. A fixed concentration of the substrate dextromethorphan was incubated with liver microsomes, appropriate cofactors, and varying concentrations of perphenazine or clozapine. Rates of formation of dextrorphan (mediated by CYP2D6) with inhibitor present were expressed as a ratio versus the control velocity with no inhibitor. The relation of the velocity ratio to inhibitor concentration can be used to calculate a 50% inhibitory concentration (IC_{50}). The results indicate that perphenazine (IC_{50} = 0.9 μM) is likely to be a clinically important inhibitor of CYP2D6, whereas clozapine (IC_{50} = 119 μM) is a weak inhibitor.

Limitations and drawbacks of *in vitro* systems should be recognized. *In vitro* studies generally utilize substrate concentrations that are one or more orders of magnitude higher than those encountered clinically, even if extensive partitioning of lipophilic drugs from plasma into liver tissue is accounted for. If mathematical models and parameter estimates are valid, the outcome of studies of higher concentrations can be extrapolated down to clinically relevant substrate concentrations. However, a clinically important “high-affinity” metabolic reaction (i.e., one with a low K_m value) could be missed if low substrate concentrations cannot be accurately measured due to limitations of assay sensitivity. The specificity of chemical inhibitor probes is of concern for *in vitro* and *in vivo* studies, because all inhibitors ultimately become nonspecific at higher concentrations. Finally, data from cDNA-expressed human cytochromes can be misinterpreted unless they are considered in the correct context. Pure cytochrome studies can yield quantitative data on the activity of one or more particular cytochromes as a mediator of a specific reaction. However, this information cannot be extrapolated to an estimate of the relative activity of different cytochromes, either *in vivo* or in liver microsomes *in vitro*, without a parallel estimate of the relative quantitative abundance of the cytochromes in question. That is, the importance of a specific cytochrome depends on both activity and abundance.

DRUG INTERACTIONS IN PSYCHOPHARMACOLOGY

Part of "38 - Pharmacokinetics, Pharmacodynamics, and Drug Disposition "

During the last two decades the general problem of pharmacokinetic drug interactions has received increased attention. New classes of medications introduced into clinical practice over this period include the selective serotonin reuptake inhibitor (SSRI) and related mixed mechanism antidepressants, the azole antifungal agents, newer macrolide antimicrobial agents, and the highly active antiretroviral therapies (HAARTs) used against HIV infection and AIDS (Table 38.4). These and other classes of medications have had a major beneficial impact on the therapy on some serious and life-threatening illnesses, but many of the drugs have the secondary pharmacologic property of inducing or inhibiting the human CYP enzymes, thereby raising concerns about pharmacokinetic drug interactions during multiple drug therapy.

One major objective of the drug development process is to generate data on drug interactions, so that treating physicians have the information necessary for safe clinical therapy involving multiple medications. However, the number of possible drug interactions is very large, and time and resources available for implementation of controlled clinical pharmacokinetic studies are inevitably limited.

Some needed studies will therefore be postponed until after a new drug is marketed, and some studies may be bypassed altogether. As discussed above, *in vitro* data are becoming increasingly important as a resource for identifying probable, possible, or unlikely drug interactions, and thereby encouraging rational planning and allocation of resources to more definitive clinical studies.

Pharmacokinetic Versus Pharmacodynamic Drug Interactions

A pharmacokinetic interaction implies that the drug producing the interaction (the “perpetrator”) causes a change in the metabolic clearance of the drug being affected by the interaction (the “victim”), in turn either decreasing or increasing concentrations of the victim drug in plasma and presumably also at the site of action. This change may or may not alter the clinical activity of the victim drug. One pharmacokinetic interaction variant involves modification by the perpetrator of the victim drug’s access to its pharmacologic receptor site, without changing the systemic clearance or plasma levels of the victim. A familiar example is the antagonism of benzodiazepine agonist activity by flumazenil; a less familiar example is benzodiazepine receptor antagonism by ketoconazole (113).

A pharmacodynamic interaction involves either inhibition or enhancement of the clinical effects of the victim drug as a result of similar or identical end-organ actions. Examples are the increase or decrease of the sedative-hypnotic actions of benzodiazepines due to coadministration of ethanol or caffeine, respectively.

Mechanisms of Inhibition Versus Induction of Metabolism

Drug interactions due to inhibition as opposed to induction of CYP-mediated metabolism involve mechanistically different processes. Chemical inhibition is an immediate phenomenon that becomes evident as soon as the inhibitor comes in contact with the enzyme, and is in principle reversible when the inhibitor is no longer present [an exception is “mechanism-based” inhibition (86)]. The magnitude of inhibition depends on the inhibitor concentration at the site of the enzyme in relation to the intrinsic potency of the inhibitor. *In vitro* systems can be used to develop quantitative estimates of inhibitory potency, such as the inhibition constant (K_i) or the 50% inhibitory concentration (IC_{50}) (Fig. 38.13). However, application of K_i or IC_{50} values from *in vitro* systems to quantitative predictions of drug interactions *in vivo* is not straightforward, and requires knowledge of the effective concentration of inhibitor that is available to the enzyme. A generally applicable scheme for relating total or unbound plasma concentrations of inhibitor to effective enzyme-available concentration has not been established. In any case, the theoretical assumption that unbound plasma concentrations are equal to enzyme-available intrahepatic concentrations is incorrect in reality, and may yield underestimates of observed *in vivo* drug interactions by as much as an order of magnitude or more (8 ,83 ,85).

Induction of CYP-mediated metabolism requires prior exposure to a chemical inducer, which signals the synthetic mechanisms to upregulate the production of one or more CYP isoforms (114 ,115 ,116 ,117 and 118). This process takes time, and the increase in CYP activity is of slow onset following initiation of exposure to the inducer, and slowly reverts to baseline after the inducer is removed. Increased CYP expression/activity due to chemical induction therefore reflects prior but not necessarily current exposure to the inducer. The extent of CYP induction probably depends on the dosage (concentration) of the inducer and on the duration of exposure. Induction, unlike inhibition, is not easily studied *in vitro*, because induction requires intact cellular protein synthesis mechanisms as are available in cell culture models.

Inducers and inhibitors of CYP3A can be expected to influence both hepatic and gastrointestinal CYP3A, although not necessarily to the same extent. Very strong inhibitors (such as ketoconazole) or very strong inducers (such as rifampin) will produce substantial changes in both hepatic and gastrointestinal CYP3A. A uniquely complex situation arises for ritonavir, which is both an inhibitor and inducer of CYP3A. Interactions of ritonavir with CYP3A substrate drugs will be time dependent. Initial exposure will produce CYP3A inhibition, but as the duration of exposure proceeds, CYP3A induction may offset the inhibitory effects of acute exposure. The net outcome typically is unpredictable and variable across individuals (93 ,94 and 95).

Perspectives on the Clinical Importance of Drug Interactions

Based on the prevalence of polypharmacy in clinical practice, noninteractions of drugs are far more common than interactions. Coadministration of two drugs usually produces no detectable pharmacokinetic or pharmacodynamic interaction, and the pharmacokinetic disposition and clinical activity of each drug proceed independently of each other. A less common outcome of drug coadministration is a kinetic interaction that could be detected in controlled laboratory circumstances, but that is not clinically important in usual therapeutic circumstances because (a) the interaction, whether or not statistically significant, is not large enough to produce a clinically important change in dynamics of the victim drug; (b) the therapeutic index of the victim drug is large enough so that even a substantial change in plasma levels will not alter therapeutic effects or toxicity; or (c) kinetics and response to the victim drug are so variable that changes in plasma levels due to the drug interaction are far less important than inherent variability. Even less common are clinically important interactions that require

modification in dosage of the perpetrator, the victim, or both. Finally, the most unusual consequence of a drug interaction is a hazardous and contraindicated combination, as in the case of ketoconazole and terfenadine. These situations are rare, but unfortunately receive excessive attention in the public media.

Many secondary sources and compendia are available as summary guides to the extensive literature on drug interactions, but these sources do not necessarily assist clinicians in deciding which interactions should generate serious concern in the course of drug therapy. A useful general guideline is that drug interactions are more likely to be important when (a) the perpetrator drug is a powerful inducer or inhibitor, and produces a very large change in the kinetics and plasma levels of the victim drug; or (b) the therapeutic index of the victim is narrow. Case (a) is exemplified by powerful inducers or inhibitors of CYP3A (ketoconazole, ritonavir, rifampin) coadministered with CYP3A substrates, or powerful inhibitors of CYP2D6 (quinidine, fluoxetine, paroxetine) coadministered with CYP2D6 substrates. Case (b) is exemplified by victim drugs such as phenytoin, warfarin, and digoxin, for which small changes in plasma levels could have important clinical consequences.

Application of Kinetic-Dynamic Methods to Study Drug Interactions

Drug interaction study protocols often incorporate pharmacodynamic endpoints to allow estimating the clinical consequences of drug interactions along with the usual pharmacokinetic outcome measures. The level of complexity of an integrated kinetic-dynamic study depends on the nature of the pharmacodynamic actions of the drug under study as well as the type of pharmacodynamic outcome measures that are required. A number of methodologic principles and dilemmas are illustrated by kinetic-dynamic design options for drug interaction studies involving sedative-hypnotic and anxiolytic drugs acting on the γ-aminobutyric acid (GABA)-benzodiazepine receptor system.

Biotransformation of the benzodiazepine triazolam is dependent on the activity of human CYP3A isoforms (119). Metabolism is strongly inhibited *in vitro* and *in vivo* by CYP3A inhibitors such as ketoconazole, itraconazole, ritonavir, and nefazodone (95 ,119 ,120 ,121 and 122). Some, but not all, of the macrolide antimicrobial agents also are CYP3A inhibitors via "mechanism-based" inhibition, in which the parent compound binds to the metabolically active site on the CYP3A enzyme, yielding a metabolic intermediate that inactivates the enzyme (86 ,87). We tested the inhibitory potency of four macrolide antimicrobial agents [troleandomycin (TAO), erythromycin, clarithromycin, azithromycin] versus triazolam hydroxylation using human liver microsomes *in vitro* (123). Appropriate mean IC_{50} values were TAO, 3.6 μM; erythromycin, 30 μM; and clarithromycin, 28 μM. These values indicate that all three compounds produce substantial *in vitro* inhibition of triazolam hydroxylation and have the potential to produce a significant interaction with triazolam *in vivo*. However, azithromycin was a very weak inhibitor of triazolam *in vitro* (IC_{50} >250 μM), and is anticipated to produce no significant interaction *in vivo*.

In a clinical pharmacokinetic-pharmacodynamic study (123), a series of healthy volunteers were exposed to the following treatment conditions:

A. Triazolam placebo plus macrolide placebo
B. Triazolam (0.125 mg) plus macrolide placebo
C. Triazolam (0.125 mg) plus azithromycin
D. Triazolam (0.125 mg) plus erythromycin
E. Triazolam (0.125 mg) plus clarithromycin

Dosage schedules of the coadministered macrolides were chosen to be consistent with usual dosage recommendations. The five trials were randomized in sequence, and the treatment conditions were double-blind.

Following each dose of triazolam (or placebo to match triazolam), multiple venous blood samples were drawn over a period of 24 hours, and multiple pharmacodynamic testing procedures were performed. Triazolam plasma concentrations were determined by gas chromatography with electron capture detection (Fig. 38.14).

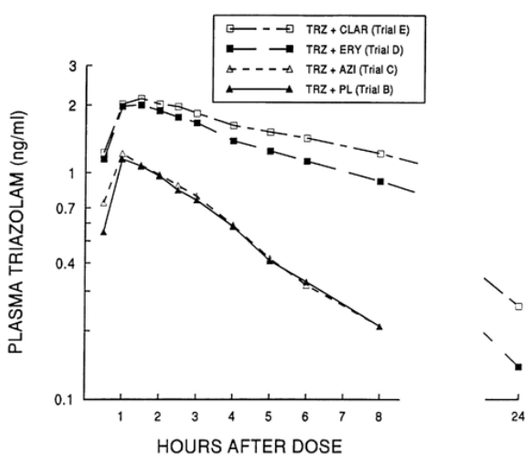

FIGURE 38.14. Mean plasma triazolam concentrations following single 0.125-mg doses of triazolam during trials B, C, D, and E. Note that coadministration of triazolam with azithromycin (AZI, trial C) produced plasma levels nearly identical to triazolam administered with placebo (PL, trial B). However, coadministration with erythromycin (ERY, trial D) or clarithromycin (CLAR, trial E) produced a large increase in plasma triazolam concentrations. (Adapted in part from Greenblatt DJ, von Moltke LL, Harmatz JS, et al. Inhibition of triazolam clearance by macrolide antimicrobial agents: in vitro correlates and dynamic consequences. *Clin Pharmacol Ther* 1998;64:278–285, with permission.)

Mean clearance of triazolam during trials B and C was nearly identical (413 and 416 mL/min, respectively); that is, coadministration of azithromycin had no effect on the pharmacokinetics of triazolam (Fig. 38.14). However, triazolam clearance was significantly reduced to 146 mL/min by erythromycin (trial D), and to 95 mL/min by clarithromycin (trial E) (Fig. 38.14). Thus the *in vivo* kinetic results are highly consistent with the *in vitro* data.

The pharmacodynamic data indicated that the benzodiazepine agonist effects of triazolam plus placebo (trial B), and of triazolam plus azithromycin (trial C) were similar to each other, and greater than the effects of placebo plus placebo (trial A). However, coadministration of triazolam with erythromycin (trial D) or with clarithromycin (trial E) augmented the pharmacodynamic effects of triazolam when compared to trials B or C. The outcome was similar whether based on subjective measures, a semi-objective measure (the Digit-Symbol Substitution Test, DSST), or the fully objective measure (the EEG) (Fig. 38.15). Kinetic-dynamic modeling indicated that the increase in benzodiazepine agonist effects of triazolam caused by coadministration of erythromycin or clarithromycin was fully consistent with the increase in triazolam plasma concentrations (Fig. 38.16).

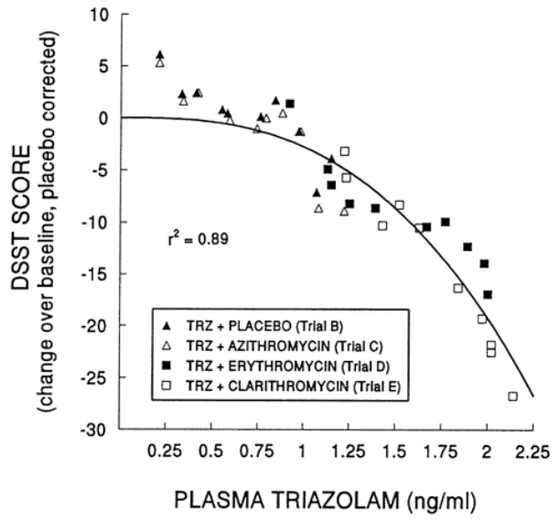

FIGURE 38.16. Relation of mean plasma triazolam concentrations to mean changes over baseline in DSST score at the corresponding times. The *solid line* represents the kinetic-dynamic model relationship based on an exponential function as shown in Fig. 38.5. (From Greenblatt DJ, von Moltke LL, Harmatz JS, et al. Inhibition of triazolam clearance by macrolide antimicrobial agents: in vitro correlates and dynamic consequences. *Clin Pharmacol Ther* 1998;64:278–285, with permission.)

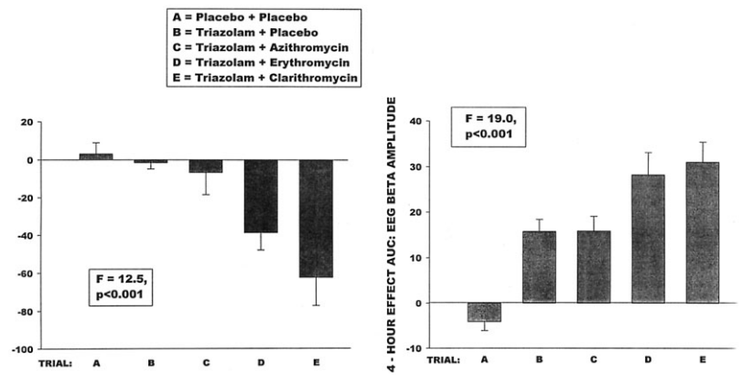

FIGURE 38.15. Mean (± standard error, SE) 4-hour pharmacodynamic effect areas for the digit-symbol substitution test (DSST) score (*left*), and for the EEG beta amplitude (*right*), during the five trials. Note that decrements in DSST score, and increases in EEG beta amplitude, were very similar between trials B and C, whereas effects were significantly enhanced during trials D and E.

COMMENT

Part of "38 - Pharmacokinetics, Pharmacodynamics, and Drug Disposition "

Pharmacokinetic drug interactions in clinical psychopharmacology are assuming increasing importance as polypharmacy becomes more common, and more drugs with enzyme-inducing or -inhibiting properties are introduced into clinical practice. Contemporary approaches to the basic and clinical investigation of drug interactions and their pharmacodynamic consequences are illustrated in this chapter. It is evident that technologic and conceptual advances in pharmacokinetics, pharmacodynamics, and drug metabolism may be usefully applied to the evaluation of drug interactions. An ideal approach would incorporate the collaborative participation of individuals representing expertise in molecular pharmacology, cytochrome biochemistry, *in vitro* metabolism, clinical pharmacokinetics-pharmacodynamics, and clinical therapeutics.

C. E. Reeder and Brian Meissner: College of Pharmacy, University of South Carolina, Columbia, South Carolina.

This chapter discusses the role of pharmaceutical outcome evaluations in mental health care. The first section discusses the importance of pharmaceutical outcome evaluations. The second section describes techniques used in economic evaluations of pharmaceuticals (i.e., pharmacoeconomic methods). The final section discusses how mental health care outcomes data may be used in practice.

WHY OUTCOMES?

Part of "39 - The Role of Pharmaceuticals in Mental Health Care Outcomes "

The idea that outcomes associated with the provision of health care are important is not new. In the 1960s Avedis Donabedian (1) presented health outcomes as changes in health status that were attributable to antecedent health care. For many years, however, evaluations of health care focused on the structure or process of care. As health care moves into the new millennium, financing of health care is evolving from individual providers being solely responsible for patient outcomes to an environment where payers, institutions, and providers are being held accountable for quality and cost of care. As financing of health care has moved to a more centralized locus of control, evaluation of outcomes has become more feasible and desirable. In a book titled *Who Shall Live*, Victor Fuchs (2) discussed three factors that can be balanced in our health care system: costs, quality, and access. Over time the pendulum swings from one to another of these dimensions. If costs containment goes too far, then quality or access may suffer. Likewise, it is possible in today's technologically driven environment to provide a level of quality that is affordable to only a small segment of our society. In an environment of limited resources and high demand for health care, a quality, cost, access trade-off is essential. The issue then becomes how do we define and measure quality so that these trade-offs can be made in pursuit of efficiency and/or equity. Many believe that quality should be defined and measured in terms of patient outcomes.
In simple terms, outcomes are the "end results." Improvement in outcomes is a primary reason for medical intervention, including use of pharmacologic therapies. There is a belief that the use of pharmaceuticals will have a positive impact on the "end results" of patient care. Historically, this belief is self-evident in the treatment of mental health disorders with the use of drugs to treat psychoses and depression—conditions for which treatment was revolutionized by pharmaceuticals (3 ,4). However, with newer, more costly pharmaceuticals, such as selective serotonin reuptake inhibitors (SSRIs) and atypical antipsychotic agents, many payers and health professionals have questioned the value that is received for the resources expended on these agents. Consequently, numerous studies have been directed at these issues. For example, SSRIs have been compared to tricyclic antidepressants (TCAs) for the treatment of depression (5 ,6 ,7 and 8). Payers are interested not only in the most efficacious antidepressant but also in which agent should be chosen as first- or second-line therapy, the appropriate course (length) of therapy, and whether initial therapy should be augmented with an additional agent (9 ,10 ,11 and 12). Given the wide variations in care and the possibility that alternative treatments could lead to similar outcomes, particularly under the less than ideal conditions of "usual care" practice, health care payers are concerned about which treatments regimens lead to the most efficient outcome. In a resource-constrained environment, it is both reasonable and responsible to ask this question:

Would the resources expended for one alternative be more efficient if devoted to another alternative? One useful way to address this question is with data on patient and cost outcomes.

There is an inextricable but sometimes complex relationship between quality of care and outcomes. Outcomes data are one way of evaluating quality. It is noteworthy, however, that establishing quality “thresholds” requires a value judgment. What is acceptable quality to one person may be unacceptable to another at any given level of cost. Outcomes data cannot provide answers to questions that require fundamental value judgments. On a macro level, an analysis using measures of quality and cost will not define the percentage of gross domestic product (GDP) that a nation should spend to achieve a certain level of quality in health care, but rather will provide tools and information to assist decision makers in efficiently allocating scarce resources. On a micro level, there is no specific quality of life score on an instrument that indicates if or when a drug product should be reimbursed. There is no single clinical measure that indicates that a patient is in perfect health. All outcomes data require the interpretation and evaluation of a medical decision maker. Outcomes data provide one more, albeit in many cases relevant, piece of information on which to base decisions.

In the previous discussion, outcomes were defined in abstract terms (i.e., changes in health status, end results). While there is an inherent belief that many pharmaceuticals improve outcomes, for outcomes to be documented and improved, this terminology must be defined in more concrete terms. One conceptualization of health care outcomes is the economic, clinical, humanistic outcomes model (ECHO) (13). This conceptualization portrays health outcomes along three dimensions. Clinical outcomes are outcomes related to the effects of medical treatments or disease on medical events such as hospitalization or death (i.e., end results). Economic outcomes are usually expressed as costs (e.g., dollars) associated with an intervention, and are often considered as ratios of costs to some measure of the consequences of a disease and its treatment. Humanistic outcomes are measures of the impact of disease or treatment on patient’s lives. In addition to these outcomes, there are many intermediate variables that are important when measuring the effects of a disease or treatment. These variables are referred to in the published literature by many names including process variables, surrogate outcomes, or intermediate variables. In many cases making a clear distinction between these consequences of pharmaceutical use is probably not necessary; however, when reviewing literature, it is important to consider whether a consequence is a “true” outcome or an intermediate variable. For example, a score on a depression inventory is probably closer to an intermediate variable, whereas events such as rehospitalization or suicide reflect the “end results” or outcomes one would like to prevent.

Mental health care is expensive. For example, it is estimated that $44 billion is spent annually on the treatment of depression and $100 billion is spent annually on the treatment of Alzheimer’s disease (14 ,15). The cost to treat schizophrenia has been estimated at $33 billion per year, accounting for 22% of dollars spent to treat all categories of mental illness and 2.5% of total health care expenditures (16 ,17). Increasing competition for scarce resources encourages decision makers to use outcomes data to evaluate the effectiveness and efficiency of treatment options for depression, Alzheimer’s disease, and other mental health disorders. These issues are not new to health care providers, but the development of drug formularies as mechanisms to control costs has generated a need for outcomes studies to evaluate the benefits obtained from new pharmacologic agents. Shortly after SSRIs were released on the market, questions arose regarding whether health care outcomes were better for patients treated with SSRIs than for patients treated with traditional TCA therapy (5 ,6 and 7). This new class of pharmaceuticals was more costly than prior standard therapy (the TCAs), prescribed for a wide variety of patients, and had (in clinical trials) fewer side effects. Although the products were shown to be superior in some domains in clinical trials, there was a practical question regarding whether these benefits were realized in real-world practice and if so, at what net incremental cost (18). Do patients treated with SSRIs consume less acute care services, require fewer specialist visits, or have lower suicide rates? Is the total cost per acute depressive episode (successfully treated case) therefore lower with the newer products despite higher drug acquisition costs? Does treatment with SSRIs cost more, but provide better humanistic outcomes such as quality of life or quality-adjusted life years? These are the types of questions that outcomes research and pharmacoeconomic evaluations attempt to answer. This chapter does not specifically address these questions, but rather uses these questions to illustrate issues in outcomes research. It is noteworthy to recognize that not all the outcome questions of interest are likely to be addressed in a single study; rather, answers will come from an evaluation of a body of literature.

Most health care professionals are familiar with the clinical aspects of the treatment of mental health diseases. Given the substantial clinical information in the remainder of this text, this chapter focuses on evaluation of the economic and humanistic outcomes related to pharmaceutical use. Specifically, the techniques of pharmacoeconomics will be reviewed as well as the instruments for evaluating humanistic outcomes in mental health care populations.

PHARMACOECONOMICS

Part of "39 - The Role of Pharmaceuticals in Mental Health Care Outcomes "

In the current health care environment, many decisions are driven by costs. At a minimum, health care systems are looking for systematic methods for reducing costs. Although

the fraction of the health care dollar spent on pharmaceuticals is low, it is clear that as both the pressure to reduce costs and the percentage of health care dollars spent on pharmaceuticals grow, so does interest in the costs of medications. Economists, however, are quick to point out that the acquisition cost of the pharmaceutical is not the most appropriate unit of analysis. It is possible that the acquisition cost of many pharmaceuticals may be offset by reductions in other more expensive forms of care. If the use of an expensive atypical antipsychotic leads to reductions in hospitalizations, then the "value" of the pharmaceutical from a total cost perspective is greater than the acquisition cost of the pharmaceutical. This is a key idea behind pharmacoeconomics. Pharmacoeconomics provides a set of techniques that allow consideration of the costs and consequences of alternative pharmaceutical therapies (19).

Studies are typically categorized by whether they consider costs, outcomes, or both cost and outcomes. In addition, studies can also be categorized by whether or not they consider alternatives. For example, traditional clinical trials focus on comparing the consequences of alternatives when one of the alternatives is typically a placebo. Although placebo comparison is highly relevant from the perspective of a regulatory agency striving to meet its special mandate, from the perspective of many health care decision makers a comparison with placebo is meaningful only if it is a relevant treatment alternative. Pharmacoeconomic studies best provide a comparison of relevant alternatives.

Studies that evaluate only cost for one alternative are referred to as cost descriptions. Other studies may also consider consequences. In these cases the study would describe both the costs and consequences of a single alternative leading to a cost-outcome description. If two alternatives are compared but only costs are considered, then the study is a cost evaluation. However, the primary concern of pharmacoeconomics is the comparison of both costs and consequences simultaneously for two for more relevant alternatives. There are four specific techniques that are typically used when conducting pharmacoeconomic studies (20):

- Cost-minimization analysis
- Cost-effectiveness analysis
- Cost-utility analysis
- Cost-benefit analysis

In each of these cases the numerators are the costs of inputs for a given decision. For example, if the total cost of care for the treatment of depression is considered, input costs might include cost of drug, cost of physician visits (family practitioner, internist, and specialist), behavioral therapy, hospitalization, and emergency department use. (Cost is discussed in greater detail below.) Next, the appropriate outcomes or consequence must be specified in the denominator.

Cost-minimization analysis assumes, not always explicitly, that the outcomes are equal. If this is a valid assumption, then the decision is based entirely on the costs of the inputs. The classic example of a cost minimization analysis is the use of generic versus branded products. If the chemical entities and formulations are identical, then there is no reason to suspect that the outcomes associated with the use of either product would be different. In this case, the decision is based solely on the costs of the inputs. The difficulty with cost-minimization analysis is establishing that outcomes are equal. Even in the case of generic pharmaceuticals there are examples where alternative formulations have been questioned. Additionally, products may be equivalent on some outcomes such as clinically significant improvement in depression, but not with regard to others such as side-effect profiles.

Cost-effectiveness assesses the consequences in natural units. These natural units may include outcomes such as years of life saved, hospitalizations avoided, or scores on a symptom scale. Jonsson et al. (21) used the Mini-Mental State Examination as a mechanism to assess time in a nonsevere disease state. This information was incorporated into a Markov state transition model to compare the cost-effectiveness of newer medications for the treatment of Alzheimer's disease to standard care. In many cases it is possible to develop several cost-effectiveness ratios for a comparison of relevant treatment alternatives. For example, in a comparison of atypical and conventional antipsychotics, cost-effectiveness ratios such as cost per hospitalization avoided, cost per symptom free day, or cost per schizophrenic exacerbation might all have meaning.

A recent cost-effectiveness study for the treatment of depression provides an excellent example of how decision makers can utilize these tools to best allocate scarce resources. Nuijten and colleagues (8) developed a Markov process to model the cost-effectiveness of long-term treatment with a new antidepressant compared to standard treatment with TCAs. The outcomes were time without depression, direct costs, and indirect costs (lost workdays). Clinical data were obtained from the published literature and costs were measured from the perspective of the German health care system. The new antidepressant was found to be associated with a 1.5 months longer time without depression than the TCA and with less cost to the health care system. In this case the new drug was less costly and more effective; thus by definition it is a more cost-effective choice.

Cost-utility analysis is a special case of cost-effectiveness analysis, in which the denominator is quality-adjusted life years (or something conceptually similar). The quality-adjusted life year may, for example, be calculated using patient utilities (from zero to one) for being in a given health state (or series of health states) and multiply them by the number of years of life expected in each health state. This analysis benefits from combining length of life with quality of life. For example, people using different antipsychotic medications may have similar life expectancy. However, if patients taking some antipsychotics have fewer side effects or greater

efficacy, they may experience an improved quality of life. As a result, the quality of the remaining years of life may not be equal for the two treatments. Cost-utility ratios factor this quality difference into the analysis. A typical ratio presented for cost-utility analysis is a cost per quality-adjusted life year (QALY).

Cost-utility analyses have the ability to compare QALYs over multiple treatment regimens. Revicki et al. (22) completed a cost-utility analysis in a managed care setting and compared outcomes of two SSRIs, a TCA, and a stepped approach that began with a TCA that was replaced with an SSRI if the TCA treatment failed. The outcomes measures were lifetime medical costs, QALYs, and cost per QALY gained. The analysis for a base case found that lifetime medical costs ranged from $15,348 to $16,669 per patient, that QALYs gained ranged from 14.32 to 14.64, and that cost per QALY gained ranged from $2,555/QALY to $6,346/QALY. The model allowed certain factors, such as compliance, to be varied.

The final pharmacoeconomic method is cost-benefit analysis. Cost-benefit analysis values the denominator in dollars and calculates a return on investment. Cost-benefit analysis allows comparison of alternatives that lead to dissimilar outcomes. Should a hospital open a gift shop or provide a vaccination program for influenza? The answer would be provided in the following terms: for every dollar invested in a gift shop, there is a return of $1.13; for every dollar invested in a vaccination program, there is a return of $1.25. Thus the vaccination program would be the more attractive investment. A disadvantage of cost-benefit analysis is that it requires all consequences to be valued in dollars. For example, suppose use of a medical alternative increases survival by 1 year. How do you put a cost on 1 year of life? In health care, valuing in dollars such consequences as life years gained and disability days avoided may be considered difficult or unacceptable by many people.

These four methods form the cornerstone of pharmacoeconomics. There are, however, many issues that affect the conduct and interpretation of pharmacoeconomic analyses. Some of the principal issues are discussed in the following sections.

Costs

Valuation of costs in pharmacoeconomic analyses can be difficult. There are two primary issues: first, which costs should be included in an analysis, and second, how should those costs be valued. The costs of inputs in a pharmacoeconomic analysis typically include direct medical costs, direct nonmedical costs, and indirect costs. Direct medical costs include costs such as physician visits, hospitalization, emergency department use, and pharmaceuticals. Examples of direct medical costs associated with the treatment of Alzheimer’s disease include diagnostic tests, medications, and efforts to monitor or treat side effects, acute hospital care, physicians’ services, home health care, and nursing home care (23 ,24). In other words, direct medical costs include any costs that are directly related to medical treatment. Direct nonmedical costs include items such as cost of transportation to the doctor’s office and cost of child care while the parent is hospitalized. An example of a direct nonmedical costs for the treatment of Alzheimer’s disease is in-home day care (25). Examples of indirect costs are costs that arise from lost work or lost patient or caregiver productivity. In conducting a cost analysis, the first challenge is to decide which costs are relevant for the comparison. The issue of perspective (who pays?) becomes critical. Once this hurdle has been cleared, then the issue arises of how costs will be assigned. For example, if prescription costs during hospitalization are included in a pharmacoeconomic analysis, how should the basis for costs be established? Should it be based on actual acquisition costs, charges, or cost-to-charge ratios as a percentage of the entire hospital bill? Clearly, these types of valuation decisions need to be disclosed and discussed in pharmacoeconomic studies.

Analyzing the results of pharmacoeconomic studies requires the evaluator to assess the types of costs included in each study. Large variations in results can be attributable to different cost components (25). In the medical treatment of Alzheimer’s disease, the acquisition cost of the medication is only a small percentage of the total cost. One major component of treating Alzheimer’s disease is the indirect costs absorbed by family members. Researchers encounter difficulties in estimating the cost of such informal care. As a result, investigators may account for those costs absorbed by family members in different ways, which may contribute to varying conclusions (26).

There may also be intangible costs. These costs include things such as pain and suffering. Intangible costs are even more difficult to value in monetary terms. In diseases where intangible costs are significant, it is important to recognize whether any effort has been made to account for these costs. In many cases they are not included. Additional analysis may need to be considered to make fair decisions.

One mechanism to quantify intangible costs is a willingness-to-pay approach. O'Brien et al. (27) performed a willingness-to-pay evaluation in a group of patients with mild to moderate depression. The study was designed to compare a new antidepressant with TCAs. The drugs had similar efficacy but different adverse event profiles. Participants were asked to rank a series of adverse effects and then to quantify the maximum amount they would pay for a new drug that reduced each adverse event. On average, participants were willing to pay an additional $14 per month to reduce the risk of blurred vision from 10% to 5%. When asked their willingness to pay to avoid multiple simultaneous side effects, the range was $23 to $77 per month.

If costs, or benefits, are analyzed over time periods that exceed 1 year it is necessary to apply discounting. Discounting costs is a concept that reflects the “time value of money.”

A dollar today is worth more than a dollar received in the future. Discounting reduces the value of dollars that will be realized more than a year in the future to reflect a present value. A similar concept applies to health benefits.

Perspective

One of the major factors that influences pharmacoeconomic analyses is the perspective taken when conducting the analysis. Using the earlier cost example, if a study is conducted from the perspective of a hospital, the use of actual costs may be appropriate. However, if the same study were conducted from the perspective of a managed care organization, charge data may be more relevant. The perspective of a pharmacoeconomic analysis should always be disclosed in a publication. Given that there are many possible perspectives, it is insightful to evaluate studies from a broad perspective. The societal perspective is the broadest and takes into consideration all costs and consequences relevant to society. For various reasons, this perspective is often used as a "reference case," to permit comparisons across studies that may otherwise use differing perspectives. When measuring the impact of pharmaceuticals on mental health disorders, the perspectives of both society and providers are important (14 ,28 ,29). Because of the desire to serve the needs of health system decision makers, the perspective taken in many studies is that of the payer. A substantial number of patients prescribed antipsychotic medications have their health care paid by Medicaid (30). Therefore, the perspective of Medicaid is important when evaluating the cost of schizophrenia treatment. The payer perspective, however, may not include all costs relevant to society. For example, lost productivity may not be relevant from the Medicaid perspective. It is critical that the study perspective is disclosed when a pharmacoeconomic analysis is published or evaluated. Generalizing results from a specific setting to a different setting is unwise because the relevant costs and outcomes vary between settings.

CONDUCTING PHARMACEUTICAL OUTCOMES RESEARCH

Part of "39 - The Role of Pharmaceuticals in Mental Health Care Outcomes "

There have been several texts and journal articles describing the steps for conducting pharmaceutical outcomes research and pharmacoeconomics (19 ,20). This section does not reproduce these lists of steps, but rather presents some of the issues from these materials that are pertinent to the evaluation of mental health applications.

Decision Analysis

Decision analysis is a systematic approach to structuring decisions over time. Decision trees are developed with branches representing alternative decisions or probabilistic relationships. For example, a decision may involve a choice between two drugs. These drugs may either have side effects or not, and treatment may be either successful or not successful (Fig. 39.1).

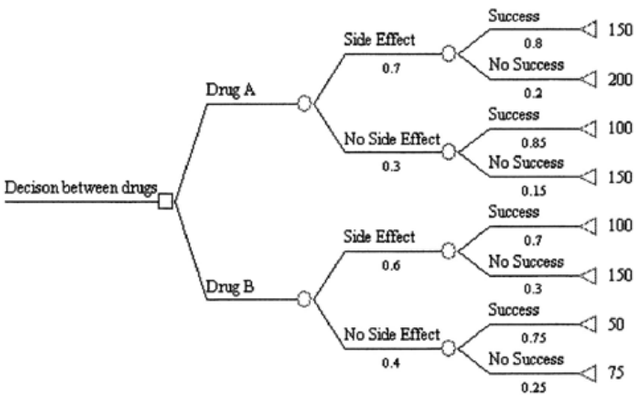

FIGURE 39.1. Example of a decision tree.

For any of the nodes where a chance relationship exists (represented by circles), the probabilities associated with that event are shown (e.g., the probability of a side effect associated with drug A is 0.7). When the outcomes are valued in dollars (i.e., the cost of following a particular path), the expected values that are calculated from a decision tree analysis can provide cost estimates that are used in the numerator of a pharmacoeconomic ratio. Expected values are calculated by summing the product of the probabilities and the costs. The expected values are shown in Fig. 39.2 .

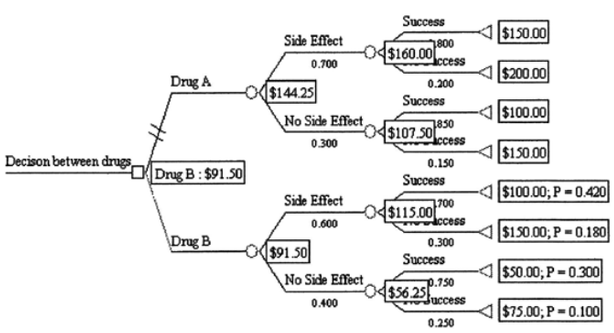

FIGURE 39.2. A solved decision tree.

In this case, assuming that the cost at the end of each branch represents the total cost of care for the selected drug, the expected costs associated with the use of drug A is $144.25 and $91.50 for drug B. If outcomes were assumed to be equal (i.e., cost-minimization) then the least expensive alternative would be drug B. However, outcomes are not equal. As can be seen from the decision tree, the probability of success while using drug A is greater than for drug B. If the path probabilities for the successful branches are summed for each alternative, it can be seen that the probability of successful treatment with drug A is 0.815, and the probability of successful treatment with drug B is 0.720. Therefore, the total cost of treatment while on drug A is higher, but so is the effectiveness (i.e., chance for successful treatment). The real question is one of cost-effectiveness. Is the additional cost of drug A worth the additional benefits? This would be assessed with an incremental cost effectiveness ratio:

$$\text{Incremental cost effectiveness ratio} = \frac{\text{Cost of Drug A} - \text{Cost of Drug B}}{\text{Effectiveness Drug A} - \text{Effectiveness Drug B}}$$

$$\text{Incremental cost effectiveness ratio} = \frac{144.25 - 91.50}{0.815 - 0.720}$$

$$\text{Incremental cost effectiveness ratio} = \$555.26/\text{each additional successful case}$$

Is an additional successful case worth paying an additional $555.26? This is a value judgment that depends on the situation surrounding the decision. Again, outcomes research does not answer the question regarding which product should be used; it simply provides information regarding the efficiency with which these two products produce a desired outcome.

This method, while powerful, is often limited by the availability of data to drive the model and the forced simplification of models, which often results from limited driving data. It is important when reading published modeling exercises such as decision trees or Markov models to evaluate them carefully, as results are highly dependent on the specifics of the structure selected (and how closely it reflects clinical reality) and on the data selected for input. The latter problem can and should properly be addressed by sensitivity analysis, for which there are several techniques. The former problem can be tested by the careful evaluation of experts or the demonstrated ability of a model to predict measurable outcomes, a relatively uncommon exercise in pharmacoeconomics.

In general, the reader should look for some effort to discuss or examine “parameter” uncertainty, “model structure” uncertainty, and “model process” uncertainty. With regard to parameter uncertainty (the term *parameter* refers, for example, to estimates of probabilities or cost or health outcome), univariate analysis alone is often inadequate, and some attempt at multivariate evaluation is desirable. There are different formal approaches to evaluation of cost-effectiveness uncertainty using either frequentist or Bayesian approaches to generation of confidence (or “credible”) regions, including simulation and the delta method. Model structure uncertainty refers to the separate uncertainty about the manner in which parameters should properly be combined (e.g., Are effects linear or nonlinear fashion? Are effects additive or multiplicative?). An approach to evaluation of this kind of uncertainty is to simply examine results for different plausible alternatives. Model process uncertainty refers to the fact that different analysts may come to different conclusions due to a spectrum of differences in approach. There are other key methodologic pitfalls in proper conduct of studies of this type (e.g., adhering to use of incremental cost-effectiveness ratios), a fact that highlights the need for readers to evaluate each study carefully.

The purpose of this discussion is not to fully explain the sometimes complex process of conducting a decision analysis, but rather to suggest the usefulness of this tool in outcomes research. It is also to encourage the reader to develop the critical skills necessary to evaluate studies of this type, much as similar skills have been developed for evaluation of ordinary controlled clinical trials. The reader is referred to *Clinical Decision Analysis* by Weinstein and Fineberg (31) for a more complete description of the process of conducting decision analyses, and to *Cost-Effectiveness in Health and Medicine*, edited by Gold (32) for in-depth discussion of many important issues in cost-effectiveness analysis.

In a final example, we refer to a study using decision analysis to permit evaluation of a systematically developed time-ordered series of events. It incorporates previously published clinical trial data into a model to estimate long-term effects. In this study, Dardennes et al. (33) developed a decision analysis model to compare outcomes and costs of treating major depression with an SSRI, a TCA, or serotonin norepinephrine reuptake inhibitor (SNRI). The perspective of the study was that of a national health care system, and the clinical outcomes data used in the model were derived from published meta-analyses. The analysis found that the SSRI and TCA had comparable efficacy but dissimilar tolerance profiles and that the SNRI had both efficacy and tolerance advantages compared to the SSRI. Direct cost data (hospitalization, medication, physician visits, and laboratory tests) and the efficacy data from the model were entered into a decision tree. The decision tree analysis provided estimates of the expected cost of treatment per

depressive episode that could be used by the health service in its treatment approval process.

Data Sources

Data for pharmaceutical outcomes studies can come from several sources. Many pharmaceutical companies routinely include pharmaceutical outcome (other than just clinical) measurements in their development trials. In addition, postmarketing studies with direct comparisons to relevant alternatives (i.e., intended to serve the needs of pharmaceutical users rather than regulators) are becoming more common. However, conducting single studies that contain all pharmaceutical outcomes of interest for a given product are expensive, and data collection of all relevant information is difficult. Therefore, many pharmaceutical outcome studies contribute to the body of knowledge by evaluating components of the overall picture. Additionally, many pharmacoeconomic analyses are based on models. These models typically use published literature, expert opinion, or data from administrative or encounter databases to get information on probabilities and costs.

The impact of this component approach to building an understanding of pharmaceutical outcomes is that data come from many sources ranging from experimental and nonexperimental research designs to expert opinion and models based on data from multiple and frequently diverse sources. Therefore, when reviewing pharmaceutical outcomes research, it is critical to understand the potential impact of the source of information on the results.

A frequent source of outcomes data in mental health research is randomized clinical trials conducted by the pharmaceutical industry. These trials, however, are often placebo controlled and typically contain (as expected) mostly clinical information. In mental health, however, patient self-reported items (i.e., humanistic measures) are frequently included. There are also many studies that rely on chart review and quasi-experimentation to document differences in resource use for patients using various pharmaceutical agents. Examples include recent comparisons of tricyclic antidepressants and SSRIs, and atypical versus conventional antipsychotic agents. Many of these studies were retrospective and were conducted through chart reviews or administrative data using quasi-experimental techniques. Finally, economic models have been built using published data or expert opinion, where data were not available.

Historically, randomized controlled trials have been the “gold standard” (5). Studies of this type allow the efficacy and safety of a drug to be established. Unfortunately, some of the strengths of such studies can also be a source of less commonly recognized weaknesses. This is a result of the artificial treatment environment purposefully created in efficacy trials, and may be particularly an issue in mental health because of the wide gap recognized to exist between the “optimal” care provided in such trials and the realistic patterns of care experienced by most patients. The primary care provider deals with other issues that influence the effects of a medication such as side effects, dose titration, and out-of-pocket expenses. As a result, real-world effects can be difficult to extrapolate from ordinary clinical trials. This issue is discussed further below. Randomized trials failed to differentiate the SSRIs and TCAs, except for their side-effect profiles. However, SSRIs may have some advantage over TCAs in the primary care practice setting (6 ,28 ,29). In summary, data for building evidence about the value of pharmaceutical outcomes in mental health has been drawn from a number of sources using a variety of experimental and nonexperimental designs. Each of these sources of data and type of experimentation affect the degree of evidence obtained. Review of pharmaceutical outcomes research in mental health care requires careful consideration of the source and strength of the evidence presented.

HUMANISTIC MEASURES

Part of "39 - The Role of Pharmaceuticals in Mental Health Care Outcomes "

Humanistic measures assess how disease or treatment affects patients. Humanistic measures are most important from the perspective of the patient. A primary goal for treatment of any disease should be for patients to function normally, have an acceptable quality of life, and be satisfied with their treatment. This is especially true for mental health disorders where impacts on both physical and social functioning may be significant. In many cases, patients and their friends and families might best judge the success of treatment. Until recently, humanistic measures have taken a back seat to traditional clinical measures and to some extent economic measures. This is in part due to greater variability from patient self-reported measures compared to standard clinical measures (34). The development of valid and reliable instruments is a relatively recent phenomenon. The most common conceptualization of humanistic outcomes used in the evaluation of pharmaceuticals is health-related quality of life.

Health-related quality of life encompasses factors such as functional status, physiologic status, social and emotional well-being, and life satisfaction (35). Health-related quality of life information allows health care providers and payers to make decisions based not only on clinical effectiveness, or costs but also on effects that are important to patients. Measurement of health-related quality of life may be especially important in chronic diseases for which we have no cure. There are many humanistic measures available for assessing mental health disorders. Generic and disease-specific instruments are available for a variety of disorders. Discussion of every instrument is not feasible; however, a few examples are provided.

Generic instruments are global in content and cover a number of dimensions relevant to overall health-related quality of life. One of the most widely used generic health-related

quality of life instruments is the Medical Outcomes Study Short Form 36 (MOS SF-36). The MOS SF-36 captures eight dimensions of health-related quality of life: physical functioning, role limitations due to physical functioning, bodily pain, general health, vitality, social functioning, role limitations due to emotional problems, and mental health (36).

A modified version of the Sickness Impact Profile has also been developed for use in patients with mental illnesses.

Disease-specific health-related quality of life instruments focus on dimensions that are most relevant to the particular disease and are therefore more sensitive to subtle changes in the disease or its treatment. Examples of disease specific instruments used in schizophrenia include the Quality of life Scale (37), the Social Performance Schedule (38), and the Quality of life Interview (39). Several review papers have been published on the use of quality of life instruments in mental health conditions (40 ,41 and 42). These articles highlight that quality of life measurement in mental health conditions, and in particular specific drug comparison, is a developing science. Many of the available studies are observational or cross-sectional. However, quality of life measurement is increasingly being built into clinical trials. There continues to be debate regarding mental health patients' ability to complete quality of life questionnaires, highlighting the importance of population-specific assessment of instrument validity and reliability. However, several articles have shown that it is possible for patients with severe mental health problems to successfully complete these forms (43 ,44). Lenert's group (45) has shown that even when posed the conceptually challenging task of the standard gamble, patients with mental illness have been able to perform adequately. It is important to note that although agreement is not universal, there are many researchers who believe that in principle the best source for measuring patients' quality of life or preferences is the patients themselves whenever such measurement is possible. Much has been published on this subject and in particular on the issue of whose values to use in creation of reference case analyses (to be used for comparisons across studies). But rarely is the view of the health care provider or other proxy considered superior to that of either the patient or of society in general.

Health-related quality of life has many applications in the treatment of mental health disorders. For example, Simon et al. (46) completed an analysis that evaluated clinical effectiveness, health-related quality of life, and economics of treating depression. The study took place within a staff model HMO and utilized net costs. Patients starting new antidepressant therapy were randomized to an SSRI or TCA for 24 months. The primary care providers were allowed to adjust doses and medications or discontinue medications as they deemed appropriate. The quality of life outcome was measured using the Medical Outcomes Study SF-36 Health Survey at 6, 9, 12, 18, and 24 months. The results indicated no significant difference in quality of life or severity of depression when comparing treatment groups (46). Other studies have evaluated health-related quality of life in the treatment of depression and utilized similar generic rating scales (47).

Numerous Alzheimer's disease–specific quality of life tools are available. However, there is a lack of understanding of how to quantify changes in scores. It is important to note that the cognitive impairment of Alzheimer's disease at times requires the administration of the tool to a care provider. The tools assess functions such as daily activities, memory, emotional well-being, and other aspects such as finances (48).

One other area of humanistic measurement concerns the relationship between humanistic and economic outcomes. Cost utility analysis uses patient preferences in the form of utilities to combine cost information with patient preferences. Utilities are usually measured by three techniques: rating scales, the standard gamble, or time trade-off technique (49). Utility scores differ from quality of life measurements. While some quality of life instruments can be used to capture utilities, most cannot. Utilities are a measure of overall patient well-being that lie on a scale between 0 and 1. Utilities typically measure the difference in patient's preferences between perfect health and impaired health states. At present, utilities have been measured for only a few health states. Unfortunately, utility values are difficult and expensive to measure. They require detailed patient interviews with large numbers of subjects with and without the disease. Additionally, there are many questions about patient's ability to give reliable and valid responses. While these techniques have been used in mental health care, more widespread use is dependent on the development of reliable and valid measures of utility or preference for alternative health states in mental health diseases.

USING OUTCOMES DATA IN PRACTICE

Part of "39 - The Role of Pharmaceuticals in Mental Health Care Outcomes "

The use of outcomes data in practice is not about applying the results of a single study. Instead, using outcomes data typically requires synthesis across a body of literature. Outcomes data, and in particular economic and humanistic data, offer additional pieces of information that should be incorporated into decisions. Economic, clinical, and humanistic data are all needed to make fair evaluations of pharmaceutical products and services. In reality, however, decisions will be made even if all these data are not available.

Uses of outcomes data in practice include reimbursement decisions, internal practice decisions, external or regulatory decisions, and marketing of pharmaceutical products. Pharmacy and therapeutics committees are using outcomes data as a component of the formulary decision. Where these decisions were once made almost entirely on clinical parameters, the use of economic and humanistic data is becoming more common.

In practice, the use of terminology such as evidence-based medicine or treatment guidelines has its roots in outcomes evaluations. The evaluation of a body of literature to make decisions about best practice is the goal of evidence-based medicine. Evidence-based medicine involves explicit use of what can be identified as the best evidence in making decisions about the care of both individual patients and populations of patients (Fig. 39.1) (50). This philosophy extends into treatment guidelines that are often established by expert panels that have reviewed the available evidence in the literature regarding effectiveness of alternative treatments. While these efforts rely most heavily on clinical information, economic and humanistic data are being included in these considerations.

Outcomes data is beginning to be considered in the accreditation of health care organizations. Although the measures currently used are more process than outcomes oriented, the evolution toward outcomes can be seen. The National Committee for Quality Assurance (NCQA) conducts accreditation of managed care organizations and has a specific program for behavioral health accreditation. NCQA also sponsors the Health Plan Employer Data and Information Set (HEDIS) report, which is a set of standardized performance measures designed to assist consumers with decisions about purchasing health care coverage. HEDIS 2000 includes several measures relative to mental health care. These measures are organized into several categories. Under the effectiveness of care category, two measures are included: follow-up after hospitalization for mental illness, and antidepressant medication management. In the use of services category, mental health care related measures include mental health utilization, inpatient discharges and average length of stay, and mental health utilization–percentage of subjects receiving services. These measures are evolving to require managed care organizations to consider the outcomes of care they provide. As HEDIS measures continue to evolve, they are expected to raise the quality of health care.

Some of the more sophisticated users of outcomes data may be pharmaceutical companies. Most major pharmaceutical manufacturers are investing resources in departments that focus on the collection and analysis of outcomes data for their products. Although these data are frequently used in the marketing of pharmaceutical products, they are also providing information about the developing science of outcomes measurement.

Efficacy and Effectiveness

The evolution of the use of data for decision making is interesting. Health care organizations have evolved from requiring evidence of efficacy to effectiveness to efficiency. *Efficacy* is defined as how well an intervention can ideally work. This is characterized by the types of ordinary clinical trials that are commonly performed for regulatory purposes. This type of trial generally creates what is believed to be ideal conditions of treatment and limits treatment to optimal patients, conditions that can be difficult or impossible to duplicate in regular practice. Blind, prospective randomization of an adequate number of patients to a study in which outcomes are assessed by raters blind to treatment is intended to minimize observer bias and confounding, and maximize internal validity. Accordingly, clinical trials are excellent for providing confidence that there is a causal relationship between drug use and the measured endpoint. Once confidence in this relationship is established, however, questions of use in the real world arise, which beg the question of effectiveness. Efficacy results, generally using highly select, often healthier, patient populations (not least because informed consent is required) under different practice conditions (tertiary vs. primary care, frequency of follow-up, compliance issues, insurance issues, dosing/titration regimens, etc.), may simply not predict patient outcomes in usual practice. This leads to the question of *effectiveness*, defined as the extent to which health improvements are achieved in real practice settings. Does a pharmaceutical product work under real-world conditions? Is it really influencing outcomes that are important to patients, payers, and clinicians? An experimental research approach to the question of effectiveness is a type of trial referred to variously as “pragmatic trials” or “effectiveness trials.” Such trials employ random treatment assignment to address confounding, but sacrifice a degree of internal validity in an effort to increase generalizability to the real world. This necessitates, for example, inclusion of as many patients as possible (minimizing exclusions), using ordinary practice settings, avoiding protocol-mandated interference in patient care, and permitting the effects of cost and payment mechanisms. The application of this useful type of trial in mental health has been described, but rarely implemented (51). Alternatively, nonexperimental research designs (e.g., cohort studies, retrospective database analyses, etc.) can often shed light on real-world outcomes when a clinical trial is impractical for reasons such as sample size, informed consent, duration of follow-up, etc. Usually, such studies must take special care to address issues of bias and confounding. When real-world data from either effectiveness trials or nonexperimental research are not available, as is often the case, the evidence basis for mental health decision makers is limited to either attempting to generalize from efficacy data or relying on some form of expert opinion.

The increasing expenditures associated with mental health disease states require decision makers to evaluate the full impact of treatment alternatives. The evaluation should include the appropriate variables to fully evaluate patient outcomes (including quality of life); an adequate evaluation of all relevant costs, which permits capture of potential offsets of simple drug acquisition costs; and consideration of issues of efficacy vs. effectiveness. The tools of pharmacoeconomics

and outcomes research provide decision makers with a mechanism for attempting to quantify and balance these factors to assist in the allocation of scarce mental health resources.

CONCLUSION

Part of "39 - The Role of Pharmaceuticals in Mental Health Care Outcomes "

Measurement of economic, clinical, and humanistic outcomes is an important tool for establishing the value of competing mental health care programs and treatments. Ultimately, measures of quality of care in relation to commensurate costs should aid decisions about which programs to implement and which treatments to reimburse. Although no single study is likely to provide an answer, careful evaluation of the economic, clinical, and humanistic outcomes literature may assist decision makers in making more informed decisions. Many of the economic and clinical studies conducted to date use descriptive designs or apply modeling techniques based on the best source of available data. As the science behind outcomes measurement evolves, the level of sophistication of the information provided will improve. Information on treatment outcomes can contribute significantly to decisions that affect the quality of care received by mental health patients.

Issues in Clinical Trial Designs

John M. Kane

J. M. Kane: Department of Psychiatry, Hillside Hospital, Glen Oaks, New York; Department of Psychiatry and Neuroscience, Albert Einstein College of Medicine, Bronx, New York.

The introduction of the randomized, double-blind, clinical trial was one of the major advances in the development of medical science. In the arena of psychotropic drug development this approach has proven to be of enormous value in advancing a field in which laboratory tests and strictly objective methods for diagnosis and outcome assessment are not currently available.

Designing trials in the treatment of schizophrenia highlights some of these challenges. Schizophrenia is a complex illness affecting to varying degrees a range of functions, including cognition, affect, behavior, mood, and motivation. The fact that this disorder affects so many different domains, varying from individual to individual, and to some extent within individuals over time, makes development of pharmacologic treatments even more challenging. Although there are core features of schizophrenia that involve perception (hallucinations), cognition (attention, working memory, etc.), motivation (avolition), inferential reasoning (delusions), and affect (blunted or inappropriate), there is no pathognomonic sign or symptom of the disease. This has important implications for the diagnostic process, which is also complicated by the fact that the evaluation of some core features (e.g., hallucinations and delusions) relies solely on subjective reporting, the accuracy of which is potentially influenced by the very symptoms themselves as well as by other social situational and personality variables.

In addition, the fact that such an array of domains and functions is disturbed in this illness creates a challenge for drug development. The tendency has been to conduct an array of assessments to evaluate drug effects in a number of domains concurrently, when in fact different domains may require different study designs, patient selection criteria, durations of treatment, etc. In the future, more attention will be given to those issues, and it is possible that multiple treatments will be studied rather with the goal of finding combinations able to improve outcome across a variety of domains. It is hoped that new treatments will be developed with a focus on specific domains such as negative symptoms and cognitive dysfunction. Although a better understanding of basic mechanisms should facilitate further treatment advances, our current knowledge of pathophysiology remains limited. Advances in imaging techniques and pharmacogenomics are also important potential developments on the horizon that could have enormous impact on drug development and clinical evaluation.

Each area of psychotropic drug development has its own challenges in terms of rates of spontaneous remission, placebo response, patterns of relapse, domains of assessment, etc., but, in general, challenges of design and methodology involve issues that cut across the diagnostic domains.

DESIGN ISSUES

Part of "40 - Issues in Clinical Trial Designs "

There are a number of critical issues in general design that need to be addressed in both the individual study as well as the particular program of drug development. A drug development program needs to be comprehensive as well as adaptive so that early results can inform subsequent evaluation. Although even when a drug is marketed there are still limitations in the amount of knowledge available to clinicians, several fundamental questions should have been at least partially addressed: (a) What benefits are likely to result from the drug? (b) What are its risks? (c) What dosage is indicated? (d) How does the new drug compare to alternative treatments? (e) Are there specific patients most likely to benefit from the drug?

There are a number of specific concerns that should be addressed when designing clinical trials of psychotropic drugs. Some of the most salient issues include dose finding; efficacy vs. placebo; efficacy vs. a standard reference compound; acute and long-term adverse effects; continuation and maintenance treatment efficacy; and relative efficacy or adverse effects in specific subgroups (e.g., early-phase illness, late-phase illness, refractory patients).

Dose-finding tolerability studies involving antipsychotic medications generally call for involvement of target patient populations earlier in the process than with other classes of drugs because it is difficult to ethically justify administering

these drugs to healthy volunteers for more than a week or two, and patterns of tolerance may be quite different in patients versus healthy volunteers.

It is not always possible to accurately predict clinical dosage requirements from preclinical studies; therefore, it is important to establish a full range of tolerable dosages in order to provide an appropriate range for efficacy studies. Drug development programs have been delayed and at times abandoned because of inadequate dose-finding efforts in the early stages of development (1). In addition, it is not unusual for dosage recommendations to change after a drug is marketed.

It is also important to have sufficient data on absorption, elimination, metabolism, and drug–drug interactions, to inform trial design.

Treatment trials generally fall into three broad categories: acute, continuation, and maintenance (or relapse prevention). Sometimes attempts are made to study two or even three phases in the same trial, but controversy surrounds the need to rerandomize patients before drawing conclusions about relative efficacy in maintenance-phase treatment. Patient characteristics may vary somewhat in terms of desirability within specific trials, but overall the following issues should be considered.

Patient Characteristics

It is important to be clear on whether or not patients are in a state of acute relapse or exacerbation as opposed to partial remission or a “stable plateau” of chronic symptomatology. At times investigators will withdraw patients from ongoing treatment in order to transition them to a clinical trial, resulting in some symptom exacerbation. The importance of these different approaches is that they may result in patients with very different degrees of drug responsiveness, different patterns of baseline symptomatology, and varying degrees of “stability” in baseline symptomatology.

The ideal sample of patients is probably those who have not already been partially treated so that the full degree and time course of response can be determined. However, given the way that subjects must be ascertained and recruited for trials, it is likely that some treatment will have already been administered. The fact that participants have been partially treated or are in a chronic symptomatic state does not necessarily preclude the detection of a subsequent, clinically significant drug effect, but it is likely that the nature and magnitude of the effect will be altered.

The subjectivity of many components of symptomatology in psychiatric disorders creates special challenges. Given the fact that many symptoms are subjective and cannot be confirmed or quantified using objective measures, the assessment of baseline status can be difficult. Clinicians are particularly familiar with patients suffering from psychoses who are more open and explicit about pretreatment psychopathology once they begin to improve. Some patients may not appear eligible for a trial or be willing or able to give informed consent until they are partially treated.

A variety of subject characteristics should be considered in terms of inclusion and exclusion criteria. Specific decisions will be influenced by the nature and goals of the particular trial.

Age is often a basis for exclusion (either too young or too old). Age can certainly affect pharmacokinetics of particular drugs. The elderly are more likely to have comorbid medical conditions and be more sensitive to some adverse effects, and there are a variety of issues when young patients are included in trials. These and other factors have led to a paucity of subjects at the extreme age ranges in clinical trials. However, there has recently been increased recognition of the need for more early data on diverse age groups, and mechanisms are being implemented to encourage their inclusion in clinical trials.

Gender can be an important variable, and women are often underrepresented in clinical trials.

Ethnicity may have implications for drug metabolism and tolerance. In addition, as pharmacogenomic strategies are developed to extend clinical trial data, more accurate documentation of race will be critical.

Marital status can be a proxy for psychosocial adjustment and illness course, and may therefore be of prognostic significance.

Weight and body mass index have become an increasing concern from a public health standpoint and because of the considerable weight gain observed with some psychotropic drugs and in particular several new-generation antipsychotic medications (2).

Diagnostic subtype can be important in helping to characterize those patients most likely to benefit from specific treatments. Duration of illness and the duration of the current episode can be important in helping to define populations in terms of drug responsivity as well as long-term course and outcome. A particular problem in many trials is categorizing patients’ histories in terms of drug responsiveness. A current episode duration of more than 2 or 3 weeks could suggest that the patient is poorly or only partially responsive to the treatments that have already been administered, or, alternatively that some other factor is complicating treatment response (e.g., noncompliance, comorbid conditions, etc.). It can often be difficult to time the onset of illness or of a specific episode. As putative novel compounds are developed, it may become increasingly important to test these agents in patients who have not already been chronically exposed to other medications.

The specific type and severity of signs and symptoms required for entry into a trial will vary depending on the overall goals. Usually a minimal threshold of severity is established for core symptoms of interest. It is hoped that studies will also focus on patients selected on the basis of significant residual or secondary symptoms if they are associated with subjective distress and/or functional impairment.

If trials are designed to focus specifically on patients who were nonresponders or intolerant to other treatments, explicit criteria should be developed to identify such groups. There is debate as to whether or not a prospective trial is necessary to confirm treatment refractoriness, but this is certainly the most conservative approach because it also addresses to some extent the potential change in treatment milieu and attention resulting from participation in a research trial. In addition, there is enormous variability in the quality of retrospective assessment of treatment response.

Drug washout is a challenge in acutely ill patients. If some exacerbation in symptoms occurs, this complicates establishment of a baseline as well as adding to ethical concerns and management issues. On the other hand, absence of a washout means a true “baseline” is not achieved, assuming that there has been some degree of response and or adverse effects from the prior treatment. The use of a concurrent placebo group in the treatment trial mitigates these concerns to some extent, but does not eliminate them entirely. The type, dosage, and half-life of prior treatments will influence how long a washout is necessary to prevent potential withdrawal effects from influencing baseline ratings. Whether or not a washout takes place (and how long it is) can have implications for assessing the effects of subsequent treatment. The effects of withdrawal are neither consistent nor predictable, which complicates establishment of an appropriate baseline.

Premorbid social adjustment is a variable that does have prognostic significance, particularly in schizophrenia. Poor adjustment is associated with poorer outcome, and may be an indicator of those patients in whom early neurodevelopmental abnormalities or prodromal symptoms were more severe.

Comorbid psychiatric disorders should be evaluated and documented. Though there are insufficient data to determine what influence comorbid conditions are likely to have on overall response to psychotropic medications, common comorbid conditions should be studied at some point to help assure generalizability and to inform clinical practice. In addition, some studies tentatively suggest that different medications may have more or less impact on measures of, for example, substance abuse, suggesting that this could also be an important outcome measure in appropriate populations.

In studying antipsychotic medications it is important to document the presence and severity of any preexisting movement disorders in order to have an adequate baseline assessment and to ensure that a preexisting condition (or withdrawal effect) is not attributed to subsequent treatment.

It is essential that patients be assessed for their capacity to give informed consent. It is beyond the scope of this chapter to discuss this in great detail, but patients should be able to describe and explain in their own words the research in which they are agreeing to participate, its goals, its experimental aspects, and its potential risks and benefits. They must understand that they have the right to withdraw at any time and that they will not be penalized in any way if they choose to do so.

Trial Design

One of the most critical and difficult aspects of trial design is weighing and balancing what is ideal and what is feasible. An ideal trial for which patients cannot be recruited or in which they cannot be retained will not achieve its goals. In addition, though many questions ultimately need to be addressed, it is usually impossible to adequately address multiple questions in a single trial.

The duration of a trial will be influenced by whether or not a placebo group is included. The longer the duration, the more difficult to justify the retention of patients on placebo, and the higher the dropout rate, the less useful are the data.

The time course of response to psychotropic medication is generally variable. The modal time frame of response has to be factored into trial design in order to allow estimates of statistical power. In the acute treatment of schizophrenia, for example, most patients will experience at least half of the ultimate degree of improvement within the first 4 to 6 weeks (assuming that there was not an inordinately long titration phase). In many studies a significant drug effect is seen after only 1 to 2 weeks; however, different signs and symptoms are likely to have a different time course of response. For example, agitation is likely to respond more rapidly than delusions or thought disorder. In addition, there may be a subgroup of patients who are slower to respond, and for such patients longer trials may be needed. If a between-drug comparison of the full extent of response is ultimately important, then much longer trials are needed (e.g., 6 months or longer), and this begins to encompass the continuation phase of treatment. As more and more domains of outcome are of interest in clinical trials (such as primary negative symptoms or cognitive dysfunction in schizophrenia), it will be important to better characterize the time course of response for these variables in order to establish minimum and optimum durations of trials for these purposes. Estimates of expected degrees of improvement in various domains will be critical for statistical power calculations.

The Role Of Placebos

The decision as to whether or not to use a placebo in short-term, acute trials remains a topic of considerable controversy, and some dynamic tension continues to exist between “regulatory” requirements, investigators, institutional review boards, patients and families, and other interested parties. There are a number of important arguments that can be made against the routine use of a placebo in clinical trials. Rothman and Michels (3) argue that when an effective

treatment exists for a particular disease, the use of a placebo is inappropriate on both logical and ethical bases. However, the argument suggests that the use of a placebo is appropriate in cases when an effective treatment is not available. A problem remains in how to define effectiveness. The use of the term *effective* in this context is not necessarily identical to the current use of *effectiveness* as differentiated from *efficacy*.

In a complex disease such as schizophrenia, we continue to struggle with establishing the most meaningful definitions of efficacy and effectiveness. If we define response narrowly in terms of positive symptoms, then certainly some response to conventional agents is expected. In the case of severe deficit symptoms or in patients who have proven refractory to other drugs, the issue is less clear.

A particular problem arises when response to a proven effective treatment (or so-called gold standard) can vary enormously from trial to trial and in some cases be rather low, or when response to a placebo is generally high (4).

The argument is often made that in developing new drugs to treat a condition for which effective treatments are already available, the question should not be is the new drug superior to placebo but rather is the new drug superior to an already available agent. Unfortunately, given the nature of the diseases and the adverse effects associated with some psychotropic drugs, a new drug could be superior in one domain and inferior in another, while being a very valuable addition to the therapeutic armamentarium. The use of placebo controls can still be important to determine whether or not in some domains a drug is inferior, but still better than a placebo, or whether its inferiority in one domain is such that it would change the overall effectiveness equation.

To provide an example, suppose drug A were somewhat less effective than drug B in controlling acute symptoms, but some patients did quite well on drug A. At the same time, drug B was associated with serious side effects that might result in a substantial number of patients discontinuing the medication within a short period of time. Would we prefer to have drug A available to treat those patients who benefited from it, while then giving drug B to those who don't. Before approving drug A, we would want to be certain that it was superior to a placebo, though inferior to drug B in the particular domain of acute response.

There are a host of issues relating to the use of placebos that have been discussed in more detail elsewhere. As Lavori (5) has emphasized, the data sets available from current placebo-controlled trials are usually "heavily truncated, differentially by treatment groups, and certainly nonrandomly." He argues that most investigators "use ad hoc statistically unjustifiable maneuvers such as last observation carried forward (LOCF)" and that "the interpretation of positive results in the context of badly truncated data requires unverifiable assumptions, external to the observed data of the study."

Another important consideration in the use of a placebo is the potential harm resulting from a delay in instituting active treatment. This is a difficult question to adequately address; however, there have been some attempts to examine the consequences, both short- and long-term, of receiving a placebo in the context of short-term trials. Overall, there do not appear to be demonstratable deleterious effects of participating in short-term trials (6 ,7). The issue of lengthy delays (i.e., 6 months or longer) in implementing treatment has been a topic of discussion in first-episode schizophrenia patients, with some authors suggesting that the longer duration of untreated psychosis is associated with poor outcome. In one patient cohort, this effect was reported in short-term outcome (8), but the effect was no longer evident in long-term follow-up (9). Short-term clinical trials usually involve durations of 4 to 8 weeks. Therefore, it is important to recognize potential differences in consequences between brief delays and relatively long delays in treatment. Lavori (5) argues that because assessments in placebo-treated patients are usually truncated because of high dropout rates, we do not know the full consequences of exposure to a placebo. The field would certainly benefit from more intent-to-treat analyses as well as long-term follow-up of patients who were involved in placebo-controlled trials.

Designs involving the treatment of patients who have failed on other treatments are another challenge. One could argue that placebo controls are more acceptable in this context because there is no effective treatment. However, it is usually the case that these patients have demonstrated some benefit from standard, albeit inadequate, treatment. Therefore, the appropriate comparison would be the new treatment versus standard treatment, with the only outcome of interest being the superiority of the former.

The decision as to whether or not to use placebo or active controls or both in a particular trial is not an easy one. There are complex issues that need to be considered, and it is hoped that further knowledge involving the determinants of heterogeneity in response will facilitate more rational and acceptable trial designs (10).

A related problem is the use of rescue medication. Balancing the desire to retain subjects and the desire to prevent harm and not withhold effective treatment is a critical issue. To what extent should other medications be available for those participants who would otherwise be dropped from a trial due to lack of efficacy and need for alternative treatment? Extensive use of rescue medication can make it difficult to accurately assess the drug effect (even though use of rescue medication can be a telling outcome in and of itself). The use of adjunctive medication to treat adverse effects that occur in the course of a trial can also be a concern (e.g., the use of antiparkinsonian medication). Here, too, rates of utilization can be an important outcome measure, yet at the same time the additional medication might have other undesirable effects (e.g., cognitive impairment).

A number of novel designs have not been widely used, and to some extent there is a disincentive to utilize them, particularly in a regulatory context.

Crossover designs have been suggested as one alternative, although some exposure to a placebo is still involved. A patient receives a potentially active compound and if response occurs, crossover to a placebo takes place. If response does not occur, the placebo phase is not required. The placebo phase in this context helps to determine whether or not the response to medication was a true drug effect or not. It is argued that this design has the advantage of each patient serving as his or her own control, allowing all patients to eventually receive active medication and increasing statistical power.

The applicability of this design varies depending on the nature of the disorder being studied, the time course of response, and the vulnerability to relapse or symptom exacerbation once active treatment is replaced by a placebo. For example, this design may be more informative in rapid cycling bipolar patients (11) than in the context of an acute treatment trial in other disorders. Also, this trial does not eliminate exposure to a placebo. From an ethical standpoint, how do we weigh the delay in providing active treatment against the withdrawal of effective treatment once a response occurs, with the outcome of interest being an exacerbation of symptoms?

Other alternative designs include adaptive allocation strategies. The intent of this approach is to reduce the number of subjects exposed to placebo, ineffective, or toxic treatments. This is achieved by altering the probability of a participant's receiving one treatment or another based on the probability established to that point in the trial of which treatment is associated with the best outcome. These designs are difficult to conduct, and they require knowledge of the results of completed subjects in order to allocate treatment for the next subject. In addition, the response criteria have to be clearly established a priori. The design becomes more complicated when three or more arms are included in a trial. Some studies have utilized such designs with success (12). The ultimate goal of reducing the number of subjects exposed to inferior treatments can be achieved; ultimately, however, the number of subjects required will depend on the effect size of interest. (For further discussion see ref. 13 .)

Active Controls

Comparisons between experimental treatments and active controls require careful consideration in terms of specific drugs, dosage, adverse effects profiles, titration requirements, etc. If a dose of the comparator is too low, efficacy could be less than possible, and if the dosage is too high, then adverse effects may occur more often. This issue is often a particular concern in industry-sponsored studies, where marketing issues often influence the choice of comparator and even its dose. This highlights the potential value of studying a range of doses of both the comparator and the experimental drug. Though this is costly, the information can be particularly valuable in informing clinical practice. Unfortunately, this is rarely done (14). To some extent, this results from unfounded assumptions that we have good data on dose-response relationships with drugs that have been in widespread use. Often that is not the case. In addition, dosage requirements will vary depending on the population. For example, in schizophrenia, first-episode patients in general respond to lower doses than multiepisode patients, and acute treatment usually requires higher doses than maintenance treatment.

Another design that is being increasingly utilized is the adjunctive or add-on strategy. This is particularly useful when subjects with partial or inadequate response are the focus of interest. Rather than switching participants from the unsatisfactory treatment to a new treatment, participants are randomized to an added placebo or added experimental treatment. In this approach, no drug withdrawal is necessary and the question of interest is whether or not the new treatment provides additional benefit.

The potential disadvantages of such a design include drug–drug interactions, particularly if a novel effect is anticipated from the adjunctive treatment. Will this be influenced by the original treatment (e.g., different receptor binding profiles)? This approach is particularly relevant when monotherapy is the exception rather than the rule. This type of design has been employed in the development of anticonvulsant medications (15).

Continuation Treatment

After improvement in acute symptomatology, there is a period of consolidation and stabilization often referred to as the continuation phase. It is assumed that discontinuation of medication during this period would be associated with a higher risk of relapse than subsequent discontinuation. It is difficult to specify when the transition from continuation treatment to maintenance (or prophylactic) treatment occurs, but at least 6 months is a reasonably conservative threshold. The question arises as to how to characterize those patients who have experienced clinically significant improvement, but continue to have more than mild symptoms. In such patients, the continuation phase could become indefinite rather than transitioning to maintenance treatment. This is a semantic distinction because the goal of maintenance treatment is to prevent a relapse or reexacerbation of psychotic signs and symptoms.

A continuation versus discontinuation design can be a sensitive test for drug effect. However, ethically, consent and protection issues are a major concern when any degree of worsening becomes an outcome measure. If such designs are considered, strategies such as sequential analyses or planned interim analysis would be important in terminating the study at the earliest appropriate time.

Maintenance Treatment

In any potentially recurring or chronic illness, the issue of long-term treatment is critical (15). Clearly, the more information on natural history and untreated course that is available from whatever source, the better in helping to define the goals and objectives of maintenance treatment. However, as is often the case, long-term outcome data in such a context are likely to be unavailable, and when comparisons are made with historical data there have often been changes in diagnostic criteria, ascertainment techniques, or other factors that would limit generalizability.

In considering the role of maintenance treatment, frequency, severity, and potential consequences of relapse are critical. Is maintenance treatment justified if a relapse is unlikely to occur for several years? This will be influenced not only by the consequences of a potential relapse, but also by the potential consequences of the prophylactic treatment itself.

In this context, the appropriateness both from a scientific and ethical standpoint of including a placebo control is an enormous concern. The fact that relapse rates on active medication and placebo can vary enormously from one study, one site, or one population to another is an important consideration. Some would argue that an active comparison involving an experimental medication could result in as many or more relapses than could occur in a placebo-controlled trial given the sample size needed to avoid a type II error. Concerns similar to those raised previously apply here as well in terms of multiple domains of outcome and benefit-to-risk ratio. If drug A had a significantly higher relapse rate than drug B but was much safer and more likely to be taken on an ongoing basis, would this drug be utilized if it were shown to be superior to a placebo? How much worse than standard treatment and how much better than placebo would a drug have to be in order to decide one way or the other? This is an unresolved issue in terms of regulatory, scientific, and ethical concerns.

Many of the issues raised previously in the discussion of acute treatment apply here as well. Patient characteristics, age, sex, ethnicity, age at onset of illness, duration of current or most recent episode, baseline psychopathology, comorbid conditions, etc. are all important issues. Even premorbid psychosocial adjustment has been shown to have some predictive power in relapse prevention studies in schizophrenia (8 ,17).

Issues such as reference comparator, dosage, route of administration, concomitant treatments (both pharmacologic and nonpharmacologic), a priori relapse or exacerbation criteria, duration, and strategies to enhance and measure compliance are all important in designing such studies.

The duration of such trials is critical in achieving overall goals. Results can be quite different during the first year of maintenance treatment as compared to the second, with relapse rates often being higher in the first year following recovery from an acute episode as compared to the second year (18). At the same time, in some studies involving dosage reduction, relapse rates were higher in the second year than in the first (19).

This discussion also relates to the issue of time course of relapse in establishing appropriate durations for maintenance trials. In schizophrenia, for example, based on historical data most relapses do not occur for several months after complete drug discontinuation in stable outpatients. One context where time course of potential noncompliance and time course of relapse was such that trial designs were probably inadequate to find meaningful differences was in the comparison of oral and depot medications. A number of double-blind controlled trials were conducted in which patients were randomly assigned to depot or oral medications and therefore had to receive both injections and tablets, one of which was a placebo. The duration of all but one of these trials was 1 year. In general, they failed to find the significant differences that had been expected given high rates of noncompliance in schizophrenia and high rates of relapse following drug discontinuation. However, meta-analysis of these studies supports the value of long-acting injectable preparations (20).

It is likely that the less than expected effects were due to an inadequate duration. Given the fact that subjects agreeing to receive both injections and tablets in a double-blind design are on the more compliant end of the spectrum, one would not expect noncompliance to occur rapidly. In fact, it could take many weeks or months, particularly given the frequent assessments and the psychosocial support involved in being part of a research project. Because the relapse that ensues after complete discontinuation of medications is not likely to occur for several months, it would be unrealistic to expect to observe a difference between depot and oral medication in such a study if the duration was only 1 year (21). The only such study that lasted 2 years found no difference between treatments in the first year, but evidence of clear separation in the second (22). However, the sample size was inadequate to have sufficient statistical power to establish a significant difference, even in the second year.

The role of nonpharmacologic treatments and environmental factors in long-term studies is also important. There is clear evidence that application of nonsomatic interventions can have significant impact on relapse rates among individuals receiving pharmacotherapy. Although ideally nonpharmacologic treatment should be controlled, if it is not there should be documentation of availability and utilization so that potential confounds can be identified.

Another important issue in the design of maintenance trials is whether or not rerandomization following recovery from an acute episode is necessary to demonstrate efficacy in the maintenance phase. In some drug development programs, those patients who respond in the context of an acute trial will be followed and relapse rates reported in comparison to a reference drug. This design provides data

from only those patients who responded to each drug acutely. The argument is made that to demonstrate efficacy in relapse prevention, patients should be rerandomized or the study should be started after patients have been stabilized on any drug. This then allows conclusions to be drawn regarding prophylactic efficacy among patients in general, not just those who responded to an acute trial of a particular drug. (In addition, it is important to recognize high rates of attrition for other causes in acute treatment trials.) This is not to say that there is no value in collecting long-term continuation data on a particular medication, because these data are important in setting the stage for subsequent evaluation and comparisons.

As more domains of interest are examined in schizophrenia, it is necessary to consider the specific designs required to establish efficacy and particular outcome measures. In recent clinical trials, attempts have been made to collect data on an array of measures when at times important confounds can compromise interpretation. For example, in schizophrenia, primary negative symptoms are difficult to study in the context of an acute treatment trial that has selected patients on the basis of having clinically significant positive symptoms. Trials need to be conducted in patients selected on the basis of having residual negative symptoms not complicated by acute positive symptoms or significant extrapyramidal side effects. Remarkably few such studies have been done.

Similar concerns surround the issue of cognitive dysfunction. Newer antipsychotics show some promise in improving measures of cognitive function (23). However, studying these measures requires designs specific to their optimum assessment. In addition, the ultimate question in measuring cognitive performance will be what impact these changes have on functioning, either psychosocial or vocational, level of care, family burden, etc. To date, such studies have not been conducted, and it is premature to conclude that measurable differences on specific cognitive tests will translate into meaningful differences in functioning.

SELECTION OF PARTICIPANTS IN CLINICAL TRIALS

Part of "40 - Issues in Clinical Trial Designs "

The issues discussed in the previous paragraph serve as examples of how patient selection becomes a critical focus in expanding our knowledge of specific drug effects.

Effectiveness Research

Increasing attention has been focused on the fact that traditional randomized clinical trials often include highly selected patients who may not be representative of the population at large. As new medications are used in routine clinical practice, there is often a considerable gap in the knowledge base needed to inform decision making. For example, many patients with schizophrenia have comorbid conditions (e.g., substance abuse) that could influence dosing patterns, adverse effects, overall response rates, compliance, drug interactions, etc. The pharmaceutical industry does not necessarily have an incentive to conduct effectiveness research, as the narrowly defined clinical trial is the most useful and probably cost-effective approach to the drug approval process. In addition, including patients with comorbid psychiatric and medical conditions can potentially increase rates of apparent adverse effects where attribution can be difficult.

At the same time, mechanisms should be sought for conducting effectiveness trials, which are extremely important in informing clinical practice and public policy decisions.

Approaches to Subject Selection

Diagnosis and Phenomenologic Characterization

At present, diagnostic classification is an important element in patient selection. Although nosology shifts over time, it is important to incorporate into the selection criteria the use of an established diagnostic system with proven validity and established reliability. Ideally, research should involve a more systematic and formal diagnostic process than simply relying on a hospital chart diagnosis. Formal evaluation instruments are available for specific diagnostic systems. Although the use of the complete interviews may be overly time-consuming and not cost-effective for some types of research, at minimum a checklist indicating how patients met specific diagnostic criteria should be completed.

As discussed previously, diagnostic subtype has not been a consistent predictor of drug response; however, as classification systems improve and, it is hoped, subtypes become more meaningful, this element will have increasing importance in clinical trial design.

Because many psychotropic drugs are effective across a range of illnesses, a phenomenologic approach to characterizing pharmacologic effect could be reasonable. Although issues of reliability and generalizability would have to be carefully addressed, it is hoped that further research will lead to advances in this perspective.

Biological Classification

Although diseases such as schizophrenia have been characterized by a broad array of biologic abnormalities, there are as yet no well-validated biological classification systems that have proven to be useful in clinical trials or in drug development. This may be largely due to lack of systematic effects in this direction rather than an absence of potentially informative relationships. As further advances take place in diverse perspectives ranging from neuroimaging to pharmacogenomics, it is just a matter of time before biological classification becomes a critical ingredient in this context.

At present, many of the findings are based on group differences and are not necessarily appropriate as selection criteria for clinical trials. In addition, a variety of concerns including sensitivity and specificity will need to be addressed in further developing this perspective.

PHARMACOKINETIC ISSUES

Part of "40 - Issues in Clinical Trial Designs "

The more knowledge available about pharmacokinetics and metabolism (including activity of metabolites) before large-scale clinical trials are designed, the better. Understanding potential relationships between blood levels and therapeutic response as well as adverse effects can be very helpful in optimizing treatment outcome. However, relevant data are often inadequate before critical decisions about dose and dosing schedules are made. If more attention were given to these issues earlier, clinicians would have to struggle less with establishing appropriate treatment strategies. Advances in brain imaging have set the stage for useful investigation during early stages of drug development; however, here, too, few systematic efforts have been made to take advantage of the potential of such studies to help establish optimum strategies for clinical trials.

Clinicians value the availability of different delivery methods for psychotropic medications, given the challenges of both acute and long-term treatment. Oral, liquid, intramuscular, and long-acting forms should be developed and tested in clinical trials as early as possible. Different clinical trial designs may be necessary with different preparations intended for different levels of acuity or phases of treatment. Here, too, the more information available about pharmacokinetic and pharmacodynamic issues, the better.

Given the heterogeneity of clinical response and the enormous variability in drug absorption and metabolism, randomly assigning patients to different plasma levels of interest can be a powerful tool in establishing dose-response relationships and optimum dosing guidelines. Though more difficult than the standard trial, such studies are feasible, but rarely done (24).

ASSESSMENT OF THERAPEUTIC EFFECTS AND CLINICAL CHANGE

Part of "40 - Issues in Clinical Trial Designs "

There are many established instruments for the assessment of psychopathology in clinical trials. In some cases, these instruments have been utilized for many years. However, there continues to be a dearth of new scale development. This is partially due to the tedious nature of the development process and the reluctance of many sponsors of clinical trials to utilize a new instrument. As new drugs are developed with potentially different spectrums of activity, it would be useful to have new scales designed to be sensitive to specific therapeutic effects. This is particularly appropriate since many of the original assessment scales were validated by proving sensitive to the effects of specific classes of psychotropic medications. (For detailed discussions of specific instruments for clinical assessment see ref. 25 and ref. 26 .)

As outcome measures of interest become more broad, an array of separate supplemental instruments are being employed to measure quality of life, social and vocational adjustment, cognitive functioning, and substance abuse. In designing assessment batteries, it is important to choose instruments with proven reliability and validity as well as instruments that are likely to be sensitive to the kind of treatment effect being measured. Meaningful clinical effects should be identified with specific measures of change in order to ensure that the sample size provides adequate statistical power.

As increasing numbers of assessments are employed, it is also important to recognize the burden created for patients and raters. Careful thought should go into selecting the most informative measures and planning a data analysis program with a priori primary and secondary hypotheses.

PROBLEMS IN ASSESSMENT

Part of "40 - Issues in Clinical Trial Designs "

Because psychiatric disorders are often complex, multifaceted diseases and some key symptoms are purely subjective, the techniques used for assessment can be critical. Information regarding psychopathology is most frequently obtained from direct patient interview and observation, though information from other sources (e.g., family, nurses) is sometimes used. Patient report can be impeded by intentional concealment, lack of insight, paranoid ideation, and the overall acuity and severity of the illness. It is not uncommon for psychiatric patients to reveal more psychopathology as they begin to respond to treatment than they did prior to its initiation. The reliability and validity of different sources of information in assessing specific domains have not been adequately studied. In many trials assessors who are not familiar with the patient on an ongoing basis are asked to rate psychopathology. Although these ratings can be sensitive to treatment effects, it is likely that a person who has ongoing contact with the patient in a treatment context will provide a more accurate assessment. Here, too, research comparing different rater allocation strategies would be helpful in determining which is most valid and cost-effective. It is critical to have the same rater evaluating the patient throughout the trial whenever possible. Despite establishing high degrees of interrater reliability, this kind of continuity is important.

The timing of assessments and the time frame chosen for a given assessment should be determined by the goals in the study. In general, when rating psychopathology, the previous week is a reasonable time frame. Patients are less likely to accurately recall specific symptoms that are more

remote in time. The time frame used for a particular assessment does not need to coincide with the interval between assessments. In a long-term trial it is not necessary to rate patients weekly. But when they are assessed, the previous week can be the focus of the assessment.

ASSESSMENT OF ADVERSE EXPERIENCES

Part of "40 - Issues in Clinical Trial Designs "

The two major goals of drug development—to enhance therapeutic efficacy and to improve tolerability—go hand in hand, particularly in the case of psychotropic medications, where many side effects of psychotropic drugs overlap clinical signs and symptoms of psychiatric illnesses. Given the frequent long-term nature of psychotropic drug treatment, adverse effects become critical in influencing compliance and determining the overall benefit-to-risk ratio.

In general, the methods for detecting adverse events have been given far less attention than the methods for evaluating efficacy. Controversy exists as to the most valid means of accurately estimating the incidence of adverse effects. Many clinical trials rely on patient self-report, with some specific queries or rating scales used to assess known adverse effects (e.g., extrapyramidal side effects or tardive dyskinesia) that are outcomes of interest. Given the subjective nature of many adverse events, there is a concern that detailed, specific queries across a broad range of possible symptoms will result in the elicitation of far more symptoms than an unstructured approach.

A methodologic comparison study (27) suggested that the general elicitation of adverse events is more practical and appropriate for routine clinical trials than a comprehensive and lengthy interview. At the same time the field needs to acknowledge the possibility of inordinate delays in recognizing the frequency of specific adverse events such as the sexual dysfunction associated with selective serotonin reuptake inhibitor (SSRI) antidepressants.

There is a strong argument for the use of data and safety monitoring boards when large and/or long-term studies are involved or high-risk treatments are being studied.

CONCLUSION

Part of "40 - Issues in Clinical Trial Designs "

The clinical trial remains the mainstay of treatment development. It is always hoped that further advances will evolve more rapidly than they do, but there is reason for considerable optimism that over the next decade there will be important advances in predicting and understanding psychotropic drug response whether via functional neuroimaging, pharmacogenomics, or other potential developments. In addition, it is hoped that increasing emphasis on studying a broader array of functionally meaningful outcome measures in the context of better informed benefit-to-risk assessment and documentation of cost-effectiveness will lead to clinical trial designs to better address the full range of public health issues.

Section V
Disorders of Development

Joseph T. Coyle

Disorders of Development - Introduction

Until recently, the developmental aspects of psychiatry were at best tenuously connected to the rapidly advancing neuroscience research informing adult psychiatry. To a significant extent, this reflected the historical accident that child psychiatry evolved out of the child guidance movement, which had a psychosocial orientation and was not associated with medical schools. Nevertheless, the last decade has witnessed a remarkable advancement in the appreciation of the neurobiologic underpinnings of behavioral disorders affecting children.

With increasing evidence of genetic risk factors for psychiatric disorders, the developmental features that transform genetic risk to phenotype have become of particular interest to psychiatric research, especially with regard to prevention. Thus, the seeds of Alzheimer's disease are sown early in the formation of the nervous system, not in the seventh decade of life. Furthermore, family studies are disclosing the early manifestations of serious psychiatric illness including affective disorders, anxiety disorders, and schizophrenia in children, raising the question of appropriate pharmacologic treatments. To this end, the Food and Drug Administration (FDA) is now requiring the pharmaceutical industry to carry out controlled studies of the efficacy of all drugs that might be used in the treatment of children, and the National Institute of Mental Health (NIMH) has funded the Research Units on Pediatric Psychopharmacology (RUPP) to provide the infrastructure to support clinical trials of psychotropic medications in children.

The chapters in this section demonstrate the scientific vigor and rigor that are transforming pediatric neuropsychopharmacology. This is especially so for those disorders that have traditionally been at the borderlands between psychiatry and developmental pediatrics that now provide fertile grounds for linking behavioral pathology to specific developmental processes.

Wassink and his colleagues review the very promising and rapidly advancing area of the genetics of autism and related pervasive development disorders. From being misperceived as being caused by poor maternal care (“refrigerator mother”), autism is now known to be highly heritable, resulting from the interaction of several genes. McDougle reviews the evidence that psychotropic medications can attenuate specific subsets of symptoms and pathologic behaviors that occur in the pervasive development disorders. For too long, this area of the psychopharmacologic management of developmental disorders has rested on anecdotes and hunches; but, increasingly now, these issues are being addressed in well-controlled clinical trials.

Attention-deficit/hyperactivity disorder (ADHD) is one of the most common psychiatric diagnosis in children. Long the subject of criticism by those who oppose psychopharmacology, recent research has elucidated the pathophysiology of the disorder, thereby establishing face validity for the diagnosis. Faraone and Biederman provide a thorough review of the area with special emphasis on the genetics of ADHD. In a related and often co-morbid clinical condition—learning disorders—much progress has been made in understanding the neurobiologic mechanisms as well as characterizing effective interventions, as reviewed by Conners and Schulte.

Psychosis is the most extreme manifestation of psychiatric illness and in children can lead to diagnostic confusion. Joshi and Towbin provide a lucid analysis of the causes of psychosis and how to treat them. Finally, Harris provides an overview of the emerging area of behavioral phenotypes of neurodevelopmental disorders. Careful analysis has differentiated subtypes of developmental disorders in which

specific behaviors can be linked to specific genes or groups of genes in the case of deletions or reduplications. These advances have important implication for the field of behavioral genetics.

The results from clinical trials with psychotropic medications in children disabuse us of the simplistic notion that children are simply small adults, who should exhibit comparable responses to treatment. Nevertheless, the advances in pediatric neuropsychopharmacology raise important questions about the interaction of family environment and social risk factors that must be considered and addressed along with or in place of psychotropic medications.

Autism is a behavioral syndrome that is generally associated with lifelong impairment and often confers a substantial burden on the families of affected individuals. Epidemiologic research over the past two decades has demonstrated a significant role for hereditary factors in the etiology of autism, stimulating an aggressive search for susceptibility genes. This chapter summarizes these efforts to elucidate the genetic basis of this severe neurodevelopmental disorder.

THE PHENOTYPE

Part of "41 - The Molecular and Cellular Genetics of Autism "

The three core symptom domains of autism are excessive ritualistic and repetitive behaviors, deficits in communication, and abnormal social interaction. These domains encompass a broad spectrum of behavioral and cognitive abnormalities such as speech delay, echolalia, decreased spontaneous affection, reduced eye-to-eye gaze, motor stereotypies, rigid adherence to routine and environment, and others. The onset of autism is variable, typically manifesting at age when the normal complements, such as speech and prosocial activity, to the disturbed behaviors are expected to develop (usually by the age of 2). Symptoms change with development and generally continue throughout life. When first described in 1943, infantile autism was narrowly defined, referring to a population of children with severe manifestations of all core features and generally higher IQ levels. Kanner, for example, in his original descriptions of autism, included elaborate stereotyped behaviors (e.g., complex rituals and marked distress in response to change in routine or environment) as an essential, pathognomonic component. The severity of this component, however, has gradually been relaxed so that current criteria require the presence of only milder behaviors in this domain.

Similarly, the concept of autism itself has been broadened and now includes the group of syndromes referred to as pervasive developmental disorders (PDDs). Specific PDDs, in addition to autistic disorder, include Asperger's syndrome, pervasive developmental disorder not otherwise specified (NOS), disintegrative disorder, and Rett syndrome. The validity of these diagnostic distinctions, however, is open to question. While the gene that causes Rett syndrome has recently been identified (1), and disintegrative disorder involves a clear loss of function that is likely to arise from a distinct mechanism, there is little evidence to support the remaining PDDs being etiologically distinct.

The existence of multiple symptom domains and the spectrum of related disorders demonstrate the complexity of the autism phenotype. The core symptom domains exist in varying combinations of severity across affected individuals, and it is unclear whether these clinically defined domains represent distinct genetic entities. Less severe symptomatology is represented as a distinct diagnostic entity, but again whether this is genetically justified is not known.

Mental Retardation

Adding to the phenotypic complexity is the wide range of IQs associated with autism. Although some individuals with autism have normal or even exceptional IQs, 70% to 80% are mentally retarded (2). Approximately one-third of those with mental retardation (MR) are in the mildly affected range, the remainder have moderate to severe deficits, and gender proportionality differs across IQ groups (see below).

Biological Correlates

Investigators have searched for biological correlates of autism hoping to better define and categorize the phenotype. Hyperserotonemia was the first biological abnormality to be reported, found by some in up to one-fourth of autistic individuals (3). There is evidence to suggest that hyperserotonemia in autism may be familial (4 ,5), and that elevated platelet serotonin levels may index genetic liability for autism (6). Dysmorphic facial features have also been investigated, with one positive finding coming from a report linking autism to an early developmental abnormality in the branchial arches (7). Epilepsy occurs in 15% to 20% of individuals with autism (8), much more frequently than expected by chance, though whether the presence of epilepsy defines an etiologically meaningful autistic subgroup is unclear.

Two other biological traits that have been investigated are head size and brain morphology. Enlarged head size was noted by Kanner in seven of the first 11 children he described in 1943. Subsequent studies have revealed that approximately 20% of autistic individuals have macrocephaly (> 98th percentile for head circumference) (9 ,10), and the few published postmortem studies report that the brains of autistic individuals are larger and heavier (megalencephalic) than those of normal controls (11 ,12). Retrospective longitudinal studies of head circumference also suggest that while some enlargement may take place before birth, an increased rate of growth appears to occur during the early postnatal period (10 ,13). Magnetic resonance imaging (MRI) studies confirm that brain volume in autism is increased (14 ,15). This enlargement, rather than being generalized, may be confined to discrete structures (16). One recent report, for example, found evidence linking abnormalities in caudate volume to ritualistic-repetitive behaviors in subjects with autism, a finding that is similar to reported relationships in Tourette's syndrome and obsessive-compulsive disorder (17).

As with the core autistic symptomatology, however, these biological correlates are highly variable across individuals, and none is yet able to independently identify cases or define meaningful subgroups. As our ability to measure these correlates becomes more precise, however, their value is likely to increase. They may then serve the purpose of adding power to genetic studies by increasing phenotypic information.

EPIDEMIOLOGY AND GENETIC MECHANISMS

Part of "41 - The Molecular and Cellular Genetics of Autism "

Prevalence

The estimated prevalence of autism has increased since the mid-1980s from 3 to 5 cases per 10,000 to a current estimate of 6 to 10 per 10,000 (2 ,18). This increase is most likely attributable to changing diagnostic practices and increased ascertainment. Epidemiologic studies in the 1970s and early 1980s were based primarily on Kanner's strict diagnostic criteria. With the incorporation of less stringent criteria into the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) and the International Classification of Diseases (ICD), some individuals are now diagnosed with autism who would not have been previously (18). The prevalence of the other PDDs, such as Asperger's disorder and PDD NOS, has not been studied as thoroughly as that of autism. Estimates, therefore, vary widely, though median figures from extant studies suggest a rate 1.5 to 2 times that of autism (2). Thus, taken together, the PDDs may affect 15 to 25 per 10,000 school-aged children. Given that autism is a lifelong condition, the prevalence in adults is likely to be similar to that found in children.

Family and Twin Studies

Family and twin studies help to determine the pattern and strength of the heritability of a disorder. The recurrence risk of autism for siblings of autistic probands is approximately 4% to 5% (19), translating to a sibling relative risk (sibling recurrence risk/population prevalence) of roughly 50 to 100. The risk to second- and third-degree relatives drops off dramatically to less than 1% (20). Twin studies, which compare concordance rates between monozygotic (MZ) and dizygotic (DZ) twins, estimate the heritability for autism to be greater than 90% (21 ,22).

Gender Differences

All epidemiologic studies of autism demonstrate a male preponderance of the disorder. The overall ratio of males to females is approximately 4:1, though this varies with IQ, approaching 6:1 in normal IQ groups and being less than 2:1 in moderate to severe MR groups (2).

Associated Medical Conditions

A host of medical conditions have been reported to cause occasional cases of autism, including neurofibromatosis, tuberous sclerosis (TS), phenylketonuria, rubella, cerebral palsy, trisomy 21, and epilepsy (23). For most of these disorders, however, whether they occur in autism more frequently than expected by chance is unclear. TS has the strongest association; its population prevalence is 1/10,000, and up to 25% of individuals with TS meet diagnostic criteria for autism or PDD (24) (discussed in more detail below). Overall, it has been estimated that approximately 5% of autistic individuals have an associated medical condition that may play an etiologic role in the development of the disorder (2).

Environmental Determinants

Investigators have repeatedly postulated that *in utero* events might predispose a fetus to the development of autism. Early twin studies, for example, suggested that obstetric complications differentiated autistic twins from nonautistic co-twins (25). Subsequent examination of these and other data, however, has shown that the obstetric complications are typically quite minor, the association between autism and complications is weak (26), and that the causality may be inverted—an impaired fetus may actually predispose to obstetric complications instead of complications having affected the fetus (27). Similarly, some studies have reported associations between viral infections [i.e., rubella (28), cytomegalovirus] during pregnancy or season of birth and the subsequent development of autism. The weight of evidence, however, either fails to support such associations or suggests that they account for only a small minority of autism cases (29 ,30). Thus, although perinatal factors are reasonably inferred in rare instances (e.g., encephalitis), in most cases they appear to have either a negligible effect or a minor effect of undetermined significance.

Chromosomal Abnormalities

Estimates of the frequency of chromosomal abnormalities in autism vary widely. Early studies reported rates as high as 20% (31), though recent surveys have reported lower frequencies ranging from 3% to 8% (32–34; Wassink et al., submitted), with the fragile X mutation accounting for one-third to one-half of these. These rates may increase, however, as more sophisticated molecular cytogenetic techniques are applied. Up to 10% of unexplained cases of MR, for example, have been found to be associated with cytogenetic abnormalities detectable only by recently developed subtelomeric probes, and similar abnormalities may be found in autism as well. The most common chromosomal abnormalities currently associated with autism include the fragile X mutation, other sex chromosome abnormalities, and abnormalities of 15q11-q13 (the Prader-Willi/Angelman syndrome (PW/AS) region).

Genetic Mechanisms

Thus, although a small proportion of cases of autism are due to chromosomal abnormalities or medical conditions, the vast majority are likely to be multifactorial, arising from an as yet unknown environmental component superimposed on a strong genetic predisposition. The heritability for autism of 90% exceeds that of other common psychiatric disorders such as schizophrenia, bipolar disorder, or alcoholism. The mode of heritability, like other psychiatric disorders, appears to be complex. Autism pedigrees have not been reported that demonstrate mendelian segregation (unless the broader autism phenotype is included—see below), and the differential gender distribution across IQs suggests genetic heterogeneity. The rapidly diminishing relative risk from first- to second- to third-degree relatives, combined with the >4:1 MZ:DZ concordance ratio, indicates that autism is likely to be due to multiple genes interacting in variable combinations in additive, multiplicative, epistatic, or as yet unknown fashions (35). Estimates of the number of genes involved have ranged from at least three (36) to more than 15 (37). Furthermore, other disorders composed of isolated components of the autism phenotype (e.g., specific language impairment) are themselves considered to be due to multiple, interacting genes, making it likely that the genetics of autism will be complicated as well.

GENETIC INVESTIGATIONS OF AUTISM

Part of "41 - The Molecular and Cellular Genetics of Autism "

Early genetic investigations of autism were hampered by a number of constraints, including small sample sizes, inconsistent diagnostic criteria, and limited molecular tools. The development of standardized diagnostic criteria and advanced molecular tools, such as high-quality, densely spaced genetic markers, FISH (fluorescent in situ hybridization) chromosomal probes, and high-throughput sequencing, is beginning to overcome these constraints. Multicenter collaborations can now gather large, consistently characterized samples, genome-wide screens are practical, sequence data are available for focused genetic investigations, and chromosomal studies are more exact and informative. These advances are reflected in the recent surge of genetic investigations of autism, which are summarized below.

Genome-Wide and Focused Linkage and Association Studies

Four genome-wide linkage studies of autism have been published to date (37 ,38 ,39 and 40). All these studies have examined families containing at least two affected siblings [affected sibling pair (ASP) families] and are summarized in Table 41.1 . The strongest single finding to emerge from these screens is a multipoint heterogeneity logarithm of odds (LOD) score of 3.0 on chromosome 13q at 55.3 centimorgans (cM) reported by the Collaborative Linkage Study of Autism (CLSA) (39), whereas the most replicated finding consists of support for linkage to chromosome 7q.

Research Group	Sample Characteristics				Findings		
	Sample	Markers	Chrom	Markers	cM	MLS	Comments
IMGSAC (38)	87 ASPs	354	7q	D7S530	134.6	2.53	Multipoint analyses were calculated using ASPEX under an additive model that assumed no dominance variance; in a subsample of 56 ASPs, all from the UK, the MLS at D7S530 was 3.55
			4p	D4S412	4.8	1.55	
			16q	D16S407	17.3	1.51	
			22q	D22S264	5.0	1.39	
			10q	D10S197	51.9	1.36	
			14q	D14S70	32.9	0.99	
			19q	D19S49	48.2	0.99	
PARIS5 (40)	51 ASPs	264	6q	D6S283	132.8	2.23	The MLS was maximized over the "possible triangle" using MAPMAKER/SIBS

TABLE 41.1. GENOME-WIDE LINKAGE STUDIES OF AUTISM

Some caution must be taken when comparing these studies, however, because none of them report exactly the same statistic. The CLSA (39) reported a maximum multipoint LOD score (MLS), calculated using the program GENEHUNTER (41) and based on a likelihood that allowed explicitly for heterogeneity (42). The Stanford group also reported an MLS (37), but the underlying likelihood was parameterized in terms of a multiplicative model allowing for dominance variance, and calculated using ASPEX (43 ,44). The International Molecular Genetic Study of Autism

Consortium (IMGSAC) also used ASPEX to calculated the MLS, but under an additive model that assumed no dominance variance (38). The Paris Autism Research International Sibpair Study (PARISS) used a related MLS, maximized over the "possible triangle" (45), using MAPMAKER/SIBS (40). While all these statistical approaches are related to one another (Huang and Vieland, in press), they may involve estimation of somewhat different numbers of parameters, or "degrees of freedom." The most appropriate use of these data in aggregate, therefore, is not to directly compare numerical results, but rather to look for regions that have either very strong support for linkage within individual studies or that have recurrent support across studies.

Focused genetic studies have examined smaller chromosomal regions chosen for one of three reasons: (a) the region showed evidence of linkage in a genome-wide screen; (b) the region contains a high rate of chromosomal abnormalities associated with autism; or (c) a "candidate" gene of interest, chosen because of its potential biological or developmental relevance to autism, is located in the region. The samples for these focused studies include both ASP families and trios (proband and both parents), and are summarized in Table 41.2 .

	Study Characteristics				Findings		
Research Group	Ref	Sample	Markers Tested (Significant) Chrom	Gene	Marker	Result	Test
IMGSAC	51	91 ASPs, 8 trios	2 (0) 17q11	*HTT*			Linkage

TABLE 41.2. FOCUSED LINKAGE AND ASSOCIATION STUDIES OF AUTISM

Chromosome 7

The most replicated evidence for linkage is to chromosome 7q (Fig. 41.1). The IMGSAC, examining 87 ASPs, reported a LOD of 2.53 at D7S530 (134.6 cM), which increased to 3.55 in a subset of 66 United Kingdom ASPs (38). A recent second-stage analysis of 125 ASPs by this same group reported, in poster format, a multipoint MLS near D7S2533 (140.5 cM) of 3.63 (46). The CLSA, examining 75 ASPs, reported an MLS of 2.2 at D7S813 (104 cM) (39), whereas the PARISS (40) and Stanford (37) studies reported modestly positive results (MLS = 0.83 and 0.93, respectively).

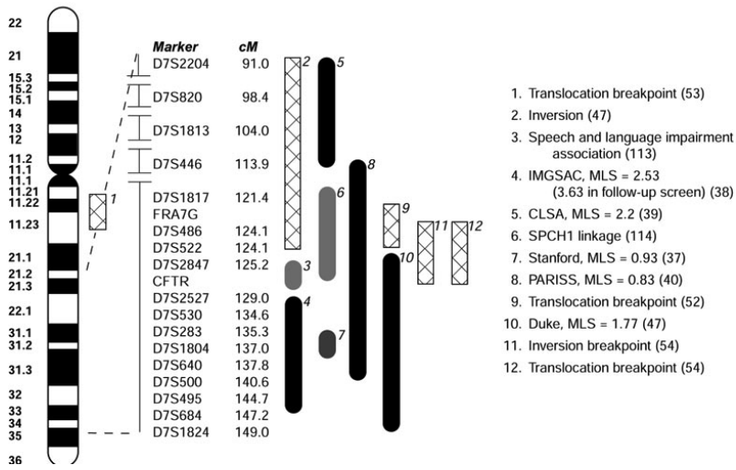

FIGURE 41.1. Chromosome 7 findings in autism. *Rectangles* represent chromosome abnormalities, *black ovals* indicate regions with evidence for linkage or association in autism, and *gray ovals* indicate regions with evidence for linkage or association in related disorders. MLS, maximum multipoint LOD score within the region indicated.

A subsequent focused examination of nine 7q markers was performed in 76 multiplex families and 32 trios by the Duke/University of South Carolina (USC) group (47). They found a peak multipoint MLS of 1.77 at D7S2527 (129.0 cM) using an additive model calculated with ASPEX. This group also found high rates of recombination throughout 7q and evidence of linkage disequilibrium at D7S1824

(149.9 cM), reporting that the linkage, excess recombination, and linkage disequilibrium appeared to be due primarily to paternal and not maternal effects.

Chromosome 15q11-Q13

Because of numerous reports of cytogenetic abnormalities (discussed below), chromosome 15q11-q13 has been intensively examined in linkage and association studies. None of the currently published genome-wide screens, which all included tightly spaced 15q11-q13 markers, identified linkage to the region. The Duke/USC group screened fourteen 15q11-q13 markers in their families and reported a maximum MLS of 1.78 at D15S217 (48). Another group has reported highly significant linkage disequilibrium with the marker GABRB3 155CA-2, a dinucleotide repeat polymorphism that was not typed in any of the genome-wide screens (Buxbaum et al., submitted). This result was obtained when the data were pooled with a number of other focused studies that included this marker.

Candidate Gene Studies

Genes tested as candidates for involvement in autism include genes involved in neurotransmission (i.e., *HTT*, *TH*, *DBH*), genes contributing to related disorders (i.e., *FMR-1*, the fragile X syndrome (FXS) gene, and *NF-1*, a neurofibromatosis gene), and genes thought to be involved in brain development (i.e., *EN2*, *HRAS-1*) (Table 41.2). Though positive results have occasionally been reported, replication has been limited. Cook et al. (49), for example, reported preferential transmission of the small allele of the *HTT* promoter polymorphism to autistic probands. Klauck et al. (50), attempting replication, reported preferential transmission of the larger allele, and the IMGSAC reported no association with either allele (51). No other candidate genes tested thus far have found consistent support.

CHROMOSOMAL ABNORMALITIES

Part of "41 - The Molecular and Cellular Genetics of Autism "

Studies of cytogenetic abnormalities can complement molecular approaches by identifying genes whose effects are either too small to be detected by linkage or are obscured by epigenetic phenomena. The X chromosome and chromosome 15q11-q13, for example, have both received scrutiny because they are frequent sites, relative to other regions, of cytogenetic abnormalities in individuals with autism. Additionally, linked regions in complex disorders are typically broad, and chromosomal abnormalities occurring in linked regions can help to pinpoint disease susceptibility genes. This can be done either by cloning the chromosomal break points and identifying disrupted genes, or by overlaying deleted regions across individuals in order to delineate a minimal deleted region that might harbor a disease susceptibility gene.

The prevalence of chromosomal abnormalities in autism has been discussed above (see Epidemiology and Genetic Mechanisms). This section, therefore, focuses on abnormalities in specific regions: 7q, 15q11-q13, the sex chromosomes, and the fragile X mutation.

Chromosome 7 Cytogenetic Abnormalities

A number of chromosome 7 cytogenetic abnormalities in close proximity to the 7q linkage findings have been identified in individuals with autism (Fig. 41.1). In one family, a paracentric inversion, inv(7)(q22q31.2), is carried by two brothers, a sister, and their mother (47). The brothers appear to have autistic disorder, the sister has expressive language disorder, and the mother has neither of these abnormalities. Another autistic individual has been described with a translocation t(7;13)(q31.2;q21) (52). The break points for these abnormalities have been cloned, and identification and screening of nearby candidate genes is in progress. Two autistic twins have been found to have translocations t(7;q20)(q11.2;p11.2) (53). The chromosome 7 break point and the gene it disrupts, named “autism-related gene 1” (*ARG1*), have been cloned; the gene is novel with an unknown function, spans an 800-kilobase (kb) genomic region, and is highly expressed in fetal and adult brain (53). Lastly, one individual with autism and another with a specific developmental disorder of speech and language (SDDSL) have been reported, both of whom have chromosomal abnormalities involving 7q31 [autism, 46,XY, inv(7)(p12.2q31.3); and SDDSL, 46,XY,t(2;7)(p23;q31.3)] (54).

Chromosome 15q11-Q13

Chromosome 15q11-13 is the most frequent site of autosomal abnormalities in autism. In a recent chromosomal survey, 6 (2.2%) of 278 autistic subjects referred for cytogenetic studies had a gross abnormality of chromosome 15 (Wassink et al., submitted). These abnormalities most commonly involve duplication of maternal DNA, typically as either interstitial duplications (55 ,56 ,57 ,58 ,59 ,60 and 61) or inverted duplicated isodicentric marker chromosomes [inv dup(15)] (62 ,63 ,64 and 65). The duplications that produce illness typically extend into the Prader-Willi syndrome (PWS) and Angelman syndrome (AS) critical region, as smaller duplications are generally asymptomatic (64 ,66). Complementing these data, individuals identified because of 15q11-q13 duplications frequently have autistic features (67). Deletions of 15q11-q13, though less frequent, have also been reported in autistic individuals, with the deleted material usually of paternal origin (68 ,69). Figure 41.2 summarizes these data, displaying the relevant genes and markers as well as a putative autistic disorder region.

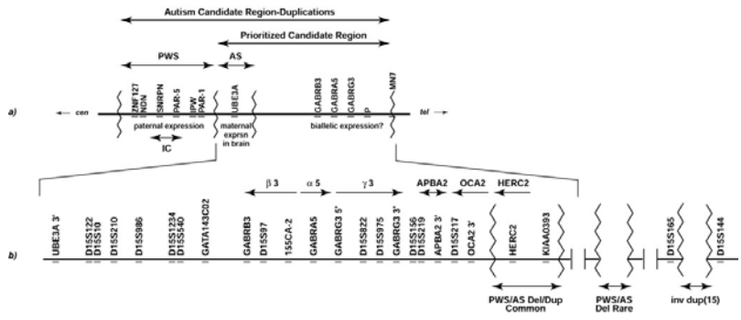

FIGURE 41.2. Schematic map of 15q11-q13 autism candidate region. The *upper part* of the figure is a low-resolution schematic representation of the 15q11-q13 interval deleted in Prader-Willi syndrome (PWS) and Angelman syndrome (AS) and duplicated in cases of autism. PWS and AS critical regions are indicated by *arrows* over the map, with relevant imprinted genes indicated in their respective regions. A prioritized autism region excludes the imprinted PWS domain based on the apparent maternal specificity of 15q11-q13 duplications [interstitial or inv dup(15) markers] in association with autism. The lower expanded region reveals gene and marker order and transcriptional orientation within the candidate region. Large break-point regions are depicted for the primary distal PWS/AS deletion break point, as well as a less common (˜10%) PWS/AS break point and a break-point interval associated with inv dup(15) marker chromosomes.

In addition to these gross abnormalities, cytogenetic abnormalities at the molecular level are also being reported. Cook et al. (70), while screening autism trios across 15q11-q13, identified a nonautistic mother in whom a duplication had arisen *de novo* on her paternally derived homologue (70). The duplication was transmitted to one child who

developed autism and a second child with atypical autism, whereas a third child who did not receive the duplication remained unaffected. In the CLSA genomic screen, which examined 75 ASP families (152 affected individuals) and included two 15q11-q13 markers, six individuals (3.9% of probands) from four families (5.3% of families) were found to have either maternal duplications or paternal deletions at one or both of these markers (Wassink et al., submitted). Forty-five unrelated autism trios were subsequently screened using 12 polymorphic 15q markers, with three (6.1%) autistic probands found to have similar abnormalities (Wassink et al., submitted).

The apparent gender specificity of the 15q11-q13 abnormalities is presumably attributable to imprinting, an epigenetic mechanism by which only one of a gene's two inherited alleles is expressed, with expression determined by the allele's gender of origin (71). The two primary 15q11-q13 syndromes, PWS and AS, are oppositely imprinted mental retardation syndromes that bear some phenotypic similarities to autism (72). In brain tissue (but not elsewhere), *UBE3A*, the AS gene, is expressed predominantly from the maternally derived allele. Disrupted expression of the maternal *UBE3A*, therefore, produces AS, whereas disruption of the paternally derived allele produces no discernible abnormal phenotype (73). PWS genes, conversely, are paternally expressed; the predominant cause of PWS, therefore, is disrupted expression of the paternal copy of the small nuclear ribonucleoprotein polypeptide N (SNRPN) gene and other contiguous genes (74). Another recently identified element of imprinting is the presence of antisense transcripts for imprinted genes. These segments of RNA are oppositely imprinted complements to an imprinted gene's coding sequence (75). *UBE3A*, for example, has an antisense transcript that is expressed solely from the paternally derived allele (71). This antisense transcript may play a role in the suppression of the nonexpressed allele, and mutations in this transcript, therefore, could contribute to some cases of AS (76). Thus, just as imprinting plays a pivotal role in PWS and AS, it is likely to significantly influence the effect of 15q11-q13 abnormalities in autism as well.

The 15q11-q13 abnormalities themselves may be due to the presence of repeated or duplicated homologous genomic segments that exist in multiple copies throughout this region (77). Duplications of large genomic segments are associated with chromosomal abnormalities in a number of specific syndromes (78 ,79). One such repeated segment (duplicon) appears near each of three most common PWS/AS duplication breakpoints (80). Another, located centromeric to the PWS/AS critical region, is repeated an increased and variable number of times in PWS/AS individuals (81). Though this does not imply a traditional repeat expansion mechanism, it may be that these repeats predispose the region to recombination abnormalities or "mistakes" (77), a finding with support from data showing increased rates of recombination across 15q11-q13 in subjects with either PWS/AS (82) or autism (48).

Interestingly, one other chromosomal region that shares many of these genomic features is 22q11 (77). Chromosome 22q11 contains large repeated segments that contribute to a high rate of deletions and duplications (83). These chromosomal abnormalities are associated with a constellation of syndromes grouped under the umbrella term *CATCH-22* (84). One of these syndromes, velocardiofacial syndrome (VCFS), is associated with a high rate of schizophrenia (85), a psychiatric disorder that, like autism, is felt to arise from disturbed brain development. In addition, a small but significant percentage of individuals with schizophrenia have now been shown to have microabnormalities of 22q11 (86). Thus, schizophrenia and autism may share a common genomic mechanism for a subgroup of cases, and insights from one disorder may inform investigations into the other.

Fragile X

The association of autism with the fragile X syndrome (FXS) was first suggested nearly 20 years ago (87 ,88). The fragile X phenotype is frequently characterized by behaviors that can resemble the core symptom domains of autism such as language abnormalities, decreased nonverbal communication, social isolation, and repetitive motor behaviors such as rocking and hand biting (89). In support of this association, early chromosomal investigations reported a rate of the fragile X mutation [fra(X)(q27.3)] in autism that approached 20% (31 ,90).

Recent studies, however, have questioned the strength of the link between these two disorders. Current surveys estimate the frequency of fragile X in autism to be 2% to 4% (91 ,92 and 93), similar to the rate of fragile X in the general MR population (94). This is more common than other types of chromosomal abnormalities in autism, though not necessarily disproportionately so. Likewise, there are subtle but significant differences between the behavioral phenotypes of the two disorders. Autism is characterized by social indifference and deficits in the perception of emotion, whereas individuals with FXS experience social anxiety and gaze avoidance with no attendant impairment of emotional perception (95).

Genetically, FXS is a disorder of unstable DNA caused by a trinucleotide repeat that expands as it is transmitted to successive generations (96). The repeat is located at Xq27.3 in the 5′ UTR (untranslated region) of the *FMR1* gene (89). Once this expanded region crosses a threshold (approximately 200 repeats), it becomes susceptible to methylation, which inhibits transcription of *FMR1*. FMRP, the *FMR1* protein, is an RNA binding protein that appears to act as a chaperone for transport of RNA from the nucleus to the cytoplasm (97). FMRP is expressed in numerous tissues including fetal brain. Intracellularly, it is found in the nucleus near the nucleolus and in cytoplasm in association

with ribosomes. It may function, therefore, as a chaperone molecule in the transportation of messenger RNA (mRNA) from the nucleus to the cytoplasm (98). How dysfunction of this protein gives rise to FXS, however, remains unclear.

Other Sex Chromosome Abnormalities

The possibility of a sex chromosome–related genetic effect is suggested by the preponderance of males affected by autism (2). In accord with this, a sizable number of sex chromosome abnormalities, in addition to the fragile X mutation, have been reported in subjects with autism (99). In a recent survey of a clinical population, six out of 265 (2.3%) autistic individuals referred for cytogenetic testing were found to have abnormalities of the sex chromosomes other than fragile X (Wassink et al., submitted). In addition, two X-linked disorders, Turner syndrome and Rett syndrome, have phenotypic features that are similar to some of the core features of autism. Skuse et al. (100) reported that Turner syndrome (45,X) females with maternally derived X chromosomes had diminished verbal skills and social cognition compared to those with paternally derived Xs. Molecular studies implicated a paternally imprinted disease locus that escapes X-inactivation in distal Xp22.3 (101). This paternal imprinting could explain why karyotypically normal males (who have a maternally derived X) are more vulnerable to developmental disorders of language and social cognition, such as autism, than females. Skuse et al. also reported three Turner syndrome females, all with maternally inherited X chromosomes, who had been diagnosed with autism. Two more XO autistic individuals have recently been reported, one with a maternally derived X (102) and the other with an X of unknown origin (Wassink et al., submitted).

The gene for Rett syndrome was recently identified on Xq28 (1). Rett syndrome, considered to be a subtype of PDD, is a disorder occurring only in girls that is characterized by mental retardation, loss of speech, and stereotypic hand movements after 1 to 2 years of normal development. The gene for Rett syndrome, (*MECP2*), is widely expressed and codes for a DNA binding protein that regulates gene expression (1).

Linkage screens of the X chromosome in autism have generally been negative, excluding genes of even small effect (37 ,103), and have contributed to a reluctance to examine the sex chromosomes for autism disease genes. The evidence from sex chromosome abnormalities and from X-linked disorders with phenotypic similarities, however, suggests that such pessimism is premature, and that the X and Y chromosomes should continue to be a focus of attention in autism.

BROADER AUTISM PHENOTYPE

Part of "41 - The Molecular and Cellular Genetics of Autism "

In addition to describing the hereditary basis of autism, family and twin studies have demonstrated, in nonautistic relatives of autistic probands, the presence of milder traits that are qualitatively similar to the defining features of autism. These collective traits, referred to as the “broader autism phenotype” (BAP), were first observed by Kanner in parents of autistic children. Bailey et al., replicating and extending findings from the original Folstein and Rutter (104) twin study, found a substantially higher concordance rate for the presence of mild social and communication deficits in MZ versus DZ twin pairs (92% versus 10%) (21). These results are supported by several family studies using the family history method of assessment (105 ,106). In the London Autism Family Study, Bolton et al. (105) reported that familial aggregation of the BAP was associated with proband verbal IQ. In the Iowa Autism Family Study (Piven and Palmer, submitted) familial aggregation of the BAP was higher in relatives from families with two autistic siblings (multiple-incidence families) than in families ascertained through a single autistic child.

A more detailed examination of the BAP has been accomplished through direct assessment of relatives. Relatives from multiple-incidence families, for example, were found to have (a) elevated rates of personality characteristics such as aloofness and rigidity, (b) diminished pragmatic language and speech abilities, (c) fewer quality friendships, and (d) decreased scores on a number of specific cognitive measures (107 ,108 and 109).

Investigation of the BAP may, by clarifying the range of phenotypic expression of the underlying genetic liability to autism, provide a complementary approach to traditional linkage that increases power to detect genes by identifying more affected individuals, thereby enabling extension of typically small autism pedigrees. Understanding the boundaries and nature of the BAP may also help our efforts to detect genes in autism by enabling focused investigation of specific BAP components (e.g., language deficits, ritualistic-repetitive behaviors, or cognitive deficits) that may map on to separate genes that together cause the full syndrome of autism. This approach to disaggregating complex phenotypes has proved successful in dyslexia, where separate linkages were found to single-word reading and phonemic awareness (110). Clearly, clarification of the genetically relevant aspects of both the autism and the broader autism phenotype is an important strategy to pursue in our search for genes in this disorder.

RELATED DISORDERS

Part of "41 - The Molecular and Cellular Genetics of Autism "

Autism is characterized by dysfunction in three symptom domains: language; social interaction; and repetitive, stereotyped movements and behaviors. As autism is a heterogeneous, genetically complex disorder, it may be that each of these domains has unique, independent genetic determinants. Studying disorders that resemble these individual domains, therefore, may provide insight into their etiology in

autism. There are also related disorders, such as tuberous sclerosis, and domains of investigation, such as immunogenetics, that may provide insight into autism.

Disorders of Language

Specific language impairment (SLI) is a disorder characterized by isolated impairment of language skills, and may be characterized by grammatical impairment, word finding difficulties, or an underlying perceptual deficit (111). Though traditionally considered distinct disorders, SLI has been found to be common in autistic individuals and to occur at higher rates than expected in their nonautistic relatives (108). Conversely, an increased rate of autistic disorder has recently been found in siblings of children with SLI (112). Tying this in to chromosome 7, an association study found significant associations between two 7q31 genetic markers and a group of SLI trios (113). Also, a family has been identified with a severe speech and language disorder characterized by deficits in grammar, expressive language, articulation, and coordination of orofacial musculature (114). A genome-wide screen of this three-generation pedigree found a maximum LOD score of 6.62 at a marker in 7q31, with fine mapping narrowing the region to a 5.6-cM interval (SPCH1 locus). These findings, therefore, may represent localizations of heritable components of the autism phenotype and are of particular interest given the evidence for linkage of autism to this same region of chromosome 7.

Disorders of Repetitive and Stereotyped Behaviors

The phenomenologic overlap between autism, obsessive-compulsive disorder (OCD), and Tourette's syndrome has led some to wonder whether these disorders have etiologic mechanisms in common. For example, caudate volumes have been found to be abnormal in both Tourette's (115) and OCD (116). Therefore, we examined caudate volumes in an MRI study of autistic children and found enlargement of the caudate that was correlated to ritualistic, stereotyped behaviors but not to social or communication deficits (17). In an earlier family study, we reported higher familial aggregation of autism and the BAP in families ascertained through a Kanner proband (more severe ritualistic behavior) versus more broadly defined (DSM, third edition, revised) probands (117). Findings such as these suggest that traits such as stereotypies or ritualistic behavior may have unique genetic determinants that, when combined with genes that give rise to other traits such as language or communication deficits, could give rise to the syndrome of autism.

Disorders of Social Activity

Examples of disorders that involve significant social deficits include Turner syndrome and the fragile X syndrome, both of which have been discussed above (see Other Sex Chromosome Abnormalities). Additional research related to social deficits that may have relevance to autism comes from studies of various neuropeptide systems. For example, nematode worms that lack receptors for neuropeptide Y become strikingly isolated in situations where they would normally congregate with other worms (118). Genetic variability in receptors for oxytocin/vasopressin in mice and other rodents is also associated with clear variability in social behavior (119). Thus, though there is significant evolutionary distance between worms, rodents, and humans, these transmitter systems may merit closer examination in individuals with autism.

Tuberous Sclerosis

Tuberous sclerosis complex (TSC) is a neurocutaneous disorder characterized by benign tumors affecting numerous organs, most commonly the brain, eyes, skin, kidneys, and heart (120), with a population prevalence estimated at 1/10,000 (121). The occurrence of autism and other behavioral and psychiatric disturbances in the context of TSC has long been recognized (122). Clinic-based and epidemiologic studies of autism in TSC suggest that up to 25% of individuals with TSC meet diagnostic criteria for autism and over 40% meet criteria for any PDD (24 ,123). Conversely, 1% to 3% of autistic individuals will have TSC (124), though this rate approaches 10% for autistic individuals with seizure disorders (24 ,123).

TSC is an autosomal-dominant disorder caused by mutation in one of either two genes, *TSC1* or *TSC2* (125). *TSC2* is located on chromosome 16p13 and codes for the protein tuberin, whereas *TSC1* is located on 9q34 and codes for the protein hamartin. Tuberin has numerous functions, acting as a tumor suppressor or a chaperone, and having an influence on cell cycle passage. Dysfunction of tuberin may result in constitutive activation of RAP1, a protein that regulates DNA synthesis and cellular transition, thereby producing excessive proliferation and impaired differentiation of a variety of cell types. Hamartin is one of the proteins for which tuberin acts as a cytosolic chaperone. Other than an ill-defined role in tumor suppression, the function of hamartin remains unknown (126). Approximately two-thirds of TSC cases are sporadic and one-third familial. Half of the familial cases and 75% to 80% of sporadic cases arise from mutations of *TSC2*, with the remainder attributed to *TSC1*. Two studies have shown that TSC due to *TSC2* mutations is more likely to be associated with either mental retardation or intellectual impairment than TSC due to *TSC1* mutations (127 ,128). Despite the strong association between TSC and autism, however, the mechanistic link between the two disorders remains unclear. Autism in the context of TSC may arise directly from the TSC mutations, from the tubers they produce, or from some other as yet undiscovered mechanism. One group, for example, has reported an association between the presence of temporal lobe tubers and autism (129), though this finding has not been replicated (24).

Immunogenetics

A number of investigators have suggested that some cases of autism may be attributable to interactions between infections, the immune system, and genetic factors (130). Subjects with autism have been shown to have deficits in the number and function of various immune cell subtypes (131 ,132 ,133 ,134 ,135 and 136). A series of investigations, therefore, performed primarily by one research group, has investigated specific components of the major histocompatibility complex (MHC) on chromosome 6p21 for association with autism (130 ,137 ,138 ,139 and 140) (Table 41.2). The samples in these studies were generally small and overlapping, and associations emerged primarily when probands were compared to a population control group as opposed to a parent-based test. Nonetheless, the authors report consistently significant findings that await replication by others.

FUTURE DIRECTIONS

Part of "41 - The Molecular and Cellular Genetics of Autism "

Alternative Sampling Designs

As noted above, all of the genome-wide linkage screens performed to date have focused almost exclusively on affected sibling-pair (ASP) pedigrees. This is in part due to the difficulty of gathering extended autism pedigrees. Also, however, because the mode of inheritance for autism is unknown, many researchers appear to be more comfortable with the simple “model-free” linkage analysis methods available for ASP data than with the more complicated methods required for the analysis of general pedigree structures. Yet, limiting pedigrees solely to ASPs may be unnecessarily and detrimentally restrictive.

The optimal pedigree structure for the detection of linkage depends on the true, underlying genetic model for the trait, which in this case is unknown. Large, multiplex pedigrees, for example, are optimal when a trait is transmitted as a rare dominant but tend to be uninformative if the trait is a common recessive. Furthermore, an ASP data set contains only two primary pieces of information—the number of sibling pairs sharing 1 allele identical by descent and the number of pairs sharing 2 alleles—thereby limiting the complexity of any model that can be fit to ASP data. By limiting the families that are gathered to ASPs, the ability to detect linkage under all possible modes of transmission may be similarly limited. It could be argued, therefore, that precisely because the mode of inheritance for autism is unknown, the optimal strategy would be to ascertain all types of potentially informative pedigree structures. This could include large multigenerational extended pedigrees and moderate-sized pedigrees with more than just two affected individuals, in addition to ASPs.

The difficulty is that there are few larger pedigrees for autism, thus highlighting the potential benefit and utility of the broader autism phenotype. As noted above, classifying individuals with familial autism–related traits as “affected” may increase the prevalence of extended pedigrees and reveal patterns of segregation within those pedigrees beyond what is seen for autism itself. Segregation of such traits (and their underlying genetic diatheses), however, will only be detected if extended pedigrees are sought to begin with. A further benefit to using the BAP is that it enables us to diagnose parents, and possibly siblings, of ASPs as well. Thus even within the nuclear families already collected through existing genomic screens, the amount of linkage information may be greatly increased if indeed the BAP is genetically related to autism.

Another sampling design enabled by the BAP is discordant sibling pair (DSP) analysis. The BAP conceptualizes and measures the traits related to autism along continua. Those subjects who exceed severity thresholds on these measures but do not meet criteria for PDDs are considered to have some form of the BAP. These measures also indicate, however, family members who are very *unaffected*, and therefore discordant, with their autistic siblings. If the traits measured by the BAP truly reflect underlying genetic diatheses toward autism, one would expect reduced allele sharing between DSPs at susceptibility loci as opposed to the excess allele sharing expected in ASPs (141).

The major advantage of the DSP method is that, theoretically, it may require far fewer sibling pairs than the ASP method under some circumstances. Risch and Zhang (142) estimated that DSP analysis may provide the same power to detect disease genes as the ASP method with a sample 10- to 40-fold smaller. The primary disadvantage of the DSP method is that DSPs are difficult to find, and require an extensive screening effort to identify enough pairs.

Microarray Technology

DNA chip microarray technology, which enables the simultaneous analysis of tens of thousands of DNA or RNA sequences, may be of significant benefit to autism research in two primary domains. First, an important focus of the current effort to sequence the human genome is the identification of single nucleotide polymorphisms (SNPs) (143). SNPs are sites of single base pair substitutions, are much more common than di-, tri-, or tetranucleotide polymorphisms, and, in contrast to current methodologies, can be easily and rapidly genotyped using DNA chips (144). The hope, therefore, is that DNA SNP chips will be used to rapidly screen a dense marker map, thereby enabling the performance of genome-wide association studies (145). Implementation of DNA chips for this purpose awaits the development of such SNP maps as well as the statistical and computational tools with which to analyze and interpret the resultant data.

The second potential use of microarray technology is to examine gene expression patterns in relevant tissues. DNA chips can be created that recognize all possible mRNAs that a tissue is currently producing (146). Thus, the expression

of thousands of genes from the brains of autistic individuals and controls can be compared in order to detect etiologically meaningful differences. The primary limitations of this method are the collection of brain tissue, which must be done rapidly and according to exact protocols, and interpretation of the data generated from such experiments (147). Altered gene expression, for example, may be due to medication effects as opposed to an etiologically relevant mechanism. The most meaningful studies of gene expression at this time, therefore, may come from animals genetically designed to exhibit autistic behaviors, where the environment and timing of the tissue analysis can be controlled.

Refining the Phenotype Through Biological Correlates of Illness

The primary purpose for investigating the BAP is to enable identification of meaningful genetic subgroups based on the core symptom domains of autism. Similar strategies are being pursued with various biological correlates of the disorder, including serotonin metabolism, minor physical anomalies, head circumference, brain morphology and function, and others.

CONCLUSION

Part of "41 - The Molecular and Cellular Genetics of Autism "

Numerous complementary strategies are currently being employed to attempt to locate autism disease genes. Linkage studies have identified a number of suggestive loci, most notably distal 7q. Interest in this region is supported by findings from language-disorder families and from a small number of 7q chromosomal anomalies in individuals with autism. Chromosomal anomalies also implicate 15q11-q13 as a region of interest, though linkage and association studies of the region have not been as impressive. These findings clearly demonstrate progress in the effort to find regions harboring genes in autism. As sample sizes continue to grow through collaborative efforts and molecular and statistical methods improve, and as complementary strategies such as the use of the BAP emerge, it seems plausible that in the near future more disease loci will be uncovered and specific autism disease genes may be identified.

Current and Emerging Therapeutics of Autistic Disorder and Related Pervasive Developmental Disorders

Christopher J. McDougle

Christopher J. McDougle: Department of Psychiatry, Section of Child and Adolescent Psychiatry, Indiana University School of Medicine; James Whitcomb Riley Hospital for Children, Indianapolis, Indiana.

DIAGNOSIS OF PERVASIVE DEVELOPMENTAL DISORDERS

Part of "42 - Current and Emerging Therapeutics of Autistic Disorder and Related Pervasive Developmental Disorders "

Pervasive developmental disorders (PDDs) are characterized by severe and pervasive impairment in several areas of development, including reciprocal social interaction skills, communication skills, and the presence of stereotyped behavior, interests, and activities (1). The qualitative impairments that define these disorders are abnormal relative to the individual's developmental level or mental age. These conditions are typically evident in the first 1 to 3 years of life and are usually associated with some degree of mental retardation. The PDDs are sometimes observed among a diverse group of identifiable biological abnormalities (e.g., chromosomal abnormalities, congenital infections, structural abnormalities of the brain). In the majority of cases, however, a specific etiologic factor is not found. Previously, terms like *psychosis* and *childhood schizophrenia* were used to refer to individuals with these conditions. However, there is now considerable evidence to demonstrate that PDDs are distinct from schizophrenia. There are five subtypes of PDD in the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV) (1). They include autistic disorder, Rett syndrome, childhood disintegrative disorder, Asperger's syndrome, and PDD not otherwise specified (NOS) (Table 42.1).

Autistic disorder

DSM-IV, *Diagnostic and Statistical Manual of Mental Disorders,* fourth ed.

TABLE 42.1. DSM-IV PERVASIVE DEVELOPMENTAL DISORDERS (1)

Autistic Disorder

The essential features of autistic disorder are the presence of markedly abnormal or impaired development in social interaction and communication and a markedly restricted repertoire of activity and interests. The clinical presentation of the disorder varies significantly depending on the developmental level and chronologic age of the individual. In the past, autistic disorder was referred to as early infantile autism, childhood autism, or Kanner's syndrome.

The clinical features must include delays or abnormal functioning in social interaction, in language as used in social communication, or in symbolic or imaginative play prior to the age of 3 years. There is usually no period of clearly normal development, although 1 or 2 years of relatively normal progression can occur. In some instances, regression in language development, typically manifest as a complete loss of speech after a child has acquired from five to ten words, has been reported. If there is a period of normal development, it cannot extend past the age of 3 years.

In approximately 75% of cases, there is an associated diagnosis of mental retardation, commonly in the moderate range (IQ 35 to 50). A number of behavioral symptoms, including hyperactivity; inattention; impulsivity; aggression toward self, others, or property; and interfering repetitive thoughts and behavior are often present. The disorder is sometimes observed in association with an identifiable medical condition (e.g., herpes encephalitis, phenylketonuria, tuberous sclerosis, fragile X syndrome, anoxia during birth, maternal rubella). Seizures may develop, particularly in adolescence, in up to 25% to 33% of cases. The disorder is four to five times more common in males than in females, although females often have a more severe cognitive disability. Epidemiologic studies have identified rates of autistic disorder of two to five cases per 10,000. Language skills and IQ are the strongest predictors of eventual outcome.

Rett Syndrome

Rett syndrome differs from autistic disorder in its characteristic sex ratio and distinctive pattern of abnormal developmental

progression. The syndrome is much less common than autistic disorder and has been diagnosed almost exclusively in females. Following apparently normal prenatal and perinatal development, and a period of normal psychomotor development through the first 5 months of life, there is a characteristic pattern of head growth deceleration, loss of previously acquired purposeful hand skills, intermittent hyperventilation, and the appearance of ataxic gait or trunk movements. Individuals with Rett syndrome may exhibit difficulties in social interaction, particularly during the preschool years, but these may improve somewhat over time. Severe or profound mental retardation, seizures, and significant expressive and receptive language impairment are typical. Recently, a mutation in the gene (*MECP2*) encoding X-linked methyl-CpG-binding protein 2 (MeCP2) has been identified as the cause of some cases of Rett syndrome (2).

Childhood Disintegrative Disorder

Childhood disintegrative disorder contrasts with autistic disorder in that there is a distinctive pattern of developmental regression following at least 2 years of normal development. In autistic disorder, some developmental abnormalities are usually noted within the first year of life. After the first 2 years of life (but before the age of 10 years), the child with childhood disintegrative disorder has a clinically significant loss of previously acquired skills in at least two of the following areas: expressive or receptive language, social skills or adaptive behavior, bowel or bladder control, play, or motor skills. The onset, in most cases, is between the ages of 3 and 4 years and may be insidious or abrupt. To date, an underlying pathologic mechanism has not been identified. The disorder has been reported in association with metachromatic leukodystrophy and Schilder's disease, in some cases. Childhood disintegrative disorder is usually associated with severe mental retardation. It appears to be very rare, much less frequent than autistic disorder, and more common among males. The disorder has also been termed Heller's syndrome, dementia infantilis, or disintegrative psychosis.

Asperger's Syndrome

Asperger's syndrome can be distinguished from autistic disorder by the lack of delay in language and cognitive development, in addition to no significant abnormality in the development of age-appropriate self-help skills, adaptive behavior (other than in social interaction), and curiosity about the environment in childhood. Motor milestones may be delayed, and motor clumsiness is often observed. The syndrome appears to be more common in males. Asperger's syndrome is usually recognized somewhat later than autistic disorder, frequently in the context of school. All-encompassing preoccupations or circumscribed interests are typically present and can contribute to significant functional impairment.

Pervasive Developmental Disorder Not Otherwise Specified

PDD NOS is diagnosed when there is a severe and pervasive impairment in the development of reciprocal social interaction or verbal and nonverbal communication skills, but the criteria are not met for a specific PDD, schizophrenia, schizotypal personality disorder, or avoidant personality disorder. Stereotyped behavior, interests, and activities are often present. This category includes presentations associated with late age at onset, atypical or subthreshold symptoms, or both.

PHARMACOTHERAPY OF PERVASIVE DEVELOPMENTAL DISORDERS

Part of "42 - Current and Emerging Therapeutics of Autistic Disorder and Related Pervasive Developmental Disorders "

The treatment of autistic disorder and related PDDs is multimodal and largely based on educational interventions and behavior management principles. Speech therapy is usually indicated, and physical and occupational therapy are often needed as well. Despite educational and behavioral strategies, many children, adolescents, and adults with PDDs remain significantly impaired. Under these circumstances, pharmacologic treatment is often appropriate and warranted.

Adequate drug treatment studies that have been focused on subjects with particular subtypes of PDD, other than autistic disorder, have not been conducted. Many investigations have included mixed samples of subjects with autistic disorder, Asperger's syndrome, and PDD NOS. Because of the extreme rarity of Rett syndrome and childhood disintegrative disorder, essentially no systematic psychopharmacologic treatment research has occurred in subjects with these subtypes of PDD. More recently, researchers have been conducting drug studies in adults with PDDs, in addition to those in children and adolescents with these disorders. The results from these investigations have allowed for some assessment of the impact of developmental factors on drug efficacy and tolerability.

Drugs that have consistent, primary effects on the core social disability of autistic disorder have not yet been developed. Studies in laboratory animals have identified particular

neurochemical systems that mediate some elements of affiliative behavior (3 ,4). The translation of these findings into investigational applications in humans, however, has not yet occurred. The pharmacotherapy of autistic disorder currently involves the identification and treatment of symptoms including motor hyperactivity (primarily in prepubertal autistic individuals); inattention; aggression directed toward self, others, or the environment; and interfering repetitive thoughts and behavior. With reduction in these associated target symptoms, improvement in some aspects of social behavior can result secondarily.

Following a brief review of earlier drug studies, results from more current investigations, including those of atypical antipsychotics and serotonin reuptake inhibitors (SRIs), will be presented in some detail. For a more comprehensive review of drug treatment of PDDs, the reader is referred to other sources (5 ,6).

Early Drug Treatment Studies

Beginning in the 1960s, numerous agents, including lysergic acid diethylamide, methysergide, levodopa, triiodothyronine, imipramine, and 5-hydroxytryptophan were studied in autistic disorder. Many of these investigations were limited by a lack of diagnostic precision and inadequate methodologic design. In general, these initial studies identified no drug that resulted in consistent target symptom reduction.

Elevated levels of whole blood serotonin (5-hydroxytryptamine, 5-HT) have long been associated with autistic disorder in a large minority of subjects (7). Following reports that fenfluramine, an indirect 5-HT agonist, decreased blood and brain 5-HT in animals, this drug received extensive investigation. Despite early enthusiasm generated by small open-label reports, most controlled studies found no consistent efficacy for fenfluramine as a treatment for autistic disorder (8). Furthermore, increasing evidence of possible neurotoxic effects of the drug on 5-HT neurons in animals and the association of fenfluramine with primary pulmonary hypertension and (in combination with phentermine) valvular heart disease have eliminated its use as a safe agent.

Most of the available typical antipsychotic drugs were studied in heterogeneous groups of children that included autistic subjects. Many of these early investigations suffered from the lack of adequate diagnostic methods and nonstandardized outcome measures. Most of these trials were direct comparisons of two drugs, usually low-potency antipsychotics, and did not include a placebo control. A number of these agents were found to be effective for behavioral symptoms including motor hyperactivity, agitation, and stereotypies. Due to significant sedation and adverse cognitive effects secondary to the low-potency drugs, however, studies of higher potency conventional antipsychotics were next pursued.

Campbell and co-workers (9 ,10 ,11 and 12) conducted several well-designed controlled studies of haloperidol in autistic children. In doses of 1.0 to 2.0 mg per day, haloperidol was found to be more efficacious than placebo for withdrawal, stereotypy, hyperactivity, affective lability, anger, and temper outbursts. However, acute dystonic reactions along with withdrawal and tardive dyskinesias were not infrequent.

Beginning in the late 1980s, the opioid antagonist naltrexone was investigated as a potential treatment for the associated behavioral symptoms of autistic disorder, as well as the core social deficits. Again, results from initial open-label reports and small controlled studies suggested possible effectiveness for naltrexone. More recent large well-designed controlled investigations involving children, adolescents, and adults with autistic disorder, however, have failed to demonstrate improvement in the majority of target symptoms or social behavior (13 ,14). The most consistent findings from these controlled studies were that naltrexone is well tolerated and may be effective for reducing motor hyperactivity.

A number of other drugs have been studied in autistic disorder, although most of the trials were either uncontrolled or contained a small number of subjects (5 ,6). For example, ß-adrenergic antagonists have been reported to reduce aggression and self-injury in some small open-label pilot trials in adults with autistic disorder. Hypotension and bradycardia were common dose-related adverse effects. Case reports and small open-label studies have described mixed results with the $5\text{-}HT_{1A}$ partial agonist buspirone. Controlled investigations of mood stabilizers, including lithium, valproic acid, carbamazepine, and gabapentin, have not been reported in well-defined groups of autistic subjects.

The pharmacologic management of motor hyperactivity and impaired attentional mechanisms in individuals with PDDs has proven particularly challenging to clinicians and researchers. These symptoms are most prominent in younger-aged autistic children. Thus, these symptoms are largely present during a time when educational programming and interventions are most critical. The psychostimulants, such as methylphenidate and dextroamphetamine, are effective treatments for these symptoms in individuals with attention-deficit/hyperactivity disorder (ADHD). Early controlled studies of these agents in autistic children, however, produced mixed results at best (15 ,16). In a more recent double-blind crossover study of methylphenidate and placebo, ten autistic children, ages 7 to 11 years, received doses of 10 or 20 mg twice daily for 2 weeks (17). Statistically significant improvement was seen on the Conners Teacher Questionnaire (18) and on the hyperactivity factor, irritability factor, and total score of the Aberrant Behavior Checklist (19). Adverse effects were minimal. The authors' impression was that the effects of methylphenidate were modest. Following completion of the study, it was necessary to add haloperidol to the treatment regimen of two of the ten children due to continued symptoms of aggression. Anecdotal reports from physicians in clinical practice and in

academic centers commonly describe the onset or exacerbation of irritability, insomnia, and aggression in individuals with PDDs with psychostimulant treatment.

The α_2-adrenergic agonist clonidine has been shown to be an effective treatment for some individuals with ADHD. In a small double-blind, placebo-controlled study of clonidine (4 to 10 µg per kg daily) in eight children with autistic disorder, statistically significant improvement was recorded in hyperactivity and irritability on some teacher and parent ratings (20). No significant drug–placebo differences were identified on clinician ratings of videotaped observations, however. Adverse effects included hypotension, sedation, and irritability. In contrast, transdermal clonidine (5 µg per kg daily) was reported to be effective in a double-blind, placebo-controlled crossover study (4 weeks in each treatment phase) involving nine males (ages 5 to 33 years) with autistic disorder (21). Significant improvement was seen on the Clinical Global Impression Scale (CGI) (22), and hyperactivity and anxiety were also reduced. The most common adverse effects were sedation and fatigue.

Guanfacine is an α_2-adrenergic agonist with a longer half-life than clonidine that may be less sedating and cause less pronounced hypotension (23). No open-label or controlled studies have been published on the use of guanfacine in PDDs.

To more rigorously address the pharmacotherapy of symptoms of hyperactivity and inattention in PDD, the National Institute of Mental Health (NIMH)-sponsored Research Units on Pediatric Psychopharmacology (RUPP) Autism Network is planning a controlled investigation of a methylphenidate vs. placebo in children with PDDs.

Current Drug Treatment Studies

Atypical Antipsychotics

Over the past 5 to 10 years, considerable interest has been generated by the introduction of the atypical antipsychotics (24). These drugs appeared to have potential as a treatment for autistic disorder for a number of reasons. Initial studies in schizophrenia indicated that these agents were better tolerated and had a lower risk of acute and tardive dyskinesias compared with conventional antipsychotics. In addition, these drugs were shown to improve both the “positive” (hallucinations and delusions) and “negative” symptoms of schizophrenia. The negative symptoms include blunted affect, emotional and social withdrawal, lack of interest in interpersonal relationships, difficulty in abstract thinking, lack of spontaneity and flow of conversation, and stereotyped thinking (25). A number of investigators suggested that the negative symptoms of schizophrenia were comparable to those that characterize the social impairment of autistic disorder. To date, reports have appeared in which clozapine, risperidone, olanzapine, or quetiapine was used in the treatment of autistic disorder and other PDDs. The reader is referred to a recent publication that provides a comprehensive review of atypical antipsychotics in autistic disorder (26).

Clozapine

Clozapine has been shown to be effective for treatment-refractory schizophrenia (27). The drug’s ability to block 5-HT_{2A}, 5-HT_{2C}, 5-HT_3, and dopamine D_1-D_4 receptors has been proposed as its mechanism of action. There has been only one report to date describing the use of clozapine in autistic disorder (28). Three children with significant hyperactivity or aggression were given clozapine after they had not responded to typical antipsychotics. Improvement was observed in the three subjects after 3 months’ treatment at dosages up to 200 mg per day. The scarcity of reports describing the use of clozapine in autistic disorder might reflect concern regarding the risk of agranulocytosis or seizures in children or adolescents that are associated with the drug. Because autistic individuals typically have an impaired ability to communicate effectively and often a high pain threshold, infections secondary to a decreased white blood cell count may not be identified in a timely manner. Additionally, as mentioned above, many individuals with autistic disorder have comorbid seizure disorders. Furthermore, the necessary frequent blood draws are not ideal for children, particularly those with autistic disorder.

Risperidone

Risperidone is a highly potent 5-HT_{2A}/D_2 antagonist that has been shown in controlled trials to improve both the positive and negative symptoms of schizophrenia (29). A number of open-label reports describing improvement in aggression, self-injury, ritualistic behavior, irritability, impulsivity, hyperactivity, and social relatedness in children, adolescents, and adults with autistic disorder have appeared (26). Only one controlled study of risperidone, or any atypical antipsychotic for that matter, has been published in individuals with autistic disorder and related PDDs (30) (Table 42.2). In that study, 31 adults (mean age, 28.1 years) with autistic disorder (*n* = 17) or PDD NOS (*n* = 14) entered the 12-week trial. For subjects completing the study, eight (57%) of 14 treated with risperidone [mean ± standard deviation (SD) dose, 2.9 ± 1.4 mg daily; range 1 to 6 mg per day] were categorized as responders compared with none of 16 in the placebo group based on the CGI. Nine (60%) of 15 subjects who received open-label risperidone following the double-blind placebo phase responded. Specifically, risperidone was effective for reducing interfering repetitive behavior, as well as aggression toward self, others, and property.

TABLE 42.2. CONTROLLED TRIALS OF CURRENT DRUG TREATMENTS FOR AUTISTIC DISORDER

Drug	Reference	Sample and Design	Results
Atypical antipsychotics			
Risperidone	McDougle et al. (30)	31 adults, autistic disorder (*n* = 17), pervasive developmental disorder not otherwise specified (PDD NOS) (*n* = 14), 12-week double-blind, placebo-controlled	Risperidone—8 of 14 (57%) responders Placebo—0 of 16 responders
SRIs			
Clomipramine vs. Desipramine	Gordon et al. (40)	7 children and adolescents with autistic disorder, 10-week double-blind crossover following 2-week single-blind placebo phase	Clomipramine > desipramine for obsessive-compulsive symptoms and autistic symptoms Clomipramine = desipramine for hyperactivity
Clomipramine vs. Placebo	Gordon et al. (41)	12 children and adolescents with autistic disorder, 10-week double-blind crossover following 2-week single-blind placebo phase	Clomipramine > placebo for obsessive-compulsive symptoms, autistic symptoms and hyperactivity
and			
Clomipramine vs. Desipramine		12 children and adolescents with autistic disorder, 10-week double-blind crossover following 2-week single-blind placebo phase	Clomipramine > desipramine for obsessive-compulsive symptoms and autistic symptoms Clomipramine = desipramine for hyperactivity
Fluvoxamine	McDougle et al. (48)	30 adults with autistic disorder, 12 week double-blind, placebo-controlled	Fluvoxamine—8 of 15 (53%) responders Placebo—0 of 15 responders

SRI, serotonin reuptake inhibitor.

Although risperidone was better than placebo for decreasing the overall maladaptive behaviors of autistic disorder, as measured by the Ritvo-Freeman Real Life Rating Scale overall score (31), this finding was largely accounted

for by significant changes in sensory motor behaviors (e.g., rocking, flapping), affectual reactions (e.g., temper outbursts), and to some extent sensory responses (e.g., spinning objects, sniffing self or objects). Significant differences between risperidone and placebo were not captured on subscales of the Ritvo-Freeman Scale that measure social relationships to people and language. For many subjects, however, clinicians, parents, and other members of the treatment teams had the impression that anxiety associated with social interactions was reduced, allowing for enhanced social function. It may be that the rating scales used to assess social relatedness in this study were not sensitive enough to detect changes in this complex aspect of behavior.

In general, risperidone was well tolerated. Thirteen (87%) of 15 subjects randomized to risperidone had at least one adverse effect, although this included only mild, transient sedation in five subjects, compared with five (31%) of 16 subjects given placebo (agitation in all five cases). Interestingly, the weight gain that has been observed with risperidone in the treatment of some children and adolescents with PDDs did not occur to the same degree in this study of adults.

Based on these results and other clinical, preclinical, and safety data, the RUPP Autism Network chose risperidone as the first drug to study in children and adolescents with autistic disorder (26). When completed, this investigation will be the largest controlled drug trial conducted to date in autistic disorder.

Olanzapine

Three case reports and an open-label case series have described positive responses to the atypical antipsychotic olanzapine in subjects with PDDs. In the case series, six of seven children, adolescents, and adults with autistic disorder and other PDDs (mean ± SD age, 20.9 ± 11.7 years; range 5 to 42 years) who completed the 12-week open-label trial were responders based on the CGI (32). Significant improvement in overall symptoms of autistic disorder, motor restlessness or hyperactivity, social relatedness, affectual reactions, sensory responses, language usage, self-injurious behavior, aggression, irritability or anger, anxiety, and depression was observed. Significant changes in repetitive behavior did not occur for the group. The mean ± SD dose of olanzapine was 7.8 ± 4.7 mg daily (range 5 to 20 mg per day). The drug was well tolerated, with the most significant adverse effects being increased appetite and weight gain in six subjects and sedation in three.

Quetiapine

Only one report of quetiapine in the treatment of autistic disorder has been published (33). Six males with autistic disorder, 6.2 to 15.3 years of age (mean ± SD age, 10.9

± 3.3 years), entered a 16-week open-label trial of quetiapine. The mean ± SD daily dose of quetiapine was 225 ± 108 mg (range 100 to 350 mg per day). Overall, there was no statistically significant improvement for the group as a whole on various behavioral rating scales. Two subjects completed the entire 16-week trial; both were considered responders based on CGI scores. However, only one of these two subjects continued to benefit from longer term treatment with the drug. The other four subjects dropped out due to lack of response and sedation (three subjects), and a possible seizure during the fourth week of treatment (one subject). Other significant side effects included behavioral activation, increased appetite, and weight gain (range 0.9 to 8.2 kg). The authors concluded that quetiapine was poorly tolerated and ineffective in most subjects, although the sample size was small. More studies of quetiapine in autistic disorder and related PDDs are needed before definitive conclusions about its effectiveness and safety can be made.

Summary

The atypical antipsychotics have potent effects on 5-HT and dopamine neuronal systems, both of which have been implicated in the pathophysiology of PDDs. Unlike the typical antipsychotic, haloperidol, which has been shown to be effective for reducing many of the maladaptive behaviors associated with PDDs, the atypical agents' $5\text{-}HT_{2A}/D_2$ ratio of receptor blockade appears to produce a lower risk of acute and chronic extrapyramidal side effects, as well as enhanced efficacy for the "negative" symptoms of PDD. Because most of the studies of this class of drugs have been short-term open-label trials in small samples, larger scale controlled investigations are needed to confirm these preliminary results. Due to the possibility that many children and adolescents who demonstrate short-term benefit from these drugs will remain on them indefinitely, the longer term safety and efficacy of atypical antipsychotics in this population also needs to be determined.

Serotonin Reuptake Inhibitors

In Kanner's 1943 landmark description of 11 autistic children, the repetitive natures of behavior, speech, and modes of social interaction were designated as core clinical elements of the syndrome (34). Verbal and motor rituals, obsessive questioning, a rigid adherence to routine, a preoccupation with details, and an anxiously obsessive desire for the maintenance of sameness and completeness were all noted. Religious and somatic obsessions, repetitive hand washing, and tics were identified in family members.

Results from a more recent study indicated that adults with autistic disorder and obsessive-compulsive disorder (OCD) can be distinguished on the basis of their current types of repetitive thoughts and behavior (35). Compared with the OCD group, the autistic subjects were significantly less likely to have aggressive, contamination, sexual, religious, symmetry, and somatic thoughts. Repetitive ordering, hoarding, telling or asking (trend), touching, tapping, or rubbing, and self-damaging or self-mutilating behaviors were reported significantly more frequently in the autistic subjects, whereas cleaning, checking, and counting behaviors were less common in the autistic group compared with the OCD subjects.

The clear efficacy of potent SRIs in OCD and their differential effects when directly compared to drugs that potently inhibit norepinephrine (NE) uptake support the hypothesized importance of 5-HT in the treatment of obsessive-compulsive symptoms (36). Consistent with these drug response data is the hypothesis that a dysregulation of 5-HT function might contribute to the pathophysiology of at least some individuals with OCD (37). Abnormalities in 5-HT function have also been identified in subjects with autistic disorder and other PDDs (38). Based on the efficacy of SRIs in the treatment of OCD, the high prevalence of interfering repetitive thoughts and behavior in subjects with PDD, and evidence indicating that a dysregulation in 5-HT neurotransmission may contribute to the pathophysiology of some individuals with autistic disorder, researchers have been studying the clinical response and side effect profile of SRIs in children, adolescents, and adults with PDDs.

Clomipramine

Clomipramine, a tricyclic antidepressant (TCA) and potent, but nonselective, inhibitor of 5-HT uptake, has been shown to be more efficacious than the relatively selective NE uptake inhibiting TCA desipramine in the treatment of children and adolescents with OCD (39). In the first controlled investigation of clomipramine in autistic disorder, the drug was found to be more efficacious than desipramine and placebo on standardized ratings of autistic disorder and anger, as well as ratings of repetitive and compulsive behaviors (40). Seven subjects with autistic disorder, ages 6 to 18 years (means age, 9.6 years), completed the 10-week double-blind crossover trial of clomipramine (mean dose, 129 daily) and desipramine (mean dose, 111 mg daily) following a 2-week single-blind placebo phase. In general, the side effects were relatively minor and did not differ between the two drugs. Mild sleep disturbance, dry mouth, and constipation were observed, and one patient developed a minor tremor on clomipramine. Two subjects taking desipramine developed uncharacteristic and severe irritability and temper outbursts. The parents of all seven subjects chose to have their children continue on clomipramine after completion of the study.

As a follow-up to this pilot study, a larger double-blind comparison of clomipramine, desipramine and placebo was conducted in children and adolescents with autistic disorder (41). Following a 2-week single-blind placebo phase, 12 subjects completed a 10-week double-blind crossover comparison of clomipramine and placebo, and 12 different subjects completed a similar comparison of clomipramine and

desipramine. The latter study included data from the seven subjects who participated in the original pilot study described above. Clomipramine (mean dose, 152 mg daily) was superior to both placebo and desipramine (mean dose, 127 mg daily) on ratings of autistic symptoms, including stereotypies, anger, and ritualized behaviors, with no difference between desipramine and placebo. Clomipramine was equal to desipramine and both drugs were superior to placebo for reducing motor hyperactivity. One child developed prolongation of the corrected QT interval (0.45 seconds) and another developed severe tachycardia (resting heart rate, 160 to 170 beats per minute) during clomipramine treatment. A third child experienced a grand mal seizure.

Subsequent open-label studies of clomipramine have been published with mixed results and increased recognition of adverse effects. Clomipramine treatment of five young adults (ages 13 to 33 years) with autistic disorder led to ratings of “much improved” on the CGI in four patients, with improvement seen in social relatedness, obsessive-compulsive symptoms, aggression, and self-injurious behavior (42). In another study, 11 consecutively referred children and adolescents with developmental disabilities and chronic stereotypies or self-injurious behavior were treated with clomipramine (43). Four of the subjects (ages 13 to 20 years) had been diagnosed with autistic disorder and of them, three had a significant reduction in stereotypic, self-injurious behavior with clomipramine at doses of 50 to 125 mg daily. Adverse effects included constipation, aggression, rash, and enuresis. In another open-label study, clomipramine 200 mg daily, was associated with decreased abnormal motor movements and compulsions in five autistic boys ages 6 to 12 years (44).

A large prospective open-label study of clomipramine (mean dose, 139 mg daily) treatment of 35 adults diagnosed with different subtypes of PDD was described (45). Of the 33 subjects who completed the 12-week study, 18 (55%) were judged responders on the CGI with improvement seen in aggression, self-injury, interfering repetitive thoughts and behavior, and social relatedness. Thirteen of the 33 subjects had significant adverse effects including seizures (in three patients, including two who had preexisting seizure disorders stabilized on anticonvulsants), weight gain, constipation, sedation, agitation, and anorgasmia.

A number of studies have suggested that younger children may tolerate clomipramine less well and show a decreased response compared to adolescents and adults with PDDs. In one report, eight children (ages 3.5 to 8.7 years) were given clomipramine (mean dose, 103 mg daily) for 5 weeks in a prospective open-label manner (46). Among the seven children who completed the trial, only one child was rated as moderately improved on a clinical global consensus measure. Adverse effects were frequent and included urinary retention requiring catheterization, constipation, drowsiness, and increased aggression and irritability. In a follow-up report to the study described above, in which five autistic children had an initial positive response to clomipramine (44), it was noted that the drug was eventually discontinued in all cases due to adverse effects or continued maladaptive behavior (47). Adverse effects included the serotonin syndrome, increased seizure frequency, and exacerbation of agitation and aggressiveness that required hospitalization.

Because of their better side effect profile compared with clomipramine, including their lower propensity to decrease the seizure threshold, selective SRIs (SSRIs) have been receiving increasing attention as a potential treatment for the interfering symptoms associated with autistic disorder and other PDDs.

Fluvoxamine

To date, only one double-blind, placebo-controlled study of an SSRI in subjects with autistic disorder has been published (48). Fluvoxamine (mean dose, 276.7 mg daily) or placebo was given to 30 autistic adults for 12 weeks. Eight of 15 subjects who received fluvoxamine vs. none who received placebo were categorized as “much improved” or “very much improved” on the CGI. Fluvoxamine was significantly more effective than placebo for reducing repetitive thoughts and behavior, maladaptive behavior, and aggression. In addition, fluvoxamine reduced inappropriate repetitive language usage. Adverse effects included nausea and sedation, which were transient and of minor severity.

In contrast to the encouraging results from this study of fluvoxamine in autistic adults, a 12-week double-blind, placebo-controlled study in children and adolescents with autistic disorder and other PDDs found the drug to be poorly tolerated with limited efficacy at best (McDougle and co-workers, unpublished data). Thirty-four patients (five female, 29 male; age range 5 to 18 years, mean age, 9.5 years), 12 of whom met criteria for autistic disorder, eight for Asperger’s syndrome, and 14 for PDD NOS, participated. Of the 16 subjects randomized to placebo, none demonstrated any significant change in target symptoms. Adverse events that occurred in the placebo-treated subjects included increased motor hyperactivity (*n* = 2), insomnia (*n* = 2), dizziness and/or vertigo (*n* = 1), agitation (*n* = 1), diarrhea (*n* = 1), decreased concentration (*n* = 1), and increased self-stimulation (*n* = 1). Eighteen of the subjects were randomized to fluvoxamine (range 25 to 250 mg daily; mean dose, 106.9 mg per day). The drug was begun at 25 mg every other day and increased by 25 mg every 3 to 7 days as tolerated. Only one of the fluvoxamine-treated children demonstrated a significant improvement with the drug. Fourteen of the children randomized to fluvoxamine demonstrated adverse effects [insomnia (*n* = 9), motor hyperactivity (*n* = 5), agitation (*n* = 5), aggression (*n* = 5), increased rituals (*n* = 2), anxiety (*n* = 3), anorexia (*n* = 3), increased appetite (*n* = 1), irritability (*n* = 1), decreased concentration (*n* = 1), and increased impulsivity (*n* = 1)].

The marked difference in efficacy and tolerability of fluvoxamine in children and adolescents with autistic disorder

and other PDDs in this study, compared with that of autistic adults, underscores the importance of developmental factors in the pharmacotherapy of these subjects. This differential drug response is consistent with the hypothesis that ongoing brain development has a significant impact on the subjects' ability to tolerate and respond to a drug, at least with respect to fluvoxamine and possibly other SSRIs. Developmental changes in brain 5-HT function may contribute to these widely varying clinical responses between subjects with autistic disorder and other PDDs of different age groups.

Fluoxetine

Several case reports have described fluoxetine treatment of autistic subjects although, to date, no controlled studies have appeared.

In a large case series, Cook and associates (49) found fluoxetine (10 to 80 mg daily), given in an open-label manner, effective in 15 of 23 subjects (ages 7 to 28 years) with autistic disorder as determined by the CGI (49). Intolerable side effects, including restlessness, hyperactivity, agitation, elated affect, decreased appetite, and insomnia, occurred in six of 23 subjects.

In a retrospective investigation, fluoxetine (20 to 80 mg daily) and paroxetine (20 to 40 mg daily) were found to be effective in approximately one-fourth of adults (mean age, 39 years) with "intellectual disability" and autistic traits (50). The sample included all intellectually disabled subjects who had been treated with an SSRI over a 5-year period within a health care service in Great Britain. The mean duration of treatment was 13 months. Target symptoms were perseverative behaviors, aggression, and self-injury. Six of 25 subjects treated with fluoxetine and three of 12 subjects given paroxetine were rated as "much improved" or "very much improved" on the CGI.

In another study, 37 children (ages 2.25 to 7.75 years) with autistic disorder were treated with fluoxetine in an open-label fashion at doses ranging from 0.2 to 1.4 mg per kg daily (51). Eleven of the children had an "excellent" clinical response and 11 others had a "good" response. Improvement was seen in behavioral, cognitive, affective, and social areas. Interestingly, language acquistion seemed to improve with fluoxetine treatment. Drug-induced hyperactivity, agitation, and aggression were frequent causes of discontinuation of fluoxetine.

Sertraline

To our knowledge, no controlled studies of sertraline in subjects with autistic disorder or other PDDs have been published, although a number of open-label reports have appeared. In a 28-day trial of sertraline (at doses of 25 to 150 mg daily) in nine adults with mental retardation (five of whom had autistic disorder), significant decreases in aggression and self-injurious behavior occurred in eight as rated on the CGI severity rating (52). In a case series of nine autistic children (ages 6 to 12 years) treated with sertraline (25 to 50 mg daily), eight showed significant improvement in anxiety, irritability, and "transition-induced behavioral deterioration" or "need for sameness" (53). In three of the responders, a return of symptoms occurred after 3 to 7 months. Two children demonstrated agitation when the dose was raised to 75 mg daily.

A large prospective open-label study of 42 adults with PDDs (including subjects with autistic disorder, Asperger's syndrome, and PDD NOS) found sertraline (mean dose, 122 mg per day) effective for improving aggression and interfering repetitive behavior, but not impaired social relatedness as assessed by various rating scales over the course of the 12-week study (54). As determined by a CGI global improvement item score of "much improved" or "very much improved," 15 of 22 subjects with autistic disorder, none of six with Asperger's syndrome, and nine of 14 with PDD NOS were judged responders. Those subjects with autistic disorder and PDD NOS showed significantly more benefit from sertraline than those with Asperger's syndrome; the authors hypothesized that this might have been because those diagnosed with Asperger's syndrome were less symptomatic at baseline. Three of the 42 subjects dropped out of the study due to intolerable agitation and anxiety.

Paroxetine

Only a few reports, none of them controlled, have appeared on the use of paroxetine in autistic disorder. Paroxetine 20 mg per day decreased self-injury in a 15-year-old boy with "high-functioning" autistic disorder (55). In another report, paroxetine resulted in a reduction of irritability, temper tantrums, and interfering preoccupations in a 7-year-old boy with autistic disorder (56). The optimal dose of paroxetine was 10 mg daily; an increase of paroxetine to 15 mg per day led to agitation and insomnia. As described earlier, a retrospective case analysis found paroxetine to be effective in approximately 25% of adults with PDD NOS (50).

In a 4-month open-label study of 15 adults with severe and profound mental retardation (seven with PDD), paroxetine at doses of 20 to 50 mg daily was effective for symptoms of aggression at 1 month, but not at 4-month follow-up (57). The investigators hypothesized that adaptive changes may have occurred in 5-HT receptor density, availability of 5-HT, or in 5-HT transporter sensitivity.

Citalopram

To date, there have been no published reports on the effects of citalopram, an SSRI that has been recently introduced in the United States, in patients with autistic disorder or other PDDs.

Summary

Recent work has determined that the types of repetitive phenomena associated with autistic disorder are different from those that characterize OCD. Nevertheless, these signs

and symptoms can interfere with the autistic individual's quality of life. Studies of SRIs, the mainstay of treatment for the obsessions and compulsions of OCD, have yielded mixed results in autistic disorder. To date, only three controlled studies of SRIs in autistic disorder have been published, as reviewed above (Table 42.2). All three of these studies found the SRI to be helpful for the interfering repetitive phenomena associated with autistic disorder, as well as for aspects of aggression, self-injury, and impaired social relatedness. On the other hand, results from an unpublished controlled study of fluvoxamine in children and adolescents with autistic disorder and other PDDs indicated that the drug was poorly tolerated and of limited efficacy. The results from that study are consistent with those from a number of open-label reports suggesting that SRIs may be less well tolerated and less effective in younger (prepubertal) autistic subjects compared with autistic adolescents and adults (postpubertal). Although this developmental difference in tolerability and response to SRIs may be a dose-related phenomena, other factors need to be considered. Recent data indicate that significant changes in measures of 5-HT function occur during puberty in autistic individuals. For example, McBride and co-workers (58) found that mean platelet 5-HT levels were significantly higher in prepubertal autistic children than prepubertal normal controls, but no significant difference was found between postpubertal male autistic subjects and postpubertal normal controls (58). Furthermore, Chugani and associates (59) reported results from a positron emission tomography brain imaging study showing that changes in brain 5-HT synthesis capacity that normally occur in developing humans are disrupted in autistic children (59). Thus, pre- and postpubertal autistic subjects may have significant differences in brain 5-HT function that influence their ability to tolerate and respond to SRIs. Pharmacogenetic differences among autistic individuals, which may affect SRI tolerability and responsivity, will also require more investigation (60).

Novel Therapeutic Strategies

Secretin

Secretin is a polypeptide hormone secreted primarily by the endocrine cells in the upper gastrointestinal (GI) tract that is involved in regulating pancreatic exocrine secretion. A synthetic form of secretin is Food and Drug Administration (FDA) approved for use in the diagnosis of particular GI diseases. In 1998, Horvath and co-workers (61) published a report that described marked improvement in language and social behavior in three children with autistic disorder who received secretin as part of a routine diagnostic workup for GI problems.

These encouraging yet preliminary results, coupled with enthusiastic media reports, led to widespread excitement and optimism among many family members of autistic individuals about a potential "cure" for the disorder. In response, researchers began conducting controlled studies of secretin in autistic children. A double-blind, controlled study of single-dose intravenous secretin (0.4 μg per kg) or placebo administration was conducted in 60 children, ages 3 to 14 years, of whom 40 had autistic disorder and 20 had PDD NOS (62). No significant differences were found between secretin and placebo on primary outcome measures that assessed changes in autistic behaviors and adaptive functioning at days 1 and 2 and weeks 1, 2, and 4 following the infusion. No significant difference was found in adverse effects between secretin and placebo. Two additional controlled studies have reported similar findings (63 ,64). Based on the results of these systematic investigations, secretin cannot be recommended as a treatment for the target symptoms associated with autistic disorder.

Glutamatergic Agents

The *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptor is central to developmental processes including neuronal migration, differentiation, and plasticity (65). Disturbances in glutamatergic function, via reduced neurotropic actions of glutamate or excessive neurotoxic effects, could alter neurodevelopment substantially (66). During the past 5 to 10 years, significant advances have been made in the identification of potential pharmacotherapies affecting glutamatergic function for a number of neuropsychiatric disorders (67).

Hypotheses regarding glutamatergic dysfunction in autistic disorder have been proposed (68). In addition, preliminary results from studies of drugs that modulate glutamate neurotransmission in autistic disorder have been published. Lamotrigine is a drug that attenuates some forms of cortical glutamate release via inhibition of sodium channels, P- and N-type calcium channels, and potassium channels. In one study, eight of 13 children and adolescents with autistic disorder given lamotrigine for intractable epilepsy showed a decrease in "autistic symptoms" (69). Another report described improvement in self-injurious behavior, irritability, and disturbed sleep in an 18-year-old woman with profound mental retardation and a generalized seizure disorder who was given open-label lamotrigine (70). Interestingly, the subject showed improvement in measures of "fixed facial expression, lacks emotional responsivity," "resists any form of physical contact," and "inactive, never moves spontaneously." The authors suggested that these changes might represent a "prosocial" effect of the drug. In a double-blind, placebo-controlled study, 39 subjects with autistic disorder, ages 5 to 19 years old, were given placebo or the NMDA receptor antagonist amantadine (71). The design included a single-blind placebo lead-in, followed by a single daily dose of amantadine (2.5 mg per kg) or placebo for the next week, and then twice daily dosing for the subsequent 3 weeks. No significant difference was found between drug

and placebo on parent ratings, although clinician-rated measures of hyperactivity and inappropriate speech showed statistically significant improvement. A trend toward greater response in the amantadine group, based on CGI ratings, occurred. Amantadine was well tolerated.

Based on these preliminary results, and reports that the “negative” symptoms of schizophrenia can be improved with drugs active at the NMDA receptor (72), additional research with these and other agents affecting the glutamatergic systems appears warranted. The group II/III metabotropic-glutamate receptor (mGluR II/III) agonists (73) and the positive allosteric modulator of α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors, CX516 (Ampakine) (74) may hold promise in this regard. Interestingly, one mechanism of action underlying the relative efficacy of atypical antipsychotics, such as risperidone, for autistic disorder (30) may be the suppression of glutamate release via 5-HT_{2A} antagonism (75).

Neuroimmune Modulation

Neuroimmunologic dysfunction has been implicated in the pathophysiology of autistic disorder (76) and other neuropsychiatric conditions (77). To date, no consistent immunologic abnormalities have been found in autistic disorder, although viral and autoimmune hypotheses, among others, have been posited (76). Neurovirologic disease and other insults to the immune system can lead to increased production of catabolites of tryptophan, including quinolinate and kynurenate, which can cause significant neurotoxicity via activity at the NMDA receptor complex (78). Thus, neuroimmune dysregulation in autistic disorder would not be inconsistent with altered glutamatergic function, as described above. Results from small open-label studies of intravenous immunoglobulin have suggested that this intervention may be helpful in only a limited minority of subjects, if at all (79). Controlled studies of agents that have direct effects on immune function, however, have not been conducted in autistic disorder. Such research on neuroimmune interactions may yield important data on pathophysiology, if not etiology, in a subset of autistic subjects.

CONCLUSION

Part of "42 - Current and Emerging Therapeutics of Autistic Disorder and Related Pervasive Developmental Disorders "

Significant progress in the neuropsychopharmacology of autistic disorder and related PDDs has been made since the fourth edition of this text (80). Future research in this area should include controlled studies of atypical antipsychotics in children and adolescents with autistic disorder and other PDDs, such as that being conducted by the NIMH-sponsored RUPP Autism Network (26). Longitudinal efficacy and safety data will need to be gathered on atypical antipsychotics in this population, as well. Larger double-blind, placebo-controlled trials of SRIs in pre- vs. postpubertal individuals with autistic disorder, as well as studies designed to determine the effects of these drugs on the target symptoms of subjects with different subtypes of PDD, including Asperger’s syndrome, are also needed. In these studies, the optimal dosage for age and developmental level and the duration of adequate treatment should be determined. In addition, genetic predictors of treatment response, such as 5-HT transporter protein genotype, should be sought (60). The scientific community needs to continue to respond to reports of putative “cures” for autistic disorder, such as those that surrounded secretin, by conducting controlled studies of such agents. Accepting this responsibility will contribute to ensuring the continued safety of autistic subjects and provide family members with data on which to base informed decisions regarding their child’s medical care. Finally, exploration of promising novel therapeutic strategies, such as those affecting glutamatergic and neuroimmune function, may provide new insights into the neurobiology and treatment of this devastating group of disorders.

Joseph Biederman: Pediatric Psychopharmacology Unit, Child Psychiatry Service, Massachusetts General Hospital; Harvard Medical School, Boston, Massachusetts.

Attention-deficit/hyperactivity disorder (ADHD) is a childhood-onset, clinically heterogeneous disorder of inattention, hyperactivity, and impulsivity. Its impact on society is enormous in terms of its financial cost, stress to families, adverse academic and vocational outcomes, and negative effects on self-esteem (1). Children with ADHD are easily recognized in clinics, in schools, and in the home. Their inattention leads to daydreaming, distractibility, and difficulties in sustaining effort on a single task for a prolonged period. Their impulsivity makes them accident prone, creates problems with peers, and disrupts classrooms. Their hyperactivity, often manifest as fidgeting and excessive talking, is poorly tolerated in schools and is frustrating to parents, who can easily lose them in crowds and cannot get them to sleep at a reasonable hour. In their teenage years, symptoms of hyperactivity and impulsivity diminish, but in most cases the symptoms and impairments of ADHD persist. The teen with ADHD is at high risk of low self-esteem, poor peer relationships, conflict with parents, delinquency, smoking, and substance abuse (1).

The validity of diagnosing ADHD in adults has been a source of much controversy (2). Some investigators argue that most cases of ADHD remit by adulthood (3), a view that questions the validity of the diagnosis in adulthood. Others argue that the diagnosis of ADHD in adults is both reliable and valid (2). These investigators point to longitudinal studies of children with ADHD, studies of clinically referred adults, family-genetic studies, and psychopharmacologic studies. Longitudinal studies have found that as many as two thirds of children with ADHD have impairing ADHD symptoms as adults. Studies of clinically referred adults with retrospectively defined childhood-onset ADHD show them to have a pattern of psychosocial disability, psychiatric comorbidity, neuropsychological dysfunction, familial illness, and school failure that resemble the well known features of children with ADHD.

Throughout the life cycle, a key clinical feature observed in patients with ADHD is comorbidity with conduct, depressive, bipolar, and anxiety disorders (4 ,5). Although spurious comorbidity can result from referral and screening artifacts (5), these artifacts cannot explain the high levels of psychiatric comorbidity observed for ADHD (4). Notably, epidemiologic investigators find comorbidity in unselected general population samples (6 ,7), a finding that cannot be caused by the biases that inhere in clinical samples. Moreover, as we discuss later, family studies of comorbidity dispute the notion that artifacts cause comorbidity; instead, they assign a causal role to etiologic relationships among disorders.

NEUROPSYCHOPHARMACOLOGY

Part of "43 - Pathophysiology of Attention-Deficit/Hyperactivity Disorder "

Pharmacotherapy

Any pathophysiologic theory about ADHD must address the large pharmacotherapy literature about the disorder. The mainline treatments for ADHD are the stimulant medications methylphenidate, pemoline, and dextroamphetamine. These compounds are safe and effective for treating ADHD in children, adolescents, and adults (8 ,9). In addition, to improving ADHD's core symptoms of inattentiveness, hyperactivity, and impulsivity, stimulants also improve associated behaviors, including on-task behavior, academic performance, and social functioning in the home and at school. In adults, occupational and marital dysfunction tend to improve with stimulant treatment. There is little evidence of a differential response to methylphenidate, pemoline, and dextroamphetamine. The average response rate for each is 70%.

Stimulants enhance social skills at home and in school.

They also improve maternal-child and sibling interactions. Children with ADHD who are treated with stimulants have increased abilities to perceive peer communications and situational cues and to modulate the intensity of their behavior. They also show improved communication, greater responsiveness, and fewer negative interactions. Neuropsychological studies show that stimulants improve vigilance, cognitive impulsivity, reaction time, short-term memory, and learning of verbal and nonverbal material in children with ADHD.

Although stimulants are the mainstay of anti-ADHD pharmacotherapy, tricyclic antidepressants (TCAs) also are effective anti-ADHD agents. TCAs include secondary and tertiary amines with a wide range of receptor actions, efficacy, and side effects. Secondary amines are more selective (noradrenergic) with fewer side effects. Most studies of TCAs have found either a moderate or robust response rate of ADHD symptoms (8 ,9 and 10). These studies show anti-ADHD efficacy for imipramine, desipramine, amitriptyline, nortriptyline, and clomipramine. Both short- and long-term studies show that TCAs produce moderate to strong effects on ADHD symptoms. In contrast, neurocognitive symptoms are do not respond well to TCA treatment. Because of rare reports of sudden death among TCA-treated children, these drugs are not a first-line treatment for ADHD and are only used after carefully weighing the risks and benefits of treating or not treating a child who does not respond to other agents.

Other noradrenergic agents help to control ADHD symptoms. Bupropion hydrochloride, which has both dopaminergic and noradrenergic effects, is effective for ADHD in children (11 ,12)as well as in adults (13). Although they are rarely used because of their potential for hypertensive crisis, several studies suggested that monoamine oxidase inhibitors may be effective in juvenile and adult ADHD (14). The experimental noradrenergic compound tomoxetine showed efficacy in a controlled study of adults with ADHD (15) and in an open study of children with ADHD (16).

In contrast to the beneficial effects of stimulants and TCAs, there is only weak evidence that either α_2-noradrenergic agonists or serotonin reuptake inhibitors effectively combat ADHD (17). A controlled clinical trial showed that transdermal nicotine improved ADHD symptoms and neuropsychological functioning in adults with ADHD (18). Consistent with this finding, a controlled study found the experimental compound ABT-418 to treat adult ADHD effectively (19). ABT-418 is a potent and selective agonist for $\alpha_4\beta_2$-subtype central nervous system neuronal nicotinic receptors.

Catecholamine Hypothesis

As the foregoing review shows, effective medications for ADHD act in noradrenergic and dopaminergic systems. Stimulants block the reuptake of dopamine and norepinephrine into the presynaptic neuron and increase the release of these monoamines into the extraneuronal space (20). Solanto suggested that stimulants may also activate presynaptic inhibitory autoreceptors and may lead to reduced dopaminergic and noradrenergic activity (21). The maximal therapeutic effects of stimulants occur during the absorption phase of the kinetic curve, within 2 hours after ingestion. The absorption phase parallels the acute release of neurotransmitters into synaptic clefts, a finding providing support for the hypothesis that alteration of monoaminergic transmission in critical brain regions may be the basis for stimulant action in ADHD (22). A plausible model for the effects of stimulants in ADHD is that, through dopaminergic or noradrenergic pathways, these drugs increase the inhibitory influences of frontal cortical activity on subcortical structures (22).

Human studies of the catecholamine hypothesis of ADHD that focused on catecholamine metabolites and enzymes in serum and cerebrospinal fluid produced conflicting results (23 ,24). Perhaps the best summary of this literature is that aberrations in no single neurotransmitter system can account for the available data. Of course, because studies of neurotransmitter systems rely on peripheral measures, which may not reflect brain concentrations, we cannot expect such studies to be completely informative. Nevertheless, although such studies do not provide a clear profile of neurotransmitter dysfunction in ADHD, on balance, they are consistent with the idea that catecholaminergic dysregulation plays a role in the origin of at least some cases of ADHD.

The catecholamine hypothesis of ADHD finds further support from animal studies. One approach has been the use of 6-hydroxydopamine to create lesions in dopamine pathways in developing rats. Because these lesions created hyperactivity, they were thought to provide an animal model of ADHD (25). Disruption of catecholaminergic transmission with chronic low-dose *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a neurotoxin, creates an animal model of ADHD in monkeys. In this latter work, MPTP administration to monkeys caused cognitive impairments on tasks thought to require efficient frontal-striatal neural networks. These cognitive impairments mirrored those seen in monkeys with frontal lesions (26 ,27). Like children with ADHD, MPTP-treated monkeys show attentional deficits and task impersistence. Methylphenidate and the dopamine D2 receptor agonist LY-171555 reversed the behavioral deficits but not the cognitive dysfunction (28 ,29).

Several investigators used the spontaneously hypertensive rat (SHR) as an animal model of ADHD because of the animal's locomotor hyperactivity and impaired discriminative performance. Studies using the SHR have implicated dopaminergic and noradrenergic systems. For example, the dopamine D2 receptor agonist, quinpirole, caused significantly greater inhibition of dopamine release from caudate-putamen

but not from nucleus accumbens or prefrontal cortex slices in SHR compared with control mice (30). In another study, dopamine release secondary to electrical stimulation was significantly lower in caudate-putamen and prefrontal cortex slices of SHR compared with control mice. These findings were attributed to increased autoreceptor-mediated inhibition of dopamine release in caudate-putamen slices but not in the prefrontal cortex. Another study showed that the altered presynaptic regulation of dopamine in SHR led to the down-regulation of the dopamine system (31). The authors hypothesized that this may have occurred early in development as a compensatory response to abnormally high dopamine concentrations.

Other SHR studies implicated an interaction between the noradrenergic and dopaminergic system in the nucleus accumbens, but they ruled out the idea that a dysfunctional locus ceruleus and A2 nucleus impairs dopaminergic transmission in the nucleus accumbens through α_2-adrenoceptor–mediated inhibition of dopamine release (32). Papa et al. used molecular imaging techniques to assess the neural substrates of ADHD-like behaviors in the SHR rat (33). Their data showed the corticostriatopallidal system to mediate these behaviors. King et al. showed that exposure to excess androgen levels early in development led to decreased catecholamine innervation in frontal cortex and enhanced expression of ADHD-like behaviors (34). Carey et al. used quantitative receptor autoradiography and computer-assisted image analysis to show a higher density of low-affinity D1 and D5 dopamine receptors in the caudate-putamen, the nucleus accumbens, and the olfactory tubercle of SHR (35). Stimulant treatment normalized these receptors by decreasing the number of binding sites and increasing affinity to the control level.

In contrast to the large body of evidence implicating dopaminergic and noradrenergic systems in ADHD, evidence implicating serotonergic systems is mixed. Although the tertiary amines (imipramine and amitriptyline) are more selective for the serotonin transporter than the norepinephrine transporter (36), the secondary amines (desipramine, nortriptyline, and protriptyline) are more selective for the norepinephrine transporter (36). Moreover, measures of serotonin metabolism appear minimally related to the clinical efficacy of the stimulants (22), a finding consistent with the lack of efficacy of serotonergic drugs for treating ADHD. This suggests that the anti-ADHD efficacy of the TCAs stems from their actions on catecholamine reuptake, particularly that of norepinephrine.

Despite these equivocal findings, work by Gainetdinov et al. suggests that we cannot rule out a role for serotonergic systems in the pathophysiology of ADHD (37). These authors studied knockout mice lacking the gene encoding the dopamine transporter (DAT). These mice have elevated dopaminergic tone, are hyperactive, and show decreased locomotion in response to stimulants. Gainetdinov et al. showed that the effects of stimulants were mediated by serotonergic neurotransmission (37).

The anti-ADHD efficacy of nicotine and ABT-418 suggests that nicotinic dysregulation may also play a role in the pathophysiology of ADHD. Patients with ADHD are more likely to smoke and have an earlier age of onset of smoking than persons who do not have ADHD (38 ,39 and 40). In addition, maternal smoking during pregnancy appears to increase the risk of ADHD in the children (41), and *in utero* exposure to nicotine in animals confers a heightened risk of an ADHD-like syndrome in the newborn (42 ,43). That nicotine dysregulation could play an important role in the pathophysiology of ADHD is not surprising considering that nicotinic activation enhances dopaminergic neurotransmission (44 ,45).

BRAIN ABNORMALITIES

Part of "43 - Pathophysiology of Attention-Deficit/Hyperactivity Disorder "

Satterfield and Dawson were among the first to propose that ADHD symptoms were caused by frontolimbic dysfunction (46). These investigators suggested that weak frontal cortical inhibitory control over limbic functions could lead to ADHD. A review of the neurologic literature showing similarities in disinhibited behavior between adult patients with frontal lobe damage and children with ADHD provided further evidence that the frontal lobes could be involved in the pathophysiology of the disorder (47). Two sources of data have tested the frontolimbic hypothesis of ADHD: neuropsychological studies and neuroimaging studies.

Neuropsychological Studies

Neuropsychological tests indirectly assess brain functioning by assessing features of human perception, cognition, or behavior that have been clinically or experimentally linked to specific brain functions (48). Although limited in their ability to localize brain dysfunction, these tests have several advantages. Many of these tests have been standardized on large populations, thus making it straightforward to define deviant performance. Because of the extensive use of these tests in brain-damaged populations, performance on many of these tests can lead to hypotheses, albeit weak, about the locus of brain dysfunction. Being noninvasive and inexpensive, neuropsychological tests are frequently used to generate hypotheses about brain dysfunction.

Given that inattention is a one of the defining clinical features of ADHD, many neuropsychological studies of the disorder have assessed the attention of children with ADHD. The most commonly used measure of attention is the *continuous performance test*, which requires subjects to sustain their attention to subtle sensory signals, to avoid being distracted by irrelevant stimuli, and to maintain alertness for the duration of the session. Most of these studies

find children with ADHD to be impaired on this measure (1).

Children with ADHD also perform poorly on tasks requiring inhibition of motor responses, organization of cognitive information, planning, complex problem solving, and the learning and recall of verbal material (49). Examples of tests that measure these functions are the Stroop Test, the Wisconsin Card Sorting Test, the Rey-Osterrieth Test, the Freedom from Distractibility factor from Wechsler's Tests of Intelligence, and the California Verbal Learning Test.

Some studies suggest that the impairments found in children with ADHD cannot be accounted for by psychiatric comorbidity (50). Moreover, having a family history of ADHD may predict a greater degree of neuropsychological impairment. This latter finding suggests that familial ADHD and neuropsychological impairment identify a more biologically based type of ADHD. In contrast, nonfamilial cases of ADHD with lesser neuropsychological impairments may have other etiologic factors. Children with ADHD do not appear to be impaired on simple motor speed, verbal fluency, or visual spatial accuracy, findings that suggest that observed neuropsychological impairments are caused by specific, not generalized, deficits (51).

Notably, neuropsychological studies have consistently found adults with ADHD to be impaired on measures of vigilance using the continuous performance test (52 ,53). These studies have also shown adults with ADHD to be impaired in other functions known to affect children with ADHD. These include the following: perceptual-motor speed as assessed by the digit symbol/coding tests (54 ,55); working memory as assessed by digit span tests (53 ,56); verbal learning, especially semantic clustering (52 ,56); and response inhibition as assessed by the Stroop Color-Word Test (57 ,58). Because neuropsychological tests are free of the potential biases of self-reported symptoms, the finding that the neurocognitive profiles of adults with ADHD are similar to those of children with ADHD suggests that the diagnosis of ADHD is valid as applied in adulthood.

Our description of neuropsychological dysfunction in ADHD describes trends that have emerged in the research literature, not findings that have been consistently replicated. Although there are inconsistencies among studies, it is notable that the pattern of deficits that has emerged is similar to what has been found among adults with frontal lobe damage. Thus, the neuropsychological data tend to support the hypothesis that the frontal cortex or regions projecting to the frontal cortex are dysfunctional in at least some children with ADHD.

Because neuropsychological tests provide indirect measures of brain function, we must be cautious in using them to make inferences about the locus of brain impairment in ADHD. Yet because many of these tests have been standardized on normative populations and administered extensively to brain-damaged populations, observed deficits tests can stimulate hypotheses about the role of specific brain regions in the pathophysiology of ADHD.

With this considerations in mind, we view the pattern of neuropsychological impairment in children with ADHD as consistent with Satterfield and Dawson's (46) idea that symptoms of ADHD derive from abnormalities of prefrontal cortex or its neural connections to subcortical structures. This inference derives from the clinical and behavioral features that have been linked to regions of the prefrontal cortex (59). Notably, orbital frontal lesions predict social disinhibition and impulsivity, and dorsolateral lesions affect organizational abilities, planning, working memory, and attention. Studies of children with ADHD find impairment in all these neuropsychological domains. Thus, the neuropsychological test data—along with the clinical features of the disorder—implicate both orbitofrontal and dorsolateral prefrontal dysfunction in ADHD. In contrast, the mesial prefrontal region, where lesions predict dysfluency and the slowing of spontaneous behavior, is not implicated in ADHD.

Given the complexity of prefrontal circuitry (60), along with the limitations of neuropsychological inference, we cannot endorse a simple lesion model of ADHD. The "prefrontal" abnormalities in ADHD may result from abnormalities of prefrontal cortex, but they may also reflect the dysfunction of brain areas with projections to prefrontal cortex. Given the known role of subcortical networks as modulators of prefrontal functioning, the term *frontosubcortical* seems appropriate for ADHD. This term denotes a behavioral or cognitive dysfunction that looks "frontal" but may be influenced by subcortical projections.

The neuropsychological findings in ADHD provide a fertile resource for speculations about the role of subcortical structures. For example, the cingulate cortex influences motivational aspects of attention and in response selection and inhibition. The brainstem reticular activating system regulates attentional tone and reticular thalamic nuclei filter interference. Working memory deficits implicate a distributed network including anterior hippocampus, ventral anterior and dorsolateral thalamus, anterior cingulate, parietal cortex, and dorsolateral prefrontal cortex. Moreover, the attentional problems of children with ADHD may implicate a wider distribution of neural networks. A system mainly involving right prefrontal and parietal cortex is activated during sustained and directed attention across sensory modalities. The inferior parietal lobule and superior temporal sulcus are polymodal sensory convergence areas that provide a representation of extrapersonal space and play an important role in focusing on and selecting a target stimulus.

Neuroimaging Studies

Fortunately, hypotheses based on neuropsychological inference can be tested with neuroimaging paradigms. Because neuroimaging studies provide direct assessments of brain

structure and function, they are ideal for testing hypotheses about the locus of brain dysfunction. Table 43.1 reviews 18 structural neuroimaging studies of children, adolescents, and adults with ADHD that used computed tomography or magnetic resonance imaging. Among these studies, the most consistent findings implicated frontal cortex, usually limited to the right side, cerebellum, globus pallidus, caudate, and corpus callosum. Several other regions were less consistently implicated. Consistent with these findings, the I/LnJ mouse strain shows total callosal agenesis along with behavioral features that resemble ADHD (61). These mice show learning impairments, impulsiveness, and hyperactivity. Metabolic mapping studies suggest that their behavioral deficits are associated with lower 2-deoxyglucose uptake in the left striatum and the frontal and parietal cortex (61).

Study	Diagnosis	Method	Findings
Shaywitz et al. (199)	ADD	CT	No abnormalities found
Nasrallah et al. (200)	HYP	CT	Sulcal widening, cerebellar atrophy
Lou et al. (201)	ADD	CT	Slight frontal cortex atrophy
Hynd et al. (202)	ADD/H	MRI	Smaller frontal cortex Loss of normal asymmetry in frontal cortex
Hynd et al. (203)	ADHD	MRI	Smaller corpus callosum
Aylward et al. (204)	ADHD	MRI	Smaller left globus pallidus
Singer et al. (205)	ADHD+TS	MRI	Smaller left globus pallidus
Baumgardner (206)	ADHD	MRI	Small corpus callosum
Semrud-Clikeman et al. (207)	ADHD	MRI	Small corpus callosum
Castellanos et al. (208)	ADHD	MRI	Smaller right prefrontal cortex, right caudate, and globus pallidus
Mostofsky et al. (209)	ADHD	MRI	Smaller inferior posterior vermis of cerebellum
Nopoulos et al. (70)	ADHD	MRI	Neural migration anomalies and excess cerebrospinal fluid in the posterior fossa but no differences in cavum septi pellucidi
Overmeyer et al. (210)	ADHD	MRI	No corpus callosum abnormalities
Mataro et al. (211)	ADHD	MRI	Larger right caudate nucleus
Kayl et al. (212)	ADHD[a]	MRI	Increased severity of attention problems was associated with small total callosal areas
Berquin et al. (213)	ADHD	MRI	Smaller inferior posterior vermis of cerebellum
Casey et al. (214)	ADHD	MRI	Poor response inhibition associated with right sided abnormalities prefrontal cortex, caudate, and globus pallidus, but not putamen
Filipek et al. (215)	ADHD	MRI	Smaller left caudate, right frontal cortex, and bilateral peribasal ganglia and parietal-occipital regions

ADD, DSM-III attention-deficit disorder; ADD/H, DSM-III ADD with hyperactivity; ADHD, DSM-III-R attention-deficit hyperactivity disorder; CT, computed tomography; HYP, DSM-II hyperkinesis; MRI, magnetic resonance imaging; TS, Tourette syndrome.
[a]In this study, ADHD was secondary to neurofibromatosis.

TABLE 43.1. STRUCTURAL NEUROIMAGING STUDIES OF ADHD

Table 43.2 reviews 14 functional neuroimaging studies of ADHD using regional cerebral blood flow, positron emission tomography, single photon emission tomography, functional magnetic resonance imaging, or electroencephalography. The most consistent findings were hypoactivity of frontal cortex and subcortical structures, usually on the right side. Because Ernst et al. found significant brain dysfunction for girls, but not boys, with ADHD (62), and Baving et al. found gender differences in lateralization (63), future studies will need to assess gender differences and to determine how they may be related to the male predominance of the disorder.

Study	Diagnosis	Method	Findings
Lou et al. (201)	ADD	rCBF	Hypoperfusion in frontal cortex and caudate, hyperperfusion in occipital cortex
Lou et al. (216)	ADHD	rCBF	Hypoperfusion in right striatal region, hyperperfusion in occipital cortex, left sensorimotor, and primary auditory regions
Lou et al. (217)	ADHD	rCBF	Hypoperfusion in striatal and posterior periventricular regions; hyperperfusion in occipital cortex, left sensorimoter, and primary auditory regions
Zametkin et al. (66)	ADHD	PET	Lower glucose metabolism in premotor and superior prefrontal cortex, right thalamus, right caudate, right hippocampus, and right cingulate
Ernst et al. (62)	ADHD	PET	ADHD girls (but not boys) show lower glucose metabolism in right prefrontal cortex, right temporal cortex, right and left posterior putamen, and middle cingulate
Amen et al. (218)	ADHD	SPECT	Decreased perfusion in prefrontal cortex
Rubia et al. (219)	ADHD	fMRI	Lower activation in right mesial prefrontal cortex, right inferior prefrontal cortex, and left caudate
Baving et al. (63)	ADHD	EEG	Boys show a less right-lateralized frontal activation pattern; girls show a more right-lateralized frontal activation pattern than healthy control girls
Schweitzer et al. (220)	ADHD	rCBF	Task-related changes in rCBF in non-ADHD men without ADHD were prominent in frontal and temporal regions; changes in ADHD men were more widespread, suggesting the use of compensatory mental and neural strategies
Silberstein et al. (221)	ADHD	EEG	Increased speed of prefrontal processing in non-ADHD children, ADHD following priming stimulus, and a deficit in such processes in ADHD children
Vaidya et al. (222)	ADHD	fMRI	ADHD is characterized by atypical frontal-striatal function, and methylphenidate affects striatal activation differently in ADHD than in healthy children
Ernst et al. (223)	ADHD	PET	More accumulation of [^{18}F]DOPA in the right midbrain correlated with symptom severity
Bush et al. (65)	ADHD	fMRI	ADHD adults show weak activation of anterior cingulate cognitive division during counting Stroop task
Dougherty et al. (67)	ADHD	SPECT	Dopamine transporter density in striatum greater in ADHD adults

ADD, DSM-III attention-deficit disorder; ADHD, DSM-III-R attention-deficit hyperactivity disorder; EEG, Electroencephalogram; fMRI, functional magnetic resonance imaging; PET, position emission tomography, rCBF, regional cerebral blood flow; SPECT, photon emission computed tomography.

TABLE 43.2. FUNCTIONAL NEUROIMAGING STUDIES OF ADHD

Ernst et al. noted that findings of frontal hypoactivity are stronger in adult ADHD compared with adolescent ADHD (64). They offered two explanations for this finding. First, the adolescent samples studied may have been more heterogeneous than the adult samples. Although all the adults had persistent ADHD, some of the adolescent cases may have remitted by adulthood. Thus, frontal dopaminergic hypoactivity may be associated with persistent ADHD only. Alternatively, Ernst et al. speculated that, because of brain maturation, the locus of ADHD's dopamine abnormality may shift from the midbrain in childhood to the prefrontal cortex in adults.

Anterior cingulate cortex, lying on the medial surface of the frontal lobe, has strong connections to dorsolateral prefrontal cortex. Bush et al. used a Stroop task to compare anterior cingulate cortex activation in adults with ADHD and those who did not have ADHD (65). In contrast to controls, the adults with ADHD failed to activate the anterior cingulate cortex. Notably, in the prior study by Zametkin et al. (66), cingulate cortex was one of only four (of 60) regions evaluated that still showed regional hypoactivity after global normalization.

The neurochemical basis of brain dysfunction in ADHD was studied by Dougherty et al. (67). They measured DAT density by single photon emission computed tomography with the radiopharmaceutical iodine 123–labeled altropane. Their findings were consistent with the catecholamine hypothesis

of ADHD in showing the DAT to be elevated by about 70% in adults with ADHD.

The functional studies are consistent with the structural studies in implicating frontosubcortical system in the pathophysiology of ADHD. Taken together, the brain imaging studies fit well with the idea that dysfunction in frontosubcortical pathways occurs in ADHD. They are also consistent with the report of a father and son, both having methylphenidate-responsive ADHD secondary to frontal lobe epilepsy (68). Notably, the frontosubcortical systems that control attention and motor behavior are rich in catecholamines, which have been implicated in ADHD by the mechanism of action of stimulants.

In a novel approach to assessing brain regions implicated in ADHD, Herskovits et al. used magnetic resonance imaging to assess the spatial distribution of lesions in children who developed ADHD after closed-head injuries (69). Compared with head-injured children who did not develop ADHD, the children with ADHD had more lesions in the right putamen and a trend for more lesions in the right caudate nucleus and right globus pallidus.

Very little is known about when ADHD-related brain abnormalities emerge. To address this issue, Nopoulos et al. assayed four brain abnormalities believed to occur before birth: neural migration anomalies, corpus callosum agenesis or partial agenesis, enlarged cavum septi pellucidi, and malformations of the posterior fossa (70). Neural migration anomalies and malformations of the posterior fossa were more common among patients with ADHD compared with control subjects. Both these abnormalities were rare. However, given that several other studies showed partial agenesis of the corpus callosum or anomalies of the cerebellar vermis (also formed before birth), it seems reasonable to conclude that at least some children with ADHD have a very early onset of brain abnormalities.

GENETICS

Part of "43 - Pathophysiology of Attention-Deficit/Hyperactivity Disorder "

Family Studies

Figure 43.1A shows rates of hyperactivity among the siblings of hyperactive probands (71 ,72 ,73 ,74 and 75). Figure 43.1B shows an elevated prevalence of ADHD among mothers and fathers of children with ADHD that provides further support for the familiality of the disorder and evidence that the adult diagnosis is valid. These studies leave no doubt that ADHD

is familial. Moreover, studies of more distant relatives are consistent with this idea as well (76).

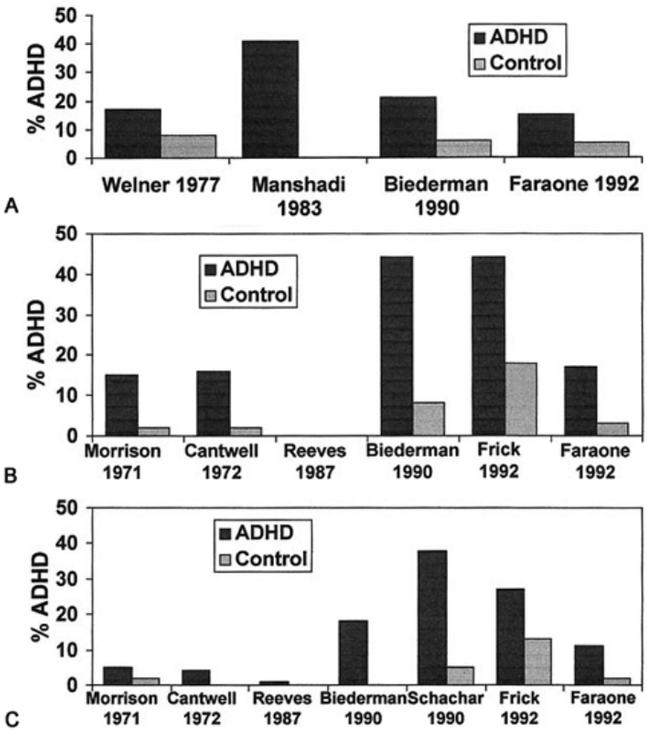

FIGURE 43.1. ADHD in relatives of ADHD and controls children. **A:** ADHD in siblings. **B:** ADHD in fathers. **C:** ADHD in mothers.

Family studies of ADHD suggest that its psychiatric comorbidities may help to clarify its genetic heterogeneity. The Harvard/Massachusetts General Hospital (Boston) ADHD family project studied two independent samples of children with attention-deficit disorder (ADD) as defined by the DSM-III (74) and ADHD as defined by the DSM-III-R (77). These data show that (a) ADHD and major depression share common familial vulnerabilities (78 ,79), (b) children with ADHD who have conduct (80 ,81) and bipolar (82 ,83) disorders may comprise a distinct familial subtype of ADHD, and (c) ADHD is familially independent of anxiety disorders (84) and learning disabilities (85). Thus, stratification by conduct and bipolar disorders may cleave the universe of children with ADHD into more familially homogeneous subgroups. In contrast, major depression may be a nonspecific manifestation of different ADHD subforms. In a sample of 132 ADHD sib-pair families, Smalley et al. reported further evidence that ADHD with conduct disorder is a distinct subtype (86). These investigators also examined comorbidity with learning disability, but these data produced equivocal results.

Faraone et al. proposed that stable or persistent ADHD may be a useful subtype of ADHD for genetic studies (87). These investigators reasoned that cases that remit before adolescence could have a smaller genetic component to their disorder than persistent cases. Evidence supporting this hypothesis derives from several studies. In a prospective follow-up study, Biederman et al. showed that by midadolescence, 85% of boys with ADHD continued to have ADHD; 15% remitted (88). The prevalence of ADHD among parents was 16.3% for the persistent ADHD probands and 10.8% for the remitted ADHD probands. For sibs, the respective prevalences were 24.4% and 4.6%. Thus, these data suggest that children with persistent ADHD have a more familial form of ADHD than those whose ADHD remits by adolescence.

Consistent with this finding, Biederman et al.(188) showed that children of parents with clinically referred, childhood-onset, ADHD were at high risk of meeting diagnostic criteria for ADHD: 84% of the adults with ADHD who had children had at least one child with ADHD, and 52% had two or more children with ADHD (89). The 57% rate of ADHD among children of adults with ADHD was much higher than the more modest 15% risk for ADHD in siblings of referred children with this disorder. These findings were consistent with a prior study by Manshadi et al. (72). They studied the siblings of 22 alcoholic adult psychiatric patients who met DSM-III criteria for ADD, residual type. The authors compared these patients with 20 patients matched for age and comorbid psychiatric diagnoses. Forty-one percent of the siblings of the adult ADD probands were diagnosed with ADHD compared with 0% of the non-ADHD comparison siblings.

In another retrospective study, Biederman et al.(188) compared adolescents with ADHD having retrospectively reported childhood-onset ADHD with children with ADHD (90). These investigators found that the relatives of adolescent probands had higher rates of ADHD compared with the relatives of child probands. Thus, a prospective study of children and retrospective studies of adolescents and adults suggested that, when ADHD persists into adolescence and adulthood, it is highly familial. This idea is consistent with one of Ernst's explanations for the finding that frontal dopaminergic hypoactivity is stronger in adult ADHD compared with adolescent ADHD; that is, frontal dopaminergic hypoactivity may be associated with persistent ADHD.

Twin and Adoption Studies

Although family studies provide much useful information, they cannot disentangle genetic from environmental sources of transmission. To do so, we must turn to twin and adoption studies. There are two types of twins: identical or monozygotic twins share 100% of their genes in common. In contrast, fraternal or dizygotic twins are no more genetically alike than siblings and therefore share only 50% of

their genes. Thus, the occurrence of twinning creates a natural experiment in psychiatric genetics (91). If a disorder is strongly influenced by genetic factors, then the risk to co-twins of ill probands should be greatest when the twins are monozygotic. The risk to dizygotic twins should exceed the risk to controls but should not be greater than the risk to siblings.

Twin data are used to estimate *heritability*, which measures the degree to which a disorder is influenced by genetic factors. Heritability ranges from zero to one, with higher levels indicating a greater degree of genetic determination. Figure 43.2 presents heritability data from 11 twin studies of ADHD. These data attribute about 80% of the origin of ADHD to genetic factors.

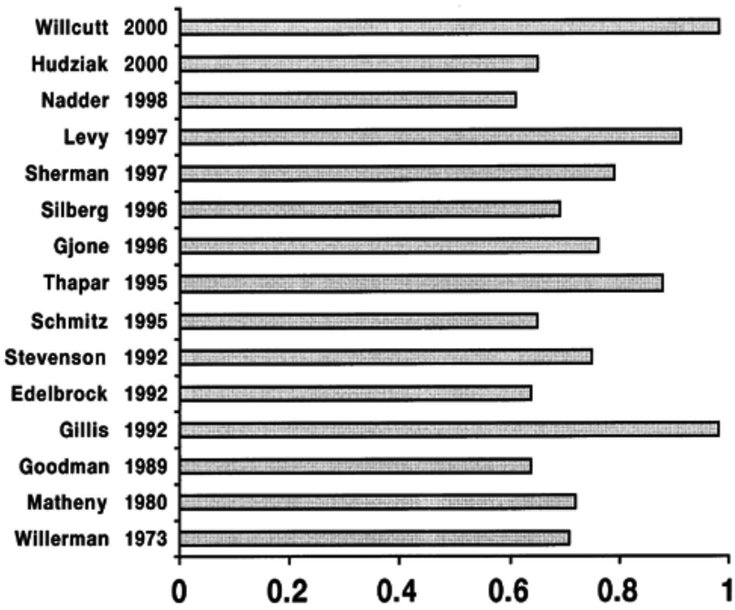

FIGURE 43.2. Heritability of ADHD.

Goodman and Stevenson found the heritability of hyperactivity to be 64% (92 ,93). In a repeat analysis of these data, Stevenson reported that the heritability of mother-reported activity levels was 75%, and the heritability of a psychometric measure of attention was 76% (94). In a study of ADHD in twins who also had reading disability, Gilger et al. estimated the heritability of attention-related behaviors as 98% (95). In a study of 288 male twin pairs, Sherman et al. examined inattentive and impulsive-hyperactive symptoms using both mother and teacher reports (96). Within both raters, the heritability of the impulsivity-hyperactivity dimension exceeded that of the inattention dimension; however, mothers' ratings showed higher heritability than did teachers' ratings. Specifically, mothers' ratings produced a heritability of 91% for impulsivity and hyperactivity and 69% for inattention. Teachers' ratings yielded a heritability of 69% for impulsivity and hyperactivity and 39% for inattention. Using the Child Behavioral Checklist as a dimensional measure, Hudziak and colleagues found a similar heritability (60% to 68%) for mother-reported attention problems (97).

Other studies of inattentive and hyperactive symptoms found a high heritability and minimal impact of the shared environment (98 ,99). Rhee et al. examined gender differences in heritability using twin and sibling pairs from Australia (99). Specific genetic and environmental influences were highly similar for boys and girls. Slight differences that emerged were related to more influence of the shared environment in girls and some evidence genetic dominance in boys.

Several twin studies examined the genetic contribution to the comorbidity of ADHD and other disorders. Data from Gilger et al. (95) were consistent with a prior family study (85) in suggesting that ADHD and reading disability were genetically independent; however, the existence of a genetically mediated subtype of both disorders could not be excluded. In contrast, two twin studies suggested that ADHD and reading disability share some genes in common (100 ,101). That this relationship may be complex is suggested by the report by Willicutt et al. of genetic overlap between reading disability and inattention but not between reading disability and hyperactive impulsive symptoms (102).

Nadder et al. examined whether ADHD and comorbid conduct and oppositional defiant disorder symptoms shared genetic risk factors (98). These investigators found that 50% of the correlation between the ADHD and comorbid conduct was the result of shared genes. Similarly, the twin study of Silberg et al. found that genes influencing variation in hyperactivity scores were also responsible for variation in conduct problems (103). Between 76% and 88% of the correlation between hyperactivity and conduct scores were attributed to genes. These investigators concluded that the results were consistent with the existence of a biologically based group of children who manifest both hyperactivity and conduct disturbances. Further evidence that the ADHD plus comorbid conduct subgroup may be etiologically meaningful comes from a study showing differences in serotonergic functioning between aggressive and nonaggressive children with ADHD (104).

Like twinning, adoption provides another useful experiment for psychiatric genetics (91). Whereas parents can confer a disease risk to their biological children by both biological and environmental pathways, to adoptive children they can confer risk only by an environmental pathway. Thus, by examining both the adoptive and the biological relatives of ill probands, we can disentangle genetic and environmental sources of familial transmission.

Adoption studies of ADHD also implicate genes in its origin. The adoptive relatives of children with ADHD are less likely to have ADHD or associated disorders than are the biological relatives of children with ADHD (105 ,106). Biological relatives of children with ADHD also do more

poorly on standardized measures of attention than do adoptive relatives of children with ADHD (107).

Segregation Analysis Studies

Segregation analysis provides evidence of genetic transmission by demonstrating that the pattern of illness in families is consistent with known genetic mechanisms. An early approach to this was reported by Morrison and Stewart, who concluded that polygenic inheritance was a likely mode of transmission for ADHD (108). Contrasting data were presented by Deutsch et al. (109). They found preliminary evidence for a single dominant gene regulating the transmission of ADHD and minor physical anomalies in 48 families. Similarly, Faraone et al. reported that the familial distribution of ADHD was consistent with the effects of a single major gene (75). Similar results were since reported in a twin study by Eaves et al. (110) and in a pedigree study by Hess et al. (111). Consistent findings also emerged from South America (112). Based on a sample of families from Colombia, the only models of inheritance that could not be rejected were those of dominant and codominant major gene effects. Finally, when families of ADHD probands were ascertained by the father's diagnosis of substance abuse, Maher et al. found that a sex-dependent mendelian codominant model was the best explanation for the pattern of transmission of ADHD (113).

Although the segregation analyses of ADHD suggest that a single gene of major effect is involved in the origin of ADHD, the differences in fit among genetic models was modest. This was especially true for the comparison of multifactorial and single gene inheritance. Several interpretations of these results are possible. If ADHD had more than one genetic cause, then the evidence of any single mode of transmission could be relatively weak. Alternatively, ADHD may be caused by several interacting genes of modest effect. This latter idea is consistent with ADHD's high population prevalence (2% to 7% for ADHD) and high concordance in monozygotic twins but modest recurrence risks in first-degree relatives.

The studies by Deutsch et al. and Faraone et al. predicted that only about 40% of children carrying the putative ADHD gene would develop ADHD. This finding and other features of the genetic epidemiology of ADHD suggest that such a gene likely interacts with other genes and environmental factors to produce ADHD. Moreover, the segregation studies indicated that about 2% of people without the ADHD gene would develop ADHD, a finding suggesting that nongenetic forms of ADHD may exist.

Chromosomal Anomalies and Molecular Genetic Studies

Anomalies in the number or gross structure of chromosomes usually lead to very early-onset disorders having severe clinical manifestations (e.g., mental retardation, gross physical anomalies). No systematic studies of gross chromosomal anomalies in ADHD have been conducted, but there are several reports that such anomalies cause hyperactivity and inattention. Examples include the fragile X syndrome, duplication of the Y chromosome in boys, and loss of an X chromosome in girls. These associations are intriguing but rare. Thus, they can account for only a very small proportion of cases of ADHD.

Molecular genetic studies use the methods of linkage and association to search for aberrant genes that cause disease. Such studies of ADHD are relatively new and far from definitive. Hauser et al. demonstrated that a rare familial form of ADHD is associated with generalized resistance to thyroid hormone, a disease caused by mutations in the thyroid receptor-ß gene (114). The thyroid receptor-ß gene cannot, however, account for many cases of ADHD because the prevalence of generalized resistance to thyroid hormone is very low among patients with ADHD (1 in 2,500) (115), and, among pedigrees with generalized resistance to thyroid hormone, the association between ADHD and the thyroid receptor-ß gene has not been consistently found (116).

Several research teams have examined candidate genes in dopamine pathways because, as discussed earlier, animal models, theoretic considerations, and the effectiveness of stimulant treatment implicate dopaminergic dysfunction in the pathophysiology of this disorder. Several groups have reported an association between ADHD and dopamine D4 receptor gene *(DRD4)* gene (117 ,118 ,119 ,120 ,121 ,122 and 123). Notably, each study showed the 7-repeat allele of *DRD4* to be associated with ADHD despite the use of different diagnostic systems (DSM-IIIR and DSM-IV) and measures of ADHD (rating scales and structured interviews). However, like many findings in psychiatric genetics (91), these positive findings are offset by some negative studies (124 ,125 ,126 ,127 and 128).

The positive *DRD4* findings could be caused by another gene in linkage disequilibrium with *DRD4* or another variant within *DRD4*. However, because the *DRD4* 7-repeat allele mediates a blunted response to dopamine, it is a biologically reasonable risk factor for ADHD (129). The 7-repeat allele has also been implicated in novelty seeking, a personality trait related to ADHD (130 ,131). Moreover, both norepinephrine and dopamine are potent agonists of *DRD4* (132).

When the D4 gene is disabled in a knockout mouse model, dopamine synthesis increases in the dorsal striatum, and the mice show locomotor supersensitivity to ethanol, cocaine, and methamphetamine. (133). D4 knockout mice also show reduced novelty-related exploration (134), a finding consistent with human data suggesting a role for D4 in novelty-seeking behaviors.

Cook et al. reported an association between ADHD and the 480-bp allele of the *DAT* gene using a family-based association study (135). This finding was replicated by Gill et al. (136), Daly et al. (126), and Waldman et al. (137), but

not in other studies (124 ,138). In the study by Waldman et al. (137), hyperactive-impulsive symptoms but not inattentive symptoms were related to the number of DAT high-risk alleles. Further support for a link between the *DAT* gene and ADHD comes from a study that relates this gene to poor methylphenidate response in children with ADHD (139) and from the neuroimaging study (Table 43.2) showing that DAT activity in the striatum is elevated by 70% in adults with ADHD (67).

In mice, eliminating *DAT* gene function leads to several features suggestive of ADHD: hyperactivity, deficits in inhibitory behavior, and a paradoxical response to stimulants (i.e., stimulants reduce hyperactivity) (37 ,140). Studies of this knockout mouse model show the potential complexities of gene–disease associations. The loss of the *DAT* gene has many biological effects: increased extracellular dopamine, a doubling of the rate of dopamine synthesis (141), decreased dopamine and tyrosine hydoxylase in striatum (142), and a nearly complete loss of functioning of dopamine autoreceptors (143). Because ADHD is believed to be a hypodopaminergic disorder, the decreased striatal dopamine may be most relevant to the disorder.

Gainetdinov et al. showed that enhancement of serotonergic transmission mediates the mouse's paradoxical response to stimulants (37). These researchers attributed this to the effects of stimulants on the serotonin transporter. To complicate matters further, Bezard et al. showed that *DAT* knockout mice did not experience MPTP-induced dopaminergic cell death (144), and another study found a gradient effect such that mice with zero, one, and two functional *DAT* genes showed increasing susceptibility to MPTP (145). These latter findings suggest that individual differences in the *DAT* gene may mediate susceptibility to neurotoxins having an affinity for the DAT.

A population-based association study has also implicated the A1 allele of the dopamine D2 receptor gene in ADHD (146). Absence of the D2 gene in mice leads to significantly reduced spontaneous movements, a finding suggesting that D2 plays a role in the regulation of activity levels (147 ,148). Mice without D2 genes also show decreased striatal DAT functioning (149), a finding that illustrates the potential effects of gene–gene interaction on simple phenotypes such as locomotion in mice. In addition, Calabresi et al. used the D2 knockout mouse to study the role of the D2 receptor in striatal synaptic plasticity (150). In these mice, these researchers found abnormal synaptic plasticity at corticostriatal synapses and long-term changes in synaptic efficacy in the striatum.

The only human study of the D3 receptor gene found no evidence of an association with ADHD (151). However, homozygous mice lacking D3 receptors displayed increased locomotor activity, and heterozygous mice showed less pronounced hyperactivity. These results led Accili et al. to conclude that D3 receptors play an inhibitory role in the control of certain behaviors (152).

Four human studies of ADHD have examined the catechol-O-methyltransferase (COMT) gene, the product of which is involved in the breakdown of dopamine and norepinephrine. Although one study found that ADHD was associated with the Val allele (153), others have found no association between the *COMT* polymorphism and ADHD in Irish (154), Turkish (155), and Canadian (156) samples. Despite the negative finding, the positive finding is intriguing because the Val allele leads to high COMT activity and an increased breakdown of catecholamines.

Another study found an association with the DXS7 locus of the X chromosome, a marker for monoamine oxidase that encode enzymes that metabolize dopamine and other neurotransmitters (157). Finally, Comings and colleagues found associations and additive effects of polymorphisms at three noradrenergic genes (the adrenergic α_{2A}, adrenergic α_{2C}, and dopamine-ß-hydroxylas) on ADHD symptoms in a sample of patients with Tourette syndrome (158), but they found no association between the tyrosine hydroxylase gene and ADHD in this sample (159).

Some investigators have used the coloboma mouse model to investigate the genetics of ADHD. These mice have the coloboma mutation, a hemizygous, 2-centimorgan deletion of a segment on chromosome 2q. The mutation leads to spontaneous hyperactivity (which is reversed by stimulants), delays in achieving complex neonatal motor abilities, deficits in hippocampal physiology that may contribute to learning deficiencies, and deficits in Ca^{2+}-dependent dopamine release in dorsal striatum (160).

The coloboma deletion region includes the gene encoding SNAP-25, a neuron-specific protein implicated in exocytotic neurotransmitter release. Hess et al. suggested that interference with SNAP-25 may mediate the mouse's hyperactivity (161). As predicted by this hypothesis, when these investigators bred a SNAP-25 transgene into coloboma mice, the animals' hyperactivity was reduced. Moreover, other work suggested that reduced SNAP-25 expression leads to striatal dopamine and serotonin deficiencies, which may be involved in hyperactivity (162).

Hess et al. tested the idea that the human homologue of the mouse coloboma gene could be responsible for ADHD by completing linkage studies of families with ADHD by using markers on human chromosome 20p11-p12, which is syntenic to the coloboma deletion region (111). These investigators used five families for which segregation analysis suggested that ADHD was the result of a sex-influenced, single gene. However, no significant linkage was detected between ADHD and markers on chromosome 20p11-p12.

ENVIRONMENTAL RISK FACTORS

Although genetic studies of ADHD unequivocally show that genes are risk factors for the disorder, they also show

that the environment has a strong influence on the emergence of the disorder. This conclusion follows from studies of identical twins, which show that when one twin has ADHD, the probability of the other, genetically identical, twin's having ADHD is only about 60%. This less than perfect identical twin concordance implicates environmental risk factors. The nature of these risk factors has emerged from studies assessing features of the biological and psychosocial environment that may increase the risk of ADHD.

Biological Adversity

The idea that certain foods could cause ADHD received much attention in the popular press after claims were made that ADHD could be cured by eliminating food additives from the diet. The Feingold diet for ADHD was popularized by the media and was accepted by many parents of ill children. Systematic studies, however, showed the diet was not effective and concluded that food additives do not cause ADHD (163). Another popular theory posited that excessive sugar intake would lead to ADHD symptoms. Although some positive studies supported this idea, the bulk of systematic, controlled research did not (164).

In contrast to the mostly negative studies of dietary factors, some toxins have been implicated in the origin of at least some cases of ADHD. Several groups have shown that lead contamination leads to distractibility, hyperactivity, restlessness, and lower intellectual functioning (165). However, many children with ADHD do not show lead contamination, and many children with high lead exposure do not develop ADHD. Thus, lead exposure cannot account for the bulk of cases of ADHD.

The literature examining the association of ADHD with pregnancy and delivery complications (PDCs) presents conflicting results; it tends to support the idea that PDCs can predispose children to ADHD (166 ,167 and 168), although some investigators do not (169). The PDCs implicated in ADHD frequently lead to hypoxia and tend to involve *chronic* exposures to the fetus, such as toxemia, rather than *acute*, traumatic events, such as delivery complications.

For example, Conners reported that mothers of children with ADHD had high rates of toxemia during pregnancy (166). Hartsough and Lambert described eight PDCs associated with ADHD: maternal illness, toxemia, eclampsia, older maternal age, parity of child, fetal postmaturity, duration of labor, and fetal distress during labor or birth (170). Nichols and Chen found that hyperactivity was significantly associated with low birth weight (171), and Chandola et al. reported antepartum hemorrhage, maternal age, length of labor, sex, and 1-minute Apgar scores to be significant prenatal and perinatal risk factors for subsequent referral for hyperactivity (172).

Sprich-Buckminster et al. showed that the association between ADHD and PDCs was strongest for children with ADHD who had psychiatric comorbidity (168). PDCs were also elevated among children with ADHD who had no family history of ADHD. These investigators concluded that PDCs may be more common among those children with ADHD having a weaker genetic predisposition, but this hypothesis was not confirmed in another study by the same group (167). The latter study found that children with ADHD and a history of PDCs showed more school failure and psychometric evidence of cognitive impairment than other children with ADHD. In addition to confirming the etiologic role of medical complications, this study showed that psychosocial stress during pregnancy predicted subsequent ADHD and poor cognitive performance in children. Notably, catecholamines are secreted in response to stress, and mouse studies showed that catecholamine administration produces uterine vasoconstriction and fetal hypoxia (173).

One extensively studied risk factor has been maternal smoking during pregnancy. By exposing the fetus to nicotine, maternal smoking can damage the brain at critical times in the developmental process. The smoking mother is at increased risk of antepartum hemorrhage, low maternal weight, and abruptio placentae (173). Her fetus is at risk of low birth weight (173 ,174), and because smoking increases carboxyhemoglobin levels in both maternal and fetal blood, it places the fetus at risk of hypoxia (175). Consistent with these effects, maternal smoking during pregnancy predicts behavioral and cognitive impairment in children and ADHD (41 ,176).

Animal studies in pregnant mice and rats have shown a positive association between chronic exposure to nicotine and hyperactivity in offspring (42). Neonatal nicotine exposure prevents the development of low-affinity nicotine receptors (177), and chronic exposure results in tolerance to the drug and an increase in brain nicotinic receptors (178 ,179 ,180 and 181). Because nicotinic receptors modulate dopaminergic activity and dopaminergic dysregulation may be involved in the pathophysiology of ADHD, it is theoretically compelling to consider maternal smoking as a risk factor for ADHD.

Little is known about the potential role of *in utero* exposure to viral infections. Because maternal viral infections can affect the fetus and can have an adverse impact on the developing brain, viral infections could be associated with later psychopathology. Because viral infections occur more commonly in winter than in other seasons, season-of-birth data have been used to implicate *in utero* viral infection for several disorders including schizophrenia (182), autism (183), and dyslexia (184)

Although Mick et al. found no evidence of a strong seasonal pattern of birth in children with ADHD (185), they did find statistically significant peaks for September births in children with ADHD who had comorbid learning disabilities and in children with ADHD who had no additional psychiatric comorbidity. Thus, it is possible that winter infections during the first trimester of pregnancy may account

for some subtypes of ADHD. Mick et al. found no evidence favoring the idea that putative viral exposure led to a nonfamilial form of ADHD. In contrast, they found a weak trend toward an increase in winter births for children with ADHD who have a positive family history of ADHD. If replicated, this finding suggests that a seasonally mediated infection at birth may be an environmental "trigger" for the genetic predisposition to the disorder.

Psychosocial Adversity

The delineation of psychosocial features in the child's environment associated with more impaired outcome in children with ADHD has potentially important clinical, scientific, and public health implications. Such efforts can help to identify etiologic risk factors associated with more impaired outcome in ADHD and can characterize early predictors of persistence and morbidity of this disorder. Moreover, finding environmental risk factors for ADHD could help to design improved preventive and therapeutic intervention programs.

The classic studies by Rutter et al. of the Isle of Wight and the inner borough of London provide a compelling example of how psychosocial risk factors influence child psychopathology (186). Compelling examples of how psychosocial risk factors affect child psychopathology, these studies examined the prevalence of mental disorders in children living in two very different geographic areas. This research revealed six risk factors within the family environment that correlated significantly with childhood mental disturbances: (a) severe marital discord, (b) low social class, (c) large family size, (d) paternal criminality, (e) maternal mental disorder, and (f) foster placement. This work found that it was the aggregate of adversity factors, rather than the presence of any single one, that impaired development. Other studies also found that as the number of adverse conditions accumulated, the risk of impaired outcome in the child increased proportionally (187). Biederman et al. found a positive association between Rutter's index of adversity and ADHD, measures of ADHD-associated psychopathology, impaired cognition, and psychosocial dysfunction (188).

Other cross-sectional and longitudinal studies have identified variables such as marital distress, family dysfunction, and low social class as risk factors for psychopathology and dysfunction in children. For example, the Ontario Child Health Study in Canada showed that family dysfunction and low income predicted persistence and onset of one or more psychiatric disorders over a 4-year follow-up period (189). Other work implicated low maternal education, low social class, and single parenthood as important adversity factors for ADHD (171 ,190). These studies suggested that the mothers of children with ADHD had more negative communication patterns, more conflict with their children, and a greater intensity of anger than did control mothers.

Biederman et al. showed that long-term conflict, decreased family cohesion, and exposure to parental psychopathology, particularly maternal psychopathology, were more common in ADHD-affected families compared with control families (191). The differences between children with ADHD and control children could not be accounted for by either socioeconomic status or parental history of major psychopathology. Moreover, increased levels of family-environment adversity predicted impaired psychosocial functioning. Measures indexing long-term family conflict showed a more pernicious impact on the exposed child than those indexing exposure to parental psychopathology. Indeed, marital discord in families has consistently predicted disruptive behaviors in boys (192). This research shows that the extent of discord and overt conflict, regardless of whether the parents are separated, predicts the child's risks of psychopathology and dysfunction (193).

Thus, dysfunctional family environments appear to be a nonspecific risk factor for psychiatric disorders and psychological distress. Reid and Crisafulli reported a metaanalysis of the impact of marital discord on the psychological adjustment of children and found that parental conflict significantly predicted a variety of child behavior problems (194). The Ontario Child Health Study provided a prospective example of the impact of parental conflict on children's mental health: family dysfunction (and low income) predicted persistence and onset of one or more psychiatric disorders over a 4-year period (189).

Low maternal warmth and high maternal malaise and criticism were previously associated with ADHD in children (195), and an epidemiologic study examining family attributes in children who had undergone stressful experiences found that children's perceptions of mothers, but not fathers, differentiated stress-resilient and stress-affected children (196).

An extensive literature documents maternal depression as a risk factor for psychological maladjustment and psychiatric disorder in children (197). This is consistent with the known familial link between ADHD and depression (79). Some investigators have suggested that depressed mood may lead mothers to perceive their children as more deviant than warranted by the child's behavior. Richters, however, reviewed 22 studies of this issue and concluded that, owing to methodologic problems with research in the area, there was no empiric foundation for this claim (198).

Other data revealed a link between maternal depression and child functioning that was independent of the mother's perceptions. These data suggested that depressed mothers accurately perceive symptomatic behavior but react to it in a negative manner that worsens the condition of the child. This conclusion was echoed by Gelfand and Teti (197). Their comprehensive review of relevant literature found many studies to document the assertion that depressed mothers have attitudes of insensitivity, disengagement, disapproval, and hostility toward their children. They also

found maternal depression to be associated with undesirable parenting practices such as intrusiveness, unresponsiveness, and inept discipline. In addition, their review supported the idea that depressed mothers had negative perceptions of their children.

Other work shows that ADHD in children predicts depression in mothers, but maternal depression provides no additional information for predicting ADHD in siblings of ADHD probands. This finding suggests that maternal depression is a heterogeneous disorder. It may be that some mothers have a disorder that is genetically linked to ADHD, whereas others may experience depression resulting from the stress of raising a child with ADHD (and perhaps living with an ADHD-affected or antisocial husband). Furthermore, it is possible that maternal depression exacerbates family conflict and poor parenting, both of which could exacerbate ADHD symptoms.

Notably, although many studies provide strong evidence of the importance of psychosocial adversity for ADHD, these factors tend to emerge as universal predictors of children's adaptive functioning and emotional health, not predictors that are specific to ADHD. Thus, they can be conceptualized as nonspecific triggers of an underlying predisposition or as modifiers of the course of illness.

SUMMARY AND CONCLUSIONS

Part of "43 - Pathophysiology of Attention-Deficit/Hyperactivity Disorder "

It is not yet possible to describe the origin and pathophysiology of ADHD completely. Nevertheless, converging evidence from the studies reviewed in this chapter supports several empiric generalizations, which should be useful in guiding future research and theory.

Catecholamine Hypothesis

Much research supports the idea that catecholaminergic systems mediate the onset and expression of ADHD symptoms. The key data supporting this idea are as follows: (a) anti-ADHD medications have noradrenergic and dopaminergic effects; (b) lesion studies in mouse and monkey models implicate dopaminergic pathways; (c) the SHR rat shows deficits in catecholaminergic systems; (d) D2, D3, and D4 knockout mice studies show that these genes regulate locomotor activity; and (e) human studies implicate the *DRD4* and *DAT* genes in the origin of ADHD.

Although the role of catecholamine systems cannot be disputed, future work must also consider other neurotransmitter systems that exert upstream effects on catecholamines. Two prime candidates are nicotinic and serotonergic systems. Nicotinic agonists help to control the symptoms of ADHD, and nicotinic activation enhances dopaminergic neurotransmission. Serotonergic drugs have not been shown to be effective anti-ADHD agents, but knockout mice studies suggest that the paradoxical effects of stimulants on hyperactivity are mediated by serotonergic neurotransmission. Moreover, SNAP-25, which has been implicated in studies of the coloboma mouse, leads to striatal dopamine and serotonin deficiencies. These data call for further studies of serotonergic and nicotinic systems.

Brain Systems

Several types of study provide information about the locus of ADHD's pathophysiology in the brain: neuropsychological studies, neuroimaging studies, and animal models. Taken together, these studies support the idea that ADHD arises from the dysregulation of frontal cortex, subcortical structures, and networks connecting them. This idea fits with the pharmacotherapy of ADHD because a plausible model for the effects of stimulants is that, through dopaminergic or noradrenergic pathways, these drugs increase the inhibitory influences of frontal cortical activity on subcortical structures.

Additional data supporting frontal-subcortical involvement in ADHD are as follows: (a) neuropsychological studies implicate orbitofrontal and dorsolateral prefrontal cortex or regions projecting to these regions; (b) the monkey model of ADHD implicates frontal-striatal neural networks; (c) studies of the SHR rat implicate caudate, putamen, nucleus accumbens, and frontal cortex; patients with frontal lobe damage show ADHD-like behaviors; (d) structural neuroimaging implicates frontal cortex, usually limited to the right side, cerebellum, globus pallidus, caudate, and corpus callosum; (e) the I/LnJ mouse strain shows total callosal agenesis along with behavioral features that resemble ADHD; (f) functional neuroimaging finds hypoactivity of frontal cortex, anterior cingulate cortex, and subcortical structures, usually on the right side; (g) ADHD secondary to brain injury shows lesions in right putamen, right caudate nucleus, and right globus pallidus; (h) disabling the D4 gene in mice leads to increased dopamine synthesis in dorsal striatum; (i) mice without D2 genes also show decreased striatal DAT functioning, abnormal synaptic plasticity at corticostriatal synapses, and long-term changes in synaptic efficacy in the striatum; and (j) the coloboma mouse shows deficient dopamine release in dorsal striatum.

Etiologic Factors

In a word, the origin of ADHD is complex. Although rare cases may have a single cause such as lead exposure, generalized resistance to thyroid hormone, head injury, and frontal lobe epilepsy, most cases of ADHD are probably caused by a complex combination of risk factors.

From the many twin studies of ADHD, we know for certain that genes mediate susceptibility to ADHD. Molecular genetic studies suggest that two of these genes may be the *DRD4* gene and the *DAT* gene. To confirm these findings, we need much more work because, even if the positive

studies are correct, they may implicate neighboring genes instead of those targeted by the studies. It seems unlikely that a single "ADHD gene" causes ADHD with certainty. Instead, it seems likely that several genes act together to form the genetic substrate of the disorder.

When the ADHD-related variants of these genes are discovered, they will probably be "normal" variants and will most certainly not have the devastating effects seen in knockout mouse models. For example, suppose future work confirms that the 7-repeat allele is a risk factor for ADHD. We would consider this a normal variant because about 20% of people who do not have ADHD carry this version of the *DRD4* gene. Most of these people do not develop ADHD despite the blunted dopaminergic transmission associated with that allele, and many patients with ADHD do not carry the allele. Thus, the 7-repeat allele cannot be a necessary or sufficient cause of the disorder. Instead, it acts in concert with other genes and environmental risk factors to bring forth ADHD.

Like genetic studies, studies of environmental risk factors suggest that most of these risks exert small but significant influences on the origin of ADHD. For example, most children with a history of PDCs do not develop ADHD, and most children with ADHD do not have a history of ADHD. Nevertheless, research suggests that such complications are more common among children with ADHD.

These considerations lead us to conclude that the origin of ADHD is multifactorial. A simple multifactorial model posits ADHD to arise a pool of genetic and environmental variables—each of small effect—that act in concert to produce vulnerability to ADHD. If a person's cumulative vulnerability exceeds a certain threshold, he or she will manifest the signs and symptoms of ADHD. According to the multifactorial model, no single factor is a necessary or sufficient cause for ADHD, and each of the etiologic factors is interchangeable (i.e., it does not matter which factors one has; only the total number is important). Whether risk factors combine in an additive or interactive manner is unknown.

The mouse models of ADHD we described provide examples of multifactorial causation in a simple system. One model showed that individual differences in the *DAT* gene could directly produce a hypodopaminergic state; these studies showed that dopamine transporter variants differ in their affinity for neurotoxins. Thus, dopamine transporter abnormalities could interact with environmental toxins to produce hyperactivity. Another line of work shows that catecholamines are secreted in response to stress, and catecholamine administration produces fetal hypoxia. Human studies implicate both stress during pregnancy and fetal hypoxia as risk factors for ADHD.

These simple examples suggest that unraveling the complexities of multifactorial causation will be a difficult task for ADHD researchers. However, because technological developments in neuroscience and molecular genetics are moving at a rapid pace, the next decade of work should provide us with more accurate assessments of the brain along with a complete sequence of the human genome. These advances should set the stage for breakthroughs in our understanding of the neurobiology of ADHD and in our ability to treat affected persons.

DISCLAIMERS

Part of "43 - Pathophysiology of Attention-Deficit/Hyperactivity Disorder "

Dr. Biederman receives research support from Shire Laboratories, Gliatec, Cephalon, Novartis Pharmaceuticals, and Eli Lilly & Company. In addition, he serves on speaking bureaus for SmithKline Beecham, Eli Lilly & Company, and Pfizer Pharmaceuticals.

NOSOLOGY AND CLASSIFICATION

Part of "44 - Learning Disorders "

Current conceptualizations of *learning disorders* (LDs), formerly referred to as “academic skills disorders” (1), follow the traditional approach of classifying learning by specific academic skills. These skills include reading, mathematics, and written expression. In each case, the skills are measured by standardized tests whose scores must fall substantially below the level expected from chronologic age, intelligence, and age-appropriate education. The deficits must significantly interfere with academic or daily living activities requiring the skills. When LDs result from sensory, medical, or neurologic conditions, they are coded on Axis III (medical conditions) within the DSM-IV nomenclature.

Commonly associated features of LDs include low selfesteem and demoralization, social skills deficits, school dropout, and difficulties in employment or social adjustment. Patients with conduct disorder, oppositional disorder, attention-deficit/hyperactivity disorder (ADHD), major depression, dysthymic disorder, and Tourette syndrome all have substantially elevated rates of LD. Academic skills in pervasive developmental disorders are often not discrepant from the measured intelligence and language abilities associated with the pervasive development disorder. Communication disorders and motor skills disorders are also common in LDs, including expressive language disorders, phonologic disorder, and stuttering. Spelling disorders are usually not considered separate from other reading- and writing-related deficits.

Although this approach to classification of LDs is useful in a practical context and allows for an operational definition for detection and remediation, it has several drawbacks from a theoretic and scientific point of view. Reading, mathematics, and writing comprise many processing skills, giving rise to subtypes with different underlying mechanisms. Thus, reading at the word level may involve visual, lexical, or semantic processes (2 ,3), with correspondingly different neuroanatomic circuitry and computational mechanisms within the brain. There are subtypes characterized both by the pattern of skills deficits (e.g., reading and spelling, but no mathematics disorder) and by different patterns of neuropsychological function, such as the relative strength of verbal and nonverbal factors on intelligence tests (4). There are also important developmental changes in LD, such that variables characterizing the disorder at earlier ages may be different from those seen in older patients (5). Advances in the genetics and neuroimaging of LDs will depend on more homogeneous clinical definitions at the symptomatic level (6).

PREVALENCE

Part of "44 - Learning Disorders "

The DSM-IV reports prevalence estimates of 2% to 10% for LDs, depending on the nature of ascertainment and the definitions applied (1). In most prevalence studies, a diagnosis of LD has been made on the basis of a significant discrepancy between IQ and achievement in one or more areas (7), with studies varying in terms of the manner in which a discrepancy has been determined and the cutoff score for considering a discrepancy “severe.” One study of the prevalence of regression-based ability/achievement discrepancies using the co-norming sample from the Wechsler Intelligence Scale for Children III and the Wechsler Individual Achievement Scales found that 17% of the norming group had ability/achievement discrepancies at the .05 significance level in one or more areas of achievement (8). This figure can probably be considered the upper limit for LD prevalence estimates based on ability/achievement discrepancies, given that a diagnosis of LD would also require determining both that the discrepancy was not the result of poor instruction and that it interfered with daily functioning.

Several researchers have questioned the conceptual and empiric basis for the use of ability/achievement discrepancies in the diagnosis of LDs, as well as current operationalizations of the exclusionary criteria. Reasons for concern on

the use of ability/achievement discrepancies are (a) findings that the cognitive profiles of children with low achievement are similar regardless of whether they evidence an ability/achievement discrepancy (9), (b) findings that the same deficits that lead to poor achievement may also lower IQ (10), and (c) the finding that the use of such definitions prevents early identification and treatment because the underlying cognitive deficits that cause the disability must retard growth in academic skills before intervention can begin (11). Alternate proposals for identification include simply using a low achievement criterion (e.g., academic functioning 1 to 2 standard deviations [SD] below the mean), using a definition that combines the ability/achievement discrepancy and low achievement approaches, and use of domain-specific rather than general cognitive ability tests as predictors of academic achievement. In general, these alternate procedures are likely to raise prevalence rates.

There is some indication that more rigorous operationalization of the exclusionary criteria in the LD definition could substantially reduce LD prevalence rates. For example, when Vellutino and his colleagues used daily tutoring as a “first cut” diagnostic criterion to distinguish between children who had reading difficulties caused by cognitive deficits and those whose deficits were the result of poor instruction, they found that two thirds of their sample scored within the average range in reading (thirtieth percentile and higher) after one semester of one-to-one tutoring (12). This relatively stringent criterion for establishing an “adequate educational environment” resulted in a drop in the prevalence rate of reading disorders (RDs) from 9% to 3%. Geary used failure to respond to short-term intensive remedial instruction as a diagnostic criterion for mathematics disability (MD) and noted a marked drop in prevalence (13). Clearly, the definition of caseness in these studies has implications for how phenotypes are characterized in genetic and neurobiological investigations. The use of the more conservative methods of case definition are clearly more costly for selecting subjects, but they may prove more valid and useful in finding biological markers of LD.

COMORBIDITY

Part of "44 - Learning Disorders "

Many psychiatric and medical conditions include LD as an associated deficit. The most common childhood condition comorbid with LD is ADHD. Estimates of comorbidity range from 20% to 90%, with the lower figures appearing in epidemiologic samples and the higher figures appearing in clinically referred samples. The high degree of overlap in clinical samples suggests that common mechanisms may be at work in the neurologic basis for both disorders. LDs were once considered a necessary criterion for minimal brain dysfunction. Although some studies suggest that ADHD may simply be the result of an LD, most studies indicate that when both conditions are present, characteristics of each are found, whereas in LDs alone, only symptoms of LD, not those of ADHD, are present, and vice versa (14). The high degree of overlap has the practical implication that when one disorder is identified, it is always prudent to expect the presence of the other and to make appropriate diagnostic probes.

PHONOLOGIC PROCESSING

Part of "44 - Learning Disorders "

As noted earlier, the present classification approach to LD subdivides the disorder on the basis of impairment in specific academic areas (reading, math, written expression). However, given that performance in each of these area draws on numerous cognitive processes, it is likely that the present classification system will eventually be replaced by one that focuses on the specific cognitive deficits that underlie poor academic performance and their impact on the development and execution of specific subskills within and across academic areas.

The greatest progress in specifying the cognitive and neuropsychological dysfunctions underlying LDs has occurred in reading. Numerous investigations using longitudinal, intervention, genetic, and neuroimaging methods have produced strong and converging evidence that deficits in phonologic processing are the proximal cause of reading difficulties in a large proportion of children with RDs (see ref. 15 and ref. 16 for reviews). Deficits in phonologic processing also appear to affect spelling, written expression, and mathematics.

Phonologic processing refers to the ability to use and manipulate the sound structure of one’s oral language (17). Although conceptualizations of phonologic processing and its components vary, within the Wagner and Torgesen model of phonologic processing, it consists of three related abilities: phonologic awareness, phonologic memory, and rapid naming (18 ,19). *Phonologic awareness* refers to the understanding that words can be broken down into phonemes and the ability to identify phonemes and manipulate them in words (16). Phonemes are the smallest sound unit that changes the meaning of a word (e.g., tap and lap differ by one phoneme). Phonologic awareness is a critical ability in learning to read because it allows beginning readers to link letters and letter combinations in text to sound strings in oral language (20). Knowledge of these links allows readers to discover the regularities in written text so written words can be rapidly translated into their spoken equivalents. Such recoding allows the reader to access the semantic code (or meaning) for the letter string. The repeated pairing of the visual letter string and its spoken equivalent is thought eventually to allow the reader to develop direct visual word recognition strategies that bypass the phonologic code (10 ,21).

Phonologic memory is an individual’s ability to represent verbal information in working memory in terms of a sequence

of sounds or a phonetic code. When children have difficulty with phonologic coding, reading acquisition is impaired because of difficulty in performing the rapid comparison and blending needed to identify unfamiliar written words. Difficulties in verbal short-term memory are also hypothesized to be a major factor underlying MDs (22), and they may affect the acquisition of foreign languages (20).

Rapid naming is the ability to access phonologic information that is stored in long-term memory rapidly. It is typically assessed by asking children to name well-known items as rapidly as possible (e.g., presentation of a series of colored squares with the child naming the color of each square as fast as possible). Such tasks are thought to tap many of the same cognitive processes required in skilled reading, such as rapid scanning, sequencing and processing of serially presented visual stimuli, and rapid access to strings of phonemes (e.g., color names) (16). There is debate about whether the difficulty with rapid naming tasks observed in many children with RDs is a reflection of a core deficit in phonologic processing or whether it represents a deficit in a second set of processes that impairs reading. If this is the case, there may be “double-deficit” readers who are impaired in both phonologic and rapid naming processes (23). Such disabled readers would be less responsive to interventions that address phonologic processing and would require additional interventions targeted toward increasing language and reading fluency.

Efforts are also under way to understand more fully the core cognitive deficits underlying other types of LD. For example, Berninger et al. proposed a model of the cognitive processes underlying written language and writing disabilities (24). Geary proposed that there are three subtypes of MDs, with corresponding deficits in semantic memory, procedural knowledge of mathematics, and visuospatial processes (22).

GENETICS

Part of "44 - Learning Disorders "

It has been known for decades that LDs run in families. In the 1990s, family aggregation studies, twin studies, and genetic linkage analyses confirmed the strong hereditary influences on RD and MD (Table 44.1). The genetic studies also confirm the heterogeneity of the phenotype, with both orthographic and phonologic traits implicated but not having identical sources of genetic influence. A genetic link between RD and MD was confirmed in several studies. A strong link of Tourette syndrome, ADHD, and LD has been suggested by studies of patients who have Tourette syndrome with and without ADHD. Evidence has accumulated that locations on the short arm of chromosome 6

(6p21.3) and the short arm of chromosome 15 are involved. Odds for linkage to chromosome 15 are reported as being 1,000 to 1, with evidence that 30% of an extended series of families showed linkage to chromosome 15 polymorphisms. Some variations in results may reflect sampling methods or trait markers. The excess of affected males with LDs identified in clinic and referred samples disappears in research-based samples (25).

Study	Subjects	Method	Comment
Comings and Comings, 1987 (99)	47 normal controls, 246 TS	Comparison of TS and control	27% of TS had LD vs 4.2% of controls
Comings and Comings, 1990 (100)	130 TS probands with 1,851 relatives, 25 control probands with 541 relatives	Comparison of TS and control	Suggests LD/ADHD are integral part of the expression of the Gts gene(s)
Comings et al., 1999 (101)	274 TS and 62 normal controls	Tested associations and additive effects between polymorphisms at 3 nonadrenergic gene sites	Suggests additive effects of nonadrenergic genes related to presence of LD
DeFries et al., 1987 (102)	64 pairs identical, 55 pairs fraternal twins in which at least one member of pair is dyslexic	Multiple regression analysis	Significant genetic etiology for dyslexia
Fagerheim et al., 1999 (103)	80 Norwegian family members	Genome search for linkage and non-parametric multipoint GENEHUNTER analysis	Localization to 2p15–16 and to 6p21.3–23 give strong evidence of genetic heterogeneity in dyslexia
Field and Kaplan, 1998 (104)	79 families having at least 2 affected sibs with phonologic coding dyslexia (617 genotyped, 294 affected)	Tested for linkage	No evidence for linkage by LOD score analysis or affected-sib-pair methods; however, affected-pedigree-member (APM) method detects significant linkage; concludes APM may generate false-positive results
Fisher et al., 1999 (105)	181 sib pairs from 82 nuclear families with a dyslexic proband	Assessed linkage directly for several quantitative measures rather than a single composite measure or categoric definition	Pointwise analysis of sib-pair trait differences suggests presence in 6p21.3 of a QTL influencing multiple components of dyslexia: reading of irregular words and nonwords; shows that both orthographic and phonological skills are affected
Gayan and Olson, 1999 (106)	—	Review with focus on twin study design and sib-pair linkage techniques	DeFries-Fulker multiple regression analyses show significant estimates of heritability for group deficits on several reading and language measures, and presence of significant common and independent genetic effects on individual differences on reading skills; linkage techniques confirm a candidate locus for RD on chromosome 6
Gayan et al., 1999 (107)	126 sib pairs	Multipoint mapping method and 8 informative DNA markers on chromosome 6	Significant linkage across a distance of at least 5 cM for deficits in orthographic (LOD = 3.10) and phonological (LOD = 2.42) skills, confirming previous findings
Gillis et al., 1992 (108)	264 RD twin pairs and 182 matched control twin pairs	Multivariate behavior genetic analysis	Individual differences in both reading and math performance are highly heritable and appear to be caused by many of the same genetic influences
Knopik et al., 1997 (109)	102 identical and 77 same-sex fraternal twin pairs in which at least one member of each pair is reading disabled; and 42 identical and 23 same-sex fraternal twin pairs in which at least one member is math disabled	Multiple regression model for the analysis of selected twin data and its bivariate extension	The comorbidity between math and RD is due in part to genetic influences
Knopik and DeFries, 1999 (110)	526 twin pairs selected for RD (290 identical and 236 same-sex fraternal); and 355 control pairs (220 identical and 135 same sex fraternal)	Confirmatory factor analyses and heritability estimation	Heritability in proband and controls were 0.81 and 0.69; and those for math 0.88 and 0.67; genetic influences accounted for 83% of the covariation between reading and math factors in the proband group and 58% in the control group; shared environmental influences did not contribute to the relationship between reading and math factors, nor to their independent variation
Petryshen et al., 2000 (111)	79 families with at least 2 affected sibs	Two-point and multipoint quantitative-trait sib-pair linkage and variance-components analyses	No evidence for a locus in the 6p23-p21.3 region for several quantitative measures; speculates that perhaps families with subtypes of dyslexia linked to this region are underrepresented in the sample, either by chance or ascertainment criteria
Reynolds et al., 1996 (112)	Twins of the Virginia Twin Study	—	69% of variability in oral reading due to heredity vs 13% due to shared environmental effects; genetic and environmental influences were equivalent for males and females, but males showed greater phenotypic variability than females

ADHD, attention deficit hyperactivity disorder; LD, learning disorder; QTL, quantitative trait locus; RD, reading disorder; TS, Tourette syndrome.

TABLE 44.1. GENETICS OF LEARNING DISORDERS

NEUROIMAGING

Part of "44 - Learning Disorders "

The neuroanatomic and functional pathways in the brain involved in LDs were greatly clarified in the 1990s by a variety of neuroimaging techniques. Reviews of neuroimaging of LDs describe rapid progress in identifying the brain regions and functional pathways involved (20 ,26 ,27 ,28 and 29). However, these reviews also call attention to discrepancies in findings, possibly the result of small cohorts, variations in sampling, and heterogeneity of the LDs. Table 44.2 provides selected studies from several hundred investigations, mainly of RDs. Many studies confirm earlier findings of abnormalities of the microstructure of the planum temporale from autopsy studies, but conflicting data emerge, possibly related to the method employed or the sampling techniques and definition of the RD (30). Although most studies implicate abnormalities in left temporal-parietal anatomic areas, additional findings have identified white matter, right hemisphere anomalies, motor cortex, cingulate gyrus, and the splenium of the corpus callosum.

TABLE 44.2. NEUROIMAGING IN LEARNING DISORDERS

Study	Method	Subjects	Results
Klingberg et al., 2000 (113)	Diffusion tensor magnetic resonance	Adults with poor or normal reading ability	Subjects with reading difficulty exhibited decreased diffusion anisotropy bilaterally in temporoparietal white matter. White matter diffusion anisotropy in the temporoparietal region of the left hemisphere was significantly correlated with reading scores within the reading-impaired adults and within the control group. The anisotropy reflects microstructure of white matter tracts, which may contribute to reading ability by determining the strength of communication between cortical areas involved in visual, auditory, and language processing.
Fersten et al., 1999 (114)	Blood flow velocity in MCA in left and right hemisphere measured with the transcranial Doppler method	10 dysgraphic or dysorthographic students and 10 normal subjects	The dysgraphic persons had significantly higher blood flow velocity in the right hemisphere compared to the reference group.
Duncan et al., 1994 (115)	Event-related brain potentials	13 severely dyslexic men, 15 matched controls	As task demands increased, visual P300 was reduced in the dyslexic men as compared with the normal readers. Dyslexics with a history of many symptoms of ADHD in childhood (high ADHD) accounted for the group differences in P300; the dyslexics with a history of few or no such symptoms (low ADHD) were indistinguishable from the controls at all electrode sites. The results are interpreted as suggesting that a distinct brain organization may characterize dyslexic men with a history of concomitant deficits in attention.
Georgiewa et al., 1999 (116)	fMRI	17 phonologically impaired developmental dyslexics and 17 normal reading children	Significant differences in Broca area and the left inferior temporal region for both, nonword reading and the phonologic transformation task.
Rumsey et al., 1999 (117)	rCBF	17 right-handed dyslexic men, ages 18–40, and 14 matched controls	Correlations between reading skill and rCBF during a series of reading tasks; uniquely identified the left angular gyrus as the most probable site of a functional lesion in dyslexia: Here, higher rCBF was associated with better reading skill in controls ($p < .01$), but with worse reading skill in dyslexia ($p < .01$).
Helenius et al., 1999 (118)	Magnetoencephalography	10 dyslexic male adults and 10 normal controls	Early visual responses were similar in dyslexic and nonimpaired readers. In contrast, the letter-string–specific responses peaking around 150 ms predominantly in the left inferior occipitotemporal cortex in fluent readers were undetectable in dyslexic readers. Thus, while the early visual processing seems intact in dyslexic adults, the pattern of cortical activation starts to differ from that of fluent readers at the point where letter-string–specific signals first emerge during reading.
Best and Demb, 1999 (32)	Sagittal magnetic resonance images of PT and magnocellular visual pathway	Dyslexics with documented MC deficits and controls	Dyslexic subjects did not deviate from normal leftward PT asymmetry, but both groups became less left-lateralized with methods that excluded sulcul tissue. Results suggest that dyslexic subjects with a magnocellular deficit do not always have abnormal symmetry of the PT. PT symmetry may instead be related to a different subtype of dyslexia. In addition, PT asymmetry in any subject group depends on the measurement method.
Nicolson et al., 1999 (119)	PET	6 dyslexic adults and 6 matched controls	Brain activation was significantly lower ($P < .01$) for the dyslexic adults than for the controls in the right cerebellar cortex and the left cingulate gyrus when executing a prelearned motor sequence, and in the right cerebellar cortex when learning the new sequence.
Pennington et al., 1999 (120)	MRI	75 subjects with RD and 22 controls	Insula and anterior superior neocortex were smaller and the retrocallosal cortex was larger in the RD group. In contrast, no group main or interaction effects for the subcortical or callosal structures. Results were not due to ADHD.
Green et al., 1999 (121)	MRI-based surface reconstruction technique that models the curvature of the cerebral cortex in three dimensions to obtain whole-hemisphere and regional surface area estimates	8 male right-handed male dyslexics and matched controls	The caudal infrasylvian surface that encompasses the supratemporal plane and the inferior bank of the posterior ascending ramus of the sylvian fissure was significantly larger than that of control subjects, and this result was not attributable to a difference in whole-hemisphere surface area.

Richards et al., 1999 (122)	MR spectroscopic imaging technique called proton echo-planar spectroscopic imaging	6 dyslexic boys and 7 age- and IQ-matched right-handed good readers	Dyslexic boys showed a greater area of brain lactate elevation (2.33+/-SE 0.843 voxels) as compared with the control group during a phonological task in the left anterior quadrant. No significant differences were observed in the nonlanguage tasks.
Price et al., 1998 (31)	fMRI	2 boys with deep dyslexia	Activation patterns primarily reflect semantic and phonologic systems in spared regions of the left hemisphere. These results preclude an explanation of deep dyslexia in terms of purely right-hemisphere word processing.
Demb et al., 1998 (123)	fMRI	Group of dyslexic and normal readers	Dyslexics showed reduced brain activity compared with controls both in primary visual cortex (VI) and in several extrastriate areas, including area MT and adjacent motion-sensitive areas (MT+) that are believed to receive a predominant magnocellular pathway input.
McPherson et al., 1998 (124)	Event-related potentials	Adolescents who were good phonetic decoders or poor (dysphonetic)	Phonetics showed both orthographic and phonological priming but had a marked reduction in their CNV. These results support the separation of the reading disabled into a group that has difficulty translating orthography into phonology and a group that is slower functioning and has reduced capacity in preparing for a response.
Shaywitz et al., 1998 (125)	fMRI	Dyslexic and normal readers	Brain activation patterns differed significantly between the groups with dyslexic readers showing relative underactivation in posterior regions (Wernicke area, the angular gyrus, and striate cortex) and relative overactivation in an anterior region (inferior frontal gyrus). These results support a conclusion that the impairment in dyslexia is phonologic and that these brain activation patterns may provide a neural signature for this impairment.
Richardson et al., 1997 (126)	*In vivo* cerebral phosphorus-31 magnetic resonance spectroscopy	12 dyslexic and 10 nondyslexic adults	Membrane phospholipid metabolism is abnormal in dyslexia.
Halperin et al., 1997 (127)	Plasma levels of MHPG	ADHD children with and without RD	Plasma levels of MHPG were significantly lower in ADHD children without RD, compared with those with RD, replicating a published finding.

Rumsey et al., 1997 (30)	MRI	16 RH dyslexic men 18–40 and 14 matched controls	Results challenge the notion that anomalous asymmetry of the PT is strongly associated with developmental dyslexia. Given the heterogeneity of the dyslexic population, some subgroup of dyslexic individuals (i.e., those with developmental language disorders) may show unusual symmetry or reversed asymmetry in this region. However, anomalous asymmetry of the planum did not contribute to functional abnormalities demonstrated in these patients by positron emission tomography.
Rumsey et al., 1996 (128)	MRI	21 dyslexic men and 19 matched controls	As predicted, the area of the posterior third of the corpus callosum, roughly equivalent to the isthmus and splenium, was larger in dyslexic men than in controls. No differences were seen in the anterior or middle corpus callosum. The increased area of the posterior corpus callosum may reflect anatomical variation associated with deficient lateralization of function in posterior language regions of the cortex and their right-sided homologues, hypothesized to differ in patients with dyslexia.
Paulesu et al., 1996 (129)	PET	5 adult dyslexics with phonological processing deficits	Proposes that the defective phonologic system of these dyslexics is due to weak connectivity between anterior and posterior language areas. This could be due to a dysfunctional left insula which may normally act as an anatomic bridge among Broca area, superior temporal, and inferior parietal cortex. The independent activation of the posterior and anterior speech areas in dyslexics supports the notion that representations of unsegmented and segmented phonology are functionally and anatomically separate.
Eden et al., 1996 (130)	Review	—	The pathophysiology of developmental dyslexia is more complex than originally thought, extending beyond the classically defined language areas of the brain.
Shapleske et al., 1999 (131)	Review	PT studies	Overall, there is a significant leftward asymmetry in normals, which is reduced in left handers and females. The leftward asymmetry is much reduced in patients with schizophrenia due to a relatively larger right PT than normal controls.
Deb et al., 1997 (26)	Review	—	Brain abnormalities can be detected in cases of idiopathic and nonidiopathic learning disability, but their significance is not clear due to discrepancies in study findings and the small cohorts involved.

ADHD, attention deficit hyperactivity disorder; fMRI, functional magnetic resonance imaging; MCA, middle cerebral artery; MHPG, XXX; MT, XXX; PET, positron emission tomography; PT, planum temporale; rCBF, regional cerebral blood flow; RD, reading disorder.

One of the older controversies regarding the functional brain basis of dyslexia is whether dyslexia represents a visual (orthographic) disorder or a language-based (phonologic processing) disorder. Neuroimaging studies now appear to provide evidence that brain structures involving both the

striate visual magnocellular pathways and specific phonologic processing pathways in the left hemisphere are involved in dyslexia, a finding possibly reflecting different subtypes at the behavioral level. As noted earlier, cognitive behavioral analysis suggests that distinctive mechanisms for visual, lexical, and semantic processing are required to explain normal human reading (2 ,3). Pathologic studies indicate that each of these mechanisms can be affected separately in acquired dyslexias. For example, in *deep dyslexia*, it is primarily the semantic aspects of reading that are disturbed, whereas orthography and lexicality are preserved. Thus, a patient may read “spirit” as “whiskey,” or “church” as “priest.” Evidence suggests that, unlike the more typical left-hemisphere–based phonologic and visual deficits in dyslexia, deep dyslexia may reflect a right-hemisphere—based processing mechanism (31).

Whereas some investigators interpret functional magnetic resonance imaging studies as giving strong support to the hypothesis that dyslexia represents a disorder of the language system, involving the segmentation and synthesis of phonemes (20), others find evidence that magnocellular pathways without involvement of phonologic regions occur in dyslexia (32 ,33). As noted by Filipek, cognitive neuroscience identifies specific computational tasks that should be used to provide more homogeneous samples at the behavioral level for further advances in the neurobiology of developmental disorders (28). For example, rather than using classic clinical criteria for dyslexia, which leads to samples with diverse subtypes, neuroimaging studies may do better to select samples by visual, lexical, and semantic criteria first.

EDUCATIONAL MANAGEMENT

Part of "44 - Learning Disorders "

Various educational treatments have been developed for LD. In general, the most effective treatment approach is one that involves careful delineation of the specific academic deficits evidenced by the child and intensive instruction in the skill areas in which deficiencies are documented (34). Response to treatment varies by individuals, so it is important that careful monitoring take place throughout treatment to ensure that an intervention is effective for a particular child (35). In this section, we briefly summarize the educational treatment literature by academic area and then summarize research related to treatment monitoring or formative evaluation of interventions.

Reading

Considerable progress has been made in the development of preventive and early intervention approaches for beginning readers. Several studies have demonstrated that explicit instruction in phonologic awareness (generally combined with letter identification and reading instruction) in preschool and early elementary years can reduce the overall rate of RDs (36 ,37) and can improve outcomes for children who are at high risk of RD (38 ,39). One metaanalysis reported a combined effect size for phonologic awareness training of 1.16 for phonologic awareness skills and .40 for reading skills across studies that used samples of normal readers and .54 and .60 for studies that used samples of students who were either at risk of, or had shown evidence of, reading difficulty (40).

The difference in training effect on phonologic awareness between normal and impaired readers appears to reflect the difficulty many poor readers have in mastering phonologic processing, even when they are provided with intensive instruction to address these difficulties (40). Torgesen examined results from five large-scale early reading intervention studies and concluded that even with use of the best current methods of early reading remediation, 2% to 6% of children would still evidence inadequate reading skills in the early elementary grades (41). Such findings point to the need for the development of even more powerful intervention techniques to facilitate the acquisition of early reading skills.

Current models of reading skill acquisition characterize phonologic awareness as a necessary, but not sufficient condition for the development of skilled reading (15). Fluent reading requires the development of orthographic reading skills or the ability to recognize words by sight (41). Impaired readers generally show deficits in this area that persist into adulthood (41 ,42). Interventions to improve fluency are less well developed than interventions for the development of decoding skills (i.e., phonologic awareness interventions). The *repeated readings technique*, which involves multiple readings of the same passages, is the most researched approach to improving fluency (43), and it has shown limited but positive effects on fluency (44). The increased attention to issues of fluency in reading research has resulted in the development of new, comprehensive intervention approaches that ultimately may be more effective than existing techniques in addressing fluency deficits (23). At present, however, fluency deficits remain one of the most persistent and intransigent symptoms of RD (20).

Although most children with RDs show deficits in word recognition skills, comprehension deficits are also common. These may occur alone or in the presence of impaired word recognition skills (45). When impaired word recognition is the primary source of the comprehension deficit, decoding and fluency interventions such as those discussed earlier can improve reading comprehension (46). However, interventions have also been developed to address comprehension deficits directly. Two metaanalyses found substantial improvements for disabled readers who receive intensive instruction in reading comprehension (47 ,48). In both studies, metacognitive approaches (e.g., self-questioning, comprehension monitoring) produced the largest effect sizes.

Math

Geary characterized research in the area of MDs as “primitive” in comparison with studies of RDs (22). Nevertheless, effective remediation techniques for MDs have been developed. Mastropieri et al. presented a comprehensive review of mathematics instructional techniques that have been effective for students with LDs (49). However, Cawley et al. questioned the efficacy of available math computation instructional techniques (50). In a metaanalysis of math word problem interventions, Xin and Jitendra found that instruction in problem representation was an effective remedial strategy for addressing this type of difficulty in children with a range of mild disabilities (51). These investigators also found that problem representation instruction was most effective when it was presented in a computer-assisted format. Long-term interventions (i.e., more than 1 month) resulted in better maintenance and generalization of training.

Written Expression

Difficulties with composition and writing fluency are common in children with LDs. Several researchers have shown that cognitive strategy instruction is effective in improving the composition skills of children with written language deficits (52 ,53 and 54). Generally, such interventions provide students with explicit instruction in thinking and problem-solving strategies that allow them to break down the complex task of composing written text into manageable substeps.

Difficulties with handwriting fluency appear not only to impair the speed with which children can take notes or copy but also to affect compositional fluency and quality (55). For example, Berninger et al. found that instruction in handwriting increased students’ scores on a writing composition test (56).

With more widespread use of computers in classrooms, word processing tools are increasingly being used to address the writing problems of children with LDs (57). When writing fluency is a problem, word processing may be used as a text entry strategy on its own, or it can be combined with word prediction programs (58). Voice recognition software has improved to the point that it may be a practical text entry strategy for many students with writing disabilities (59). However, research on the efficacy of these tools remains sparse. In one of the few studies to compare the efficacy of different word processing strategies for improving writing fluency, accuracy, and composition in students with LDs, Lewis et al. compared groups of students after a year of writing instruction using either keyboarding, keyboarding with word prediction software, or keyboarding with word prediction and synthesized speech software (60). All groups using word processing tools showed *decreases* in speed of text entry over handwriting, although the keyboarding with text prediction group showed the smallest decrease. There were no improvements in composition skills in any of the treatment groups.

Treatment Monitoring

The unexpected results of the foregoing study by Lewis et al. reinforce the need to monitor response to treatment and to verify that interventions for children with LDs achieve their intended results. *Curriculum-based measurement* (CBM) is a relatively new development in special education and provides a useful tool for continuous monitoring of children’s response to treatment in a number of academic areas (61 ,62 ,63 and 64). CBM involves the collection of brief samples of students’ performance on basic skills on a weekly or monthly basis. For example, CBM procedures in reading involve the administration of short reading probes (e.g., passages of 200 words) to children once or twice per week. The number of correct responses per passage is charted, and slope is then used as an indicator of a child’s response to treatment. Slopes that do not differ from zero are an obvious indicator of the need for a new treatment approach. However, estimates of typical response to treatment for students with LDs are also available and can be used as a basis for deciding whether a given treatment is producing sufficient progress (65). When formative evaluation strategies such as CBM are incorporated into treatment strategies, outcomes for students with disabilities improve markedly (66).

PSYCHOPHARMACOLOGY

Part of "44 - Learning Disorders "

Psychostimulants

Early studies of psychostimulants in children with LDs suggested strong immediate effects in enhancing reading, spelling, and arithmetic as well as in laboratory measures of learning (67 ,68 ,69 ,70 and 71). However, reviews concluded that lasting educational gains resulting from psychotropic drugs have not been demonstrated (72 ,73). Stimulant drug effects have generally been dose related, with linear increases in performance with higher doses (74 ,75 ,76 and 77). Drug-induced changes reflect increased output, accuracy, efficiency, and improved learning acquisition. There is also evidence of increased effort and self-correcting behaviors (78). Some studies suggest a positive effect of stimulants on memory consolidation that is not accounted for by concomitant effects on acquisition (79). Because most studies involve students with comorbid ADHD, measures of specific effects of stimulants on LDs are rare. However, because improvement in learning acquisition occurs in both clinical cases and neurologically normal persons treated with amphetamine (80), it seems likely that stimulant effects on learning are nonspecific with respect to diagnosis.

Stimulants have been widely used in rehabilitation of memory and LDs in brain injuries and encephalopathies

secondary to medical X-irradiation of the brain. Animal models of selective exposure to X-irradiation during infancy show enhanced learning from amphetamine treatment (81).

Nootropics

Piracetam (Nootropil, Nootropyl, 2-oxo-l-pyrrolidone acetamide) was originally developed as a molecular analogue of γ-aminobutyric acid (GABA) for the purpose of altering vestibular function in motion sickness, but it is probably neither a GABA receptor agonist nor antagonist. Numerous analogues of the piracetam molecule are currently under study, including oxiracetam (Neuromet), pramiracetam, etiracetam, nefiracetam, aniracetam, and rolziracetam. This group of nootropics is commonly referred to as the "racetams." Piracetam has virtually no detectable peripheral effects at any dose in animals or humans and does not affect cerebral blood flow, unlike other putative cerebral enhancers. It appears to alter cellular brain metabolism, however, because it increases the concentration ratio of brain adenosine triphosphate. In neurologically normal volunteers, a single dose of piracetam was found to change brain global functional state as measured by multichannel electroencephalographic recordings (82). Investigators have suggested that the defining characteristics of nootropics should include lack of peripheral effect, absence of action on blood flow, and an increase in brain metabolism (83).

Animal research indicates that memory deficits induced by epileptogenic kindling procedures are prevented by pretreatment with piracetam (84). Piracetam (100 mg/kg, IP) and oxiracetam (10 mg/kg, IP) prevented the negative effects of microwaves on memory processes in exposed rats (85). Hypobaric hypoxia of pregnant rats is followed by the reduction of weight gain of the newborn pups, delayed impairment of memory (passive and active tasks), and changes of extrapolative water escape. Piracetam (200 mg/kg/d) administered at early postnatal period (from the eighth to the twentieth day of life) corrected behavioral disturbances and physical development in rats (86). Piracetam (800 mg/kg) administered orally once daily for 5 days before training completely antagonized the scopolamine-provoked amnesia in step-through–trained mice, and piracetam (600 mg/kg) administered orally once daily for 5 days before training abolished the memory-impairing effect of clonidine in shuttle-box–trained rats and the amnestic effect of methergoline in step-down–trained rats.

Early studies by Dimond and Brouwers suggested that piracetam could facilitate transfer of information across the callosal pathways and hence is a "superconnector" drug (87). Numerous studies with neurologically normal and dyslexic adults indicated that the drug could enhance verbal learning. These studies were reviewed by Wilshire (88). An early report on reading involved 16 dyslexic men matched with 14 student volunteers for a 21-day trial of piracetam. It was found, using a double-blind crossover technique, that the dyslexic men significantly increased their verbal learning by approximately double that of control students (89). Early uncontrolled trials with a broader group of LDs were followed by a series of systematic studies of learning, memory, and reading (90).

Studies of 60 dyslexic boys 8 to 14 years old, who were carefully selected for exclusion of intellectual, sensory, psychiatric, and neurologic impairment and educational deprivation, were conducted to determine the efficacy of piracetam, over a 12-week period, in improving reading and other related skills (91). There were no changes at the end of 12 weeks to distinguish the groups in accuracy or comprehension of prose reading. Short-term memory gains, however, were recorded for the treated group on two different tests, digit span, and a test (Neimark) of immediate and delayed recall. The mean digit span scaled score for the entire group was 1 SD below their mean IQ. Considering only the performance of children whose digit span scaled scores were 1 SD or below the mean (7 or less), the treated group made a significant gain at the end of 12 weeks. On the Neimark test, the treated group was significantly superior to the untreated group on first trial learning, and they also lost significantly fewer object names after a delay. Improved retrieval from long-term storage could be demonstrated for the treated group on the rapid automatized naming test. Although there was no significant difference between the groups at screening, the treated group was significantly faster on letter naming at the end of the drug trial. The treated group also improved their single word reading on the Wide Range Achievement Test (WRAT).

After previous research suggested that piracetam improves performance on tasks associated with the left hemisphere, a 12-week, double-blind, placebo-controlled study of developmental dyslexics was conducted. Six study sites treated 257 dyslexic boys between the ages of 8 and 13 years who were significantly below their potential in reading performance. The children were of at least normal intelligence, had normal findings on audiologic, ophthalmologic, neurologic, and physical examination, and were neither educationally deprived nor emotionally disturbed. Piracetam was found to be well tolerated in this study population. Children treated with piracetam showed improvements in reading speed. No other effects on reading were observed. In addition, improvement in auditory sequential short-term memory was observed in those piracetam-treated patients who showed relatively poor memory at baseline (92).

Piracetam was given in a 3,300-mg daily dose to half of a group of 55 dyslexic boys aged 8 to 13 years, in a 12-week, double-blind, placebo-controlled study. The other half of the subjects received placebo. Compared with the placebo control group, the boys treated with piracetam did not show statistically significant improvements above their baseline scores on measures of perception, memory, language, reading accuracy or comprehension, or writing accuracy. However, reading speed and numbers of words written in a timed

period were significantly enhanced in subjects treated with piracetam as compared with placebo. Effective reading and writing ability, taking both rate and accuracy into consideration, were also significantly improved in the piracetam group as compared with the placebo treatment group (93).

Two hundred twenty-five dyslexic children between the ages of 7 years 6 months and 12 years 11 months whose reading skills were significantly below their intellectual capacity were enrolled in a multicenter, 36-week, double-blind, placebo-controlled study. Piracetam-treated children showed significant improvements in reading ability (Gray Oral Reading Test) and reading comprehension (Gilmore Oral Reading Test). Treatment effects were evident after 12 weeks and were sustained for the total period (36 weeks) (94).

The neurophysiologic mechanisms involved in the effects of piracetam were examined in studies using event-related potentials. Eight- to 12-year-old dyslexic boys were randomly assigned to 3.3 g of piracetam or matching placebo per day in two divided doses over a 12-week period. Children performed a vigilance task in which they pressed a key when two alphabetic letters or shapes occurred in sequence. Event-related potentials to letters and shapes, for active and passive responses, were recorded at the vertex and left and right parietal areas of the scalp. Performance measures included letter and form hits, misses, commission errors, and reaction times. Piracetam increased the amplitude of a late positive component (believed to correspond to P300) at the vertex for letter hits. Piracetam also increased the latency of this component in both hemispheres, but only for active responses (letter hits) in the left hemisphere and passive responses (correct rejections and misses) in the right hemisphere. Reaction time to letter hits was significantly correlated with the latency of the P300 component, a finding suggesting that letters created increased effort or attentional demand on the subjects compared with forms. An early event-related potential component (P225) also showed increased amplitude to piracetam in both hemispheres, and effects were limited to form hits. These effects were thought possibly to reflect slow negative potentials arising from stimulus anticipation in the CNV-like paradigm. The results were cautiously interpreted as indicating a facilitation of verbal processing mechanisms responsible for analyzing the verbal significance of visual stimuli (95).

In a subsequent study, 29 dyslexic children (aged 7 to 12 years) were assigned to piracetam or matching placebo for 36 weeks. Event-related potentials were obtained at the end of treatment from a vigilance paradigm that required a response to letter or form matches. The drug group showed a significant advantage in letter hits compared with placebo and a reduced variance in reaction time. The drug increased the amplitude of three factors from a principal components analysis of event-related potentials and was interpreted as increasing a processing negativity when stimuli were letters. Piracetam was interpreted as enhancing feature analysis and increasing attentional resources among dyslexic children when the stimuli are recognized as having linguistic significance (96). These effects were shown to be dose related in a subsequent study (97).

One negative study examined the interaction of piracetam and tutoring (98). Sixty children with dyslexia (41 boys, 19 girls; ages 9 to 13 years) were enrolled in a 10-week summer tutoring program that emphasized word-building skills. They were randomly and blindly assigned to receive either placebo or piracetam. The children were subtyped as “dysphonetic” or “phonetic” on the basis of scores from tests of phonologic sensitivity and phoneme-grapheme correspondence skills. Of the 53 children who completed the program, 37 were classified as dysphonetic and 16 as phonetic. The phonetic group improved significantly more in word-recognition ability than the dysphonetic group. Overall, the children taking medication did not improve more than the nonmedicated children in any aspect of reading. However, within the medication-treated group, the phonetic subgroup gained most in word recognition.

SUMMARY AND CONCLUSIONS

Part of "44 - Learning Disorders "

Significant difficulties continue to bedevil the definition of LD, including problems surrounding various criteria such as an IQ/learning discrepancy or low absolute achievement level. Approaches that define the disorder by resistance to high-quality instruction may be the most valid for purposes of identifying persons with LDs in genetic, neuroimaging, and pharmacologic studies. The high degree of comorbidity with many psychiatric disorders raises further issues for studies requiring a homogeneous symptom pattern, and it seems likely that further advances will require replacing broad clinical patterns with more specific processing deficits based on cognitive neuroscience. Despite these limitations, existing research is encouraging regarding the possibility of precise genetic and neuroanatomic localization of LDs, particularly for RDs. Again, however, subtyping issues at the phenotypic level require elucidation before further progress is likely.

Much of the pharmacologic work has been confounded by the comorbidity of LD with ADHD and other childhood disorders. Evidence generally supports the finding that psychostimulants (e.g., dextroamphetamine and methylphenidate) have positive effects on immediate learning *performance* but less impact on long-term academic gains. Work with nootropic drugs shows intriguing effects on verbal learning, single-word reading, and left-hemisphere processing of alphabetic stimuli. Good controlled trials indicate that piracetam may be a safe and effective enhancer of reading in school-aged children, with gains double the rate expected in seriously impaired readers. LD remains a large public health problem, is significantly undertreated, has devastating lifetime outcomes, and therefore merits greater

research efforts to understand its neurobiology and treatment needs.

Kenneth E. Towbin: Complex Developmental Disorders Clinic, Department of Psychiatry and Behavioral Sciences, George Washington University School of Medicine Children's National Medical Center, Washington, DC.

The appearance of *psychotic symptoms in childhood*, albeit rare, is an important clinical entity. This importance extends beyond their clinical prevalence and has begun to influence our understanding of the principal psychotic conditions. The term *psychosis* is generally categoric and includes subgroups within it. It is clear that the peak onset of the most common psychotic disorders, schizophrenia and bipolar disorder, is in adolescence (1 ,2). This points directly toward developmental events in biological, social, and psychological domains of late childhood and adolescence that set the stage for activating psychotic disorders. However, in addition, it appears increasingly likely that certain early childhood characteristics and developmental deficits may presage psychosis and are related to the outcome of psychotic disorders.

For the purposes of this chapter, *psychosis* is defined as the presence of disruptions in thinking, accompanied by delusions or hallucinations, along with an alteration in the thought processes, termed a *thought disorder*. Delusions and hallucinations are considered to be positive psychotic symptoms. *Delusions* are fixed, false, idiosyncratic beliefs that the child cannot be deterred from, with logical reasoning, whereas *hallucinations* are percepts that arise in the absence of external sensory stimulus. Psychotic symptoms always encompass a broad range of conditions, but it is particularly so when they appear in children and adolescents. Psychotic symptoms in children present distinctive diagnostic and clinical challenges because of the powerful influences of immaturity and the moving target produced by development.

Although there may at one time have been confusion about whether children are capable of having psychotic symptoms, it is now certain that children, like adults, can and do experience psychoses (i.e., disruptions in the form of mental life). Children and adolescents experience the same range and types of psychotic symptoms as do adults. They can lose the connections between their thoughts (formal thought disorder) and have perceptions without external stimuli (hallucinations). The term psychosis as described by McHugh and Slavney (3) is intended simply to indicate that mental life has been disrupted in its capacities or forms, as a result of a process that generates new forms of psychological experience.

Psychotic symptoms can be considered as general or nonspecific phenomena emerging with different disorders and etiologic possibilities. Modern psychiatry eschews the misleading dichotomy of functional versus organic causes and recognizes that some of these disorders stem from known brain or metabolic disorders, whereas for other conditions the pathophysiologic sources have yet to be discovered. The interplay between environmental and biological forces is at work across the spectrum of these conditions. The psychiatrist who must determine whether a young patient suffers from a psychotic disorder faces a challenging array of possibilities, more extensive than when the patient is an adult. The influences of development, environment, and cognition are greater for young or developmentally immature patients than for adults. Nonbiological events are clearly more influential because, in most respects, children are more vulnerable to their surroundings. Immaturity makes children more susceptible to environmental stressors and cognitive distortions. Children routinely have intrusions of fantasy into ordinary mental life; determining when this becomes pathologic can be a matter of degree. Children learn and experiment with imitation, and they can acquire habits and strategies used by those around them. They have not developed the cognitive abilities that permit them to observe and compare their experiences in an objective manner. The range of normal functioning is greater in childhood, so the child's behavior may simply be a result of immaturity, rather than a deviation from a normal pathway.

With the advent of categoric classification of psychiatric disorders, the criteria for psychotic disorders have become more stringent, and the concepts have been defined more narrowly. When one examines a 5-year old child who claims that he is “superman and can fly,” the challenge is to determine whether the child has a delusion. Similarly, in a child who complains about hearing a voice telling her to “do bad things,” one must determine whether she is talking about her conscience or is experiencing auditory hallucinations. This must be distinguished from *make-believe* (e.g., having an imaginary friend). Children can describe this makebelieve phenomenon, and clinicians need to discern the differences as they work with children with symptoms of psychosis. Such characteristics are sought by the clinician in the child’s answers to particular questions. The task and challenge as child and adolescent psychiatrists are to ask the right questions, to differentiate delusions and hallucinations from other forms of thought, such as a vivid imagination in a young child.

HISTORY

Part of "45 - Psychosis in Childhood and Its Management "

Interest in childhood psychosis can be traced to the nineteenth century, when Maudsley first wrote a description of the “insanity of early life” in 1874 in his textbook, *Physiology and Pathology of Mind* (4). He took a developmental approach by noting that the mental faculty of children was not organized, and hence the insanity in children must be of the simplest kind, influenced more by “reason of bad descent or of baneful influences during uterine life.” However, De Sanctis may be credited first with setting out childhood schizophrenia as different from mental deficiency and from certain neurologic disorders, such as epilepsy or postinfectious encephalopathy (5). It was not until 1919, that Kraeplin introduced the concept of *dementia praecox* and noted its onset in late childhood and adolescence (6). Given the insidious onset of the disorder, Kraeplin cautiously suggested that 3.5% of patients with schizophrenia had the onset of their illness before the age of 10 years. This led to an increased interest in understanding the developmental aspects of psychosis. Historically, despite this early description of the syndrome by Kraeplin that is now recognized as schizophrenia, other diagnostic terms were put forward as well. These included *dementia praecossima* (5) and *dementia infantilis* (7). Potter offered clearer descriptions of schizophrenia, with consideration of the child’s developmental age, and offered specific diagnostic criteria for children (8).

Despite efforts to recognize childhood schizophrenia as a distinct clinical entity, during the decades between 1920 and 1970, the term *childhood psychosis* comprised all forms of severe mental disorders in children, including schizophrenia and autism. Kanner’s description of early infantile autism catalyzed an alternative view of the conceptualization of these disorders.

Beginning with the works of Loretta Bender (9), Leo Kanner (10), and others (11), all considered childhood schizophrenia to fall under the broader category of childhood psychoses. Nevertheless, there came an acknowledgment and new awareness of major developmental differences in the perception of reality (12) and that developmentally or culturally appropriate beliefs (e.g., imaginary playmates and fantasy figures) did not, of themselves, suggest psychosis. This cluster of syndromes, including infantile autism, was defined by developmental lags in the maturation of language, perception, and motility (11). Although psychotic speech and thoughts were initially considered inherent components of childhood schizophrenia, hallucinations and delusions were not required criteria (6 ,13 ,14 and 15). DSM-II adopted this nosology and grouped all childhood psychoses under childhood schizophrenia. As a result of this broad grouping, the literature regarding childhood schizophrenia from this period overlaps with that of autism and does not differentiate autism from other psychotic disorders. With further development of psychiatric taxonomy and elucidation of the phenomenology (course, onset, family history, and associated features), the distinctiveness of the various childhood psychoses and the similarity between child and adult schizophrenia were demonstrated (16 ,17). This change had a pronounced influence on the nosology of these disorders and led eventually to changes with the DSM-III (18). Schizophrenia arising in childhood and infantile autism came to be recognized as distinct clinical syndromes, each with its unique and distinct psychopathologic phenomenology, theories about causes, and longitudinal course. Research since the advent of DSM-III generally validated this decision (19 ,20). This distinction has had an impact on how children with these disorders are currently evaluated, managed, and treated.

COGNITIVE ASPECTS

Part of "45 - Psychosis in Childhood and Its Management "

Although children do not describe disorders, they nevertheless may complain of changes in their mental and cognitive states. To these changes, clinicians add signs, based on observations derived from the mental state examination of the children and data obtained from laboratory or cognitive tests. Subsequently, a distinctive pattern may emerge over the course of the child’s illness. A collection of symptoms and signs occurring in a certain temporal pattern is then used to categorize the child’s problem. Psychotic symptoms can be attributed to distinct mental illnesses (functional psychoses), which are contrasted with the psychotic symptoms that usually result from a demonstrable underlying pathologic mechanism and organic origin (organic psychoses), such as delirium. Cognitive impairments, particularly impaired concentration and ability to focus, usually accompany psychosis in children. However, when the psychosis is secondary to an organic origin, there is often accompanying

impairment in the sensorium presenting as confusion and disorientation, as is typical of delirium.

From a cognitive and developmental standpoint, certain clinical features in children create diagnostic challenges. One problem is distinguishing true psychotic phenomena in children from nonpsychotic idiosyncratic thinking, perceptions caused by developmental delays, exposure to disturbing and traumatic events, and overactive and vivid imaginations. Furthermore, because the onset of childhood schizophrenia is insidious, with a lifelong history of developmental and personality abnormalities, differentiating between the premorbid state and the active psychotic state can be difficult. It has also been suggested that the development of psychotic conditions during childhood may have major adverse effects on development, a feature further complicating diagnostic assessment (21).

Investigators have noted that social withdrawal, “shyness,” and disturbances in adaptive social behavior seem to be the first signs of dysfunctional premorbid development. Eggers et al. suggested that these should be considered vulnerability factors, indicative of a risk of psychotic illness (22). Recent work has also pointed to early language deficits and motor impairments as being significant for very early-onset schizophrenia, in children younger than 12 years (23). However, a socially odd child is not usually schizophrenic. In fact, most children who have hallucinations are not schizophrenic (24 ,25 and 26), because they lack the requisite persistence and associated symptoms. Intellectual delays have long been considered as general risk factors for psychopathology and psychosis in children (27). In fact, the estimated rates may be low, because most studies examining psychosis in children exclude patients with mental retardation (28 ,29).

CLINICAL AND DEVELOPMENTAL CONSIDERATIONS

Part of "45 - Psychosis in Childhood and Its Management "

Developmental factors influence the detection, form, and context of psychotic symptoms in children. One problem of assessing psychotic disorders in very young children compared with older children is that these symptoms in young children tend to be more fluid and less complex. Isolated hallucinations can occur in acutely anxious but otherwise developmentally intact preschool children. In older children, hallucinations may occur in the absence of other signs of psychosis, but they are usually associated with other psychopathologic conditions, such as depression, severe anxiety, and posttraumatic stress disorder.

Often, there is an underestimation of the subtle differentiation among age-related cognitive preoccupations, pseudohallucinations, and imaginative experiences. Further, it is often too difficult to tease out the physiognomic-animistic interpretations of the inner and outer world on one hand and the first prominent psychotic phenomena such as delusions and hallucinations on the other.

It is critical to avoid rushing to a premature conclusion about unusual behaviors and beliefs in children. Such atypical mental experiences in children can be recognized as prodromal or prepsychotic signs only after the manifestation of frank psychotic symptoms. Odd beliefs and unusual behaviors deserve close observation, but they cannot be ascribed to psychosis without the concomitant presence of a thought disorder.

For example, a young schizophrenic girl lived by the railroad tracks all her life. At age 11 years, about the time when her disorder had its onset, she noted that the sound of the train whistle changed, and she began to wonder why. She came to believe that it had a specific purpose and meaning—that it beckoned her. Until that time, such events were inconsequential and unimportant, but at about age 11 years, she started to attach a different meaning to them. She was uncomfortable with these thoughts and realized that it was not her usual pattern of thinking. Things around her started to have special meaning, her thoughts were “strange,” and she was puzzled and bewildered.

This may be considered a *predelusional phenomenon*, idiosyncratic but not yet fixed. Over the next several years, she developed ideas of reference, thought broadcasting, and thought insertion. She believed that the train whistle was sending special messages from God to her. She no longer questioned these perceptions and believed them to be real. By age 14 years, she was diagnosed with childhood-onset schizophrenia.

A formal thought disorder in a child is more ominous and requires careful psychiatric and neurologic evaluation. Distinguishing between the formal thought disorder of schizophrenia and that of developmental disorders, personality disorders, and speech and language disorders also presents diagnostic problems (30). Symptoms such as thought disorder have been noted to arise in persons with pervasive developmental disorders, particularly those with good language skills, such as (often referred to as “high functioning”) autistic persons and those with Asperger syndrome (31 ,32).

Although loose associations and incoherence are valid diagnostic signs of early-onset schizophrenia, these symptoms are also sometimes seen in schizotypal children (33). The inclusion criteria of disorganized speech according to DSM-IV (34), rather than a formal thought disorder, presents a particular challenge when assessing children, because disorganized speech is an inherent component of many of the developmental disorders. Clearly, the assessment and ascertainment of delusions, hallucinations, and thought disorder in linguistically impaired children are difficult and complicated.

Therefore, developmental disorders must be considered in the differential diagnosis of a child presenting with psychotic symptoms. The use of comparable criteria across the age span facilitates analyses of progressive symptoms from

childhood to adulthood. However, one of the difficulties in assessing psychotic disorders in very young children is to determine whether nonspecific behavioral disturbances represent an incipient psychosis or are signs of autism or pervasive developmental disorders (35 ,36).

Further, the conceptualization of psychoses in childhood as a neurodevelopmental disorder has drawn increasing attention, especially as it relates to childhood-onset schizophrenia (37). Therefore, another alternative in the conceptualization of psychotic episodes is a grouping of symptoms that are not part of the formal DSM or International Classification of Diseases (ICD) scheme. For decades, clinicians recognized that a pattern of brief psychotic episodes, affective dysregulation, and poor social abilities occurs in children. Early references on schizophrenia (17) and later writings (38 ,39) noted the diagnostic problem of children with poor social development and psychosis. Now, the absence of a formal single diagnostic address for this syndrome has produced a wide variety of terms applied to the same phenomena. The older literature suggested that such children may be considered to have "borderline syndrome of childhood" (40), and then later "schizotypal disorder of childhood" was considered (38). In 1986, Cohen et al. suggested the term *multiplex developmental disorder* and proposed that this condition was best understood as a developmental deviation within the group of pervasive developmental disorders (41). Towbin and co-workers offered operational criteria and preliminary validating evidence for the concept and criteria and used the term *multiple complex developmental disorder* (42). Following Cohen et al., the view of Towbin and co-workers was that multiple complex developmental disorder was a higher-functioning type of pervasive developmental spectrum disorder. Rather than pointing to one particular outcome, Towbin and coworkers suggested that multiple complex developmental disorder was a nonspecific risk factor for a poor adaptation in adult life but with a myriad of adult diagnostic outcomes such as schizophrenia, bipolar illness, or any of the more severe unstable personality disorders. Further elaboration of these criteria have shown support for the concept and validated that children with pervasive developmental disorder not otherwise specified and autism can be meaningfully separated from those with multiple complex developmental disorder (43). Further exploration of the concept of multiple complex developmental disorder has received support from neurophysiologic studies as well (44).

The National Institute of Mental Health (NIMH) project on early schizophrenia culled children for a study of clozapine. The most common referrals were children whose symptoms closely resembled those of multiple complex developmental disorder. The NIMH group suggested the term *multidimensionally impaired* (45 ,46) and offered criteria that were analogous to those described by Towbin and co-workers. However, despite findings that many of these children met partial criteria for pervasive developmental disorder not otherwise specified, the NIMH group preferred to consider the constellation a *forme fruste* of schizophrenia (46). Yet longitudinal studies suggested that the constellation remains stable and does not progress to schizophrenia (46). Other work reporting on similar children has used terms like such as "pervasive developmental disorder plus bipolar" (47) or "obsessive difficult temperament" (48). As further exploration now points to "high rates of speech and language, motor, and social impairments in patients with childhood-onset schizophrenia," the association with pervasive developmental spectrum disorders is drawn even closer for this very early-onset subgroup (23).

In addition to the developmental factors and disorders described earlier, the other differential diagnoses of childhood psychoses can be classified as described in the following sections.

Functional Psychoses

Childhood-Onset Schizophrenia

Schizophrenic psychoses with onset before age 11 years are rare. The prevalence in this age group is about 0.01 to 0.05 per 1,000. In addition, developmental status can affect the expression of the disorder. The earliest descriptions by DeSanctis (5), Bleuler (49), and Kraeplin (6) reported the onset and occurrence during childhood and considered schizophrenic psychoses to be an early onset of the same disease, which appeared to be on a continuum phenomenologically, that they observed in adolescents and adults. Furthermore, it has been shown that schizophrenic psychoses can be diagnosed reliably in children using the same criteria as for adults (20 ,36 ,50 ,51). Very few studies to date have dealt with the long-term outcome in childhood-onset schizophrenia. Most studies have followed children for between 1 and 5 years (52). Because of methodologic difficulties, there is a striking absence of data before the age of 11 years on the long-term course of psychosis. Asarnow emphasized the "crucial importance" of long-term follow-up data for establishing the validity of psychotic symptoms manifested in early childhood (53). This is especially important because children often describe "hearing voices," especially in clinical populations. An astute clinician will delve into this symptom in greater depth, to obtain a qualitative appreciation of these "voices." Often, the child will describe this "voice" inside his head as if hearing his own voice or that of an adult in his life. He most likely will not hear this voice through his ears and seems affectively not to be too troubled by it. Conversely, a child experiencing true auditory hallucinations is frightened, puzzled, and unable to be reassured. This differentiation is especially important because management of these youngsters often includes the use of psychotropic medications, which, in and of themselves, require serious consideration because of their long-term adverse effects. If the phenomenology of these so-called psychotic

symptoms is not clarified, many youngsters with pseudohallucinations will be prescribed psychotropic medication needlessly. In addition, they will wrongly be labeled with a psychotic disorder.

Premorbid developmental peculiarities have been reported in children with childhood-onset schizophrenia who have been followed into their thirties. These peculiarities are primarily internalizing such as shyness, isolatory behaviors, lack of interest, awkwardness, being fickle with peculiar facial expression, aggression, paranoia, anxious thoughts, and being mistrustful of others, along with symptoms of depression. These signs have been reported to be much more common than externalizing, acting-out behaviors such as temper tantrums, aggression, opposition, and hostility (22). From a developmental standpoint, the age of first manifestation of nonpsychotic symptoms is younger than the age of onset of schizophrenic symptoms (53 ,54 ,55 and 56). However, the predictive relevance in prepsychotic symptoms in children seems to be extremely uncertain because of the high variability of developmental peculiarities.

The nature of the diagnostic subtypes varies markedly across the course of the illness. In patients with continuous predominantly catatonic symptoms, the outcome is poor. Eggers et al. suggested that detailed case description helps to illuminate the heterogeneous psychopathology of childhood-onset schizophrenia (22). These investigators found that various temporary premorbid behavioral peculiarities were precursors of childhood-onset schizophrenia. Children with early-onset schizophrenic psychosis develop a phenomenology of positive and negative psychotic symptoms that are similar to those seen in adult patients with schizophrenia, and the course variability is perhaps even greater than in adult patients. Their findings contradicted the assumption that childhood-onset schizophrenia is characterized only by negative symptoms, because a differentiation between premorbid and prodromal signs proved to be arbitrary.

Since Kraeplin's first description of *dementia praecox* in 1889, the onset and course of schizophrenia relied heavily on first admission data and on the subsequent course of the disease. However, Hafner et al. argued that items taken from the preadmission phase of the disease were often incorrectly used as premorbid characteristics (57). In an attempt systematically to account for the age and gender distribution of the true onset and the symptoms and pattern of the early and later course, Hafner et al. developed an Interview for the Retrospective Assessment of the Onset of Schizophrenia (IRAOS) (57). This instrument allows an objective, reliable, and valid assessment of the symptoms, psychological impairments, demographic and social characteristics, and the referring points in time of the early course of psychosis. Their findings suggested that the IRAOS provides information on the earliest course of the disease and enables them to separate premorbid characteristics, possibly the most powerful predictors of the later course and outcome, from contamination with symptoms and deficits belonging to the early phase of the disease. The influence of certain life events on the early course is also made accessible to empiric research. Other instruments that have been used for assessing psychotic symptoms in youngsters have been the Interview Schedule for Children (58), the Diagnostic Interview Schedule for Children (59), the Schedule for Affective Disorders and Schizophrenia for School-Aged Children (60 ,61).

Several nonspecific and nondiagnostic neurobiological abnormalities have been reported in patients with schizophrenia. These include deficits in smooth pursuit eye movements and autonomic responsivity (62 ,63). Neuroimaging findings include a progressive increase in ventricular size and a fourfold greater decrease in cortical gray matter volume during adolescence, with the greatest differences occurring in the frontal and temporal regions (64 ,65 ,66 and 67). Others findings reported in the literature are a smaller total cerebral volume, correlated with negative symptoms (37), and frontal lobe dysfunction (68).

Schizophrenia with childhood onset is usually a severe and chronic disorder with a more guarded prognosis and poorer therapeutic response to neuroleptic agents than schizophrenia with adolescent or adult onset. New research and data will help to clarify the origin and pathogenesis of schizophrenia in children. Subsequently, development of more effective treatments and preventive measures may reduce its severity.

Mood Disorders

Mood disorders such as major depression and acute mania can often be accompanied by psychotic symptoms. Over the past several decades, the prevalence of mood disorders appears to have been increasing (69). Although information on the epidemiology of psychotic depression in children is limited, Chambers et al. described the occurrence of psychotic depression in children (61). The psychotic symptoms usually are mood congruent, but at times they can be quite like those seen in childhood schizophrenia (20 ,70 ,71 and 72). This overlap in symptoms increases the likelihood of incorrect diagnosis, especially at the time of onset. Sometimes, the negative symptoms of schizophrenia in children can be mistaken for those of depression. However, it has been shown that children with schizophrenia have poorer premorbid adjustments, lower IQs, and more chronic dysfunction, when compared with children who suffer from a depressive disorder (50). It is therefore prudent to make only a tentative diagnosis at the outset that must be confirmed longitudinally. Careful follow-up of psychotic patients is needed to detect diagnostic errors. This issue can be compounded, however, if the symptoms resolve with antipsychotic medications. It becomes unclear whether the child improves because of treatment or spontaneous remission. Approximately one-half of adolescents with bipolar disorder may

be originally diagnosed as having schizophrenia (20 ,70). Therefore, it is extremely important that longitudinal reassessment is needed to ensure accuracy of the diagnosis. Despite an increased family history of depression in schizophrenic youth (20), family psychiatric history can be an extremely helpful differentiating factors. However, the opposite is not true, that is, an increased family history of schizophrenia in depressed or bipolar youngsters. Often, the rule of thumb is first to rule out mood disorder in a child or adolescent before the diagnosis of schizophrenia is more strongly considered.

Even though there is an overlap of the quality of psychotic symptoms in children with mood disorders and childhood-onset schizophrenia, often with careful examination, some of the mood-congruent symptoms can be ascertained. As clinicians, it is important that we ascertain chronologically what came first, that is, a change in mood and then the onset of delusions or hallucinations, or a disturbance in thought followed by a change in mood. For example, the child who first starts to have “strange thoughts” and to hear voices over time becomes puzzled, fearful, distraught, and depressed. This is quite different from the child who first starts to lose interest in activities, to feel irritable or depressed, to not want to play with friends, and who demonstrates neurovegetative symptoms, such as a decrease in appetite, sleep disturbance, and lethargy. Subsequently, the child starts to think he is a bad and evil person and then hears a voice that tells him he is a bad boy and that he should kill himself. The phenomenology in this instance is quite different. However, it is not always this clear, and there is a high rate of misdiagnosis in both directions (72 ,73).

Psychotic symptoms during a manic episode have been recognized for many years, although misdiagnoses of schizophrenia were, and remain, relatively common (74). Bipolar disorder eventually develops in a minority of children initially hospitalized for major depression (1). This is particularly so if the child has a positive family history of bipolar disorder, psychomotor retardation, rapid onset of symptoms, mood-congruent psychotic symptoms, or pharmacologically induced mania or hypomania. The characteristics of the delusions and hallucinations are often mood congruent (expansiveness, grandiosity, and euphoria). Therefore, a child experiencing mania may have delusions of being “superman” with special powers, of being able to fly and leap from high places. Conversely, the child may believe that he or she has special skills playing baseball, even though the child perhaps may have problems with gross motor skills and is clumsy and uncoordinated. Similarly, the child may hear voices, the content of which are mood congruent, with the altered state in mood (i.e., grandeur), and may believe that the voice is saying that he or she is superior and can do anything.

Brief Reactive Psychosis

Occasionally, children and adolescents suddenly develop psychotic symptoms that can last from a few hours or days. The child experiences these symptoms when under tremendous stress, such as after a death in the family, witnessed acts of violence or destruction, or physical or sexual abuse. The *acute psychotic symptoms* often resolve quickly, with total recovery in a few days. These youngsters may suddenly become disorganized, confused, agitated, or withdrawn. At times, their speech becomes nonsensical and incomprehensible. They may also experience delusions and hallucinations. These, too, are usually short-lived.

Anxiety Disorders

Children who experience *acute anxiety* or who have a history of maltreatment, abuse or neglect report significantly higher rates of psychotic symptoms when compared with controls (75). Several studies have documented psychotic-like symptoms in children with *posttraumatic stress disorder*. In such instances, the psychotic symptoms actually represent intrusive thoughts or worries regarding the traumatic event (73 ,76 ,77). Mental status examination usually reveals the lack of a formal thought disorder, and the psychotic-like symptoms are more akin to derealization or depersonalization, as is often observed in traumatized children. Furthermore, there is often a qualitative difference in the way children with anxiety disorders and those with childhood-onset schizophrenia relate. The former have better-developed relationship and prosocial skills compared with the socially isolated, awkward, and odd behaviors of a child with schizophrenia. An identifiable traumatic event, abuse, or neglect in the child’s history, in and of itself, does not necessarily rule out a psychotic disorder, because children with both schizophrenia and mood disorders may have had such experiences (73).

Organic Psychoses

Neurologic Conditions

Seizure Disorder

Children with *seizure disorders* can experience hallucinations as part of the seizure activity. Complex partial seizures, especially those with a temporal focus, may be associated with interictal psychotic symptoms of delusions, hallucinations, and unusual preoccupations. Caplan and co-workers described a formal thought disorder in children with partial complex seizures (78 ,79), although their way of defining thought disorder makes it intertwine closely with language organization deficits. However, they did emphasize that these epileptic children usually do not display negative symptoms such as those seen in schizophrenia. Hallucinations in children with epilepsy typically are brief. Therefore, these children experience mainly positive symptoms, which

are often short-lived. Caplan and co-workers also described a higher incidence of formal thought disorder in those children who have lower IQs, earlier onset of the seizure disorder, and poor seizure control. They postulated that these symptoms may either reflect the underlying neuropathology that produces the seizures or result from the “kindling phenomenon” as a secondary effect of the seizure activity.

Deteriorative Neurologic Disorders

Psychotic symptoms have been described in children who have a *deteriorative and degenerative neurologic disorders* such as subacute sclerosing panencephalitis (80). Other disorders include Wilson disease, lipid storage disorders, and Huntington chorea. These are usually differentiated from childhood-onset schizophrenia by the presence of neurologic findings on physical examination of the child, further corroborated by abnormal findings on laboratory testing. Children suffering from such neurologic deterioration often have a gradual, persistent, but global decline in their neurologic condition.

Central Nervous System Lesions

These conditions include brain tumors, congenital malformations, and head trauma.

Metabolic and Hormonal Disturbances

Various *metabolic and hormonal conditions* can be responsible for psychotic symptoms in children. Endocrinopathies may include disorders of the adrenal, thyroid, or parathyroid glands. Exogenous metabolic disturbances leading to psychotic symptoms can include exposure to heavy metals.

Toxic Psychoses

Toxic psychosis or delirium usually occurs secondary to bacterial or viral infections, high fevers, and exogenous toxins including medications, illicit drugs, alcohol, and poisonings. Unlike childhood schizophrenia or other psychotic disorders, in which impaired thinking and communication are the most salient symptoms, toxic psychosis is more likely to cause vivid, disturbing visual or tactile hallucinations and other perceptual problems. Auditory hallucinations can also occur, but their content is qualitatively different from those experienced in childhood schizophrenia or mood disorders. These sensory experiences may be extremely frightening and may be accompanied by agitation or by uncontrolled or even aggressive behaviors. Children and adolescents often describe the experience as “losing their mind”—a frightening concept, and they can become disoriented, unable to orient to person or place, or comprehend why they are behaving in an unusual manner. They may also experience fluctuating levels of alertness.

In children, infections (bacterial or viral) can cause encephalitis, meningitis, and human immunodeficiency virus–related syndromes, which can result in delirious states. High fevers, regardless of origin, have been known to cause delirious states with perceptual disturbances. In addition, chronic liver and kidney disease may cause delirious states associated with psychotic symptoms in children, manifested by states of confusion, distortions in perceptions, and frank hallucinations.

The best example of medication-induced psychosis is that resulting from high doses of stimulants (the most commonly prescribed group of medications in this age group). In young children, normal doses of common medications, such as over-the-counter antihistamines and decongestants, can induce similar symptoms. Some of the other medications that can have a similar result are steroids, which can cause not only a disturbance in mood (depression and manic symptoms), but also delirium. Children prescribed anticholinergic drugs are also vulnerable to developing delirium, presenting with psychotic symptoms.

Other causes, especially in older children and adolescents, are alcohol intoxication, amphetamine-like drugs (“speed” and cocaine), hallucinogenic drugs (LSD and psilocybin), solvents, and cannabis. Most children who develop drug-induced psychosis recover once the drugs are out of their system.

The psychotic symptoms sometimes experienced by patients after anesthesia should be included in the category of toxic psychoses. Although usually short-lived, this phenomenon is reported by patients to be a very frightening experience. Support, reassurance, and ensuring safety at the time are usually sufficient in the management of patients after anesthesia.

MANAGEMENT AND TREATMENT

Part of "45 - Psychosis in Childhood and Its Management "

Assessment

Effective treatment requires knowledge of the psychotic disorders, diagnostic criteria, symptoms, and longitudinal course, in addition to an understanding of the youngster’s developmental, social, educational, and psychological needs. Treatment strategies therefore need to focus on the clinical symptoms and morbidity of the underlying disorder, while also addressing any comorbid disorders or biopsychosocial stressors. The physician must prioritize symptoms and diagnoses, so a reasonable treatment plan addresses multiple problems. A clinician examining a child for psychoses must first ascertain whether the child comprehends the clinician’s question about delusions and hallucinations and whether the child endorses the psychotic symptoms only to please the interviewer or to get attention. In addition, it is important to determine whether the child acts on the basis of the delusional or hallucinatory perceptions—associated with an affective response of fear, dread, avoidance, or elation.

The assessment of the child with psychotic symptoms should include a careful, comprehensive, and thoughtful

evaluation. The history is often obtained from multiple informants, and several sessions may be required to gain accurate assessment of the child's mental status. The assessment should include a detailed evaluation of the symptom presentation, course of illness, and phenomenology. A developmental history of the child and a detailed family psychiatric history are invaluable components of the evaluation and assessment. A positive family history, especially for an affective disorder or schizophrenia because these disorders tend to run in families, often helps the clinician with the differential diagnosis in the child.

Once it is determined that the child is experiencing psychotic symptoms, it is important foremost to ascertain the cause of such symptoms. This will, in large part, determine the management and treatment of the child presenting with psychosis. A thorough physical examination is essential, and pertinent tests and procedures may be necessary, as clinically indicated. These may include imaging studies, an electroencephalogram, toxicology screens, and renal and liver function tests. Some children may require consultation with other pediatric specialists.

Psychological and projective testing are not indicated as a method of diagnosing specific disorders causing the psychosis. However, they can be helpful for intellectual assessment and to determine developmental delays, because these deficits may influence the presentation or interpretation of symptoms. Routine use of adaptive function measures is important for understanding actual function in social, daily living, and communication domains. These can be quite helpful in planning and maintaining developmentally relevant treatment goals. Similarly, speech and language evaluations are often helpful, especially with a child who appears to have linguistic impairments on examination.

Treatment

If it is deemed that the cause is organic, then the first step is to diagnose and treat the underling cause of the psychotic symptoms. This may include treating a partial complex seizure disorder, managing a metabolic imbalance, or treating an underlying infection or reducing a fever. Conversely, if it is determined that there is no medical cause for the psychotic symptoms, then the next step is to ascertain whether the psychosis is functional. If so, is it secondary to severe depression or acute mania with psychotic symptoms or secondary to a schizophrenic illness?

Adequate treatment requires a combination of pharmacotherapy and various psychosocial interventions that target the child's specific difficulties. Some of this depends on the phase of the underlying illness (81):

Stage 1 (prodromal phase): The child may experience some period of deteriorating function, which may include social isolation, idiosyncratic preoccupations and behaviors, and academic difficulties.

Stage 2 (acute phase): This is usually the time when the child comes to the attention of a mental health professional, when the clinical picture is dominated by frank delusions and hallucinations and other positive symptoms such as a formal thought disorder or strange and idiosyncratic behaviors.

Stage 3 (recovery phase): The symptoms usually begin to remit and dissipate. However, often there may still be the presence of some psychotic symptoms, although they are less disturbing to the child. In this phase, the child may continue to experience some levels of confusion, disorganization, or lability in mood.

Stage 4 (residual phase): The positive symptoms continue to subside, but the child continues to experience apathy, lack of motivation, withdrawal, and restricted or flat affect.

Unfortunately, some children remain symptomatic and chronically impaired, despite what would be considered adequate treatment. Usually, such impairment is characterized by persistent symptoms, which occur especially if the psychosis is secondary to a schizophrenic illness, rather than the result of depression or mania.

Psychosocial interventions should include working with both the parents and the child. Interventions targeted at improving family functioning, problem solving, communication skills, and relapse prevention have been shown to decrease relapse rates in adults (82). Children may benefit from social skills training and may require specialized educational programs, academic adjustments, and support at school. Ongoing illness teaching and medication education, are important to promote compliance with treatment and to help in coping with the daily and sometimes long-term implications of the child's illness. Every effort should be made for the child to be maintained in the least restrictive setting, such as home. However, in some cases, the severity and chronicity of the underlying illness may warrant long-term placement in a hospital or residential facility.

Pharmacotherapy is instituted in an attempt to treat the underlying cause of the psychosis, or for symptom control, in those children who have psychotic symptoms secondary to a known origin. Informed consent from the parents or guardian should be obtained before treatment with psychopharmacologic agents is instituted.

It is not in the purview of this chapter to discuss each medication in detail. For the treatment of major depression, the following antidepressants have been used in children:

Tricycle antidepressants (nortriptyline, imipramine, desipramine)

Selective serotonergic reuptake inhibitors (fluoxetine, paroxetine, sertraline, fluvoxamine, citalopram)

Nonselective serotonergic reuptake inhibitors (nefazodone, mirtazapine)

Monoamine oxidase inhibitors (phenelzine, tranylcypromine) (seldom used currently)

Others: bupropion, venlafaxine

Mood stabilizers that have been used for the treatment of manic-depressive illness in children include the following:

Anticonvulsants (divalproex sodium, carbamazepine, gabapentin)
Lithium

Often, the use of antipsychotic medications in addition to the use of antidepressants or mood stabilizers is indicated in functional psychosis.

If the suspicion is that of early-onset schizophrenia, then antipsychotics are first-line medications. Although children may metabolize neuroleptics more rapidly than adolescents and adults, optimum doses for children are typically less than those required in adolescents and adults.

First-line agents include traditional neuroleptic medications that block dopamine receptors or the atypical antipsychotic medications that have a variety of effects including antagonism of serotonergic receptors. The atypical antipsychotic medications are reported to be at least as effective for positive symptoms and may even be more helpful for negative symptoms. Further, there is some suggestion that they have fewer adverse effects. Except for clozapine, the novel agents also appear to produce tardive dyskinesia. Experience with novel antipsychotic agents is too scant to determine whether the risk of tardive dyskinesia is equal to or less than with the older antipsychotics. Newer antipsychotic medications that have been used in children are risperidone and olanzapine. They may be less sedating than the traditional neuroleptic agents such as haloperidol, fluphenazine, thioridazine, and chlorpromazine. There have been some case reports in the literature of the use of clozapine for children and adolescents with schizophrenia in whom normally adequate treatment with other traditional antipsychotic medications has failed.

For a child suffering from acute reactive psychosis, support and safety are the two primary considerations. If the child is extremely stressed and acutely ill, hospitalization may be necessary to provide a safe and structured environment. Brief treatment with antipsychotic mediations has often been effective for the alleviation of psychotic symptoms in some children. However, medications will not eliminate the problem that originally caused the brief psychosis. Thus, psychotherapy is often helpful in helping the child learn to cope with the emotional trauma that may have precipitated the episode.

Toxic psychosis requires immediate medical intervention to identify the cause and to provide appropriate treatment. Identifying the cause may include laboratory tests such as serum electrolytes, liver function tests, toxicology screens, blood alcohol level, serum levels of prescribed medications including theophylline, tricyclic antidepressants (nortriptyline, amitriptyline, imipramine, desipramine), or mood stabilizers (valproic acid, lithium, carbamazepine). Neuroleptics, because of their common usage, comprise another important group of medications that needs to be considered in the psychiatric population. The rare but possible development of *neuroleptic malignant syndrome*, manifesting as a disturbance of sensorium, fever, rigidity, and high blood pressure, should be considered. A history of treatment with neuroleptics and an elevated creatinine phosphokinase usually enable one to determine this cause (83). Most children who develop drug-induced psychosis recover once the drugs are discontinued and out of their system. The gravest danger occurs during the psychotic episode, when a child may cause serious harm to himself or herself or to others, because judgment is impaired. Some children may need brief hospitalization until the cause is determined and the psychotic symptoms dissipate. Except for the presence of neuroleptic malignant syndrome as the cause, brief treatment with antipsychotic medications may be necessary to decrease the child’s agitation and to control the distorted perceptions.

In addition to the foregoing treatment strategies, other interventions and services may be needed to address either comorbid conditions or associated sequelae of the underlying disorder causing the psychosis, such as substance abuse, depression, and suicidal tendencies.

CONCLUSIONS

Part of "45 - Psychosis in Childhood and Its Management "

From the clinical perspective, the rapid change and development of childhood have immediate implications for diagnosis and intervention. When one is treating children, it is important to maintain diagnostic fluidity and to tolerate the pressure of uncertainty.

In the realm of childhood-onset psychopathology, we have a great deal to learn from the psychoses. The stability of a diagnostic category over time is usually considered to be one measure of the construct validity of that category. One possibility is that lack of stability of a diagnosis during childhood implies that it lacks validity. This is only important if one is trying to establish a unique direct link with later-onset disorders and to apply the same terminology. However, another possibility is that some childhood diagnoses are only risk factors for development of more enduring adult conditions, such as the relationship between conduct disorder and antisocial personality disorder. Variability of normal and psychopathologic development and the heavy influence of environmental features and familial functioning during childhood make it difficult to be certain about diagnoses in children. Although categoric classification has its advantages and at times is necessary (34), dimensional perspectives can be important for understanding these phenomena as well.

It is useful to recognize the close, reciprocal relationship between diagnostic classification and biological or genetic advances. Advances in genetic and imaging studies should open the way to a different classification system that links

symptoms, neural circuitry, and biological (genetic) markers more closely than any current system. We should not be too surprised to discover that conditions once considered to be quite distinct are now closely linked, as has been found for Tourette syndrome, obsessive-compulsive disorder, and attention-deficit/hyperactivity disorder (84). “Diagnostic stability” may refer to the stability of these biological features, rather than the stability of clinical signs and symptoms. One could expect that developments in molecular biology would shed light on the natural history, protective factors, and risk factors for a specific biological risk. However, these developments will depend on increasingly reliable, reproducible diagnoses. The success of these strategies demands that probands or cohorts have been reliably diagnosed according to the most valid criteria at the time. Thus, the diagnoses inform the biological work, and the biological work, in turn, influences our classification and criteria. This process fosters a more accurate understanding of the natural history, pathophysiology, and etiology of disorders and the relationships among disorders. It will inform us about prenatal psychoneurohormonal factors that influence development, sexual differentiation, and maturation of the central nervous system. In time, we stand to gain a much clearer understanding of the complex, diverse contributions to the development and maintenance of psychotic disorders. We look forward to developing treatments that will offer more comfort and better functioning to the patients and families afflicted with these chronic conditions. There is, in addition, a real prospect of finding protective factors and preventive interventions that can avert the worst manifestations of these disorders.

Behavioral Phenotypes of Neurodevelopmental Disorders: Portals into the Developing Brain

James C. Harris

James C. Harris: Departments of Psychiatry and Behavioral Sciences, Pediatrics, and Mental Hygiene, Johns Hopkins University School Medicine, Baltimore, Maryland.

HISTORICAL BACKGROUND

Part of "46 - Behavioral Phenotypes of Neurodevelopmental Disorders: Portals into the Developing Brain "

Increasing evidence indicates that specific neurodevelopmental disorders may be associated with particular patterns of behavior. A description of behavior was included by Langdon Down in the first published description of a specific mental retardation syndrome, Down syndrome (1). In his description, Down observed: “They have considerable powers of imitation, even bordering on being mimics. Their humorousness and a lively sense of the ridiculous often colors their mimicry.” Later, he added: “Several patients who have been under my care have been wont to convert their pillow cases into surplices (vestments) and to imitate, in tone and gesture, the clergymen or chaplain which they have recently heard.” He also commented on personality traits, saying: “Another feature is their great obstinacy—they can only be guided by consummate tact.” Although these stereotypes were not confirmed in subsequent studies (2 ,3), the prospect of linking behavior and genetics was introduced in this first description of a neurogenetic disorder. Subsequent early clinical descriptions, such as that of tuberous sclerosis complex by Critchley and Earl (4), identified peculiar, and severe, behavioral problems in children and adults with that condition. Yet despite the early recognition of syndrome-specific behavioral and psychiatric features, neurogenetic disorders were not empirically investigated for behavioral deficits until 1990s, when new conceptual and methodologic procedures were introduced (5).

Two main reasons may explain this lack of interest after the early reports by Down and others. First, there was a general negative reaction against eugenics and claims for genetic bases of personality (6). This negative reaction established a climate in which it was not considered appropriate for academic investigators to emphasize the genetics of behavior. Second, there has been a major emphasis on learning theory and its applications to the field of mental retardation, in which most genetic disorders are found. Tremendous strides have been made in the education of even the most severely mentally retarded persons. Advances in academic and social adaptive education, in conjunction with motor treatment, have placed greatest emphasis on how severely and multiply handicapped people could attain greater degrees of independence and social integration. With the emphasis on normalization, research into severe disorders in learning tended to be deemphasized. Moreover, the occurrence of associated psychiatric and behavioral problems was interpreted more in terms of learning theory rather than in being unlearned behaviors associated with behavioral phenotypes. The focus has been on addressing the potential of the individual person and the developmental possibilities. Yet this focus could not continue to ignore reports from families and clinical observations of characteristic patterns of behavior and stereotypes.

With the establishment of active and refined learning-based approaches and a better understanding of the interpretation of genetic findings, reappraisal and revision of attitudes toward research with behavioral phenotypes have begun. O'Brien suggested three reasons for this shift (7). First, research findings have been reliably reported with various syndromes. Second, there are continued reports from family members as large family organizations have developed in the United States and other countries that describe characteristic behavioral patterns and interpersonal responses. In meetings, parent groups frequently report similar behavior problems and difficulties in management across syndromes. The interest in parent groups in improving the life of their children has led to additional hypotheses and more refined observations on behavioral characteristics. Third, new techniques in genetics provide new insights into

the extent and mechanisms of the human genome as the basis of behavior. Advances in other aspects of neuroscience, including neurophysiology and neuroanatomy, provide additional means of designating brain mechanisms that may be involved. With the establishment of these new methods of evaluation and the identification of rating scales to measure behavioral phenotypes, there is now an increased focus on behavioral phenotypes in developmental neuropsychiatry. Finally, comprehensive study of children with different developmental disabilities may increase our appreciation of the relative contribution of genetic variables in the pathogenesis of specific affective and behavioral disorders.

Nyhan introduced the term *behavioral phenotype* to describe outwardly observable behavior so characteristic of children with genetic disorders that its presence suggests the underlying genetic condition (8). In speaking of compulsive self-injury in Lesch–Nyhan disease (LND), a disorder that he initially described, Nyhan noted: “We feel that these children have a pattern of unusual behavior that is unique to them. Stereotypical patterns of behavior occurring in syndromic fashion in sizable numbers of individuals provide the possibility that there is a concrete explanation that is discoverable. In these children, there are so many anatomical abnormalities, from changes in hair and bones to dermatoglyphics, that it is a reasonable hypothesis that their behaviors are determined by an abnormal neuroanatomy that would be discoverable, possibly neurophysiologically, ultimately anatomically… these children all seem self-programmed. These stereotypical patterns of unusual behavior could reflect the presence of structural deficits in the central nervous system” (8).

Such observations have led to greater emphasis on assessment of behavior, and the recognition of behavioral phenotypes in some disorders has led to closer scrutiny of known neurodevelopmental conditions. Initially, the focus was on documenting the patterns of behavior because the study of brain and behavior requires the identification of welldefined syndromes for investigation. Now that developments in the neurosciences provide a means to understand the biological bases of such behavioral patterns, the focus has shifted to understanding the neurobiological mechanisms underlying characteristic behavioral patterns, including cognitive processes and social interactions. Such patterns are reported in numerous syndromes arising from genetic or chromosomal abnormalities. Thus, molecular analysis of the underlying genetic disorder has been initiated in several syndromes with the hope of revealing the biological basis of the behavioral phenotype. However, because of the rarity of many of these syndromes and the complexity of their genetic basis, establishing the validity of the association between syndrome and behavioral phenotype is difficult. Nevertheless, Flint pointed out that evidence from animal studies with relevance to human behavioral phenotypes shows that the pathway from genotype to phenotype may be accessible after careful delineation of each of the features of the behavioral phenotypes (9 ,10). However, in regard to the study of cognition, he suggested that we require a greater integration of different levels of understanding of cognition to exploit the genetic discoveries, “a rapprochement between molecular and systems neuroscience” (10).

Much of the research in behavioral genetics uses a “top-down” approach to the qualitative analysis of complex traits such as novelty seeking, memory, personality traits, and intelligence (11). Linkage or association strategies are used to examine naturally occurring alleles of candidate genes in a “wild-type population.” These alleles are usually functional polymorphisms rather than mutations and, if they are quantitative trait loci, may be associated with individual differences in the trait in question. However, Tully suggested that such genes may have minor effects on the phenotype of the individual because alleles with a more striking effect could reduced fitness and would be selected against in evolution (12). Specifically, chromosomal deletions that may have cognitive and behavioral consequences may be associated with monosomy (13). The loss of one copy of genes that are dose sensitive may be significant in brain development. Such genes may play a fundamental role in development of the functional organization of the brain, but they may not be as important for individual differences in the general population. Moreover, partial variants of disorders such as LND that result in a range of enzyme levels may allow study of dose response to enzyme deficits.

This chapter uses a developmental perspective to provide a definition and characterization of behavioral phenotypes in neurodevelopmental disorders, and it discusses etiologic factors, methods to understand underlying mechanisms, and natural history. It addresses the question: What do behavioral phenotypes that occur in specific neurogenetic disorders teach us, and how may they provide a portal to understand the developing brain? This question is considered by reviewing studies of neurogenetic disorders with behavioral phenotypes: (a) LND, an X-linked disorder, that results from the absence of an enzyme, hypoxanthine-guanine phosphoribosyltransferase (HPRT), that is involved in purine metabolism; (b) Prader–Willi syndrome (PWS) and Angelman syndrome (AS), in which the parental origin of the genes involved (uniparental disomy or UPD) is an important factor in the cause; (c) fragile X syndrome, a disorder caused by unstable trinucleotide repeat expansion that results in the absence of a gene that encodes an RNA-binding protein thought to play a role in translational regulation of selective messenger RNA transcripts; and (d) Williams syndrome (WMS), a contiguous gene disorder with an unusual cognitive phenotype in which language is preserved but the patient has severe visual spatial disabilities. Each of these neurogenetic disorders provides a portal to understand neurodevelopment. Other nongenetic disorders that are environmentally induced, such as fetal alcohol syndrome, are not discussed but also offer keys to understanding the developing brain (23).

DEFINITION AND CHARACTERIZATION

The study of behavioral phenotypes emphasizes the discovery, among individuals with known chromosomal, genetic, or neurodevelopmental disorders, of those mental and behavioral features causally related to the underlying condition. Examples are the characteristic self-mutilation of fingers and lips in LND, the hyperphagia and compulsive behaviors in PWS, gaze aversion in fragile X syndrome, and the superficial sociability, hyperlalia, and language disorder in WMS. When present, the behavior suggests the syndrome. As Nyhan suggested, these are “syndromes of behavior” (14). Still, despite their behavioral presentations, not all individuals with the disorder show the classic behavioral features, but the probability is greater that they will. The essential issue is that the behavior suggests the diagnosis.

Efforts to define what is meant by a behavioral phenotype are continuing. Harris proposed that behavioral phenotypes are stereotypic patterns of behavior that are reliably identified in groups of individuals with known neurodevelopmental disorders and are “not learned” (15 ,16). They may be the consequence of neurodevelopmental abnormalities that are potentially discoverable. This approach to definition is a phenonic approach that takes as its starting point observations of the behavior itself rather than beginning with a discrete and genetically identifiable condition, such as Down syndrome. Using the phenomic approach, the behavioral phenotype of Rett syndrome (17), with its characteristic hand and hand-to-mouth stereotypies, identified it as disorder with a behavior phenotype many years before the genetic origin was recognized. Moreover, the phenomic approach does not discount acquired disorders, such as fetal alcohol syndrome, as having behavioral phenotypes. The impact of alcohol on cellular signaling is now well known, with its consequences of cell death, abnormal midline brain development, behavioral problems, and learning disabilities (16 ,23).

Such considerations led Flint and Yule to propose the following definition that includes the characteristic types of behaviors: “The behavioral phenotype is a characteristic pattern of motor, cognitive, linguistic, and social abnormalities that is consistently associated with a biological disorder” (18). This does not mean that the behavior is present in all instances but that the probability of its occurrence is increased. In the future, more may be learned about brain mechanisms by comparing persons with behavioral involvement with others who have the same syndrome but without the behavioral features.

Although some investigators have sought to limit the study of behavioral phenotypes to known genetic disorders (11), knowledge of the genetic disorder is only the first step. Links from gene to behavior are complicated in that one gene may lead to the encoding of many, perhaps ten or more, different proteins; the number of genes and type of mutation determine complexity. For example, in LND, the disorder of purine metabolism clearly leads to the overproduction of uric acid and renal stones, but the pathway to the movement disorder and self-injury is not direct and may be mediated through effects on the arborization of dopamine neurons (19). Moreover, there are variants of LND with different degrees of enzyme deficit, ranging up to 20%, that have clinical effects.

Thus, several caveats are necessary as we consider pathways from genes to behavior (11): (a) the behavioral descriptions, like other physical features of neurodevelopmental disorders, have increased probability of occurring and do not occur in all cases; they are not be fully expressed in all affected individuals; (b) the genetic background of the individual may affect the phenotypic expression; (c) the possibility exists that environmental factors may modify expression; (d) the behavioral presentation may be modified by the extent of mental retardation associated with the disorder; and (e) variability occurs in mouse models in which there may be species-specific factors so mutant mouse models do not replicate the behavioral features. One must consider the genetic background, strain differences, and the differences in the rodent physiology. In LND, the HPRT-deficient mouse has a uricase enzyme that breaks down uric acid. Therefore, it is not a model for the hyperuricemic metabolic disorder, but it still may be a useful model to study dopamine deficiency in the brain. Thus, aspects of the disorder may be modeled in transgenic mice or in other species.

In some animal models, links to specific pathophysiology have been established. The canine model of narcolepsy (20) is an interesting example of an approach to a human clinical disorder. Mutations for canine, autosomal recessive, narcolepsy were identified by linkage analysis in canine backcrosses, and homology was demonstrated between human chromosome 6 and canine chromosome 12. Canine narcolepsy is caused by a disruption of a G-protein–coupled receptor, the hypocretin (orexin) receptor 2 gene (Hcrt2) in three canine breeds. However, human narcolepsy is not associated with frequent hypocretin gene mutation (20). Nonetheless, most humans with narcolepsy have undetectable hypocretin 1 levels in cerebrospinal fluid.

PSYCHOPATHOLOGY AND BEHAVIORAL PHENOTYPES

Part of "46 - Behavioral Phenotypes of Neurodevelopmental Disorders: Portals into the Developing Brain "

Numerous neurogenetic disorders are associated with nonspecific behaviors that may be found in several syndromes. These include attention problems, hyperactivity, impulsivity, self-injury, aggression, autistic-like behavior, and preservative behaviors. Such presentations indicate vulnerability of the developing brain and perturbation of brain systems resulting in these clinical conditions. However, because these behaviors occur across many syndromes, they lack specificity and do not qualify as specific behavioral phenotypes.

Still, these behavioral features should be included in the description of the disorders. For example, the relationship between aggression and antisocial behavior has been suggested in monoamine oxidase A (MAOA) deficiency. Brunner et al. described an association between abnormal behavior and MAOA deficiency in several males from a single large Dutch kindred (21). The affected males differed from unaffected males in that they tested in the borderline range of mental retardation and demonstrated increased impulsive behavior, that is, aggressive behavior, abnormal sexual behavior, and arson. Yet a specific psychiatric diagnosis was not made in four affected males who were examined by psychiatrists. Because MAOA deficiency leads to increased 5-hydroxytryptamine (5-HT) levels, the aggressive behavior in these persons may be an exception to studies linking low 5-HT with impulsive aggression. Brunner et al. suggested that even if a possible association between MAOA deficiency and abnormal behavior is confirmed in other kindreds, “the data do not support the hypothesis that MAOA constitutes an ‘aggression gene’.” These investigators noted that genes are essentially simple and code for proteins, whereas behavior is complex; thus, a direct causal relationship between a single gene and a specific behavior is highly unlikely. In MAOA deficiency, complexity is shown by the variability in the behavioral phenotype and by the highly complex consequences of MAOA deficiency on neurotransmitter function. Thus, the full pathway from gene to complex behavior must be considered; the concept of a gene that directly encodes behavior is simplistic (21). Still, a great deal may be learned by considering such pathways in neurogenetic syndromes.

PREVALENCE

Part of "46 - Behavioral Phenotypes of Neurodevelopmental Disorders: Portals into the Developing Brain "

With increasing attention to neurogenetic disorders, the number of identifiable behavioral phenotypes is increasing. Careful observations of behavior are necessary when considering intervention for neurogenetic disorders. Although standardized rating scales and personality profiles have been developed to measure behavioral phenotypes (22 ,23), profiles pertinent to the specific disorder are needed. Besides behavioral phenotypes, isolated special abilities that occur in genetically based syndromes require assessment. These include special abilities in calculation and in music (24). These special abilities may potentially be related to the proposed modular organization of the central nervous system.

BEHAVIORAL PHENOTYPES OF SPECIFIC NEURODEVELOPMENTAL DISORDERS

Part of "46 - Behavioral Phenotypes of Neurodevelopmental Disorders: Portals into the Developing Brain "

The sections that follow discuss four syndromes in which behavioral phenotypes have been identified: LND, PWS/AS, fragile X syndrome, and WMS. Characteristic behaviors are highlighted, findings on origin are discussed, and potential neurochemical and neuroanatomic abnormalities are reviewed. Behavioral and pharmacologic therapies have had limited success in many of these conditions, so better characterization of the individual condition is essential to establish treatment. Neuroanatomic studies, brain imaging studies, and continuing investigations of neurotransmitter systems, endocrine rhythms, and sleep studies may provide information that will be helpful in the future in treatment.

Lesch–Nyhan Disease

LND is a rare (1:380,000) sex-linked recessive disease caused by an inborn error of purine nucleotide metabolism. It is caused by an almost complete deficiency of the enzyme HPRT, which is involved in the purine salvage (purine base recycling) pathway (25). Self-injury is the major behavioral manifestation; this behavior was sufficiently characteristic that Nyhan introduced the term “behavioral phenotype” as a descriptor (8). LND is of psychosocial and psychiatric importance because of the lifelong suffering experienced by the involved child and his family, the uniqueness of the behavioral phenotype, and the resources needed for lifelong patient supervision. Moreover, an understanding of the neurobiological basis of this disease may contribute to a better understanding of brain mechanisms involved in self-injurious and compulsive behaviors.

Genetic and Metabolic Aspects

The HPRT-encoding gene is located on the X chromosome in the q26-q27 region and is made up of nine exons and eight introns totaling 57 kilobases (kb). The *HPRT* gene is transcribed to produce a mRNA of 1.6 kb that contains a protein-encoding region of 654 nucleotides. More than 270 mutations throughout the coding regions have been identified (79). Techniques that provide information on the three-dimensional structure of the HPRT protein make it possible to correlate structure and function of the enzyme (26). Eads et al. reported the effects of single amino acid substitutions on the stability and activity of HPRT (26).

The gene involved in LND is on the X chromosome, so the disorder occurs almost entirely in males; occurrence in females is extremely rare. The metabolic abnormality is the result of an abnormal gene product—a deficiency in the enzyme HPRT. This enzyme is normally present in each cell in the body and is highest in the brain, especially in the basal ganglia. Its absence prevents the normal metabolism of hypoxanthine and results in excessive uric acid production and manifestations of gout without specific drug treatment (i.e., allopurinol). The full disease requires the virtual absence of the enzyme. Other syndromes with partial HPRT deficiency are associated with gout without the neurologic and behavioral symptoms. Page and Nyhan reported that HPRT levels are related to the extent of motor symptoms,

the presence or absence of self-injury, and possibly the level of cognitive function (27). Hypoxanthine accumulates in the cerebral spinal fluid, but uric acid does not because it is not produced in the brain and does not cross the blood–brain barrier.

Behavioral Phenotype

Self-injurious behavior usually is expressed as self-biting; however, other patterns of self-injurious behavior may emerge with time. It is not uncommon for self-injury to progress to deliberate self-harm (19 ,28). Characteristically, the fingers, mouth, and buccal mucosa are mutilated. The biting pattern is often asymmetric, so the patient may mutilate the left or right side of the body and may become anxious if he perceives that this side of the body is threatened. Other associated maladaptive behaviors include head or limb banging, eye poking, pulling of fingernails, and psychogenic vomiting (28).

Self-mutilation in LND is conceptualized as a compulsive behavior that the child tries to control but generally is unable to resist. With increasing age, the affected child becomes more adept at finding ways to control his self-injury. He may enlist the help of others to protect him against these impulses or may learn self-restraint.

A language pattern that consists of repeated ambivalent statements with anxiety and coprolalia (vulgar speech) is characteristic. Moreover, the patient may be compulsively aggressive and may inflict injury on others through pinching, grabbing, or using verbal forms of aggression. Frequently, he will apologize for this behavior immediately afterward and will say that the behavior was out of his control.

Etiologic Factors

The cause of the neurologic and behavioral symptoms is not clearly established; however, abnormalities in dopamine function have been demonstrated in three autopsied cases (29). The behavior is not caused by either hyperuricemia or by excess hypoxanthine because LND partial variants whose HPRT levels are greater than 2 do have hyperuricemia but they do not self-injure. Moreover, infants treated for hyperuricemia from birth whose uric acid level is normalized still develop self-injury despite having normal levels of uric acid.

Wong and Harris et al. used positron emission tomography to investigate how dopamine dysfunction contributes to the self-injurious behavior (30). These authors documented reductions in dopamine transporter density of 68% in putamen and 42% in caudate in six patients with classic LNS and self-injurious behavior. To clarify the relationship between presynaptic dopamine transporter binding in the striatum and self-injurious behavior further, Harris, Jinnah and Wong (30a) studied seven patients with Lesch–Nyhan variants (HPRT levels 1.8% to 20.0%) and two patients with HPRT levels less than 1.5%, all nine without self-injurious behavior (age range, 12 to 37 years). The extent of motor findings was documented on quantitated neurologic examination. Two patients with HPRT levels less than 1.5% and two patients with HPRT levels of l.8% and 2.5% with severe movement disorder were not different in WIN 35,428 dopamine transporter binding in positron emission tomography imaging than the previously described classic patients with LND who did injure themselves. The study of variant cases with motor symptoms but with no self-injurious behavior suggests that reductions in dopamine receptor density are not a sufficient explanation of the self-injury. However, these authors found that HPRT level and the extent of motor deficit were correlated with dopamine transporter binding in caudate and putamen in the nine cases. Dopamine transporter binding was significantly correlated with HPRT levels in whole cells. Moreover, when the movement disorder was rated on the Fahn-Marsden dystonia rating scale, putamen dopamine transporter density was significantly correlated with symptom severity. These findings suggest that dopamine reduction is linked to the extent of the movement disorder, but it may not be a sufficient explanation for self-injurious behavior, and other neurotransmitters need to be examined. Moreover, these variant subjects with levels from 2% to 20% showed cognitive deficit profiles similar to those of classic LND (31).

Future investigation will need to take into account the existence of a variety of mutations in the *HPRT* gene structure. Why partial HPRT deficiency does not lead to neurologic and behavioral symptoms remains unclear; perhaps neurotrophic factors are active with minute amounts of the enzyme. It is advisable to study combined drug and behavioral treatment. An emphasis on parental training is of particular importance for drug compliance and generalization of treatment effects. As in other inborn errors, continuous family support is essential. Harris provides a description of a comprehensive treatment program for LND (19).

Prader–Willi Syndrome

PWS is a neurodevelopmental disorder characterized by obesity, short stature, cryptorchidism, mental retardation, hyperphagia, learning disability, short stature, hypogonadism, hypotonia, small hands and feet, and dysmorphic facies. Patients have an increased prevalence of daytime sleepiness, scoliosis, and other orthopedic abnormalities. Because of the obesity, heart failure and diabetes may occur as complications. Although it is a rare disorder (1 in 10,000 to 15,000), its behavioral phenotype has assumed prominence in genetics because of its relationship with AS, which has a different behavioral phenotype, although both disorders involve genomic imprinting of the same region of chromosome 15.

Genetics

PWS may result from both chromosomal deletion and maternal UPD. In UPD, two copies of the maternal chromosome

are inherited with no paternal contribution (32). Without the presence of the chromosome donated by the father, the normal imprinting of the two maternally donated chromosomes leads to absence of gene expression in this interval. This results in a functional abnormality that is essentially equivalent to the structural abnormality found in a deletion in the 15q11-q13 region that is associated with the disorder. Moreover, in about 5% of cases, abnormalities in the mechanism of imprinting may occur when the imprinting control center itself has a mutation.

Several genes are included in the most commonly deleted region in PWS. Some are paternally imprinted, and others are maternally imprinted (33). Among these, *ZNF 127, NDN, SNURF-SMRPN, IPW* are paternally imprinted. Another gene, *UBE3A* (E6-AP ubiquitin lipase), is maternally imprinted. Others genes in this region that are expressed from both maternal and paternal chromosomes include three γ-aminobutyric acid (GABA) receptor subunits *(GABRB3, GABRA5, GABRG3)* (33). Because similar phenotypes result from deletions and from imprinting in PWS, it is less likely that nonimprinted genes play a role in PWS or AS. Among these genes, a specific gene for PWS has not been established, so several of these genes may contribute to the phenotype. For example, the *SMRPN* gene is involved in protein slicing and is expressed throughout the brain; however, it is not thought that the PWS is the direct outcome of this deficit. The *NCD* (necdin) gene does lead to failure to thrive in certain mouse strains, so it may be a factor; however, those mice that survive do develop into apparently normal adults. Thus, the disorder is most likely linked to the loss of more than one gene in this region. Conversely, the mutation of a single gene, *UBE3A*, has been found in cases of AS (34).

Behavioral Phenotype

The extent of cognitive impairment is variable in PWS. Some patients test in the normal range of intelligence, but most test in the mild to moderate range of mental retardation. Others may test in the severe range of mental retardation. The behavioral phenotype includes unusual food-related behavior (compulsive food seeking, hoarding, gorging), skin picking, irritability, anger, low frustration tolerance, and stubbornness. Standardized methods of assessment have substantiated increased rates of depression, anxiety, and compulsive behavior. Up to 50% of children and adults with PWS demonstrate behavioral disorders.

Compulsive eating is the most disabling of these behavioral manifestations and leads to obesity and the complications of severe obesity, such as respiratory impairment and diabetes. The hyperphagia, which has been consistently found, has received the most systematic behavioral evaluation. When not carefully supervised, patients may steal food and, in some instances, eat unpalatable food, although this can be avoided with appropriate supervision. Holm and Pipes evaluated food-related behavior in the PWS (36). They found that behavioral problems were most commonly related to food and included food stealing, foraging for food, gorging, and indiscriminate eating with little food selectivity. No special circumstances that resulted in food stealing or gorging were identified.

Besides the food-related compulsions, emotional lability with temper tantrums, stubbornness, negativism, skin picking and scratching, and non–food-related obsessions have been examined. A questionnaire survey involving 369 cases identified compulsive and impulsive aggressive behavior (37). These authors used the Overt Aggression Scale, the Yale-Brown Obsessive-Compulsive Disorder Scale, a clinical global rating, and DSM-III-R criteria to diagnose self-stimulation and self-injury, compulsive behavior, and obsessive behaviors. These investigators found that skin picking was the most common form of self-injury, observed in 19.6% of this sample. Other types of self-injury with lower frequency were nose picking, nail biting, lip biting, and hair pulling. The second behavioral problem area was compulsive behavior; food hoarding was the most severe manifestation and occurred in 17.7%. Other compulsive behaviors included counting, symmetric arrangements of objects, checking, and hand washing, but they were less common. Obsessive thinking was far less characteristic, with only 1.4% rated in the severe range on an item dealing with concerns about contamination. State et al. reviewed the evidence in regard to compulsive behaviors in PWS and the relationship with obsessive compulsive disorder (38). Behavioral problems identified in the preschool years persist throughout the school years and continue into adolescence and adulthood.

Etiologic Factors

Investigators have proposed that the genetic abnormality in PWS leads to hypothalamic dysfunction that results in aspects of the clinical phenotype, such as dysregulation of feeding, delay in sexual development, sleep disorder, and abnormality of thermoregulation. In support of hypothalamic dysfunction, Swaab et al., in a postmortem study, found reduction in oxytocin cells in certain regions of the hypothalamus (35). However, other brain regions and neuropeptides may be involved in PWS. Because the loci of GABA subunits is in the area around the 15q11-13 region, GABA has been measured in PWS, and abnormalities have been reported in plasma levels in some patients.

To clarify the mechanism leading to the behavioral phenotype further, differences between deletion and maternal UPD causes have been assessed (39). Similar studies have been completed in AS (40). Differences in intellectual functioning in PWS with a paternal 15q11-q13 deletion versus maternal UPD of chromosome 15 were evaluated using measures of intelligence and academic achievement in 38 patients with PWS (24 with deletion and 14 with UPD).

The patients with UPD had significantly higher verbal IQ scores than those with deletion ($p < .01$). The magnitude of the difference in verbal IQ was 9.1 points (69.9 versus 60.8 for UPD and deletion PWS patients, respectively). Only 17% of subjects with the 15q11-q13 deletion had a verbal IQ greater than or equal to 70, whereas 50% of those with UPD had a verbal IQ greater than or equal to 70. Performance IQ scores did not differ between the two PWS genetic subtype groups. This report documents the difference between verbal and performance IQ score patterns among patients with PWS of the deletion versus the UPD subtype. Comprehensive treatment of behavioral problems in PWS is described by Holm et al. (41).

Angelman Syndrome

In contrast to PWS, investigators have shown that one gene in the deleted region can lead to AS (34). AS is a neurologic disorder with a heterogeneous genetic origin. It most frequently results from a *de novo* interstitial deletion in the 15q11-q13 region, but it is also caused by paternal UPD or an imprinting mutation. The remaining 20% to 30% of patients with AS exhibit biparental inheritance and a normal pattern of allelic methylation in the 15q11-q13 region. In this biparental inheritance group, mutations in the *UBE3A* gene have been shown to be a cause of AS. Moncla et al. described the phenotypic expression in 14 patients with AS involving eight *UBE3A* mutations (34). These were made up of 11 familial cases from five families and three sporadic cases. Some subtle differences from the typical phenotype of AS were noted. Consistent features were psychomotor delay, a happy disposition, a hyperexcitable personality, EEG abnormalities, and mental retardation with severe speech impairment. The other main features of AS—ataxia, epilepsy, and microcephaly—were either milder or absent in various combinations among these cases. Moreover, myoclonus of cortical origin was commonly observed with severe myoclonic seizures. Most of these patients were overweight. This study showed that ataxia, myoclonus, EEG abnormalities, speech impairment, characteristic behavioral phenotype, and abnormal head circumference are attributable to a deficiency in the maternally inherited *UBE3A* allele. Finally, analysis of mutation transmission showed an unexpectedly high rate of somatic mosaicism in normal carriers. These clinical findings have important consequences for genetic counseling in AS.

Fragile X Syndrome

The fragile X syndrome is characterized by mental retardation, behavioral characteristics, and the physical findings of a long face with large, protruding ears and macroorchidism (42). Fragile X syndrome is the most common known cause of inherited mental retardation, and it may also result in learning disabilities and social deficits in those who do not test in the mentally retarded range. After the identification of the fragile X mental retardation *(FMR1)* gene, the cytogenetic marker (a fragile site at Xq27.3) was replaced by molecular diagnosis. Recognition of this gene has broadened our understanding of the spectrum of the fragile X syndrome.

Genetics

Fragile X syndrome is caused by massive expansion of CGG triplet repeats located in the 5′-untranslated region of the *FMR1*. The cloning of the *FMR1* gene led to the characterization of its protein product FMRP. The full mutation is associated with a process of methylation; the addition of methyl groups along the “backbone of the DNA helix” (42). In patients with fragile X syndrome, the expanded CGG triplet repeats are hypermethylated, and the expression of the *FMR1* gene is repressed, which leads to the absence of FMR1 protein (FMRP) and subsequent mental retardation. The encoded protein is a ribosome-associated, RNA-binding protein thought to play a role in translational regulation of selective messenger RNA transcripts. FMRP is an RNA-binding protein that shuttles between the nucleus and cytoplasm. This protein has been implicated in protein translation because it is found associated with polyribosomes and the rough endoplasmic reticulum (43). A similar mechanism is proposed for *FMR2*, which encodes a large protein of 1,311 amino acids and is a member of a gene family encoding proline-serine–rich proteins that have properties of nuclear transcription factors (44).

The fragile X syndrome was one of the first examples of a “novel” class of disorders caused by a trinucleotide repeat expansion in the X chromosome. In the genetically normal population, the CGG repeat varies from six to 54 units. Affected subjects have expanded CGG repeats (more than 200) in the first exon of the *FMR1* gene (the full mutation). Phenotypically normal carriers of the fragile X syndrome have a repeat in the 43 to 200 range (the premutation). The process of methylation silences transcription so a fully methylated full mutation results in no FMR1 protein’s being produced. The absence of FMR1 protein results in fragile X syndrome. Two additional disorders result in a fragile site at Xq27.3; there are *FRAXE*, which is usually associated with a milder form of mental retardation, and *FRAXF*, which is not consistently associated with mental retardation. These two mutations also have CGG repeat expansions and are distal to the *FMR1* site. The transcriptional silencing of the *FMR2* gene also has been implicated in *FRAXE* mental retardation. *FRAXE* individuals have been shown to exhibit learning deficits, including speech delay and reading and writing problems.

The frequency of the premutation and mutation may be variable in different populations because of founder effects (42). Thus, the prevalence in an English study was 1 in 2,200, and in an Australian study it was 1 in 4,000, but it

was higher in Finland, where it is proposed that the initial settlers included one or more fragile X carriers.

Behavioral Phenotype

There is a substantial degree of genetic and phenotypic heterogeneity in the physical, cognitive, and behavioral phenotype. The behavioral phenotype has been the subject of considerable study and includes mental retardation and learning disabilities, language impairment, hand flapping, gaze aversion, perseveration, and neuropsychiatric disturbance, principally attention-deficit/hyperactivity disorder and pervasive developmental disorder–like symptoms. These patients are more interested in social interactions than those with autistic disorder; the avoidance of social contact may be secondary to hyperarousal or increased sensitivity to stimuli associated with social situations. The behavioral phenotype may be more helpful than the physical phenotype in diagnosis because most prepubertal patients do not have macroorchidism or the characteristic long face.

Attentional difficulty and concentration problems are commonly associated, and hyperactivity may be a presenting symptom in nonretarded boys with fragile X syndrome. Self-injury, most commonly hand biting and scratching, may be elicited by excitement and by frustration. Female patients with fragile X syndrome may be unaffected, although abnormalities in social interaction, thought process, and affect regulation have been reported in carriers. Both schizotypal features and depression have also been found in carriers.

Most girls with the full mutation show shyness and social anxiety. In women with the full mutation, the social anxiety is associated with social awkwardness and schizotypal features. Anxiety disorders, avoidance disorder, and mood disorder symptoms are common (42).

Gaze Aversion

Gaze aversion is a striking feature of affected males with fragile X syndrome. There is consistency in gaze aversion over repeated trials in the same individual; nearly all male patients with fragile X syndrome who are more than 8 or 9 years old avert their gaze on greeting another person. Their unusual greeting is characterized by both head and gaze aversion along with an appropriate recognition of the social partner (45). This greeting response is qualitatively different from gaze aversion that is described in autistic patients. Those with Down syndrome and nonspecific mental retardation do not show this behavioral pattern on greeting. The idiosyncratic gaze behavior in fragile X syndrome may disrupt social interactions. Despite their apparent social anxiety and aversion to eye contact, male patients with fragile X syndrome are otherwise socially responsive and can be affectionate.

Speech and Language

Speech and language in fragile X syndrome is generally delayed, even thought the IQ may be in the normal range. Deficits in both receptive and expressive language include dysfluency, production of incomplete sentences, echolalia, palilalia (reiteration of the speaker's own words and phrases in a perseverative manner), verbal perseveration, and poor fluency in conversation. Compulsive utterances and shifts in speech pitch are common, and auditory processing and memory deficits are present.

Etiology

The FMR1 protein is expressed most abundantly in neurons and testes with the localization primarily in the cytoplasm. High concentrations of FRM1 mRNA have been found at the synapse in rat brains, especially in areas involved in synaptogenesis in the hippocampus, cerebral cortex, and cerebellum (46). Hinton et al. found thin and immature dendritic branches with small synapses in neuroanatomic studies of the neocortex in three male patients with fragile X syndrome (47). The expression of the FMR2 protein also has been characterized. To characterize the expression of the FMR2 protein, polyclonal antibodies were raised against two regions of the human FMR2 protein and were used in immunofluorescence experiments on cryosections of mouse brain. The FMR2 protein is localized in neurons of the neocortex, Purkinje cells of the cerebellum, and the granule cell layer of the hippocampus. FMR2 staining is shown to co-localize with the nuclear stain 4,6-diamidino-2-phenylindole (DAPI) and confirms that FMR2 is a nuclear protein. The localization of FMR1 and FMR2 protein to the mammalian hippocampus and other brain structures involved with cognitive function is consistent with the learning deficits seen in patients with fragile X syndrome. Comprehensive treatment of fragile X syndrome is described by Hagerman and Cronister (48).

Williams (Williams–Beuren) Syndrome

WMS is a rare (1 in 25,000), genetically based neurodevelopmental disorder associated with a characteristic physical, linguistic, cognitive, and behavioral phenotype. This syndrome provides a unique opportunity to study personality development, linguistic functioning, and visuospatial development. The syndrome is characterized by congenital facial and cardiovascular anomalies (supravalvular aortic stenosis and peripheral pulmonary stenosis), failure to thrive, and mental retardation that may be accompanied by transient idiopathic infantile hypercalcemia (49). Adolescents with WMS have expressive language abilities that are better than expected for their mental age. Because of their hyperverbal speech, the investigation of WMS allows the study of the dissociability of components of language and other cognitive brain systems. In mentally retarded patients with WMS, linguistic

abilities may be selectively spared, unlike language learning disability occurring in normally intelligent children (50).

In WMS, a deletion of 1.5 Mb on one copy of chromosome 7 results in the specific physical, cognitive, and behavioral features. Molecular dissection of the WMS phenotype may lead to identification of genes important in human cognition and behavior.

Genetics

WMS is caused by a chromosomal deletion at 7q11.23. A contiguous gene deletion disorder, it results from hemizygous deletion of about 20 genes (51). This chromosomal region is highly repetitive, and the deletion arises from recombination between misaligned repeat sequences flanking the WMS region. The deletion breakpoints cluster within the repeats, so most patients with WMS have similar, although not identical, deletions of 1.5 Mb.

The first deleted gene identified in the critical region was that for elastin *(ELN)*. Studies of patients having deletions or point mutations confined to this gene showed that hemizygosity for *ELN* causes supravalvular aortic stenosis but not the other typical features of WMS.

Several other genes have now been identified that are deleted in most patients with WMS. These include the following: *LIMK1*, which codes for a protein tyrosine kinase expressed in the developing brain; that for syntaxin 1A *(STX1A)*, which encodes a component of the synaptic apparatus; *RFC2*, which codes for a subunit of the replication factor C complex involved in DNA replication; and *FZD3*, homologous to the *Drosophila* tissue-polarity gene, “frizzled” (51).

Cognitive Phenotype

Bellugi et al. proposed that “the cognitive hallmark of WMS is dissociation between language and face processing (relative strengths) and spatial cognition (profound impairment)” (50). The WMS phenotype demonstrates specific dissociations in the higher cognitive functions. These investigators proposed that general cognitive deficits are present but linguistic abilities are spared. They found extreme spatial cognitive deficits with intact face processing. Of special interest is the social phenotype in WMS: an overly friendly, engaging personality and excessive sociability with strangers (52). WMS subjects show an unusual positive response in their social judgments of unfamiliar persons.

Howlin et al. investigated cognitive, linguistic, and academic assessments in a representative sample of 62 adults with WMS (average age of the group was 26 years; mean full-scale IQ was 61) (53). Less difference was found in verbal and performance IQ and between receptive and expressive language skills in the adults than that found in children. Still, subtest scores documented an almost identical cognitive profile to that found in children. Reading, spelling, arithmetic, and social adaptation remained at a low level, with functioning around a 6- to 8-year age equivalent. The consistency in intellectual abilities in both child and adult studies of patients with WMS supports the notion of a syndrome specific pattern of cognitive, linguistic, and adaptive functioning.

The use of adult neuropsychological models to explain developmental disorders of genetic origin such as WMS has been challenged (54 ,55). It is assumed that uneven cognitive profiles found in childhood or adulthood in WMS characterize infant starting states and that modules underlying these abilities start out either intact or impaired. However, findings from two experiments with infants with WMS (selected for study based on claims of innate modularity) suggest a within-syndrome double dissociation: for numerosity judgments, WMS subjects do well in infancy but poorly in adulthood, whereas for language, WMS subjects show poor performance in infancy but do well in adulthood. The theoretic and clinical implications of these findings in WMS emphasize the importance of an developmental approach to neurogenetic disorders. Karmiloff-Smith et al. previously proposed that in WMS, language follows a different path to normal acquisition and may turn out to be more like second language learning (56).

Finally, Tager-Flusberg et al. tested the hypothesis that the WMS phenotype involves sparing abilities involved in the domain of understanding other minds (mentalizing or theory of mind) (57). They compared a group of mentally retarded adults with WMS to an age-, IQ-, and language-matched group of adults with PWS, and a group of age-matched normal adults, on a task that tests mentalizing ability. The task involved identifying the correct labels to match photographs of complex mental state expression focused on the eye region of the face. The adults with WMS performed significantly better than the adults with PWS on this task, and about half the group performed in the same range as the normal adults. Such findings provide support for the proposal that mentalizing is a distinct cognitive domain. The authors proposed that this sparing of cognitive capacity could be “linked to the relative sparing of limbic-cerebellar neural substrate in WMS, which is also connected to cortico-frontal regions that are known to be involved in understanding complex mental states.”

Linking Genes and Cognition

An approach to studying cognition is to carry out genetic and psychometric testing of patients who have small deletions within the WMS critical region. *LIMK1* and *STX1A* are good candidate genes to investigate cognitive or behavioral aspects of WMS. The gene for *LIMK1* was implicated as a cause of the visuospatial characteristics of WMS (58); however, other investigators were unable to substantiate this association in three further cases (59). The genes for *STX1A*

and *FZD9* were proposed as involved, based on brain-specific gene expression in the developing *(FZD9)* or adult *(STX1A)* central nervous system. However, when these genes were underexpressed by 50%, as is expected in WMS, Korenberg et al. reported that deletion of these genes was not associated with significant effects on overall cognition (51). However, these authors did propose that genes responsible for mental retardation and other features of the disorder are “located in the region telometric to RFC2 through GTF21 at the telometric border of the deletion.” Moreover, mild cognitive deficits reported in a subject deleted for elastin and *LIMK1* genes (59) were consistent with findings in those with deletion of genes in the *WMSTF* through *LIMK1* region having mild cognitive deficits. Thus, studies of patients with rare and atypical deletions may be informative in identifying candidate genes to understand the cognitive deficit.

Linking Anatomic and Behavioral Changes

WMS is associated with specific neuromorphologic and neurophysiologic findings. There is proportional sparing of frontal, limbic, and neocerebellar structures on magnetic resonance imaging (60). Abnormal functional organization of the neural systems that underlie language processing is revealed through studies using event-related potentials (61). Event-related potential studies suggest abnormal cerebral specialization for spared cognitive functions in WMS. The lack of uniformity in the cognitive, neuromorphologic, and neurophysiologic domains of WMS makes it a compelling model for elucidating the relationships among cognition, the brain, and, ultimately, the genes.

Another approach is to investigate anatomic changes in brain regions in WMS that may the result of gene deletions. In WMS, Galaburda and Bulligi found that the overall shape of the brain is not consistently abnormal (62), although in some cases abnormal brain shape is apparent. The most consistent anatomic finding is abnormal length of the central sulcus producing an unusual configuration of the dorsal central region. This includes the distal portion of the superior-parietal lobule and dorsal frontal gyrus. These regions may be linked to abnormal behavior in patients with WMS. Cytoarchitecture of WMS forebrain appears mostly normal, although subtle dysplastic changes are noted. Abnormal neuronal size of cortical neurons was suggested in one region and may be linked to increased subcortical connectivity. Elastin does not stain in the cerebellum, whereas Lim kinase does stain in cortical neurons.

Thus, in WMS, the link of neuroanatomy and behavior seems to fit a dorsal ventral dichotomy and not a frontal-caudal, left-right, or cortical subcortical dichotomy. Gallaburda and Bellugi proposed that the dorsal portions of the hemispheres, the frontal and parietal-occipital regions, may be involved (62). They noted that some language functions are preserved that are linked to ventral systems. Face recognition, also a ventral function, is preserved despite severe visuospatial dysfunction, a dorsal function. Anatomic findings also suggest possible involvement of the visually linked lateral nucleus of the amygdala. Galaburda and Bellugi speculated that this could be related to the lack of appropriate fear in WMS of new and unfamiliar faces, perhaps also threatening ones. Moreover, because this region may receive auditory projections, WMS subjects may not be sensitive to threatening voice and speech. Further work is needed at architechtonic and histologic levels to confirm sparing of ventral regions. To understand the linking of genes with neuroanatomy, it is necessary to find more genes with brain developmental effects. Of particular interest in this regard is the proposal that the region deleted in WMS may be a hotspot in mammalian brain evolution (51). Hagerman outlined a comprehensive approach to treatment of WMS (63).

ANIMAL MODELS: SIMULATIVE OR SUBSTITUTIVE

Part of "46 - Behavioral Phenotypes of Neurodevelopmental Disorders: Portals into the Developing Brain "

Animal models may be used to elucidate critical brain mechanisms involved in disorders with behavioral phenotypes. Early animal models focused on the impact of traumatic events during the developmental period, as exemplified by the social isolation and chronic stress (learned helpless) models of depression (64). These animal models generally simulated rather than substituted for the disorder. Animal models have used pharmacologic challenges to study neurochemical mechanisms linked to aberrant behavior or have introduced transgenic mice as substitutive models of conditions with behavioral phenotypes. Examples of these models include pemoline models of stereotyped self-biting behavior in the rat (65), SNAP mutant mouse model of attention-deficit/hyperactivity disorder (66), and transgenic and knockout mouse models for fragile X syndrome (67 ,68), MAOA deficiency (69), and LND (70 ,71 and 72). These models may contribute to the understanding of psychopathology. However, despite genetic replication of a disorder in the mouse, the behavior may not be replicated, so even these animal models often simulate aspects of the condition and are not fully substitutive.

Molecular genetic techniques combined with techniques to manipulate the developing mouse embryo make it feasible to produce such genetic animal models. Embryonic stem cells are isolated from a pregnant mouse with identifiable coat color that acts as a donor. The embryonic stem cells are grown in cell culture and then are genetically modified with the insertion of genetic material or through mutation of endogenous genes. Modified embryonic stem cells are microinjected into a blastula that is isolated from another mouse that ordinarily has a different coat color. The blastula is then reimplanted into a female host mouse and develops *in utero*. The inserted stem cells are incorporated into the

developing fetuses, and progeny that contain genetically altered cells are chimeras that can be identified by their mosaic coat colors. As adults, these chimeras, in which genetically modified cells have been involved in the establishment of the germ cell line, may then transmit the altered gene to their own offspring. It takes several generations to produce an affected animal, by using these embryonic stem cell techniques that depend on whether the needed phenotype can be produced in the heterozygous, homozygous, or hemizygous condition.

To illustrate these animal models, we may contrast animal models of LND based on the use of the neurotoxin 6-hydroxydopamine (6-OHDA), transgenic mouse models of LND, calcium channel blocker models of self-injury, and the mutant mouse model of fragile X syndrome.

Lesch–Nyhan Disease 6-OHDA (Rat Model)

After the demonstration of dopamine deficiency in striatum in autopsies of brain in three human patients with LND (35), Breese et al. administered 6-OHDA to neonatal and adult rats to test the effects of dopamine depletion in an animal model (73 ,74). These authors demonstrated that the age at which neural function is disrupted is an important factor in the type of motor and behavioral symptoms observed after a neural insult to basal ganglia structures. They documented a relationship between dopaminergic supersensitivity and self-injurious behavior. Rats treated with 6-OHDA in the neonatal period demonstrated self-biting with mutilation when they were challenged as adults with L-DOPA or a D1 dopamine agonist, but no such self-injurious behavior was found in the adult rats treated with 6-OHDA. Because of the self-biting, the neonatal 6-OHDA–treated rat was proposed as a model for LND, and dopamine deficiency was linked to self-injury. In these studies, rats that were not HPRT deficient were given injections of 6-OHDA at 5 days of age to denervate basal ganglia regions. These brain regions developed supersensitive dopamine receptors. Self-biting was documented in the lesioned animals when they were challenged as adults with a dopamine agonist; however, untreated adult rats did not show this behavior.

HPRT-Deficient Mouse

For LND, molecular techniques were used to produce two HPRT-deficient strains of mice. One strain was produced by retroviral interruption of the human *HPRT* gene in the embryonic stem cells (72). Another model was produced through the selection of embryonic stem cells for spontaneous mutations in the *HPRT* gene (70 ,71). In both instances, the mouse strains produced had nondetectable levels of HPRT. However, neither strain showed the spontaneous behavioral abnormalities or neurologic presentation seen in patients with LND. Tests of both cognitive functions and motor functions were intact in these animals. Similar findings were documented in a double knockout that is HPRT/APRT deficient (75).

This HPRT-deficient transgenic mouse model of LND (70) may still contribute to our understanding of LND. Reductions in dopamine of 40% or more (76) have been documented (77) in these animals. Because of questions about strain differences, Jinnah et al. studied the caudate nucleus in five HPRT-deficient strains of mice and made comparisons to littermate controls (77). Reductions of dopamine and also of the dopamine transporter of 35% to 40% were found in these animals. These results indicate an abnormality in the dopamine system despite apparently normal spontaneous behavior.

The absence of behavioral changes in the HPRT-deficient mice was unexpected. Originally, it was thought that uricase, which is present in rodents but is not present in primates, may act in a protective manner to lessen behavioral manifestations because uric acid, which normally builds up in the blood in LND, and hypoxanthine, which accumulates in cerebrospinal fluid, would not do so in mice because of the presence of uricase. This explanation is consistent with the inability of treatment with allopurinol, a xanthine oxidase inhibitor that prevents the accumulation of uric acid, to improve the behavior disorder in patients with LND. However, the mice were still found to have reduced dopamine in brain (76). Thus, it is the consequence of the HPRT deficits on dopamine, and possibly other neurotransmitter systems, that leads to the behavior in humans. This mouse differs from the Breese rat model in that dopamine depletion is complete in the Breese rat model but only 40% to 50% reduced in the HPRT-deficient mouse. Dopamine depletion is substantially greater in human subjects (76) than in the mice; therefore, this difference may account for the differences in behavior.

Bay K 8644 Model of Self-Injurious Behavior

Another approach to study self-injury is the calcium channel blockers model proposed by Jinnah et al. (78). The L-type calcium channel agonist (+/-) Bay K 8644 causes motor abnormalities in adult mice. These authors showed that administration of this drug could also cause the self-injurious biting, particularly when it was given to young mice. Self-biting was provoked by injecting small quantities of (+/-) Bay K 8644 directly into the lateral ventricle of the brain, a finding indicating a central effect of the drug. Similar behaviors can be elicited by administration of another L-type calcium channel agonist, FPL 64176. The self-biting elicited by (+/-) Bay K 8644 can be inhibited by pretreating the mice with dihydropyridine L-type calcium channel antagonists such as nifedipine, nimodipine, or nitrendipine. Moreover, self-biting is not inhibited by nondihydropyridine

antagonists including diltiazem, flunarizine, or verapamil. The known actions of (+/-)Bay K 8644 as an L-type calcium channel agonist, the reproduction of similar behavior with another L-type calcium channel agonist, and the protection from this behavior that results from certain L-type calcium channel antagonists implicate calcium channels, and their possible association with neurotransmitter deficits, in the mediation of the self-biting behavior (78).

Fragile X Mouse Model

The mutant mouse model of fragile X syndrome demonstrates another use of an animal model for a neurogenetic disorder. Transgenic fragile X knockout mice were developed to provide an animal model to study the physiologic function of the fragile X gene *(FMR1)* and to understand better the clinical phenotype caused by the absence of the fragile X protein.

The fragile X mouse model demonstrates macroorchidism and cognitive, affective, and behavioral features similar to the human condition (79). In the Morris water maze test, the Fmr1 knockout mice learned to find the hidden platform nearly as well as the control animals, but they showed impaired performance after the position of the platform was modified. The fragile X knockout mouse exhibited subtle deficits in spatial learning but normal early-phase long-term potentiation.

Jin and Warren expanded these studies by examination of late-phase hippocampal long-term potentiation, the protein synthesis–dependent form of long-term potentiation, in the Fmrl knockout mice (43). Initially, they found that late-phase long-term potentiation was normal and proposed that either absence of fragile X mental retardation protein has no influence on long-term potentiation or that any such influence is too subtle to be demonstrated by this technique. Moreover, when they examined spatial learning in this knockout mouse using the hippocampus-dependent Morris water maze, near-normal performance was observed. However, because the knockout mouse strain they used differed from that used in the earlier investigations that did show learning deficits, their studies were repeated using the same mouse knockout line that showed the deficit. Now significant, but subtle, increased swim latencies on the Morris maze test in reversal trials were found to be in agreement with the earlier studies. Thus, strain differences among mouse strains influence the behavior in the Fmrl knockout phenotype. Because the finding were subtle, these authors chose to investigate a paradigm less dependent on hippocampal function, one using the conditional fear paradigm. In this paradigm, the knockout animals showed significantly less freezing behavior than their wild-type littermate with two types of stimuli, contextual and conditional fear stimuli. These researchers concluded that that amygdala dysfunction may also be involved in fragile X syndrome.

These examples from LND and fragile X syndrome illustrate how animal models may contribute to our understanding of behavioral phenotypes: self-biting in LND and learning and fear responses in fragile X syndrome.

CONCLUSION

Part of "46 - Behavioral Phenotypes of Neurodevelopmental Disorders: Portals into the Developing Brain "

The study of behavioral phenotypes in neurodevelopmental disorders demonstrates the complexity in mapping pathways from genes to cognition and complex behavioral phenotypes. Behavioral phenotypes occur in disorders with mendelian inheritance (LND) and nonmendelian inheritance (PWS/AS, FRX). An investigation of these syndromes demonstrates that recognition of the involved gene is only the first step. Identification of the involved protein and of its expression in brain is critical. To clarify the mechanism, the use of animal models, neuroanatomic study, brain imaging techniques, systems neuroscience, and detailed descriptions of behavior are needed. The study of partial variants of the disorder (LND, WMS), comparison of deletion versus UPD (PWS, AS), and the study of atypical subjects who exhibit some but not all features of the disorder (WMS) are essential in understanding developmental pathways. Moreover, a neurodevelopmental model is essential because brain modularity of function cannot be assumed. Animal models must be carefully chosen because genetic background may influence the expression of the disorder. Such models may be important in simulating aspects of the disorder, but they may not substitute for the human condition. Flint proposed that success in the study of behavioral phenotypes requires a screen for regions of monosomy, the use of a sophisticated battery of neuropsychological and behavioral tests to describe the phenotype, a transcript map to identify quickly the genes that are likely to affected by the deletion, and a way to of deciding which genes are dosage sensitive (5). These are challenges that lie ahead as we continue to investigate behavioral phenotypes as portals to understanding the developing brain.

Section VI
Schizophrenia and related disorders

Daniel R. Weinberger

Schizophrenia and related disorders - Introduction

The schizophrenia section of the *Fifth Generation* reflects both a subtle shift in emphasis in schizophrenia research and a refinement of earlier trends. Molecular and systems neuroscience and genetics are the basic biological sciences of psychiatry, and their increasingly important role in research is reflected in the schizophrenia section. Schizophrenia research is inexorably on a path from clinical phenomenology to cellular and molecular pathogenesis. Although this complex disease will never be reducible to one gene or one signal-processing pathway, the molecular origins of risk and of manifest psychopathology are being elucidated. The main topics covered in the *Fourth Generation* volume, including treatment of acute psychosis, mechanisms of antipsychotic drug action, basic models of pathophysiology, application of brain imaging technologies, and efforts to characterize symptoms in terms of failures of specific neuronal systems, are represented here, but the presentations are more scientifically mature. Consistent with the completion of the reference sequence for the human genome and the increasing sophistication of approaches to complex genetic disorders such as schizophrenia, clinical and molecular genetics are now reviewed as a new chapter in this section. Because of the introduction of more effective and much better tolerated antipsychotic drugs, the economics of treating schizophrenia has changed, and this topic also is now covered as a new chapter. Finally, a new chapter is devoted to the issue of developing informative animal models of schizophrenia. The traditional view that a disorder of human perception, cognition, and comportment could not be modeled in the experimental animal has yielded in the face of heuristic models of neurochemical, physiological, and molecular aspects of schizophrenia. These models promise to open new pathways for drug discovery and to test specific hypotheses about etiology and pathophysiology.

Neuroimaging has been a popular tool for asking specific questions about brain anatomy and function that may help to unravel the pathophysiology of the illness. There is no doubt, after more than 2 decades of neuroimaging research in schizophrenia, that the schizophrenic brain is abnormal in a variety of experimental domains. The details of the abnormalities are still to be fully clarified, but the level of analysis has been meaningfully elevated. New technologies in brain imaging have allowed testing of much more sophisticated hypotheses. Magnetic resonance imaging has replaced positron emission tomography as the primary functional mapping tool, and new approaches to *in vivo* chemistry with nuclear medicine resonance spectroscopy and to anatomic tract tracing with diffusion tensor imaging have revealed abnormalities not approachable with earlier methods. Positron emission tomography has become primarily a neurochemical assay technique. Positron emission tomography imaging of dopamine systems has refined our understanding of the role of dopamine in the pathophysiology of a symptomatic episode and of the mechanism of an antipsychotic response.

Progress in schizophrenia research has followed discoveries in the basic neurosciences. This is illustrated in several chapters that address the development and plasticity of the prefrontal cortex and the importance of intrinsic prefrontal circuitry and prefrontocentric distributed networks to the pathophysiology of schizophrenia. The study of postmortem

tissues has been revived by the availability of cellular and molecular assay tools that permit surveys of gene and protein expression at an industrial scale. Numerous provocative molecular findings have emerged from these preliminary forays into the cell biology of the illness. Although the mystery of this devastating illness is still unsolved, the clues that have emerged in the past 5 years and the opportunities for discovery that now exist make it very likely that much more of schizophrenia will be understood at the cellular level in the next 5 years.

Schizophrenia: Course Over the Lifetime

Philip D. Harvey

Michael Davidson

Philip D. Harvey: Mount Sinai School of Medicine, New York, New York.

Michael Davidson: Sheba Medical Center, University of Tel Aviv, Tel Aviv, Israel.

Among the lifelong remitting and relapsing illnesses, the course of schizophrenia is among the most widely debated. At the core of the debate are the following questions:

1. What is the best way to investigate the course of schizophrenia?
2. What are the manifestations preceding and shortly after the first psychotic episode?
3. How do the manifestations of the illness, both clinical and biological, change over the life span, especially during later life and senescence?
4. Should schizophrenia be conceptualized as the response of a stable encephalopathy to different stages of the life cycle (1), as a progressive, degenerating disease (2), or as a hybrid of the two concepts (3)?

This chapter attempts to provide a critical assessment of these questions in light of the latest empiric data and current conceptualization of this disease.

The results of the major studies on the course of the illness over 20 to 40 years of follow-up are consistent in reporting a chronic, generally persistent course of illness for 50% to 70% of the patients who receive an initial diagnosis of schizophrenia (4 ,5 ,6 ,7 ,8 and 9). However, a more careful examination of the reports reveals marked heterogeneity in course both between and within cohorts (10 ,11 and 12). The reason for this heterogeneity may be that different studies have examined widely diverse samples of subjects and may also be related to the different definitions of what constitutes a good outcome. These definitions range from disease-free for the majority of life to simply not floridly psychotic at the time of last assessment (13). Very few of these studies included elderly patients in their samples or accounted for attrition, and even fewer examined longitudinal biological changes. This is unfortunate because accurate information on the course of schizophrenia is essential to plan the delivery of care, to evaluate treatment effectiveness, to provide information to newly diagnosed patients and their families, and to advance schizophrenia research. The paucity of data on the course of schizophrenia is mostly the result of limitations inherent in studying a relatively low-incidence illness of unknown origin and pathophysiology, with an insidious onset and a course affected by a multitude of personal and social factors.

WHAT IS THE BEST WAY TO INVESTIGATE THE COURSE OF SCHIZOPHRENIA?

Part of "47 - Schizophrenia: Course Over the Lifetime "

Study Design

The ideal way to determine the course of schizophrenia is to follow a randomly sampled birth cohort throughout the entire age of risk for schizophrenia and then continue to follow the incident cases, and appropriately selected controls, through the entire life span. A related but less informative strategy is to follow-up apparently healthy persons hypothesized to be at high-risk of schizophrenia such as first-degree relatives of affected persons (14 ,15 ,16 and 17). An alternative strategy is the prospective follow-up of patients from the first time they seek help for psychosis (18 ,19 ,20 ,21 ,22 ,23 ,24 ,25 ,26 ,27 ,28 and 29). Unfortunately, the birth-cohort strategy is impractical because schizophrenia is a very low-incidence disease (.87%) (30), the age of risk spans over more than 4 decades of life, and the age of risk appears different for males and females. Thus, following a birth cohort of 10,000 individuals for 40 years, starting at age 5 years, would detect approximately 90 cases of schizophrenia (not accounting for attrition), a number that is insufficient to make any statement regarding the course of a heterogeneous syndrome such as schizophrenia. Similarly, the high-risk strategy is limited in scope because it excludes most future patients with schizophrenia who do not have affected first-degree relatives, in addition to the problems of investing in a very large research effort for a

relatively small number of persons who will convert into cases.

Therefore, the most often employed strategy to map out the course of schizophrenia has been to start the follow-up only after a diagnosis of psychosis is established (first psychotic episode cohorts). However, these are selected cohorts in that they include only persons who seek help (often in an academic center) and consent to participate in research (31). Furthermore, this strategy does not provide prospectively collected information on events preceding the first psychotic episode. Moreover, it is conceivable that some of the patients recruited for the first-episode studies have been chronically ill for several years but undiagnosed (32 ,33). This, in turn, could explain the discrepancies between studies finding differences between first-episode patients and patients hospitalized on a long-term basis and other studies that do not find such differences (34).

Regardless of the study design, all prospectively followed schizophrenic cohorts will be characterized by high attrition. There are many reasons for attrition: lack of insight, disappointment with the care received, recovery accompanied by the wish to forget and conceal the experience of illness, and being too sick to maintain contact. Whether following-up 100% of the cohort would find the outcome to be better, worse, or the same (and in which aspect) remains unclear. Even if the debate on the best way to follow patients to describe the course of the illness could be settled, and the attrition rate could be reduced (both of which are unlikely), it still is not clear what defines a case of schizophrenia and therefore who should be followed to elucidate the long-term course of illness.

What Is a Case of Schizophrenia?

The debate on the nosologic boundaries of schizophrenia is as old as the term itself, and the last hundred years of research have done little to settle this debate (35 ,36 ,37 ,38 and 39). On the contrary, the pendulum has swung back and forth between a discrete nuclear definition of schizophrenia based mostly on psychotic features and severely impaired functioning and a continuum that includes questionable psychotic manifestations, schizophrenia spectrum personality disorders, and moderate to severe deviations from normality based on psychometric indicators (32 ,40).

Despite the contribution of the modern diagnostic classifications to the definition of schizophrenia, the abandonment of the continuum-based concept and adoption of the dichotomous model have not occurred, largely because the continuum model has received considerable pathophysiologic support. On the contrary, the schizophrenia-nonschizophrenia distinction is a matter of operational convenience brought about by treatment and economic developments emerging since the 1960s. The emergence in the 1950s of antipsychotic drug treatments that ameliorated psychosis while producing severe adverse effects called on the medical community to distinguish between patients who should and who should not be treated with these medications. Throughout the 1980s, as the accounting between providers of health care and health insurance organizations was becoming more thoughtful, the latter began to demand definitions of which patients were entitled to reimbursement and which were not. Finally, clinical investigators into the biology of schizophrenia also supported a model clearly distinguishing between schizophrenia and nonschizophrenia as more amenable to research. Needless to say, the course of illness of a cohort of schizophrenic patients depends on the definition of the cases enrolled in the cohort (41). Hence, until objective biological markers can be combined with phenomenologic criteria to define a case, the question of the course of “exactly what illness?” will continue to be raised.

It would also be reasonable to assume that regardless of the degree of the cohort’s heterogeneity, part of the variability in the course of illness is determined by the interaction between the affected individual and a wide array of societal, familial, and personal interactive influences (42 ,43 ,44 ,45 ,46 ,47 and 48). A few of these influences can be captured by careful collection of demographic and treatment information. However, the effects of changes that occur over many decades, such as changes in health care delivery, changes in the public perception of severe mental illness, and the interactions between these changes and aging, may not be amenable to survey and quantification. For example, how will deinstitutionalization, reduction of stigma, intensive community care, managed care, novel neuroleptics, open international borders and resultant migration, and the influence of advocacy groups affect the definition and course of schizophrenia?

In summary, the inherent limitations of studying birth and high-risk cohorts, coupled with the observation that many of the dynamic changes occur over a time span of 3 to 5 years before and immediately after the first diagnosed episode of psychosis, have been the impetus for the proliferation of first-episode studies in the 1990s. These studies can provide some useful information about schizophrenia, particularly because most patients experiencing schizophrenic symptoms in Western societies are likely to be diagnosed and treated at least once by mental health professionals.

WHAT ARE THE MANIFESTATIONS PRECEDING AND SHORTLY FOLLOWING THE ONSET OF THE FIRST PSYCHOTIC EPISODE?

Part of "47 - Schizophrenia: Course Over the Lifetime "

Premorbid Phase

The observation that that some schizophrenic patients have premorbid abnormalities dates back to Bleuler (49). History taken on the first contact with a mental health professional

often reveals subtle or flagrant motor, cognitive, emotional, and behavioral deviations during childhood, social withdrawal and mood and personality changes during adolescence, and attenuated psychotic symptoms several months to several years before the first treatment contact and the diagnosis of psychosis (51 ,52 ,53 ,54 ,55 ,56 ,57 ,58 ,59 ,60 ,61 and 62). The period immediately preceding the onset of psychosis, during which behavior and functioning deteriorate from a stable, premorbid level of functioning, as well as the behavioral changes that identify it, is referred to as the *prodrome*. However, the factors that precipitate the transition from prodrome to the first incident of help seeking and the resultant diagnosis are not necessarily distinctly related to the illness itself.

Factors such as the educational level of patients and their families, socioeconomic status, and availability of health care may all determine when the first contact occurs (63 ,64 ,65 ,66 ,67 and 68). Moreover, events such as the sudden unavailability of a caregiver able to maintain a highly symptomatic patient in the community or any change in the threshold of abnormal behavior tolerated by the community can precipitate treatment contact, hospitalization, and diagnosis. Hence, the presence of the premorbid manifestation, the onset of the prodrome, the emergence of the symptoms that define an episode of the illness, and ascertainment of the full syndrome of illness including formal diagnosis do not necessarily coincide and are not always clearly distinct points in time (31). Methods employed to investigate the phenomena preceding the first contact for help and the diagnosis of schizophrenia are the high-risk method, the birth-cohort method, and the historical prospective (or follow-back) method.

The high-risk studies that followed-up children and siblings of patients affected by schizophrenia into adulthood demonstrated that these relatives were more likely than the general population to be affected by emotional and behavioral abnormalities and abnormal psychophysiologic reactions (69 ,70 ,71 ,72 ,73 ,74 ,75 ,76 ,77 ,78 ,79 ,80 and 81). For instance, one study compared cognitive and behavioral assessments of twin pairs healthy at the time of testing and discordant for psychoses later on with twin pairs who both remained healthy. The healthy twin from the ill pair performed better than the ill co-twin but worse than the average of the twins from the healthy pair (82) (Fig. 47.1). Thus, abnormalities were found to be associated both with schizophrenia and with being a nonpsychotic identical twin of a schizophrenic patient. Even though the increased risk can be demonstrated in targeted populations, this strategy has not been completely successful in defining the premorbid aspects of schizophrenia. This is because most persons who belong to the high-risk groups represent a small, atypical subgroup of patients with schizophrenia and because of the relatively small number, approximately 10% to 15% at most (30), of high-risk persons who eventually develop schizophrenia.

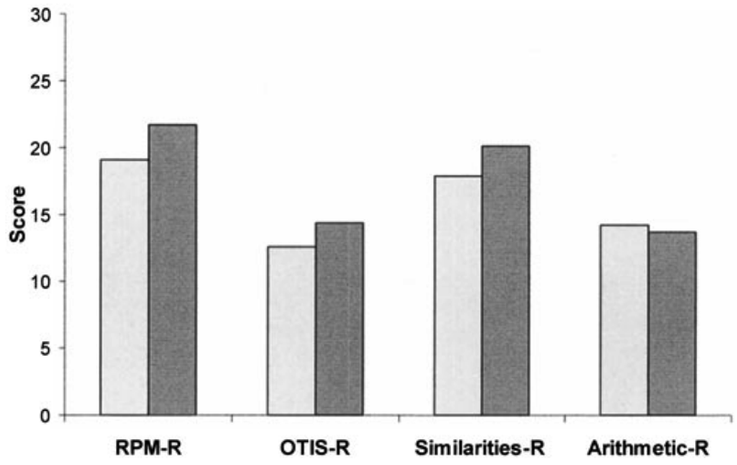

FIGURE 47.1. Intellectual functioning in members of twin pairs concordant and discordant for schizophrenia.

National health authorities have conducted follow-up studies of persons born in a geographically defined area over a specified period (birth cohort) to study protective and risk factors for healthy development and disease. Among the most publicized and complete studies are two British studies: the Medical Research Council National Survey of Development, covering all births during the week of 3 to 9 March 1946, and the National Child Development Study, covering all births during 3 to 9 March 1958 (83 ,84). Persons born during these 2 weeks were interviewed and assessed, together with their parents, several times during early childhood and adolescence. Developmental and scholastic achievement data collected on these cohorts were later linked to the data in a registry containing diagnoses of patients discharged from psychiatric hospitals. An overview of these studies indicates that, as a group, persons with future schizophrenia cases had delayed developmental milestones, speech and behavioral difficulties, and lower IQ scores compared with noncases (individuals who did not appear in the psychiatric registry). Although future cases were overrepresented in the lowest third of the IQ scores, these future cases had scores that were distributed over the entire range. The decline in IQ was not limited to a particular test, and the magnitude of decline ranged between 0.25 and 0.75 standard deviations (SD). Thus, the level of performance seen was not necessarily even outside the average range of IQ scores (defined as IQs between 90 and 110, which is 0.67 SD above or below the average score of 100).

Follow-back or historical prospective studies examine the archival premorbid histories of individuals who are already diagnosed as suffering from schizophrenia. They can be based on the linkage of databases containing routine psychometric tests administered by educational or military authorities to large numbers of healthy adolescents with national psychiatric registries. This strategy takes advantage of large-scale, readily available data enabling the testing of hypotheses with high statistical power. The disadvantage of the strategy is that, like birth-cohort studies, the data contained in the archival assessments are not aimed at the detection

of schizophrenia or its premorbid manifestations, which may be responsible for the low predictive specificity found in many of these studies. Several follow-back studies have produced results very similar to the birth-cohort studies, findings confirming, both quantitatively and qualitatively, the cognitive and behavioral abnormalities of future schizophrenic patients (85).

For instance, one study based on a national population of adolescents called by the nonselective Israeli Draft Board revealed that apparently healthy persons who several years later developed schizophrenia had lower mean group scores than their healthy classmates by about 1 SD on items reflecting social adjustment and IQ (53). The differences derived from a “shift to the left” of the future patients, one that was clearly more pronounced on social adjustment than on IQ.

Despite the consistency between the studies’ results, their interpretation remains uncertain. The premorbid signs of the illness are widely variable, and a single “typical prodrome” cannot be identified. For example, for some persons, the premorbid manifestations consist of shyness detectable in elementary school, many years before the manifestation of psychosis. For others, the premorbid manifestations consist of IQ scores 0.67 SD lower than expected, detected in adolescence, or in nonpsychotic paranoid thoughts manifested several years before the first psychotic episode in persons with unimpaired IQ. Yet for others, the premorbid manifestations consist of withdrawn behavior and depressed mood preceding psychosis only by a few months. Furthermore, for some patients, the prodrome is manifested as a crescendo of progressive, continuous deterioration during childhood and adolescence and for others as the barely detectable presence of a few minor cognitive abnormalities. Finally, it is possible that some of the variability in the quality and time of manifestations of premorbid manifestations reflects limitations of the study designs, which are often cross-sectional assessments (34). It is conceivable that a true prospective follow-up study, specifically designed to detect signs of premorbid schizophrenia and conducted from birth through age of risk, would reveal that the same person who manifests mild delay in developmental milestones as a toddler (56), shyness and learning difficulties in elementary school (50 ,52), restricted peer interaction as a teenager (86), and depressed mood and unusual thoughts in adolescence (87) would have psychosis in early adulthood (30). Alternatively, a particular premorbid manifestation could lead to a particular subtype of schizophrenia (86). It is uncertain whether these various premorbid or prodromal manifestations, which differ in quality, severity, and time of onset, bear the same relation to the first psychotic exacerbation or to the course of the schizophrenic illness.

Despite these uncertainties and even though with current psychometric tools, premorbid abnormalities are detected only in a few persons with future schizophrenia, their presence has opened up both conceptual and practical lines of investigation. Conceptually, it would be interesting to explain the pathophysiologic relationship between the premorbid symptoms and the manifestation of the illness. Practically, it would be helpful if the prodrome could be developed into a reliable predictor of future illness, based on which a secondary prevention strategy could be implemented.

Because the clinical manifestation of schizophrenia could represent an accumulation of genetic and environmental risk factors (or lack of environmental protective factors), the premorbid abnormalities, particularly the early-life ones, could be conceptualized as markers of vulnerability. This is consistent with a “multiple-hit” hypothesis by which, in addition to the genetic and environmental factors that have led to the premorbid manifestations, an environmental insult or a gene expressed later in life may be necessary to develop the full syndrome of schizophrenia. A corollary hypothesis would suggest that, depending on the additional, later insults, the same early-life manifestations (e.g., avoidant personality traits) could remain stable through life with no pathologic implication, could evolve into milder mental disorders such as a schizophrenia spectrum personality disorder, or could lead to schizophrenia. If indeed the phenotype of schizophrenia reflects the consequences of an accumulation of genetic and environmental risk factors, studying the course of the disease from birth through the end of the age of risk may be required to identify specific etiologic patterns. Alternatively, it is possible that a subgroup of these persons who manifest certain premorbid abnormalities may be inevitably destined to manifest schizophrenia in the future, and for these, and only these persons, the prodromal manifestations are obligatory precursors of the illness.

Is Secondary Prevention a Realistic Goal?

From a practical point of view, it would be tempting to use the occurrence of the premorbid and prodromal manifestations of the illness to identify persons at imminent risk of developing schizophrenia and to intervene before the onset of the first psychotic episode, in an attempt to delay or ameliorate it (47 ,57 ,88 ,89 ,90 ,91 ,92 and 93). It would be reasonable to hypothesize that any intervention that would delay or attenuate the first psychotic episode would have a major impact on the long-term outcome of the illness. This idea draws support from studies indicating that patients with shorter duration of untreated psychosis have more rapid symptomatic remission and may incur less deterioration in the long run (94 ,95 and 96).

However, the relatively low specificity of the premorbid symptoms such as subtle cognitive deficits, poor social adjustment, changes in personality, and depressed mood has given rise to concerns that an excessive number of persons could be exposed unnecessarily to the stigma of a provisional diagnosis of severe mental illness. Although it is possible to improve the specificity of prediction, for example, by

targeting only persons at very high risk (e.g., first-degree relatives of schizophrenic patients who also manifest putatively prodromal symptoms), this strategy would exclude the 90% of future patients who do not have an affected relative. Furthermore, even if the prediction could be improved, it is not certain that effective prevention exists. Antipsychotic drugs proven to reduce symptoms and to prevent exacerbation in patients who already experienced psychosis may or may not be effective in delaying the onset of psychosis.

Moreover, the notion that psychosis exerts a toxic effect on the brain and that longer duration of untreated psychosis should result in worse outcome has been challenged (20 ,97). It has been argued that (a) duration of untreated psychosis cannot be accurately assessed, (b) the delay in requesting and obtaining treatment is not the cause of a worse outcome but the result of an insidious-onset illness that is a more severe form, and (c) long duration of persistent untreated psychosis and persistence of psychosis despite treatment both reflect the same psychosis-severity phenomena without proving a causal relationship between the two. Finally, the proof that the duration of untreated psychosis correlates with the more relevant indices of outcome such as quality of life or overall illness outcome is still equivocal.

For all these reasons, the question of treating persons who are not yet floridly psychotic has stirred public debate beyond the professional community. Yet because of the potential benefits of secondary prevention on one hand and the risks and ethical implications associated with it on the other, it is essential to search for rational strategies to assess the risk-to-benefit ratio. Examining such ratios in an area where preventive measurements are already an accepted reality would be such a strategy. For example, even though after remission from the first psychotic episode, only 60% of drug-free patients have an exacerbation of their illness within the first year, 100% of patients are routinely treated with neuroleptics. Hence 40% are exposed to the adverse effects of neuroleptics, although they are not likely to experience a worsening of their symptoms. Similarly, seven families of schizophrenic patients must go through the effort, expense, and potential adverse effects of intensive family therapy for 1 year, to prevent relapse on the part of one of seven recently discharged patients with schizophrenia (98).

The dilemma of preventive treatment is not limited to psychiatry. For instance, approximately 70 elderly patients with moderate hypertension must be treated with antihypertensive drugs for 5 years to save one life, and 100 men with no evidence of coronary heart disease must be treated with aspirin for 5 years to prevent one heart attack (99). In a study using the number needed to treat method, which is the number of persons who need to receive treatment to prevent one bad outcome, it was calculated that one must administer antipsychotics to 35 adolescents with paranoid or schizotypal personality disorder for 1 to 3 years to delay hospitalization for schizophrenia by 6 months to 1 year in a single patient. This calculation assumes that approximately 5% of these adolescents will convert to schizophrenia, and it also assumes a 60% treatment success rate in delaying conversion, which is the same rate by which neuroleptics can induce extended remission in first-episode patients (100).

The early detection and treatment strategy is supported by preliminary results from a community clinic where youths with prodromal symptoms were treated with open-label neuroleptics plus supportive measures or supportive measures alone (101 ,102). The results indicated that more members of the neuroleptic-treated group were symptom-free for a longer period than similar youths given only supportive therapy or those who refused to enroll in the trial. In a different study, nonpsychotic, first-degree relatives of patients complaining mostly of cognitive deficit also were found to benefit from neuroleptic treatment (103). In summary, although there is much interest in the events leading to the first psychotic episode and a strong appeal for secondary prevention, the information currently available is still tentative. In contrast, much information and a few solid practical implications regarding the first episode of psychosis are known.

First Episode of Psychosis

Most studies of patients followed for 2 to 5 years after the first episode of illness have provided highly informative data regarding the early course of positive (3 ,34 ,105) and negative (19 ,104 ,106 ,107 and 108) symptoms, cognitive functioning (109 ,110 ,111 ,112 ,113 ,114 ,115 and 116), functional status (117 ,118 and 119), and response to treatment (95). Furthermore, some of the studies have described radiologic changes in the brain after the first episode (120 ,121 and 122).

Often, the appearance or worsening of psychotic symptoms constitutes the trigger for the first contact with a mental health professional and subsequent diagnosis and hospitalization. Hence, it is no wonder that what is described as the first episode of schizophrenia is dominated by the presence of positive symptoms, mostly fully formed delusions and hallucinations. Almost 90% of first-episode patients treated with neuroleptics experience a rapid, albeit transient, remission of their psychotic symptoms. Despite the good initial response to treatment, relapse with reoccurrence of psychotic symptoms is common. Predominance of negative symptoms and hebephrenic, catatonic presentations are not part of the characteristic presentation of the first episode. Occasionally, however, negative symptoms of insidious onset are present on the first episode, and the response of these symptoms to treatment is very limited. Cognitive deficits are common and relatively severe at the time of the first episode. Performance on most cognitive tests is approximately 1 SD below age- and education-adjusted expectations, with more that 50% of the first-episode patients performing even worse (123). The impairment affects almost

all aspects of cognition; however, specific areas of impairment are distributed unevenly. For example, deficits in memory, abstraction, and attention are more severe than deficits in verbal or perceptual skills (124). This impairment, measured on remission from the first episode, goes beyond the one-third to two-thirds SD deficit that characterizes the premorbid cognitive performance of the schizophrenic patients, and it raises the question whether it reflects a progressively deteriorating process. In a cross-sectional comparison of Raven Progressive Matrixes scores (a valid measure of IQ), it was found that apparently healthy adolescents closer to their first hospitalization for psychosis performed more poorly than adolescents who were tested several years before their first exacerbation, but better than patients whose disease had already exacerbated (125) (Fig. 47.2). Furthermore, cognitive performance appears to be slightly worse in patients with chronic disease (114) in comparison with first-episode patients, a finding providing indirect evidence of further cognitive deterioration beyond the first episode (110 ,111). In contrast to psychotic symptoms, cognitive functions are less responsive to the neuroleptic treatment administered for schizophrenia (126).

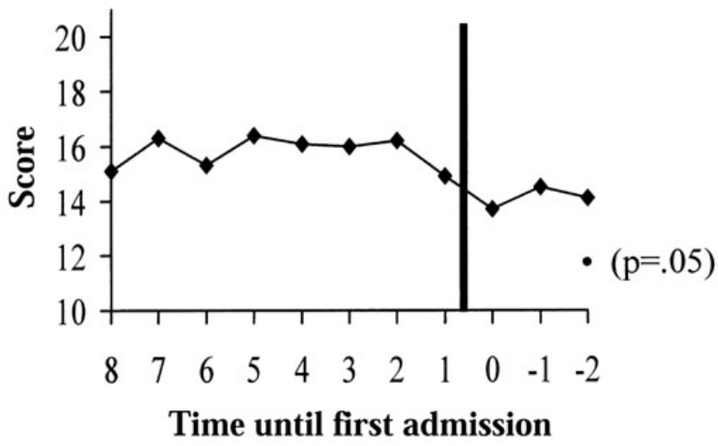

FIGURE 47.2. Scores on the Ravens Progressive Matrices as a function of time until first admission for schizophrenia.

In contrast to the evidence from studies of conventional antipsychotic treatments that suggest little improvement in cognition with treatment, two separate studies demonstrated modest longitudinal improvements in certain areas of cognitive functioning (111 ,127). These findings suggest diversity in the course of cognitive deficit even early in the illness, although they also indicate that there is no consistent pattern of specific dimensions of improvement. Furthermore, even though an improvement in cognition was seen in these studies, no research to date has demonstrated that many first-episode patients show evidence of normalization in their cognitive functioning. Thus, although evidence of worsening in cognitive functioning associated with duration of illness was collected from the study of patients with a longer duration of illness (124), patients with multiple psychotic episodes (116), and elderly patients with continuous psychosis (reviewed later), there is still marked heterogeneity of recovery of cognitive functioning immediately after the first episode.

Despite the good remission of psychosis achieved by most first-episode patients (95), and even though negative symptoms and cognitive impairments are not very severe at this stage of the illness, most patients are already affected by persistent social and vocational decline in the first psychotic episode. For instance, in a study reported by Ho and colleagues (128), more than half of a sample of first-episode patients with schizophrenia were found to be supported by public funds within 12 months of their first episode of illness, and fewer than 25% of them had a job or went to school. Despite evidence of improvement in cognition on the part of some patients at the time of the first episode, continuing cognitive and functional deficit is the rule.

Taken together, the premorbid and first-episode studies indicate that many of the manifestations of schizophrenia, including psychosis, are present many months to few years before the formal diagnosis, and most, but not all, patients respond well to treatment in terms of their positive symptoms and have a better course of illness in several different domains for the first year or 2 of illness than later. Occupational and cognitive deficits are clearly disproportionate compared with the severity of psychotic symptoms in most cases, despite evidence of improvement on the part of some patients. However, these results may be biased, because most first-episode studies enroll patients who (a) were sufficiently sick to need hospitalization, but (b) became sufficiently well to be able and willing to consent to be followed-up after discharge, yet (c) are not sufficiently recovered to be completely out of the treatment network. More important, most first-episode studies last less than 5 years because of attrition, funding, or other factors.

HOW DO THE ILLNESS' MANIFESTATIONS CHANGE DURING LATER LIFE AND SENESCENCE?

Part of "47 - Schizophrenia: Course Over the Lifetime "

Middle Course of Schizophrenia

Until the early 1990s, the characteristics of schizophrenia in patients older than 55 years were largely the subject of speculation. As of 1993, it was estimated that less than 5% of all of the research ever performed on patients with schizophrenia had included any patients older than 55 years (129). It was "common knowledge" that by age 55 to 60 years the illness has run its course, psychotic symptoms had burned out, and most patients did not need or did not benefit from medications. Since the early 1990s, however, a substantial amount of research on this topic has been completed, with this area one of the fastest developing aspects of research on schizophrenia. This research has considered all the topic areas covered by studies on younger patients

and has yielded a considerable amount of information that has helped to refine thinking about schizophrenia in general.

One of the sources of the common knowledge that the course of schizophrenia was established into old age was the consistent findings of symptomatic, cognitive, and functional stability on the part of patients after their first few episodes. Although many patients experience multiple psychotic episodes through middle age and many patients experience continuous psychotic symptoms, there was little evidence of change in cognitive or functional status on the part of these patients. Most research on the course of functional status suggests that the impairments noted at the time of the first episode are rarely reduced. Estimates of the proportion of patients with schizophrenia who are employed are in the range of about 40%, with most patients employed in noncompetitive, sheltered settings (130). Likewise, independent living is the exception for patients with schizophrenia. There is also no significant evidence that functional status in patients with schizophrenia changes markedly over time or is altered by treatment with older antipsychotic medications (131). This large body of data raises issues of importance when older patients are studied, including whether changes seen in later life are part of the natural course of the illness or whether they are the result of additional comorbidities.

Cognitive and Functional Deficits in Older Patients

It has been consistently reported, however, that many patients older than 65 years who have a lifelong course of schizophrenia, especially those with a history of long-term institutional care, have marked deficits in cognitive and functional status (132 ,133 and 134). Similar findings have been reported at different research sites in the United States and in the United Kingdom (135). Because of the lack of data regarding the lifetime course of functional and cognitive deficits in schizophrenia, it is not clear whether the presence of severe deficits in functioning seen in these elderly institutionalized patients with schizophrenia is the result of deterioration in their cognitive and functional status or is a lifelong feature of their adjustment. There are multiple potential methodologic issues associated with the study of older patients, particularly patients with a history of long-term institutional stay. Among these issues are the difficulty in identifying the patients' "true premorbid status," long-term treatment with antipsychotic medications, extremely invasive somatic treatments, and institutionalization and demoralization, potentially leading to poor motivation to cooperate with testing. There is no question, as would be expected from studies of younger patients, that chronically institutionalized patients have low levels of premorbid functioning, in domains of educational, social, occupational, and independent living skills (132 ,133 and 134). However, the functional history of these institutionalized patients is inconsistent with the idea that their current, grossly impaired status could possibly be their lifelong level of functioning.

Many of these questions are being addressed by a longitudinal cohort study carried out by the Mt. Sinai School of Medicine group since the late 1980s, as well as other investigators who have become increasingly interested in this population. A study of the baseline characteristics of the Mt. Sinai sample demonstrated that these elderly patients manifested moderate to severe negative and positive schizophrenic symptoms not dissimilar to the symptoms present in younger institutionalized patients (133). Many of these patients had cognitive and social performance compatible with dementia (136) that could not be accounted for by somatic treatment, lengthy institutionalization, poor motivation and education, or comorbidity. For example, in the original publication on this population (133), it was demonstrated that psychosurgery, insulin coma, electroconvulsive therapy, and the severity of negative symptoms were not the factors accounting for cognitive deficits. Relevant to the issue of motivational deficits, in a subsample of the patients from that study (137), the average level of education was found to be more than 11 years, and their reading performance was higher than the tenth grade level. In contrast to these indicators of educational achievement, the current average Mini-Mental Status Examination (MMSE) score was 20 (consistent with moderate dementia). Thus, some elderly institutionalized patients with schizophrenia appear to manifest decline in their functioning relative to premorbid functioning.

Studies of the cognitive performance of elderly schizophrenic patients have identified "double dissociation" performance profiles that discriminate them from patients with clearly identified dementia (138 and 139), and a profile of differential deficits has been identified. Differential deficits cannot be caused by a single constant factor, such as failing to provide adequate effort when assessed. These data suggest that studies of very poor-outcome long-stay patients, although clearly reflecting the most seriously ill subset of the population, are not hugely biased by the obvious factors associated with long institutional stay.

Longitudinal Course of Cognition and Functional Status in Late-Life Schizophrenia: Patients with Chronic Illness

As noted earlier, some elderly institutionalized patients with schizophrenia appear to manifest decline in their functioning well past premorbid levels at some time in the course of their illness. The time course, prevalence, and correlates of this decline are as yet undiscovered. There is surprisingly little longitudinal research on cognitive functioning and functional skill deficits in schizophrenia. One metaanalysis suggested that indicators of cognitive performance were

largely stable over time in 15 follow-up studies of patients with schizophrenia (140). The total sample size in all these previous studies was only 639, and 225 of those patients were chronically institutionalized patients studied by the Mt. Sinai group in a short-term (1- to 2-year) follow-up study (141). In contrast, in two separate published longitudinal studies of the course of cognitive and functional status in elderly poor-outcome patients with schizophrenia (142 ,143), the Mt. Sinai group found that about 15% of these patients per year showed evidence of cognitive and functional worsening. The second study also demonstrated statistically significant cognitive and functional decline over an average of 2.5 years in 57 geriatric schizophrenic patients who entered the study as chronically hospitalized but were reassessed after discharge to nursing home care (143). These data suggest that some proportion of elderly patients with schizophrenia with a history of long-term institutional care experience a notable decline in their functioning over a relatively brief follow-up period. These data suggest the possibility of some adverse effect of aging after a lifetime of poor functional outcome and extensive cognitive deficits.

The Mt. Sinai group completed a larger follow-up study based on 1,102 patients. Some of these patients were unavailable for later study at each of the subsequent reassessments, because they had died or were discharged to nursing home care, where follow-up could not be performed. The primary analyses examined the development of new-onset severe cognitive and functional impairment. Patients were divided on the basis of their baseline Clinical Dementia Rating (CDR) (148) score, such that patients with baseline scores of 1.0 or less were considered less impaired. Worsening in cognitive and functional status was defined as having a CDR score at a subsequent follow-up of 2.0 or greater. At baseline, there were 456 patients with CDR scores of 1.0 or less, whose average MMSE score was 20.8.

The actuarial life-table method, with discrete interval procedures, was used to assess the cumulative risk of cognitive and functional decline over the three intervals between assessments, while considering subject attrition. The cumulative “survival” (i.e., no worsening in cognitive and functional impairment) was then calculated, and survival curves were constructed. At the first follow-up time beginning at 15 months, 17% of patients met criteria for worsening (corrected), and at the second follow-up time beginning at 30 months, 20.4% of the remaining patients met criteria for worsening. At the third follow-up time beginning at 48 months, 25.3% of the remaining patients manifested worsening of their cognitive and functional deficits. Thus, over the entire follow-up period, a corrected rate of cognitive decline of 51% was noted.

The influences of potential risk factors on rates of cognitive and functional decline over the entire follow-up period for the initially higher-functioning patients were examined. The Wilcoxon statistic was used to measure the difference in survival curves as a function of risk factor status. Gender was unassociated with risk for cognitive and functional decline, as were neuroleptic treatment status, age, and age at first psychiatric admission. In contrast, three risk factors were associated with increases in risk for cognitive and functional decline. Patients with more severe positive (Wilcoxon statistic [1df] = 4.28; $p < .05$) and negative (Wilcoxon statistic [1df] = 17.03; $p < .0001$) symptoms were found to be at higher risk for decline. In addition, patients with more education were less likely to experience a cognitive and functional decline than were patients with lower levels of formal education (Wilcoxon statistic [1df] = 8.65; $p < .01$).

In the final analysis, presented in Fig. 47.3 , the influences the risk factors previously demonstrated as significant predictors of risk for decline were examined for their influence on the rate of cognitive and functional decline over the entire follow-up period. First, patients were divided at the median level for both baseline severity of symptoms and education levels and were assigned to one of four groups

on the basis of their status for symptom severity and education level. The Wilcoxon statistic was then used to measure the difference in survival curves as a function of combined risk factor status. Patients below the median level for education and above the median for severity of symptoms were at the highest risk of cognitive and functional decline. This group's level of risk was significantly greater than those with similarly high levels of positive symptoms but higher levels of education (Wilcoxon statistic [1df] = 8.49; $p < .001$) and those with lower levels of positive symptoms and higher levels of education (Wilcoxon statistic [1df] = 15.31; $p < .001$). Similarly, a significant interaction was seen between the influences of negative symptom severity and education level on risk rates for cognitive and functional decline.

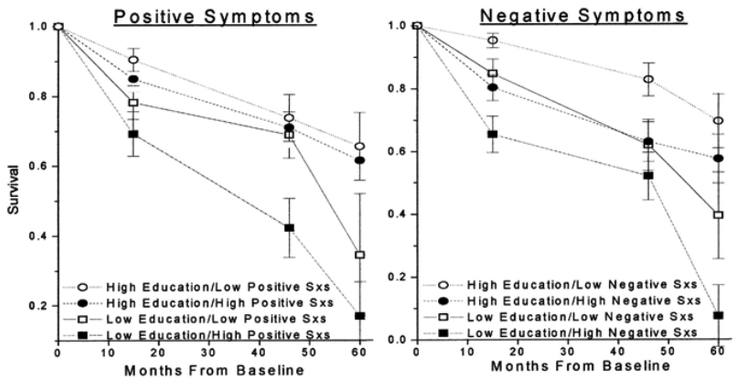

FIGURE 47.3. Effects of combined symptom (positive and negative) severity and educational level factors on survival from cognitive and functional decline over a 60-month follow-up period.

Certain potential limitations that must be addressed in the interpretation of these data. No control for institutionalization as a direct risk factor was used in this study. Despite the difficulty in identification of such as a group, there is no other direct way to index institutionalization effects. Similarly, these data do not control specifically for the development of subtle new-onset medical conditions. This is a less difficult question to address in later research. Finally, as noted earlier, multiple additional factors, including subtle environmental changes, may interact with the easily measured risk factors examined in this study.

Longitudinal Course of Cognition and Functional Status in Late-Life Schizophrenia: Better-Outcome Patients

Although the studies just reviewed indicate that some proportion of poor-outcome patients experience cognitive and functional decline, there is no evidence to date of cognitive decline in patients with a history of better lifetime functional outcome. Cross-sectional comparisons of older and younger better-outcome patients conducted by the University of California at San Diego (UCSD) group found little evidence of relatively poorer cognitive performance on the part of older patients (138 ,144 and 145). It is impossible to determine, of course, from cross-sectional data that these older better-outcome patients, with minimal evidence of previous decline in their cognitive and functional status, would never experience a decline at a later date. Furthermore, the proportion of patients in the UCSD samples older than 65 years was only about 15%, a finding suggesting that if the risk of cognitive and functional decline increases with age, these patients may only be entering the period of increased risk. Finally, few of these patients had a history of symptom severity consistent with extended periods of treatment-refractory psychosis, and very few would have met the criteria for kraeplinian status previously demonstrated to be associated with very poor lifetime functional outcome (146 and 147). These data suggest the need to determine whether long-term institutionalization or the patient characteristics that cause institutionalization are the operant factors in the cognitive decline seen in worse-outcome patients. One of the best possible strategies could be to perform a longitudinal comparison of outpatients with and without a prior history of long-term institutional stay, to separate patient characteristics from current environmental factors.

Persistent Symptoms Revisited: Duration of Continuous Psychosis

The data from follow-up studies of poor-outcome patients suggest that persistent schizophrenic symptoms, combined with evidence of premorbid educational underachievement, are associated with marked increases in risk for functional decline over relatively short follow-up periods. These data again raise the issue of persistent symptoms as a risk factor for the later course of illness and also suggest that evidence of lifelong intellectual compromise may increase this risk. These data may help to address some of the differences in findings between previous studies of ambulatory patients and these extremely impaired, continuously refractory patients. First, these institutionalized patients have persistent symptoms that have kept them hospitalized for decades and clearly distinguish them from ambulatory samples. As previously demonstrated, functional deficits and negative symptoms do not interfere with discharge to nursing home care in this population, whereas persistent positive symptoms do (149 ,150). Second, these patients are all older than 65 years. In previous longitudinal studies, even institutionalized patients younger than 65 years old had essentially no risk of cognitive and functional decline over a 6-year follow-up period (151). It would not be a surprising finding that ambulatory patients in this age range who have never been institutionalized would not have elevations in their risk for decline either.

These data may provide a heuristic for understanding the variance in outcome, measured by cognitive performance and ratings of functional status, in older patients with schizophrenia. In institutionalized patients with similar periods of institutional stay, MMSE scores range from 0 to 30, and functional limitations range from moderate deficits in social skills to incontinence and complete dependence on others for feeding and bathing. In addition, better-outcome patients clearly have indications of higher levels of premorbid and current cognitive functioning. These data suggest that the interaction of reduced levels of educational attainment, often referred to as a marker of cognitive reserve (152), and particularly persistent symptoms of illness, may predict functional decline. The previous suggestion that education attainment is an indicator of a cognitive risk-protective factor for dementia (153) appears relevant to schizophrenia. Thus, patients with schizophrenia in late life who have severe and persistent psychotic symptoms, as well as reduced levels of educational attainment, appear to have a much greater risk of worsening in functional status than

patients whose positive symptoms are less treatment refractory and whose cognitive reserve may be greater.

The length of time that some of these patients have experienced continuous psychotic symptoms, despite conventional antipsychotic treatment, is staggering. Some of these patients have been treated since the 1950s with conventional medications, with little relief of their symptoms. The duration of untreated psychosis seen in typical samples of first-episode patients with schizophrenia pales in comparison with these histories of continuous psychosis. This duration of continuous psychosis is much more similar to that typically seen at the time of the initial introduction of antipsychotic medication in the 1950s. At that time, long duration of untreated psychosis was found to be associated with risk for greater functional deficit after initiation of antipsychotic treatment than for patients whose symptoms were treated sooner after the development of illness (96). Much later research will need to address the issues of the impact of continuous psychotic symptoms, in terms influence on the course of illness and whether continuous psychosis despite treatment has the same impact on development as lengthy periods of untreated psychosis at the outset of the illness.

SCHIZOPHRENIA: STABLE ENCEPHALOPATHY OR PROGRESSIVE DISEASE WITH CORRESPONDING LIFELONG BIOLOGICAL CHANGES?

Part of "47 - Schizophrenia: Course Over the Lifetime "

A most controversial aspect of schizophrenia is whether the few biological and many phenomenologic abnormalities reported are consistent with a degenerative, progressively deteriorating course of the illness (154 ,155 ,156 ,157 and 158) or a static course for accounted by an early (developmental) insult (1 ,159 ,160 and 161). The neurodevelomental models suggest that a perinatal neuronal insult disrupts normal neural maturation and results in disruption of neuronal circuits and thus abnormal neuronal function. It is further postulated that the clinical manifestation of symptoms is triggered by interaction between the initial defect with neuronal maturation processes such as neuronal migration, glial proliferation, and synaptic pruning. This maturation process, in turn, accounts for the gap between the hypothesized early-life insult and later clinical manifestation.

The neurodevelopment concept has prevailed mostly because schizophrenia lacks specific biochemical and histologic changes (gliosis, cellular debris, or amyloid deposits) closely paralleling behavioral abnormalities that define progressive degenerative disorders. Furthermore, because Alzheimer disease has been seen as the prototype of a progressive neurodegenerative disorder, the absence of fast and relentless worsening of illness has been taken as evidence against a degenerative hypothesis in schizophrenia. However, an overview of the data regarding the course and the biology of schizophrenia reveals no sufficient evidence to settle this debate, and the same behavioral evidence can be interpreted to support either of the two hypotheses. For example, subtle cognitive, behavioral, and motor deviation from norms are present in childhood, are amplified in adolescence, and exacerbate shortly before and after the first psychotic episode. This can be interpreted a classic interaction between an early defect and brain maturation or as the behavioral consequence of a slowly progressive degenerative brain process. In addition, lack of consistent worsening of psychosis across episodes argues for the static hypothesis, whereas progressively poorer antipsychotic response after each additional episode could be interpreted as evidence of a slowly progressive degenerative process.

Similarly, biological findings, mostly structural neuroimaging studies, have produced results compatible with both hypotheses (120 ,121 ,162 ,163). Some investigators reported no evidence of progressive brain disease, in either the domains of overall cerebral size (i.e., cortical atrophy) or the size of the cerebral ventricles (i.e., ventricular enlargement) (164 ,165). However, some cross-sectional and longitudinal studies have produced different results. There are several limitations, of course, in using neuroimaging to make direct inferences about changes in the brain, particularly in reference to whether these changes are degenerative.

Brain Structure Immediately after the First Episode

One of the interesting recent topics in the area of the course of schizophrenia is that of changes in brain structure after the first episode. Research by DeLisi and colleagues suggested that some patients recovering from the first episode of the illness have evidence of progression in the size of their cerebral ventricles (166 ,167). This progressive ventricular enlargement is consistent with that seen in patients with more chronic illness, both during adolescence for childhood-onset patients (168) and during middle age for poor-outcome patients with a more typical age of onset (169). These changes are modest, but they are also detected in relatively short follow-up periods. Because the patients in the studies by DeLisi et al. experienced an increase in the ventricular size of about 3.5% in 5 years, the amount of change that would be expected over a lifetime, if this change were continuous, could be substantial.

Changes in Brain Function in Patients with Established Illness

Changes in cerebral structure have also been noted in patients with an established illness. In a 5- year prospective study (169) comparing middle-aged patients with schizophrenia who varied in their lifetime functional outcome from chronic “kraeplinian” patients with community dwellers, the kraeplinian patients demonstrated progressive ventricular enlargement. These data, consistent with those of

the first-episode and childhood-onset studies, suggest that the cerebral change is dynamic over the life span in patients with schizophrenia. In addition, two separate sets of cross-sectional studies, examining p300 prolongation, suggested that older patients have longer latencies (170 ,171). The finding of prolonged p300 latency can be associated with the presence of neurodegenerative diseases (172). Finally, cross-sectional studies have also found that older patients show relatively greater atrophic changes in the size of the olfactory bulb (173), and this has been found to correspond to a concurrent deterioration in olfactory sensitivity (174). Because olfactory deficits are also detected with consistency in patients with degenerative conditions, these data are consistent with the p300 data just reviewed. The data to date on the processes of dynamic cortical change in schizophrenia are hardly conclusive. There are, however, multiple, albeit indirect, suggestions that the idea that brain structure and function in schizophrenia are immutably stable over the life span in all patients is open to question. These are important issues that will shape future research in this area.

Is Integration Possible?

In an attempt to account for the phenomenology, course, and epidemiology of schizophrenia, McGlashan and Hoffman postulated that reduced synaptic connectedness resulting from early, developmental disturbance of synaptogenesis or faulty synaptic pruning is at the root of schizophrenia (3). More specifically, an innately sparse synaptic substrate combined with normal pruning in childhood and adolescence or a normal substrate combined with abnormally accelerated pruning could theoretically reach a critical threshold at which deficient synaptic connectivity manifests as abnormal perceptions and ideas. Because the model incorporates both static and dynamic components, it can account for some of the apparently competing postulations of schizophrenia pathophysiology. Caution is required, however, because integrative models of the development of schizophrenia have been foiled in the past by the remarkable heterogeneity of the illness.

CONCLUSIONS

Part of "47 - Schizophrenia: Course Over the Lifetime "

From the time schizophrenia was defined, it has been viewed as a chronic, lifelong disease. Yet its specific manifestations along the life cycle have been poorly described, mostly because of inherent methodologic difficulties. Improved medical record keeping and the realization that understanding the course of illness is essential to the understanding the pathophysiology of the illness have been behind the modern long-term follow-up studies. Determining, for example, the earliest manifestations of the illness or the trigger and the length of the window of deterioration has implications for preventive and palliative treatment. Even if otherwise possible, the identification of clinical correlates of progressive cortical atrophy by computed tomography, magnetic resonance imaging, or the biological meaning of spectroscopic abnormalities in synaptic connectivity requires detailed description of the illness course. As more research is focused on these issues, important information about the nature of schizophrenia itself will result.

Increasingly, neurocognitive paradigms are used to study patients with schizophrenia. With such paradigms, the cognitive abnormalities in schizophrenia are characterized by means of experimental and clinical tests. These techniques have indicated that some types of cognitive impairment are not only reliably present in schizophrenia, but are also central and enduring features of the disease. This chapter, a revision of the one published in 1995, focuses on certain recent advances in characterizing the precise nature of cognitive impairments in schizophrenia, on understanding the implications of these for treatment given the course and relationship to outcome of these variables, and on novel applications of neurocognitive approaches to the genetics of schizophrenia.
Cognitive abnormalities were noted by early investigators of schizophrenia. In the original clinical descriptions of schizophrenia made by Kraepelin (64), he commented, “Mental efficiency is always diminished to a considerable degree. The patients are distracted, inattentive… they cannot keep the thought in mind.” Some years later, Shakow (95) began a series of studies in which he examined abnormalities in patients’ reaction time in response to different types of readiness information and imperative stimuli. Hunt and Cofer (54) noted the intellectual quotient (IQ) of schizophrenic patients to be lower than that of normal controls. However, the increasing influence of psychodynamic theory tended to minimize the significance of the cognitive deficits of schizophrenia. It was thought that the deficits displayed on formal psychologic testing were secondary to impaired motivation or cooperation, gross breakdowns in reality testing, or disordered thought processes.

This view changed rapidly with the advent of *in vivo* techniques of brain imaging. First, it became evident that the lateral cerebral ventricles of patients with schizophrenia are larger than those of controls on computed tomography (96). Second, functional brain imaging suggested that the frontal lobe blood flow or metabolism of schizophrenic patients is decreased. Moreover, it was shown that one type of cognitive impairment, poor performance on the Wisconsin Card Sorting Test (WCST), is directly linked to impaired activation of the prefrontal cortex in regional cerebral blood flow (106). It was within this context that a series of studies in which broad neuropsychological test batteries were used demonstrated that patients with chronic schizophrenia could not be reliably discriminated from heterogeneous brain-damaged populations (69). These findings led to a reinterpretation of the original neuropsychological studies; it was increasingly realized that patients with schizophrenia perform in the range typically found in brain-damaged populations because schizophrenia involves structural and functional abnormalities of the brain that are, in some sense, primary, and compromise to a differential degree frontal lobe and temporal lobe function. From this perspective, schizophrenia is viewed as a disease of cortex in which information processing dysfunction is an obligatory concomitant.

We examine certain crucial, conceptually driven issues that derive from this view: What is the course of global cognitive impairment in schizophrenia? What is the character of neurocognitive impairments in schizophrenia? What is the relevance of traits like neurocognitive impairment to linkage or association studies in which the goal is to discover susceptibility genes relevant to the etiology of schizophrenia? We conclude this chapter by noting that neurocognitive impairments may be of prognostic significance in schizophrenia because of the importance of such functions in providing orientation to and encoding relevant environmental information, remembering new information, propitiously

retrieving old information, and working on line with old and new information to make responses or decisions. In this account, cognitive impairments in schizophrenia can be considered target symptoms that must be corrected.

COURSE

Part of "48 - Neurocognitive Functioning in Patients with Schizophrenia: An Overview "

Several contrasting views of the course of cognitive function in schizophrenia are extant. One view suggests that cognitive deficits become progressively worse throughout the long duration of the illness. After an insidious onset, patients' intellectual functions become weaker and social skills become coarser (73). A second view suggests that cognitive deficits, once they arise, remain relatively stable; this view is thus consistent with the notion of a static encephalopathy.

It is clear that once the clinical manifestations of the illness become overt, a sharp decline in cognitive ability takes place in many patients. In longitudinal studies spanning the premorbid and morbid periods, Schwartzman and Douglas (92) found a significant decrement in the performance of schizophrenic patients tested on an army intelligence examination (standard deviation of nearly 0.5), whereas the score of controls improved. (The patients were similar to controls in the premorbid period.) In the study of Weickert et al. (105), about 50% of a large series of treatment-refractory patients exhibited a large decline in IQ (> 10 points) from estimated premorbid levels, although a minority of patients had marked cognitive limitations from early on (see ref. 89). This is not say that subtle premorbid deficits do not exist in the majority of patients. Recent population-based studies have demonstrated attenuations in intelligence measures in schizophrenic patients-to-be (13 ,16), in addition to delays in the attainment of some early developmental milestones (58).

Studies of patients during their first episode of schizophrenia substantiate the view that marked cognitive abnormalities are present at the very onset of the illness. In several studies (8 ,36), the neuropsychological profile of first-episode schizophrenic patients was remarkably similar to that of patients with chronic schizophrenia and did not show a decline at 1- to 2-year follow-up. Both groups of patients performed poorly on a wide range of tests, including tests assessing memory, executive functioning, and attentional abilities.

A number of cross-sectional studies searched for evidence of decline during the chronic phases of the illness. Davidson et al. (14) reported a decline of two to three points per decade in a global measure of cognitive functioning, the Mini-Mental State Examination, across the range of 25 to 95 years. (To place this in perspective, the decline in patients with Alzheimer disease is 1.5 points per year.) Consistent with these results, Harvey et al. (49) recently found that elderly patients in this cohort display a marked decline on a clinical global rating of functioning. However, when patients were followed longitudinally on a variety of cognitive measures for 1- to 2-year periods, little change was evident. As Harvey noted, the changes were not continuous, nor did they occur in the sample as a whole. It is possible the effects observed were secondary to the interaction between compromised cognitive reserve in schizophrenia and normal aging; it is also possible that high doses of neuroleptics and long-term institutionalization had a significant effect on daily living skills and some cognitive functions.

In contradistinction to these findings, Goldstein and Zubin (41) found no differences in performance on the complex cognitive tasks of the Halstead Reitan Battery between large samples of younger and older patients with chronic schizophrenia. Heaton et al. (51) demonstrated that a large sample of older schizophrenic outpatients did not manifest deterioration in performance above and beyond that of normal aging. Hyde et al. (55) used a cross-sectional approach in which successive cohorts of schizophrenic patients were assessed. The study design allowed comparison over an extremely wide range of duration of illness (patients ranged in age from 18 to 70 years). In addition, each cohort was matched on a measure of premorbid intellectual ability, and patients with confounding neurologic or systemic diseases were excluded. No significant differences between age cohorts were noted on tests known to be sensitive to progressive dementias: the Mini-Mental State Examination, Dementia Rating Scale, verbal list learning, and semantic fluency. Thus, over five decades of illness, no progression was noted. A synthesis of these results suggests that in the modal patient, a sharp decline in cognitive ability, including general intellectual efficiency, occurs around the time of the onset of clinical symptoms (± 3 to 5 years), which is followed by an arrest in deterioration and a long period of impaired but stable cognitive function.

This view of the natural history of schizophrenia is consistent with a neurodevelopmental perspective (107) in that a prenatal lesion remains silent for years before manifesting itself in overt symptomatology and cognitive impairment. Contrary to some interpretations, Kraepelin (64) held to this account, stating, "As a rule, if no essential improvement intervenes in at most two or three years after the appearance of the more striking morbid phenomena, a state of weak mindedness will be developed which usually changes slowly and insignificantly." At the very least, the set of findings suggests that cognitive impairment in schizophrenia is an enduring feature of the disorder.

COGNITIVE IMPAIRMENTS

Part of "48 - Neurocognitive Functioning in Patients with Schizophrenia: An Overview "

It is possible that nearly every cognitive function of a schizophrenic patient is impaired, and to an equivalent degree (1 ,2). However, we examine three functions in detail because (a) evidence has been found of differential impairments,

especially in the cognitive domains related to frontal system executive and attentional systems and medial temporal memory systems; (b) these measures are important in regard to outcome (see below); (c) ongoing and systematic experimental work indicates that these cognitive functions can be mapped onto neural systems in a principled manner in normal and schizophrenic persons (30); and (d) such measures are useful in intermediate phenotyping.

Attention

Early descriptions of the clinical phenomenology of schizophrenia emphasized impairment of volitional attention. This clinical observation has been amply supported by many years of experimental study with the use of a wide variety of tasks. Recent models have sharpened the lines between selective attention, shifting attention, and biasing for and encoding relevant target information. We investigate some of these functions by examining three tasks: the Continuous Performance Test (CPT), the Covert Visual Orienting test, and the Stroop Test.

The classic test of selective attention is the Stroop color–word task, in which a word (e.g., red) can be printed in incongruent colors (e.g., green). Depending on instructions, the task is either to name the actual word or name the ink color in which the word is written. The attentional task requires the subject to focus selectively on one dimension of the stimulus and ignore or inhibit contextually inappropriate response tendencies. Normal subjects are slowed when they have to name a color of ink that is incongruent with the word because they have to inhibit their overlearned tendency of reading the word (see ref. 68 for review). Schizophrenic patients may have differential problems on this task in reaction time or accuracy, a finding that has been taken to suggest that they have disproportionate difficulty in inhibiting overlearned tendencies (of reading the word), and may be susceptible to failure in conditions of cognitive conflict more generally, because they are unable to use the contextual information appropriately (e.g., by focusing) (22 ,83).

Another type of task requires covert shifts of attentional resources in response to task instructions or cues, but this time in anticipation of a target in a particular location. It was pioneered by Posner and Dehaene (84). In this paradigm, participants view a central fixation point flanked by two small squares, within which a target is to appear. Participants are to respond as quickly as possible to the target. The reliability with which a preceding cue predicts the location of the target is manipulated and thus provides a measure of two components of selective attention: *engagement* (the benefit of a valid cue as evidenced by a fast response) and *disengagement* (the cost of focusing on an invalid cue followed by orientation and response to the actual location of the target). Although qualitative problems have been reported in patients in this domain (e.g., hemifield-dependent RT effects or a disproportionately slow response to invalid cues), several other studies have not found differences beyond general slowing (35).

A test of “sustained” attention, the CPT, has been used to demonstrate consistently that patients with schizophrenia “miss” targets (77). This task involves monitoring a random series of numbers or letters that are represented continuously, often at a rate of approximately one per second. Participants are asked to detect a target event by pressing a response button and to avoid responding to foils or distracting stimuli.

In an important study of the CPT, Servan-Schreiber et al. (94) showed that when the delay interval between the cue and the stimulus to which a response is to be made was increased to 5 seconds, patients were disproportionately inaccurate in their responding. It is possible that the use of rather long delays changes the basic nature to one of delayed response. Thus, in a recent study, Elvevaag et al. (26) were unable to replicate these findings of delay-induced impairment. Indeed, of the numerous errors made by the patients with schizophrenia, disproportionately more were omission errors at short delay intervals and low target probabilities, a finding taken to suggest a specific problem in rapidly encoding and acting on the imperative stimulus (i.e., constructing a representation of the stimuli to be attended to) under certain unengaging situations (i.e., when few responses are required) or in biasing perceptual representations for target recognition, presumably by an executive system. Based on work on a very different paradigm involving short-term memory in the auditory system, Javitt et al. (56) also proposed that precision or efficacy of encoding is impaired in schizophrenic patients.

Memory

Memory impairment is often the most striking feature of neurocognitive impairment in schizophrenia. Newer work has sought to determine if patients with schizophrenia have qualitative abnormalities in specific stages of mnemonic processing. Toward this end, Elvevaag and colleagues conducted an encoding study in which subjects had to state whether the letter *a* was present in a word (shallow level) or make a decision as to whether the word represented a living thing or not (deep level). Much previous work has demonstrated that words are recalled better when they are encoded deeply. Preliminary results indicated that although patients’ performance was worse than that of controls, they showed the same benefit of deep encoding (B. Elvevaag and T. E. Goldberg, 2001, *unpublished observations*). Although Kareken et al. (60) noted that failures in strategy-driven semantic encoding on this task contributed to impaired performance, their measures were indirect. Elvevaag and colleagues (24) also examined schizophrenic patients’ susceptibility to “false recognition.” They found that patients not only did patients make fewer false-positive errors by incorrectly recognizing semantic lures when poor general memory

(e.g., impaired recall or recognition) was covaried, but they also again were not differentially impaired (24). Consistent with this finding, another study found that susceptibility to interference effects in patients with schizophrenia in so-called AB-ABr paradigms (in which an initial list of paired associates is presented, followed by representation after the items have been "shuffled") is not a differential problem, but rather one that is confounded by general memory problems (B. Elvevaag and T. E. Goldberg, *unpublished observations*). Together, these findings demonstrate that patients with schizophrenia respond in a systematic and lawful manner to a variety of manipulations that target specific mnemonic encoding and orthogonalization (e.g., resistance to interference) processes. Thus, patients may have subtle impairments in different mnemonic processing stations that additively or interactively produce effects of large magnitude.

Moreover, the memory problem in schizophrenia does not appear to be one of binding (the ability to learn associations between various items and distinguish those items from other items that may be similar). This has implications for those who premise aberrant consciousness based on so-called binding abnormalities (12).

Working Memory

Patients with schizophrenia often seem unable to maintain some form of volitional control over the maintenance and manipulation of even basic information. They appear to have difficulty in formulating plans, initiating them, and flexibly changing a strategy once it is no longer effective; they also have difficulty in using feedback efficiently. Moreover, patients sometimes have problems when interrupted; they appear to forget what they were doing after only short periods of interference. One construct that attempts to capture these types of processing failures is working memory, which can involve not only the storage of information over brief delays, but the simultaneous storage and processing of information in a capacity-limited store or computational workspace. These types of behavior have been investigated in various laboratory-based neurocognitive tasks, including the Brown–Peterson test, digit span, WCST, Intradimensional/Extradimensional Set Shifting Test, and various delayed-response tasks.

Patients with schizophrenia have difficulty on the Brown–Peterson test, in which words have to be remembered over short delays during which covert rehearsal is prevented, presumably because of a compromised executive component. Patients are differentially sensitive to longer delays and larger memory sets (38a). However, patients perform abnormally even on basic short-term verbal working memory tasks, including digit span (100)

Several investigators demonstrated that schizophrenic patients exhibit deficits on the WCST, which demands set shifting, response to feedback, and abstraction (28). Patients seem to have difficulty abstracting concepts, and they also make perseverate responses to incorrect responses. Shallice et al. (95a) stressed the consistency of executive deficits in their detailed analyses of single cases, as most patients in their series displayed difficulties in generating rules for the WCST or solving puzzles of the Tower of Hanoi type.

Strong evidence indicates that the WCST may involve the working memory system. For instance, Sullivan et al. (101) found that WCST perseveration is strongly associated with other tests that are thought to require working memory, including self-ordered pointing (in which a subject monitors his or her own series of responses). Gold et al. (34) found the WCST to be highly correlated with a letter–number span task that involves information maintenance and manipulation over short delays. Statistical differences between normal and schizophrenic subjects on the WCST were eliminated when letter-number span performance was covaried, which suggests that both tasks are performed in a similar multimodal or all-purpose cognitive workspace

Much recent work has focused on a task requiring both intradimensional and extradimensional set shifting, in effect a componential version of the WCST. In intradimensional shifts, subjects are required to change their response set to an alternative design within a category (e.g., a new exemplar of a line design) while an irrelevant dimension (e.g., shape) introduced earlier continues to be ignored. In a later stage, an extradimensional shift is demanded as new exemplars are introduced, but subjects are now required to respond to the previously irrelevant dimension (e.g., shapes rather than lines). Subjects make decisions based on feedback after each trial. Patients with chronic schizophrenia display markedly impaired attentional set shifting on the intradimensional/extradimensional task. They demonstrated a significantly higher rate of attrition at the intradimensional shift stage in comparison with patients with frontal lobe lesions, and they were similarly impaired in comparison with patients with frontal lobe lesions at the extradimensional shift stage (79). Patients with chronic disease also showed impairments in regard to Tower tasks, spatial memory span, and spatial working memory tasks. Thus, patients with schizophrenia showed an overall deficit in executive function, often greater than that observed in patients with frontal lobe lesions (80).

Several studies have indicated that an impairment of working memory is present in schizophrenia, even in patients who are relatively intellectually intact. For instance, Pantelis et al. (79) found that although patients with a high IQ performed better than patients with low IQ on the intradimensional/extradimensional task, their performance was still remarkably abnormal, especially in the extradimensional shifts. Elliot et al. (21) were able to confirm these results, even in patients with preserved intellectual function (i.e., IQs > 100). Weickert et al. (105) used a different methodology to reach similar conclusions. They found that nearly all patients—irrespective of whether they exhibited

developmentally compromised intellectual function, normal premorbid intellectual function that declined significantly (the modal subgroup in this study), or preserved intellectual function (i.e., both current and putative premorbid IQ was normal)—displayed deficits in comparison with a normal control group on the WCST measure of perseveration. These results indicate that working memory may represent a core deficit in schizophrenia.

Another set of studies also argues for a deficit in working memory's "visual scratchpad." They are particularly important because failure on this class of delayed response tasks is often taken to be the signature of abnormalities in dorsolateral prefrontal cortex, an area uniquely positioned and designed to exert control over a wide variety of information processing. Using an ocular motor-delayed response paradigm developed by Goldman-Rakic (40) for use in primates, Park et al. (82) found that patients with schizophrenia have grave difficulties maintaining information for location over a brief delay in which they have to perform an interference task. Fleming et al. (29) replicated the findings of this study by using short-term memory for visual patterns. Because patients in these studies also were impaired on control tasks that did not have delays, encoding problems may have contributed to overall level of performance.

NEUROCOGNITION AS AN INTERMEDIATE PHENOTYPE

Part of "48 - Neurocognitive Functioning in Patients with Schizophrenia: An Overview "

Although schizophrenia is a heritable condition, linkage studies in which diagnosis is used as a phenotype have been disappointing, as few significant or replicable chromosomal loci have been identified (20). Using psychiatric diagnosis as the major phenotype may be a major confound. One possible reason is that people may not inherit schizophrenia *per se*, but rather a variety of information-processing deficits from which schizophrenia emerges. In other words, although impairment in any given cognitive process may exact only a small cost in social and vocational functioning, a constellation of impairments may be disabling and result in the emergence of psychosis. Thus, understanding the genetic architecture of individual processes may well be critical for understanding the genetics of "schizophrenia." This account is consistent with a polygenic model of schizophrenia, which implies that the genetic complexity of schizophrenia qua schizophrenia can be reduced by determining affected status based on neurobiological or neurocognitive dimensions; the genetic architecture of these dimensions is simpler than that of schizophrenia but segregates both illness and family risk for illness. This approach involves identifying abnormalities that (a) are quantitative, stable, and enduring; (b) have a pathophysiology that involves neural systems implicated in the disorder; and (c) have a clear effect on outcome. Certain cognitive functions may meet these criteria.

A spate of work has examined early stimulus processing and cognition in relatives of patients with schizophrenia. This so-called high-risk approach has several strengths; for example, abnormalities cannot be attributed to florid psychopathology, cooperation, and medication. It can also be used to identify cognitive processes that may serve as intermediate phenotypes. Several recent studies, in addition to many older ones (65), have produced strong evidence that relatives of patients have subtle impairments in select cognitive functions. In a study of Cannon et al. (6), siblings showed deficit profiles intermediate between those of patients and controls in verbal memory, abstraction, attention, and language. Faraone et al. (27) examined neurocognitive performance in 35 relatives (sibs and children) and 72 normal controls and found deficits in abstraction, attention, and verbal memory in relatives. Classification analysis was highly significant. Studies with other paradigms, including backward masking, delayed response, and verbal working memory, also revealed differences between sibling and controls (10 ,46 ,82). In an important study, Cassens et al. (7) showed that a variety of tasks demanding frontal lobe processing, including complex verbal working memory, semantic encoding, and source monitoring, are not only heritable but are impaired in a stepwise genetically-at-risk fashion in the monozygotic and dizygotic co-twins of schizophrenic persons.

However, simply examining group differences does not directly address issues of familiality/heritability. A newer approach uses computations of relative risk (RR) (88) in necessarily large samples of controls, sibling, and index cases. One type of RR is based on comparisons of concordance rates for impairment on a given trait within sibships with the rate of impairment in the general population. The statistic indicates whether a given quantitative trait is familial and by inference heritable. It is important for predicting the strength of genetic effects on a given phenotype.

In an earlier study in which Goldberg et al. (39) examined monozygotic twins discordant for schizophrenia, they found subtle attenuations of performance in otherwise-well co-twins when they were compared with normal twins on neurocognitive measures indexing working memory, speed of information processing, and episodic memory. The concordance for these traits was thus higher than the concordance for illness. Based on these results, Egan and colleagues (19a) have used a variety of paradigms to assess specific cognitive functions in a sample of schizophrenic index cases, their well siblings, and healthy controls. Specific tests were selected because they reliably measure impairments in schizophrenic patients, are stable, and, in many cases, are known to be heritable. These criteria are obviously of key importance in determining if a person is impaired because of genetic or environmental factors, or simply because of measurement error.

They first assessed RR of the CPT, given that prior work from other groups had suggested that this type of test might be sensitive to certain cognitive impairments in relatives of

patients (19). In the study of Chen et al. (9), who reported an extremely high RR in a Chinese cohort when degraded and nondegraded versions of a CPT were used, seemingly minor features of the methodology, including a sample in which siblings and parents with attendant age differences and a low educational level were combined and psychotic relatives were included, might have led to artifactual inflation of risk computations. Egan et al. (19a) examined 147 patients with schizophrenia, 193 of their siblings, and 47 controls. They did not include parents, and the educational of the groups was high and equivalent in siblings and controls (above grade 13). The IQ of index cases was 94, for their siblings it was 107, and for controls it was 108. The percentage of siblings carrying the schizophrenic spectrum diagnosis was relatively low—under 5%. In a version of the CPT that had flanking distracters, they found that 50% of patients, 24% of siblings, and 18% of controls performed one standard deviation below the control mean when *d′* was used as a dependent measure. The RR for this phenotype was 2.1. This finding suggested that the cognitive demands that this test imposes are under genetic control, the alleles that control this type of information process may be overrepresented in some families of schizophrenic patients, and that this finding is not redundant with diagnosis. However, it was not clear whether CPT impairment is a disease-modifying variable or a susceptibility trait, given that the sibling group as a whole did not differ from controls. In contrast, examination with a test of continuous working memory (the so-called *n*-back task, which demands rapid encoding of stimuli, temporal coding, interference by a restricted set of stimuli, and maintenance) revealed that at "2-back" the RR was above 7.5 and that the sibling group as a whole was significantly impaired in comparison with normal controls, which suggests that the genetic structure that underlies impaired performance may also confer liability (37).

Impairments in several other domains of cognition have also been examined. To assess the suitability of cognitive function for use as a phenotype in genetic studies, Egan et al. estimated RR (19a) in the aforementioned cohort of siblings. They hypothesized that the RR of cognitive dysfunction would be moderate and that different subgroups of families would demonstrate different patterns of impairment. A set of instruments measuring these constructs included IQ, set shifting and working memory, memory, speed, and fluency. RR was estimated by using cutoff scores of one and two standard deviations below the control mean. Patients performed markedly worse than controls on all tests except a measure of premorbid intelligence. The entire sibling group showed impaired performance on the WCST, letter fluency, and Trails B. Siblings of patients with impaired performance also showed deficits on the CVLT, Wechsler Memory Scale-Revised (WMS-R), and Trails A. When one standard deviation was used as the cutoff, the RR of siblings was elevated on the Trails B (RR, 3.8). Trends (p = .01 to .05) toward an increased RR were also seen with the California Verbal Learning Test (CVLT), WCST, letter fluency, memory for stories, and Wide Range Achievement Test (WRAT) (RR, 1.7 to 2.8). When two standard deviations was used as the cutoff, the RRs were generally higher, ranging from 4.3 to more than 13. Correlations between tests of different cognitive functions were weak, which suggests they measure relatively independent processes; factor analysis confirmed this. Multiple regression analysis also demonstrated that impairment on one test did not predict impairment on another test in the sibling group. Thus, cognitive dysfunction along several dimensions is familial and probably genetic. The use of cognitive phenotypes may reduce clinical and genetic heterogeneity and improve the power of genetic studies of schizophrenia.

NEUROCOGNITIVE DEFICITS AND FUNCTIONAL OUTCOME IN SCHIZOPHRENIA

Part of "48 - Neurocognitive Functioning in Patients with Schizophrenia: An Overview "

By any standard, schizophrenia is a remarkably disabling illness. Among young adults in developed countries, it ranks near the top of causes of disability in both men and women (75). There is now increasing support for the idea that key aspects of disability, such as reductions in social competence and the capacity for independent living and vocational success, are the result of neurocognitive compromise.

Although the neurocognitive deficits of schizophrenia have been long recognized, their functional consequences have only recently been appreciated. Throughout most of the twentieth century, studies of the neurocognition of schizophrenia focused rather narrowly on attempts to define and characterize the deficits. However, initial forays to study the implications of these deficits for daily living suggested that neurocognitive deficits may be critical for functional outcome (50). Starting in the early 1990s, a large number of studies examined the associations between rather specific neurocognitive measures and functional outcome in schizophrenia. This being said, individual studies were underpowered with small sample sizes and were mainly atheoretic. To make inferences even more difficult, there was little overlap in either the neurocognitive or the functional outcome measures. Nonetheless, some conclusions from this literature can be drawn.

The literature generally supports the conclusion that neurocognitive deficits are related to functional outcome in schizophrenia (42 ,45), including skill acquisition in psychosocial rehabilitation programs, laboratory assessments of social problem-solving ability or analogue measures of instrumental skills, and broader aspects of behavior in community outcome and activities of daily living.

Indeed, using intrapair differences in twins concordant for schizophrenia, Goldberg et al. (38) observed that virtually

all the variance on the Global Assessment Scale could be accounted for by differences in the performance of four neuropsychological variables: IQ, memory for stories, fluency, and card sorting. In this design, the experience of illness, institutionalization, medication, psychotic symptomatology, and, of course, genome is shared. Although in one sense the design "stacks the deck" because of its artificiality, it does illustrate the importance of neurocognition in predicting level of functioning. This is not to say that symptoms do not have an impact on social and vocational outcome; they do, at least in the short term. What is important to note is that cognitive impairment may also contribute in a unique manner to outcome. These results suggest that patients' deficits in learning new information, rapidly completing tasks, purposefully recalling old information, and generating novel plans or hypotheses may have an impact on their capacity to perform a job efficiently, take part in social transactions, and make decisions.

It is not clear which neurocognitive measures are the most useful predictors and correlates of functional outcome. Despite this lack of consensus, studies on the relationships between neurocognition and functional outcome have frequently included assessments for one or more of the neurocognitive constructs listed in Table 48.1 .

TABLE 48.1. NEUROCOGNITIVE CONSTRUCTS EXAMINED IN STUDIES OF FUNCTIONAL OUTCOME

Secondary memory	*Secondary* (also called *episodic* or *strategic*) *memory* refers to the ability to acquire and store information over a period of time that lasts for at least several minutes. Typically, this type of memory is assessed with a list of words or passages of text. The amount of information in the words or passages exceeds the immediate memory span.
Working or immediate memory	*Immediate memory* refers to the ability to maintain a limited amount of information for a brief time (usually a few seconds). Immediate memory is considered to be a component of working memory. Most of the studies of neurocognition and functional outcome have used passive tasks instead of more typical working memory tasks that require the information to be both maintained and manipulated.
Attention/vigilance	Sometimes called *sustained attention*, this ability involves maintaining a readiness to respond to a particular target stimulus and inhibiting responses to nontargets over a period of time. It requires one to distinguish signal (targets) from noise (nontargets), an ability known as *sensitivity*. It is typically measured with a CPT in which a series of briefly presented stimuli appear on a computer screen; subjects are asked to respond only to selected targets.
Executive functioning/ card sorting	*Executive functioning* refers to volition, planning, purposive action, and self-monitoring of behavior. Problem solving tests such as the WCST are frequently used to assess executive functioning. These tests assess the subject's ability to attain, maintain, and shift cognitive set.

CPT, Continuous Performance Test; WCST, Wisconsin Card Sorting Test.

This literature includes a substantial number of replicated findings (Fig. 48.1). A tally of replications by themselves is not entirely useful because they do not indicate how many times an association was sought, nor the strength of the relationships. Metaanalysis is more useful for examining the strengths of associations across studies. Table 48.2 shows the results of metaanalyses of four key neurocognitive constructs collapsed across the three outcome domains. In this type of analysis, the combined sample sizes are large and the relationships between neurocognition and functional outcome are highly significant. The metaanalyses demonstrate that these four neurocognitive constructs are significantly related to functional outcome and that the effect sizes for these relationships are generally in the medium range.

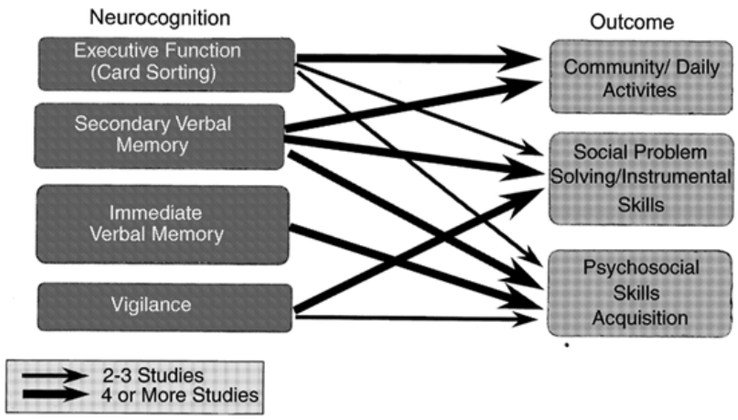

FIGURE 48.1. Neurocognitive constructs and functional outcome. Two levels of replication are represented. A *heavy arrow* indicates that at least four studies found a significant relationship between the neurocognitive construct and the outcome domain; a *thin arrow* indicates that significant relationships were uncovered in two or three studies.

TABLE 48.2. METAANALYSES: NEUROCOGNITIVE PREDICTION OF FUNCTIONAL OUTCOME

Domain	Total Sample Size	Pooled Estimated r^a	Effect Size	*p* Value
Secondary verbal memory	727	.29	Medium	<.0001
Immediate verbal memory	188	.40	Medium–Large	<.0001
Executive functions (card sorting)	1002	.23	Small–Medium	<.0001
Attention/vigilance	682	.20	Small–Medium	<.0001

[a]Estimates weighted by sample size.
From Green MF, Kern RS, Braff DL, et al. Neurocognitive deficits and functional outcome in schizophrenia: are we measuring the "right stuff"? *Schizophr Bull* 2000; 26:119–136, with permission.

Most of the studies in this area have used rather specific measures of neurocognition, and it is the results of these

studies that are reflected in Fig. 48.1 and Table 48.2 . Although effect sizes for the individual constructs are mainly in the medium range, they can become quite large when global or composite measures of neurocognition are used instead of individual measures (48 ,104). Such composite measures indicate that neurocognition can explain between 20% and 60% of the variance in outcome.

How do these relationships compare with those for clinical symptoms? In general, psychotic symptoms (hallucinations and delusions) fare rather poorly as predictors and correlates of functional outcome (43). Negative symptoms are more highly correlated with functional outcome, but across studies, the relationships are neither stronger nor more consistent than those for neurocognitive deficits (17 ,48 ,104). Little is known about disorganized symptoms, which often constitute a separate syndromal dimension that includes formal thought disorder, although recent studies suggest that this type of symptom may be related to functional outcome (76 ,86).

The relative contributions of symptoms and neurocognition to functional outcome have only rarely been tested with appropriate statistical analyses, including multiple regression (48 ,71). These studies do, however, support the idea that the neurocognitive contributions to outcome are stronger than those of symptoms. In one study (104), sophisticated path analyses were used to test the associations among positive symptoms, negative symptoms, cognition, and activities of daily living in two separate samples of schizophrenic patients. A global measure of cognition had strong relationships with activities of daily living (48% and 42% of the variance in the activities of daily activities for the two samples). Various causal models were tested in which certain pathways were omitted. The pathway from cognitive impairment to functional outcome was necessary in the model; the fit was poor when it was omitted. To the extent that symptoms were correlated with functional outcome, the relationships seem to be indirect. In other words, although negative symptoms covary to at least a modest extent with neurocognition (17 ,104) and their relationship to function appears to be mediated through this overlap, *in toto* the results suggest that cognitive impairment, rather than symptoms, most strongly influences functional outcome.

Just as the neurocognitive deficits in schizophrenia are not fully specific to schizophrenia, the correlations with functional outcome are unlikely to be specific to schizophrenia. Based on the role of neurocognitive deficits in other disorders, one would not one expect them to be. The functional consequences of neurocognitive deficits have been observed in a variety of neurologic conditions, including head injury, Alzheimer disease, multiple sclerosis, Parkinson disease, and AIDS encephalopathy (51 ,87 ,103). In fact, neurocognitive deficits have been associated with activities of daily living even in a nonclinical sample of elderly persons (74).

The work so far has been aimed at determining *whether* neurocognition is related to functional outcome. At this time, it can be concluded that it is related, and the effect sizes are generally medium for individual constructs and generally large for composite measures. However, rather little is known about *how* neurocognition is related to functional outcome. It is likely that some cognitive domains have direct, causal relationships, although others may be related to functional outcome through mediators, such as social cognition or the application of knowledge and reasoning to problem solving.

EFFECTS OF MEDICATIONS ON NEUROCOGNITIVE DEFICITS

Part of "48 - Neurocognitive Functioning in Patients with Schizophrenia: An Overview "

One of the most surprising aspects of conventional antipsychotic medications is that although they usually have a profound impact on psychotic symptoms, their effects on neurocognitive

deficits tend to be negligible (7 ,11 ,98). Occasionally, treatment with conventional antipsychotic medications has led to improvement in basic perceptual or attentional processes (3 ,98). However, it can be concluded that changes in neurocognition, if they occur, are small compared with the changes in psychotic symptoms. In terms of disability, this presents a rather unfortunate mismatch in which the domain of illness most affected by conventional medications is not the domain most closely linked to functional outcome.

Conventional antipsychotic medications probably do not directly impair neurocognitive abilities, but they can do so indirectly when they involve the simultaneous administration of anticholinergic medications. Anticholinergic medications given for extrapyramidal side effects compromise certain neurocognitive abilities. Although the range of effects of anticholinergic medications is not well characterized, they may disrupt aspects of secondary verbal memory that rely on rehearsal strategies (18). Other aspects of memory, including immediate or working memory, appear to be less affected (4 ,38), and the effects on other neurocognitive abilities, such as visual processing, are relatively unknown.

The situation with newer atypical antipsychotic agents appears to be more promising. Initial interest in the neurocognitive effects of new antipsychotic medications was stimulated by a series of (mainly open-label) studies of clozapine (4 ,38 ,47 ,53 ,67). The results of these studies were surprising in two respects: First, in most of the studies, clozapine treatment resulted in improvement in verbal fluency (i.e., the ability to generate words that begin with a certain letter or belong to a certain semantic category) and possibly psychomotor speed. Second, the initiation of clozapine treatment in some studies appeared to have at least short-term detrimental effects on visual memory and possibly verbal working memory (38 ,47 ,53).

A large number of studies are emerging for recently approved antipsychotic medications: risperidone, olanzapine, and quetiapine (31 ,85 ,90 ,99). These studies (again, mostly open-label) have generally shown that they have benefits for neurocognition in comparison with conventional antipsychotic medications. Indications of short-term detrimental effects, similar to those seen in some clozapine studies, have so far not been reported for the other newer antipsychotic medications. A rather comprehensive review (72) and a metaanalysis (61) of the existing literature have both provided a basis for optimism about the beneficial neurocognitive effects of newer medications. The metaanalysis of Keefe et al. (61) showed significant effects for the new generation of medications in comparison with conventional agents across a range of neurocognitive areas, including attention, executive functions, and verbal fluency.

The emerging optimism in this area should be tempered by the fact that the lion’s share of the studies have been “open-label,” with the associated risks of experimental bias that can accompany such studies. In many of these studies, a single group was assessed at baseline while on a conventional medication and then assessed again after being switched to an atypical medication. Inferences from these types of studies are necessarily tentative because no control is made for repeated testings and possible practice effects. A small number of parallel group blinded studies are emerging for clozapine (4 ,108), risperidone (44 ,62), and olanzapine (85). These studies offer more convincing support for the proposal that new medications convey neurocognitive benefits in comparison with conventional medications.

Even more than clinical trial studies of symptom reduction, studies of neurocognitive effects raise questions about alternative explanations for treatment effects. For the most part, studies have not been designed or analyzed in a way that allows one to rule out indirect effects. For example, if a newer antipsychotic medication has a better clinical effect than a conventional medication, it may improve neurocognition as an indirect benefit of greater symptom reduction. This explanation, although plausible, seems unlikely. Several studies have noted that changes in neurocognition appear to be independent of any changes in symptoms (38 ,44 ,47 ,67 ,62). An alternative explanation is that the neurocognitive benefits of newer medications are mediated by a reduced need for anticholinergic medications. Although this may turn out be true in some instances, the differential use of anticholinergic medications did not explain the effects of risperidone on immediate and secondary verbal memory in one project (44 ,92). The beneficial effects of newer medications on neurocognition may be mediated by lower rates of extrapyramidal symptoms. It is not known whether such effects will be seen in comparisons with very low doses of conventional medications, when side effects are minimal. Moreover, although a number of mechanisms have been proposed (5-hydroxytryptamine subtype 2A antagonism, indirect glutamate release, dopamine D4 antagonism), all are problematic, and simple reduction of D2 blockade or transient D2 blockade remains a viable explanation of “atypicality” (59). Thus, it is possible that the administration of conventional neuroleptics in inappropriately high doses resulted in a lack of improvement, although dose-reduction studies do not support this explanation (93 ,97). The pharmacologic basis for cognitive enhancement remains obscure. In any event, a single neurotransmitter effect seems unlikely to account for the effects, which probably involve a constellation of actions at serotonergic, adrenergic, cholinergic, and dopaminergic receptors (72). However, it is important to recognize that such actions probably are initiators of changes that ultimately effect gene expression for major excitatory and inhibitory transmitters and their receptors and neuroplasticity.

Although these alternative explanations require serious consideration, it remains possible that the neurocognitive effects of the new generation of antipsychotic medications

are a direct result of the medications themselves (rather than indirect effects of a reduction of clinical symptoms or anticholinergic medications). If so, the effects are serendipitous. These medications were not developed or initially evaluated with neurocognition in mind. The possible role of adjunctive pharmacology specifically for neurocognitive deficits is now receiving serious consideration.

A key challenge for directing studies of adjunctive nosotropic medications in schizophrenia is deciding which neurotransmitter systems are most critical in the pathophysiology of neurocognitive deficits in schizophrenia. One that has been implicated is the glutamate system (78). Based on the cognitive and behavioral effects of antagonists of the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptor, such as phencyclidine and ketamine, it has been suggested that schizophrenia may involve hypofunction of this receptor (66 ,70). Because the NMDA receptor is modulated by glycine, glycinergic agents can provide a useful means for manipulating glutamate function. Glycine itself has been utilized by Javitt et al. (56) with some effect on negative symptoms. The administration of D-cycloserine, a partial glycine agonist, resulted in a benefit in choice reaction time when it was utilized in conjunction with conventional antipsychotic medications (32), but not when added to clozapine (33). A full glycine agonist, D-serine, demonstrated some success in improving WCST performance (102). If these studies of adjunctive agents result in reliable improvement in neurocognition in schizophrenia, it may become routine for schizophrenic patients to receive a medication for each of the major domains of illness, clinical symptoms and neurocognitive deficits.

CONCLUSIONS

Part of "48 - Neurocognitive Functioning in Patients with Schizophrenia: An Overview "

In the lay imagination, schizophrenic patients experience problems in living because they are divided against themselves, out of touch with reality, and disorganized. The view of scientists, once not altogether different, has changed. Not only have the symptoms been defined and codified, but the neurobiological underpinnings of the disorder have begun to be described. Emerging also is a view in which cognitive impairments may be a relatively central feature of the disorder. Cognitive impairments are involved in the genetic etiology of schizophrenia. They seem enduring in that they are present for much of the clinical history and are associated with outcome. Cognitive impairments also may have a relatively well-delineated profile in which executive, memory, and attentional deficits are prominent. This account carries with it implications for treatment, in that cognitive impairments should be considered target symptoms in the same way as hallucinations, delusions, and anergia.

Michael J. Owen: Department of Psychological Medicine, University of Wales College of Medicine, Cardiff, Wales.

For much of this century, we have believed that genes play a role in the etiology of schizophrenia, but we have been frustrated in the search for specific mutations by diagnostic dilemmas and technologic shortcomings. Slowly, however, we have made substantive strides in the diagnosis and treatment of schizophrenia, and considerable progress toward an explication of its underlying neurobiology. In this chapter, we focus on the epidemiologic and genetic work that underlies much of the current clinical progress and the promises, perhaps to be fulfilled in the not-too-distant future, to facilitate the treatment, and even prevention, of this devastating disorder. We begin with updates on the epidemiology of schizophrenia and related disorders, followed by a review of its molecular genetic bases. We then consider research strategies that promise to explicate the genetic etiology of schizophrenia further in the next few years.

EPIDEMIOLOGY OF SCHIZOPHRENIA

Part of "49 - Molecular and Population Genetics of Schizophrenia "

Psychiatric epidemiology studies the distribution of disorders in well-defined populations. Its methodology emphasizes the use of representative samples with reliable and valid diagnoses, and a specified time of onset (1 ,2), to identify risk factors that explain why some populations are more vulnerable to psychiatric illness than others. Epidemiologic methods are also critical to an understanding of how frequently a disorder occurs, a concept often expressed in terms of prevalence, incidence, and lifetime risk. We consider the risk for schizophrenia by focusing on these measures.

Prevalence Rate

The prevalence rate of a disorder is the number of people in whom the disorder is diagnosed divided by the total number of persons examined in the population under study. The computed rate depends on several factors: the definition of the disorder, the total number of individuals examined in the population, and the procedure used to choose whom to examine. Ideally, the sample used to compute prevalence should be representative of the population as a whole. The prevalence rate is usually expressed as the number of cases per thousand people surveyed within a year, which is called the *1-year prevalence per thousand*. Studies of schizophrenia from around the world usually report these rates to range from a low of 0.6/1,000 to a high of 17/1,000 (3 ,4 ,5 and 6). Lifetime prevalence rates usually range from 0.9/1,000 to 3.8/1,000 (7 ,8 ,9 and 10), depending on the diagnostic criteria and methods of ascertainment.

The prevalence rates for schizophrenia are relatively constant between countries. Whether we consider East versus West, developed countries versus less developed countries, or other classifications, the 1-year prevalence of schizophrenia is approximately 0.5% and the lifetime prevalence is approximately 1.0%. In other words, schizophrenia is found in approximately one-half of one percent of the population at any point in time.

Incidence Rate

Another way of reporting the rate of schizophrenia in a population is to estimate the number of *new* cases that appear in the population during a specified period of time; this is called the *incidence rate*. Prevalence rates (as discussed above) include both new and old cases because once schizophrenia has emerged, it usually demonstrates a chronic, unremitting course. In other words, once patients are classified as schizophrenic, they usually remain schizophrenic. Like prevalence rates, incidence rates vary according to a number of variables, including the standards of diagnosis. In addition, incidence studies of schizophrenia entail the difficulty

of how to define onset. Unlike the onset of some disorders (e.g., stroke or head injury), that of schizophrenia is often insidious and confused easily with other problems. For example, early symptoms like social withdrawal or unusual thinking may be ignored or mistaken for indications of depression or substance abuse. Because the time of onset is difficult to determine, incidence rates are usually based on a patient's first visit to psychiatric services for schizophrenic symptoms. Thus, misdiagnosed and untreated cases can affect the accuracy of incidence rates significantly.

The incidence rate is usually expressed as the number of new cases in a given period per 100,000 population. For schizophrenia, incidence rates range from a low of 0.10 to a high of 0.70 (11 ,12). As was the case with the prevalence figures, the incidence of schizophrenia is generally stable over time and across geographic areas (13).

Lifetime Risk

Most persons with schizophrenia first become ill between 20 and 39 years of age. We call this the *high-risk period* for schizophrenia. Men tend to be younger at the time of onset than women (14 ,15 and 16), although schizophrenia develops in men and women at approximately equal rates (2). Because of the variability of age at onset, prevalence and incidence rates vary according to the age and sex composition of the population studied. The age distribution is particularly important when the probability or risk that schizophrenia will develop in a person during his or her lifetime is estimated (i.e., the lifetime risk). To estimate lifetime risk, the age distribution of the population surveyed should be taken into account (17).

The lifetime risk for schizophrenia ranges from 0.3% to 3.7%, depending on the definition of schizophrenia and the method of survey used (11 ,12 ,18 ,19). The World Health Organization study shows a narrow range of lifetime risks in 10 countries around the world (0.5% to 1.7%) (13), although it is higher in some genetically isolated populations in Palau, Micronesia, and areas of Finland (20 ,21). Taken together, studies of the lifetime risk for schizophrenia in the general population suggest it is around 1%. In other words, a schizophrenic disorder will develop in approximately one in every hundred people at some time in their life.

Risk Factors

Schizophrenia occurs around the world and in all cultures. International differences in rates of the disorder are usually attributed to diagnostic differences rather than to differences in true rates of illness. The use of broad, ambiguous diagnostic criteria before the late 1970s was an important factor underlying artificial differences in rates of mental disorders recorded in different geographic locales. In the 1960s, for example, the hospital incidence of schizophrenia in the United States significantly exceeded that of Great Britain (28.0/100,000 vs. 17.9/100,000 population), whereas the incidence of mood disorders in British hospitals exceeded that in the United States (36/100,000 vs. 7/100,000). These differences disappeared, however, when identical methods of diagnosis and assessment were used (22). Similarly, in the World Health Organization study, differences in incidence among 10 countries diminished when narrow, standardized diagnostic criteria were utilized (13 ,23).

A variety of risk factors have received attention in schizophrenia. These include, among others, a family history of the disorder, low socioeconomic status, complications during pregnancy and childbirth, sex, and fetal viral infection (18 ,24 ,25 ,26 ,27 and 28). A family history of the disorder and a negative relationship to social class are especially strong and frequently replicated risk factors. The familial basis of schizophrenia is considered further in the section on the genetic epidemiology of schizophrenia. It should be emphasized that although the focus of this chapter is the genetics of schizophrenia, many of the risk factors for the illness cited above are environmental, a fact that underscores the combination of genetic and environmental factors underlying the disorder. This point is stressed further in the discussion of twin studies, below; given an identical twin with schizophrenia, the risk that the disorder will develop in the other twin (who has identical genes) is far less than 100%.

GENETIC EPIDEMIOLOGY OF SCHIZOPHRENIA

Part of "49 - Molecular and Population Genetics of Schizophrenia "

Family Studies

There is little question that schizophrenia (and related disorders) runs in families. In a review of 40 European studies, selected for similarities in diagnostic and ascertainment procedures and performed between 1920 and 1987, the lifetime risks for schizophrenia in relatives of schizophrenic patients were as follows: parents, 6.0%; siblings, 9.0%; offspring of one parent with schizophrenia, 13.0%; offspring of two parents with schizophrenia, 46%; and identical twin of a patient with schizophrenia, 46% (18 ,19). Note that the risk to offspring exceeds the risk to parents. Because the biological relationship is the same (i.e., first-degree relatives), the risk to offspring of patients should be identical to the risk to parents of patients. This would be true under any genetic model. The difference occurs because, by definition, parents have reproduced, and the presence of schizophrenia has an adverse affect on the probability of doing so. The risks to second-degree relatives ranged from 6.0% for half-siblings to 2.0% for uncles and aunts. First cousins, a type of third-degree relative, had an average risk of 2.0%. Consistent with a genetic etiology, these figures show that as the degree of biological/genetic relatedness to a schizophrenic patient increases, so does the risk for schizophrenia.

Although recent studies have used more rigorous research methods and narrower, criterion-based definitions of schizophrenia,

they have essentially confirmed the familial basis of schizophrenia and provided evidence consistent with the genetic hypothesis. In their family study of the Roscommon area in Western Ireland, for example, Kendler et al. (29) reported that the risk to siblings of schizophrenic probands is 9.2%, consistent with the rates reported by Gottesman (18 ,19). The risk to parents of schizophrenic probands was 1.3%, somewhat lower than the 6.0% reported by Gottesman. In general, narrower definitions in modern studies result in somewhat lower risk figures than those reported previously. This point was demonstrated by Tsuang et al. (30), who reported the risk for schizophrenia in first-degree relatives of schizophrenics as 3.2%, compared with 0.6% for relatives of nonpsychiatric controls. Similarly, Guze et al. (31) reported rates of 3.6% and 0.56%, respectively. Despite the lower prevalence figures, both these studies reconfirmed that in comparison with the general population, relatives of people with schizophrenia are at significantly greater risk for development of the disorder. This in itself, however, is not sufficient to demonstrate a genetic basis. Additional strategies, such as twin and adoption paradigms, are necessary to parse out genetic and environmental determinants, and these are considered next.

Twin Studies

The two types of twins are monozygotic and dizygotic. Monozygotic twins (i.e., identical twins) share 100% of their genes, whereas dizygotic twins (i.e., ordinary brothers and sisters) share 50% of their genes. If both members of a twin pair have schizophrenia, they are considered *concordant* for the disorder; if one is schizophrenic and the other is not, they are considered *discordant*. If schizophrenia were caused by genetic factors alone, then concordance rates for monozygotic and dizygotic twins would be 100% and 50%, respectively. On the other hand, if it were caused essentially by environmental variables, then concordance rates for monozygotic and dizygotic twins reared in a common environment would be similar.

The empiric data lie between these extremes but provide clear evidence for a genetic component. For example, concordance rates from twin studies pooled by Kendler (32) were about 53% for monozygotic twin pairs and 15% for dizygotic twin pairs. A similar review by Gottesman (18 ,19) demonstrated median concordance rates of 46% and 14% for monozygotic and dizygotic pairs, respectively. Interestingly, monozygotic twins reared apart have about the same concordance rates as do twins reared together (33). At the same time, monozygotic concordance rates lower than 100% demonstrate an important role for environmental factors. When they obtained quantitative estimates of the relative roles of genetic and environmental factors by translating genetic concordance rates into “heritabilities” (the proportion of the variance between individuals that is attributable to genetic factors), Kendler and Diehl (34) found that about 70% of the variance could be attributed to genetic factors in a series of twin studies. Several recent studies in which DSM-III, DSM-III-R, or DSM-IV diagnostic criteria were used provided even higher estimates of heritability, in the range of 80% to 86% (35 ,36 ,37 and 38).

Studies of twins discordant for schizophrenia have also shed light on the role of genetic and environmental factors. Gottesman and Bertelson (39), for example, followed the Danish schizophrenic twin sample of Fischer (40). They reasoned that if genetic liability is transmitted to the unaffected member of the twin pair, but not expressed because of environmental factors, then their offspring should demonstrate the same genetic liability. This hypothesis was supported when 24 children of unaffected co-twins showed a monozygotic concordance rate of 17%, a rate almost identical to that in the offspring of the twins who had schizophrenia. In contrast, although the risk for schizophrenia in the offspring of dizygotic twins with schizophrenia was similar to the risk in monozygotic twins, the risk in the offspring of unaffected dizygotic twins was only about 2%. What type of environmental factors might contribute to the risk for schizophrenia? A variety of possibilities exist, but adverse events occurring early in development (e.g., gestation, birth) have received the most attention recently, in part because the occurrence of such events during that period may have particularly far-reaching biological consequences. McNeil et al. (41) showed, for example, a relationship of smaller hippocampi and larger ventricles to complications of labor and delivery in the ill member of monozygotic twin pairs discordant for schizophrenia. Tsujita et al. (42) showed evidence of postzygotic genomic discordance in discordant twins, which could influence subsequent transcription in one or more genes. It is thus evident from twin studies with a variety of designs that both genetic *and* environmental factors underlie the expression of schizophrenia. Adoption studies, considered below, further support this conclusion.

Adoption Studies

Like twin studies, adoption studies can disentangle genetic and environmental causes of disease (43). An important series of studies was performed in Denmark, thanks in part to its system of national registers. Among these, Kety et al. (44) studied 5,500 children from the Greater Copenhagen area who were separated from their biological families and adopted between 1923 and 1947. Although schizophrenia or a related disorder developed in only 1.9% of the control adoptees, schizophrenia or a related illness was diagnosed in 8.7% of the adoptees who were separated from a schizophrenic parent. When the biological relatives of schizophrenic and control subjects were compared, 5.8% of the relatives of schizophrenic probands had (definite or probable) schizophrenia, in comparison with 0.9% of the control relatives. The rates of schizophrenia did not differ between the adoptive relatives of the schizophrenic and nonschizophrenic

adoptees. Moreover, children born to nonschizophrenic parents but raised by a schizophrenic parent did not show rates of schizophrenia above those predicted for the general population.

Limitations of adoption studies include the possibility of transmission by the mother during pregnancy or delivery of a liability for schizophrenia via nongenetic biological, or other type of environmental, factors, even if the child is adopted away soon after birth. However, Kety et al. (45) found that 13% percent of paternal half-siblings of schizophrenic adoptees had schizophrenia, in comparison with only 2% of paternal half-siblings of nonschizophrenic adoptees. Because paternal half-siblings have different mothers, these results cannot be attributed to *in utero* (environmental) effects. Many of Kety's findings were replicated recently for schizophrenia (45) and for certain schizophrenia spectrum conditions (46) in a sample drawn from the rest of Denmark.

Data from the Finnish adoption studies (47 ,48) provide additional support for both genetic and environmental influence in the transmission of schizophrenia. Together, family, twin, and adoption studies show consistently that the biological relatives of people with schizophrenia themselves show higher rates of schizophrenia and related disorders when compared with appropriate control groups, regardless of whether they are raised by biological or adoptive parents.

EPIDEMIOLOGY OF SPECTRUM DISORDERS

Part of "49 - Molecular and Population Genetics of Schizophrenia "

The term *related disorders* is used to describe schizophrenic illness of (generally) lesser severity. In fact, genetic studies provide evidence for a spectrum of disorders that are similar to schizophrenia and caused by the same genes. A disorder is considered to be in the schizophrenia spectrum if it occurs more frequently among the biological relatives of schizophrenic patients than it does among the relatives of people who do not have schizophrenia. Many of the behavioral genetic methodologies used to delineate genetic and environmental factors in the etiology of schizophrenia (e.g., family, twin, and adoption studies) have also provided evidence of a genetic etiology in schizophrenia spectrum conditions. Evidence for inclusion in the schizophrenic spectrum is considered next for several candidate disorders.

Psychotic Spectrum Disorders

In about 9% of the first-degree relatives of schizophrenic patients, a psychotic disorder develops that does not meet the criteria for either schizophrenia or a mood disorder (18 ,49). Two prominent examples are schizoaffective disorder and psychosis not otherwise specified (NOS). As the name suggests, the term *schizoaffective disorder* describes patients with features of both schizophrenia and affective disorders (also known as *mood disorders*), although subgroups may exist in which either schizophrenia or affective symptoms predominate. *Psychosis NOS* is a residual diagnostic category for patients with psychotic symptoms who do not fit into a more narrowly defined category. In many cases, the NOS designation serves as a temporary diagnosis for patients with new onset of disease until the course of their symptoms reveals their true diagnosis.

Both schizoaffective disorder and psychosis NOS are more common among the relatives of schizophrenic patients than among the relatives of nonschizophrenic persons. For example, in a survey of family history and family, twin and adoption studies, Prescott and Gottesman (33) found that 13 of 15 studies demonstrated evidence of a familial/genetic component for schizoaffective disorder. Consistent with this finding, monozygotic twins show higher concordance rates for schizoaffective disorder than do dizygotic twins (36 ,50).

Nonpsychotic Spectrum Disorders

Personality Disorders

Milder forms of schizophrenic illness are characterized by nonpsychotic symptoms, such as poor social relationships, anxiety in social situations, and limited emotional responses. Less frequently, mild forms of thought disorder, suspiciousness, magical thinking, illusions, and perceptual aberrations are also present. These symptoms are observed most frequently in three personality disorders, including schizotypal, schizoid, and paranoid personality disorders. Several studies found that (DSM) cluster A personality disorder traits often precede the onset of psychosis in subjects in whom schizophrenia subsequently develops (51 ,52). Moreover, in the New York high-risk project (53), offspring of schizophrenic mothers demonstrated elevated rates of these personality disorders when they were considered together, although not separately.

Most studies of familial prevalence in the biological relatives of schizophrenic patients have related schizotypal personality disorder to the schizophrenia spectrum more strongly than they have either schizoid or paranoid personality disorder (54 ,55). Evidence in favor of including schizotypal personality disorder is consistent across family (56 ,57 and 58), adoption (45), and twin studies (59 ,60). Although not all studies have detected a higher rate of schizotypal personality disorder among relatives of schizophrenic probands (54), most investigations, and particularly those with large samples, show higher rates of schizotypal personality disorder among the relatives of index cases with schizophrenia than among the relatives of control subjects (61). The incidence of the disorder in schizophrenic families has been estimated at between 4.2% and 14.6% (57 ,58 ,62 ,63). In contrast, results for schizoid and paranoid personality disorders have been somewhat more controversial and contradictory, with positive findings sometimes occurring in combined paranoid–schizotypal or schizoid–schizotypal

samples (55). Thus, although some symptoms may overlap between schizotypal, schizoid, and paranoid personality disorders, schizotypal personality disorder is currently the strongest candidate among this group for a nonpsychotic, relatively mild condition that is related genetically to schizophrenia.

Schizotaxia

Paul Meehl (64) first used the term *schizotaxia* in 1962 to describe a genetic vulnerability to schizophrenia. He suggested that a subtle but widespread neurointegrative defect results from this vulnerability that predisposes individuals to the development of either schizotypy or schizophrenia, depending on the protection or liability afforded by environmental circumstances. Later, Meehl reformulated the concept to allow for the possibility that some people with schizotaxia would not progress to either schizophrenia or schizotypal personality disorder, although most would (65). Eventually, the term *schizotypy* entered the psychiatric nomenclature in the form of schizotypal personality disorder. *Schizotaxia* did not, although the term was used in a general sense by researchers to describe the liability for schizophrenia. Now, almost 40 years after the concept was introduced, a broad literature shows that the liability for schizophrenia can be characterized clinically by deficits or abnormalities in psychiatric, neuropsychological, neurobiological, and psychosocial domains in nonpsychotic, first-degree relatives of people with schizophrenia.

Psychiatric features in such relatives frequently include negative symptoms (e.g., asociality and anhedonia) that are qualitatively similar to, but quantitatively milder than, those often seen in schizophrenia (66). Positive symptoms, however, are usually less evident in these relatives than they are in schizophrenia or schizotypal personality disorder. Neuropsychological impairments in biological relatives of people with schizophrenia are also similar to those in patients with schizophrenia, but are generally of lesser severity (67 ,68 ,69 ,70 and 71). The most extensively documented of these impairments involve working memory/attention, verbal memory, and concept formation/abstraction.

We recently suggested a reformulation of Meehl's concept of schizotaxia that focuses on these features of negative symptoms and neuropsychological deficits (67). In addition to specifying the clinical consequences of schizotaxia more specifically, our view of the concept differs from Meehl's in a few other respects. Among these is whether schizotaxia always or even usually progresses to schizotypal personality disorder or schizophrenia. Our empiric analyses suggest that the basic symptoms of schizotaxia occur in 20% to 50% of adult relatives of patients with schizophrenia (68 ,69). This rate is considerably higher than the rates of schizophrenia or schizotypal personality disorder likely to develop in first-degree relatives (≤ 10% for each condition), which suggests that schizotaxia does not lead inevitably to schizophrenia or schizotypal personality disorder. Our view of schizotaxia also differs somewhat from Meehl's formulation in that we include both genetic and nongenetic, adverse biological alterations occurring early in development (e.g., pregnancy and birth complications) in our conception of the syndrome.

Tsuang et al. (72) recently described a set of specific criteria for schizotaxia, but the clinical characterization is still evolving and the syndrome requires independent validation and further research before it can be used clinically (73). These criteria underlie a conception of schizotaxia as a neurodevelopmental condition resulting from genetic and adverse environmental (e.g., pregnancy or delivery complications) factors. Current criteria in adult, nonpsychotic, first-degree relatives of schizophrenic patients include moderate or greater levels of negative symptoms and neuropsychological deficits (as described above). The concept of schizotaxia demonstrates considerable utility because it accounts for clinical deficits in a sizable proportion of relatives who may not otherwise meet the criteria for a schizophrenia-related disorder. Moreover, because schizotaxia may be considered as a risk factor for schizophrenia, as well as a clinically meaningful syndrome in its own right, its recognition may eventually facilitate the development of early intervention and prevention strategies.

MODE OF INHERITANCE

Part of "49 - Molecular and Population Genetics of Schizophrenia "

Given the evidence outlined above for a substantial genetic contribution to the etiology of schizophrenia, methods such as complex segregation analysis (74) can be used to identify the most likely mode of inheritance. Commonly, a mixed model (75) comprising both major gene and polygenic effects is compared with the submodels of a single major locus and polygenic inheritance. However, large sample sizes are required to distinguish between models, especially the polygenic and mixed models, so that the practical usefulness of this approach has been limited to date.

Based on complex segregation analysis and related approaches, the pattern of risks in family and twin studies has been found to be incompatible with a single locus accounting for all the genetic liability to schizophrenia (76 ,77 and 78). However, it has not been possible to distinguish between a polygenic and a mixed model (77). The pattern of risks in family studies, in which the risk decreases rapidly as the degree of genetic relatedness decreases, is also compatible with a model of multiple loci with epistasis (interaction between genes) (79). However, the number of susceptibility loci, the disease risk conferred by each locus, and the degree of interaction between loci all remain unknown. The contribution of individual genes to the familiality of a disorder can be expressed in terms of *(s* (i.e., the relative risk to siblings resulting from possession of the disease allele (79). Risch (79) has calculated that the data for recurrence risks

in the relatives of probands with schizophrenia are incompatible with the existence of a single locus having a value of *(s* greater than 3. Unless extreme epistasis (interaction between loci) exists, models with two or three loci having values of *(s* of 2 or less are more plausible. It should be emphasized that these calculations are based on the assumption that the effects of genes are distributed equally across the whole population. It is quite possible that genes of larger effect are operating in a subset of patients—for example, those from families with a high density of illness.

These quantitative genetic investigations provide strong evidence that genetic factors increase the risk for schizophrenia. However, although it is possible to state that, as a group, siblings of individuals with schizophrenia, for example, have a roughly 10-fold increased risk in comparison with the general population, it is not currently possible to translate this figure to the level of risk for a particular sibling in a particular family. Similarly, heritability estimates refer to variations in liability to schizophrenia in the general population and have no simple meaning for an individual. Another important point is that risk to related individuals does not directly equate with genetic risk because some relatives carry one or more susceptibility alleles for schizophrenia but remain unaffected throughout their lives. In other words, the accumulation of susceptibility alleles, environmental risk factors, and complex interactions between risk factors probably all play a role in determining who becomes ill. Therefore, to quantify genetic risk, it is necessary to identify the susceptibility loci themselves at the molecular level.

MOLECULAR GENETICS: LINKAGE STUDIES

Part of "49 - Molecular and Population Genetics of Schizophrenia "

The first generation of systematic molecular genetic studies of schizophrenia effectively ignored the evidence for genetic complexity and targeted large, multiply affected pedigrees for analysis. This was done in the hope that such families, or at least a proportion of them, were segregating genes of sufficiently large effect that they could be detected unequivocally in this way. This approach has been successful in other complex disorders—Alzheimer disease, for example, in which mutations in three genes, *APP, PS1*, and *PS2*, are now known to cause rare forms of the disorder. In such cases, the disease is of unusually early onset and is transmitted through multiplex pedigrees in an autosomal dominant fashion (80 ,81 and 82).

Unfortunately, it has not proved possible to identify a phenotypic trait analogous to age at onset in Alzheimer disease by which to classify multiplex families segregating schizophrenia. Studies of such large families also initially produced positive findings in schizophrenia (83), but unfortunately these could not be replicated. The reasons for this have become clear as data from systematic genome scans have accumulated; highly penetrant mutations causing schizophrenia are at best extremely rare and quite possibly nonexistent (84 ,85). The false-positives were largely the consequence of a combination of multiple testing and the use of statistical methodology and significance levels derived from work on single-gene disorders.

Despite the failure to identify regions of unambiguous linkage in multiply affected families, modest evidence for several regions has been reported in more than one data set. Areas implicated for which supportive data have also been obtained from international collaborative studies include chromosomes 6p24-22, 8p22-21, and 22q11-12 (86 ,87 ; see refs. 84 and 88 for review). A number of other promising areas of putative linkage are also currently under investigation by international consortia. These include 13q14.1-32 (89 ,90 and 91), 5q21-31 (92 ,93), 18p22-21 (94), 10p15-11 (95 ,96 and 97), 6q (98 ,99), and 1q21-22 (100). However, in each case, both negative and positive findings have been obtained, and in only two cases, those of chromosomes 13q14.1-32 and1q21-22, did any single study achieve genome-wide significance at values of *p* of .05 (90 ,100).

These positive findings contrast with those from a large systematic search for linkage in which a sample of 196 affected sibling pairs, drawn typically from small nuclear families rather than extended pedigrees, was used (101). The results of simulation studies suggest that the power of this study is greater than 0.95 to detect a susceptibility locus of *(s* = 3 with a genome-wide significance of 0.05, but only 0.70 to detect a locus of *(s* = 2 with the conservative assumption that a locus lies midway between two adjacent markers. This study yielded evidence at the level of the definition of Lander and Kruglyak (102) of “suggestive” linkage to chromosomes 4p, 18p, and Xcen. However, none of the findings approached a genome-wide significance of 0.05, corresponding to Lander and Kruglyak’s definition of “significant” linkage.

The findings from linkage studies of schizophrenia to date demonstrates several features that are to be expected in the search for genes for complex traits (103 ,104 ,105 and 106). First, no finding is replicated in all data sets. Second, levels of statistical significance are unconvincing and estimated effect sizes are usually modest. Third, chromosomal regions of interest are typically broad [often > 20 to 30 centimorgan (cM)].

At the present time, therefore, the linkage literature supports the predictions made by Risch (79); it is highly unlikely that a commonly occurring locus of effect size [*(s*] greater than 3 exists, but suggestive evidence implicates a number of regions, consistent with the existence of some susceptibility alleles of moderate effect [*(s* = 1.5 to 3]. Moreover, encouraging results in several chromosomal regions suggest that rarer alleles of larger effect may be segregating in some large, multiply affected families.

Linkage methods in sample sizes that are realistically achievable can detect smaller genetic effects than those in the studies to date. For example, it is possible to detect alleles with values of *(s* of 1.5 to 3 in a sample of 600 to

800 affected sibling pairs (107 ,108). We therefore suggest that priority should now be given to collecting such samples with a robust clinical methodology that is comparable across all interested research groups. However, if liability to schizophrenia is entirely a consequence of the operation of many genes of small effect, then even these large-scale studies will be unsuccessful.

CANDIDATE GENE ASSOCIATION STUDIES

Part of "49 - Molecular and Population Genetics of Schizophrenia "

Once genes of smaller effect than *(*s =1.5 are sought, the number of affected family members required becomes prohibitively large (107 ,108 and 109). For this reason, many researchers have tried to take advantage of the potential of candidate gene association studies to identify such loci (109 ,110). Although a potentially powerful means of identifying genes of small effect, association studies are not without their problems. First, for a complex and poorly understood disorder such as schizophrenia, the choice of candidate genes is limited largely by the imagination and resources of the researcher. This places a stringent burden of statistical proof on positive results because of low prior probability and multiple testing (111). Second, case–control association studies have the potential to generate false-positives because of population stratification. This problem can be addressed by using family-based association methods (112), but because of stigma, adult age at onset, and the disruptive effects of mental illness on family relationships, family-based samples may be unrepresentative in addition to limited in size. Consequently, family-based studies may introduce more spurious results than do case–control studies (113). It would seem unwise, therefore, to discard the case–control study design, which has served epidemiology so well through the years. A third problem common to all molecular genetic studies in complex diseases is that they are prone to type 2 errors simply because they are often underpowered, and therefore to draw satisfactory conclusions from negative studies, larger sample sizes are required than have typically been used to date in psychiatric genetics (111). Fourth, even with larger samples, it is by no means certain that a given replication study will be sufficiently powered to replicate a particular effect. This is because variations may be noted in the contribution of a given susceptibility allele in different patient populations as a result of different allele frequencies at the locus of interest or at interacting loci. Further potential for heterogeneity occurs if the association with the marker is a result of tight linkage with the true susceptibility allele, or if different subtypes of the disease exist. Given that all the above factors may influence power, and that none of the above is known in advance, it is difficult to obtain an accurate measure of the power of a replication study. Because we cannot specify accurately the prior probability of a candidate gene, nor know the true power for replication, it is difficult to draw definitive conclusions from conflicting findings. However, the purpose of experiment is to reject a null hypothesis, and in the face of uncertainty, the burden of proof remains with the proponents of a particular candidate gene.

Most candidate gene studies have been based on neuropharmacologic studies, which suggests that abnormalities in monoamine neurotransmission, in particular dopaminergic and serotoninergic systems, play a role in the etiology of schizophrenia. Overall, the results in this extensive literature are disappointing, but it should be noted that the sample sizes in many of the older studies would now generally be regarded as inadequate, particularly in view of the fact that the polymorphic markers in question did not in themselves represent functional variants and that few genes have been systematically screened even for common functional variants. However, more promising reports of candidate gene associations have recently appeared, three of which are considered here.

Serotonin 5-HT$_{2A}$-Receptor Gene

Many novel antipsychotic drugs affect the serotoninergic system. The first genetic evidence that serotoninergic receptors may play a role in schizophrenia came from a Japanese group reporting an association between a T-to-C polymorphism at nucleotide 102 in the 5-HT$_{2A}$-receptor gene in a small sample (114). A large European consortium comprising seven centers and involving 571 patients and 639 controls then replicated this finding (115), which was further replicated with use of a family-based design (116). Although many other studies followed with mixed results, a recent metaanalysis of all available data from more than 3,000 subjects supports the original finding (p = .0009), and this does not appear to be a consequence of publication bias (117).

Since this metaanalysis was undertaken, a few further negative reports have followed, but none has approached the sample sizes required. If we assume homogeneity and if the association is true, the putative odds ratio (OR) for the C allele can be expected to be around 1.2 in any replication sample. Sample sizes of 1,000 subjects are then be required for 80% power to detect an effect of this size, even at a relaxed criterion of p = .05. Thus, the negative studies are effectively meaningless, but it is also true that the evidence for association, even in the metaanalysis (p = .0009), is not definitive if genome-wide significance levels are required (109). At present, all we can conclude is that the evidence favors association between the T102C 5-HT$_{2A}$ polymorphism and schizophrenia, but the most stringent burden of proof has not yet been met.

If the association is real, it is unlikely that the T102C polymorphism is the susceptibility variant because this nucleotide change does not alter the predicted amino acid sequence of the receptor protein, nor is it in a region of obvious significance for regulating gene expression. T102C is

in complete linkage disequilibrium with a polymorphism in the promoter region of this gene, but no evidence has as yet been found that this has a functional effect either (116). Recent evidence of polymorphic monoallelic expression of the 5-HT_{2A} gene points to the possible existence of sequence variation elsewhere that influences gene expression (118), and this may be the true susceptibility variant.

D3 Dopamine-Receptor Gene

Association has been reported between schizophrenia and homozygosity for a Ser9Gly polymorphism in exon 1 of the D3 dopamine-receptor gene (*DRD3*) (119). As with the 5-HT_{2A} association, the results have now been confirmed in several independent samples, including one family-based study (120), but several negative studies have also been reported. Metaanalysis of data from more than 5,000 individuals has revealed a small (OR = 1.23) but significant (p = .0002) association between homozygosity at Ser9Gly and schizophrenia (120). Again, this cannot easily be ascribed to selective publication (120). Because it is a fairly uncommon genotype, we cannot be certain that homozygosity for the 9Gly allele alone is not associated with an increased risk for schizophrenia, and therefore it is not certain that the findings at D3 are an example of heterosis. However, a plausible biological explanation for D3 heterosis has been put forward in that possession of two different molecular forms of the receptor may allow the dopaminergic neuron to respond more flexibly (119).

At present, then, the status of the D3 dopamine-receptor gene is similar to that of the 5-HT_{2A}-receptor gene—that is, the balance of evidence at present favors association, but the null hypothesis still cannot be confidently rejected. Those wishing to replicate or reject these findings should bear in mind that to obtain power greater than 0.80 to detect an effect of this size at a criterion of p = .05, a sample of 1,500 cases and 1,500 controls is required. So far, no other polymorphisms have been found that might explain the putative D3 association, but several new polymorphisms have been identified in previously unknown exons 5′ to the exon referred to above as *exon 1* (121). These are currently being tested to establish whether variants in this region in linkage disequilibrium with the Ser9Gly polymorphism provide a more functionally plausible explanation of the association with schizophrenia.

ANTICIPATION AND TRINUCLEOTIDE REPEATS

Part of "49 - Molecular and Population Genetics of Schizophrenia "

The term *anticipation*, the phenomenon by which the age at onset of disease becomes earlier from one generation to the next, was first described in connection with severe mental disorder (122). A series of recent studies applying modern diagnostic criteria have now confirmed that the inheritance of schizophrenia is at least consistent with the presence of anticipation, although ascertainment biases offer an alternative explanation (123). Because pathogenic expanded trinucleotide repeats are the only known genetic mechanisms for anticipation, these findings have been taken as suggesting that such mutations may account for at least some of the complexity in the pattern of inheritance in this disorder (124). This hypothesis was supported by two groups who observed that the maximum length of the most common known pathogenic trinucleotide repeat, CAG/CTG, was greater in patients with schizophrenia than in unaffected controls (125 ,126). These findings were later replicated in a European multicenter study (127). Unfortunately, the early repeat expansion detection (RED) studies were followed by a series of unsuccessful attempts to identify the relevant repeat-containing loci by a variety of methods, and by several failures to replicate the RED findings (128 ,129 and 130), thus casting doubt over the CAG/CTG repeat hypothesis.

The trinucleotide repeat hypothesis was rejuvenated, however, with the report of an association between schizophrenia and alleles of a member of the family of calcium-activated potassium channel genes, *KCa3* (*hKCa3*/*KCCN3*) (131). For several reasons, *KCa3* seemed a remarkable candidate gene for schizophrenia. First, the gene contained two CAG repeats, one of which is highly polymorphic. Second, the family of genes to which it belongs is thought to play an important role in regulating neuronal activity, and it was therefore considered a functional candidate gene. Third, the gene was also thought to be a positional candidate, as it was believed to map to chromosome 22q11. Ironically, *KCa3* maps not to 22q11 but to 1q21 (132), which is also a region implicated by linkage studies as possibly containing a susceptibility locus for schizophrenia (100). Two further case–control studies have subsequently supported the findings of Chandy and colleagues (132 ,133).

However, although evidence from three case–control studies lends support to the hypothesis of *KCa3* as a susceptibility gene for schizophrenia, in other respects the case for this gene as a candidate is less certain. First, the RED data cited above lend no support to *KCa3* as a candidate because the polymorphic trinucleotide repeat in this gene is far too short to account for the RED associations (133). Second, a series of case–control and family studies have failed to replicate the findings (134 ,135 ,136 ,137 ,138 ,139 and 140). Thus, we are back to our familiar position in candidate gene analysis; although the data are insufficient to draw firm conclusions, we believe at present that the case for *KCa3* remains firmly with the null hypothesis.

What then is the status of the original associations between large CAG/CTG repeats and schizophrenia? It has been reported that large CAG/CTG RED products (repeat size > 40) are explained by repeat size at two autosomal loci, one at 18q21.1 and the other at 17q21.3 (141 ,142). If the explanation is correct, then it follows that one or both of these loci should be associated with schizophrenia.

Unfortunately, data from Vincent and colleagues (128) and unpublished data from Cardiff unequivocally show that expansions at these loci are not responsible for the RED associations. However, in both samples, only around 50% of large CAG/CTG repeats detected by RED could be explained by polymorphisms at these two loci, which suggests that at least one further locus is responsible for the RED data, a possibility supported by two recent studies on protein extracts from schizophrenic tissues (143).

HIGH RATES OF SCHIZOPHRENIA IN ADULTS WITH VELOCARDIOFACIAL SYNDROME

Part of "49 - Molecular and Population Genetics of Schizophrenia "

Velocardiofacial syndrome (VCFS), also known as *DiGeorge* or *Shprintzen syndrome*, is associated with small interstitial deletions of chromosome 22q11 in 80% to 85% of cases (144). First described by Shprintzen and colleagues (145), VCFS has an estimated prevalence of 1/4,000 births (146). Distinctive dysmorphology, congenital heart disease, and learning disabilities characterize the syndrome, although considerable phenotypic variability occurs. As the first recognized cohort of children with VCFS was followed into adolescence and early adulthood, evidence began to accumulate for a high prevalence of major mental illness. Early reports suggested that psychiatric disorders had developed in more than 10% of the cohort, which mostly resembled chronic schizophrenia with paranoid delusions, although operational criteria were not used (147). In a follow-up study of teenagers (age 17 years) in which DSM-III-R criteria were used, Pulver et al. (148) reported that 11 (79%) of their sample of 14 patients had been given a psychiatric diagnosis: 29% had schizophrenia (22%) or schizoaffective disorder (7%), 29% had simple or social phobia, 21% had depression, and 14% had obsessive-compulsive disorder. More recently, Papolos et al. (146) reported that of their sample of 15 children and 10 adults, four (16%) had psychotic symptoms and 16 (64%) met DSM-III-R criteria for a spectrum of bipolar affective disorders. Although none had schizophrenia, the two oldest members of their patient cohort (ages 29 and 34 years) both had schizoaffective disorder.

To try to gain a more precise determination of the prevalence and nature of psychopathology in adults with VCFS, rather than rely on clinical diagnosis, Murphy and colleagues (149) recently evaluated 50 cases with a structured clinical interview to establish a DSM-IV diagnosis. Fifteen patients with VCFS (30%) had a psychotic disorder, with 24% (n = 12) fulfilling DSM-IV criteria for schizophrenia. In addition, six (12%) had major depression without psychotic features. They were unable to replicate the findings of Papolos and colleagues (146) of a high prevalence of bipolar spectrum disorders in VCFS. However, these workers studied a small sample that included few adults, and in view of the fact that their oldest cases satisfied criteria for schizoaffective disorder, it is possible that the psychotic phenotype in VCFS varies with age. Prospective studies are now required to test this hypothesis.

The current balance of evidence favors the view that the high prevalence of psychosis results from hemizygosity for a gene or genes at chromosome 22q11 rather than ascertainment bias or a nonspecific association with a low intelligence quotient (IQ) (149). In particular, the prevalence of psychosis and schizotypy in VCFS appears to be much greater than that seen in most other congenital abnormalities affecting neural development, and appears not to be correlated with the degree of intellectual impairment (149). Many lines of evidence suggest that schizophrenia is a neurodevelopmental disorder (150). In VCFS, defective development and migration of mesencephalic and cardiac neural crest cells are believed to play a significant role in the pathogenesis of midfacial and cardiac abnormalities (151). Consequently, it has been postulated that a gene or genes causing disruption of neural cell migration may be a common neurodevelopmental mechanism for both VCFS and schizophrenia (152).

What then is the importance of 22q11 and VCFS in the etiology of schizophrenia as a whole? Karayiorgou et al. (153) reported that among 100 randomly ascertained patients with schizophrenia, two were found to have a 22q11 deletion. In contrast, when subjects with schizophrenia were selected for the presence of clinical features consistent with VCFS, 22q11 deletions were identified in 20% to 59% of cases (154 ,155). These findings suggest that a small proportion of cases of schizophrenia may result from deletions of 22q11, and that clinicians should be vigilant, especially when psychosis occurs in the presence of dysmorphology, mild learning disability, or a history of cleft palate or congenital heart disease (156). The question of whether genetic variation in 22q11 confers susceptibility to schizophrenia in cases without a deletion is more difficult to answer. As we have seen, the results of some linkage studies suggest the presence of a schizophrenia susceptibility locus on 22q. However, the linkage findings tend to point telomeric to the VCFS region (86 ,157). Nevertheless, modest evidence for linkage to the VCFS region has also been claimed (90 ,158 ,159), and as we have noted above, linkage mapping in complex diseases is somewhat imprecise. It remains possible that the relationship between VCFS and “typical” schizophrenia is less direct, with little common ground between the genetic and neurodevelopmental mechanisms involved but with convergence on identical or at least similar psychopathologic syndromes.

Another important question concerns the factors that determine whether schizophrenia will develop in a person with VCFS. When adults with VCFS were tested with a quantitative measure of schizotypy, the patients with psychosis had the highest scores (149). However, perhaps of greater interest, those without psychosis had intermediate

scores in comparison with controls (149). If schizotypy is a trait marker for increased liability to psychosis, this suggests that the majority if not all of those with 22q11 deletions are at increased risk for psychosis, but that other genetic or environmental factors are required for this risk to be expressed. The genetic loci involved may reside elsewhere in the genome and include those involved more widely in psychosis, or lie within 22q11. The occurrence of psychosis does not appear to be related to the size of the deletion (153). However, it is possible that susceptibility to psychosis reflects allelic variation of a hemizygous gene or genes within the deletion. The gene encoding catechol-*O*-methyltransferase (COMT), an enzyme involved in the catabolism of catecholamine neurotransmitters, maps to the VCFS region and is therefore an obvious candidate for influencing the expression of psychosis in VCFS probands. This gene exists in two allelic forms encoding high- and low-activity isoforms of the enzyme, and it has been suggested that possession of the allele for low-activity COMT may be associated with the occurrence of schizophrenia in VCFS (160). However, Murphy and colleagues (149) found no evidence for an association between the allele for low-activity COMT and either schizophrenia or schizotypy in patients with VCFS.

FUTURE DIRECTIONS

Part of "49 - Molecular and Population Genetics of Schizophrenia "

Refining the Phenotype for Molecular Genetic Studies

The effectiveness of molecular genetic studies depends on the genetic validity of the phenotypes studied. Perhaps if we were better at defining phenotypes, we would be better at finding genes. It is worth reiterating at this point that the commonly used diagnostic criteria define phenotypes with high heritability. In principle, therefore, it should be possible to identify the genes predisposing to schizophrenia, as defined by current diagnostic criteria, if sufficiently large samples are studied. However, perhaps genetic validity could be improved by focusing on aspects of clinical variation, such as age at onset or symptom profiles, or by identifying biological markers that predict degree of genetic risk or define more homogeneous subgroups. Unfortunately, despite much work, it has not been possible to identify genetically distinct subtypes of schizophrenia. Instead, clinical variation is likely to reflect at least in part a combination of quantitative variation in genetic risk for the disorder and the effect of modifying genes that influence illness expression rather than the risk for illness *per se*. Examples of this phenomenon are probably age at onset and symptom pattern in schizophrenia (161 ,162).

The search for trait markers aims to move genetic studies beyond the clinical syndrome by identifying indices of genetic risk that can be measured in asymptomatic persons or by identifying markers of pathophysiologic processes that are closer to the primary effects of susceptibility genes than are clinical symptoms—so-called intermediate phenotypes or endophenotypes. Work in this area is developing fast; for example, candidate trait markers for schizophrenia include schizotypal personality traits, measures of cognitive processing, brain evoked potentials, and abnormalities in eye movements (163). It is also hoped that advances in brain imaging will lead to the identification of genetically valid trait markers. However, it seems unlikely that these phenotypes will provide a rapid solution to the problem. First, we will need to ensure that the measures used are stable and determine the extent to which they are affected by state. Second, to be of use in gene mapping, such measures will have to be practicably applied to a sufficient number of families or unrelated patients. Third, we will need to ensure that the traits identified are highly heritable, which will itself require a return to classic genetic epidemiology and model fitting. Finally, we cannot assume that the genetic architecture of such intermediate phenotypes will be simple.

Efforts to improve the selection of phenotypes are also concerned with enhancing the traditional categoric approach to defining psychiatric disorders by identifying genetically valid phenotypes that can be measured quantitatively. These can be used in quantitative trait locus approaches to gene mapping. Work in this area has begun but still faces problems, particularly those relating to the confounding influence of state-related effects. Perhaps the best hope of taking account of the complexity and heterogeneity of the schizophrenia phenotype comes from new methods of analysis in which aspects of the phenotype can be entered as covariates in linkage analyses (164).

Genome-wide Association Studies

In recent years, interest has increased in the possibility of systematic, genome-wide association studies (109 ,165). These have the potential of allowing systematic searches for genes of small effect in polygenic disorders. Optimism has been fueled by the fact that the most abundant form of genetic variation, the single-nucleotide polymorphism, is usually bi-allelic and potentially amenable to binary, high-throughput genotyping assays such as microarrays (so-called DNA chips). Moreover, as sequence data accumulate, it has become possible to contemplate the construction and application of very dense maps of hundreds of thousands of single-nucleotide polymorphisms (165).

Essentially two types of genome-wide association study have been proposed: direct and indirect. In the former, association is sought between a disease and a comprehensive catalogue of every variant that can alter the structure, function, or expression of every single gene. In contrast, indirect studies seek associations between markers and disease that are caused by linkage disequilibrium between the markers and susceptibility variants. The hope is that if sufficiently dense marker maps can be applied, it will be possible to screen the whole genome systematically for evidence of linkage

disequilibrium without actually having to screen every functional single-nucleotide polymorphism in the genome. However, a number of uncertainties and difficulties remain. These include, in particular, the difficulty of identifying functional single-nucleotide polymorphisms in regulatory rather than coding regions of the genome, uncertainty about the distances over which linkage disequilibrium is maintained, and the lack at the present time of a rapid, accurate, and cheap method for single-nucleotide genotyping (165).

Given these considerations, it seems clear that the era of genome-wide association studies, direct or indirect, is not yet at hand. Instead, studies in the next few years should probably focus mainly on the direct approach utilizing single-nucleotide polymorphisms from the coding sequence that actually alter protein structure in a wide range of functional and positional candidate genes. Preferably, complete functional systems should be dissected by the application of sensitive methods for mutation detection, followed by association studies in appropriately sized samples. We should also use our knowledge of functional pathways to make predictions about likely epistasis. However, given our ignorance of pathophysiology, the expectation should be that most reported associations will be false and resolved only by replication in large, well-characterized samples. At present, although the indirect approach is not widely applicable at a genome-wide level, smaller-scale studies focusing on specific regions indicated by the results of linkage studies may allow us to map loci. Additionally, such studies will generate the sort of data concerning patterns of linkage disequilibrium in typical “association samples” that will be required to determine whether genome-wide studies are likely to be feasible and what density of map will be required.

If the results are encouraging—that is, if linkage disequilibrium exists across useful distances in the genome—then until genotyping technology has sufficient capacity to permit mass genotyping at low cost, linkage disequilibrium analyses at the genome-wide level are most likely to be based on DNA pooling technologies (166 ,167 ,168 and 169).

Identifying Modifying Genes

It is sometimes assumed that variation in the clinical features of a disease or treatment response simply reflects pleiotropic effects of etiologic risk factors. However, it is becoming increasingly apparent that specific genes probably exist that influence clinical features and treatment response independent of those affecting liability. Thus, another potentially fruitful line of inquiry may be to design studies aimed at seeking modifying rather than causative genes, as these genes may in themselves allow novel drug targets to be identified. Evidence has already been found that variations in age at onset and symptom pattern in schizophrenia are probably caused at least in part by modifying genes (161 ,162). Furthermore, interest is increasing in pharmacogenetics in psychiatry (170), although with some trait markers, we need to exercise caution in the absence of genetic epidemiologic evidence that variations in drug response are under genetic control. We should also not forget that there is no *a priori* reason why responses to behavioral and psychological treatments should be less influenced by genetic factors than by pharmacologic treatments.

Animal Models

Another important challenge will be the development of suitable animal models to allow functional studies of putative disease loci (165). Disorders that predominantly involve higher cognitive function, such as schizophrenia, are likely to prove difficult to model in animals. However, certain features of the human phenotype, such as subtle abnormalities of cell migration, enlarged cerebral ventricles, and abnormalities of information processing, including defects in prepulse inhibition, can be detected in animals (171). In fact, a possible approach to producing a mouse model for at least some of the schizophrenia phenotype is suggested by the finding of an increased prevalence of schizophrenia in VCFS. Currently, attempts are under way to produce transgenic mice in which the syntenic region of mouse chromosome 16 is deleted (172). These animals should be investigated closely for neuroanatomic and behavioral phenotypes of possible relevance to schizophrenia, and such studies are already yielding encouraging findings (173).

Functional Studies

The most important and most obvious implication of identifying genetic risk factors for schizophrenia is that it will inspire a new wave of neurobiological studies from which, it is hoped, new and more effective therapies will emerge. However, although the unequivocal identification of associated genetic variants will represent a great advance, many years of work will be required before this is likely to translate to routine clinical practice. An early problem will be to determine exactly which genetic variant among several in linkage disequilibrium within a given gene is actually responsible for the functional variation. Even when a specific variant within a gene can be identified as the one of functional importance, functional analysis, in terms of effect at the level of the organism, is likely to be particularly difficult for behavioral phenotypes in the absence of animal models. An extra level of complexity is that we will need to be able to produce model systems, both *in vivo* and *in vitro*, that allow gene–gene and gene–environment interaction to be studied.

Genetic Nosology

Although the development of new therapies will take time, it is likely that the identification of susceptibility genes will

have an earlier effect on psychiatric nosology. If genetic risk factors are correlated with clinical symptoms and syndromes, it should be possible to study heterogeneity and comorbidity to improve the diagnosis and classification of psychosis. The prospects will also be enhanced for identifying clinically useful biological markers as an aid to diagnosis, so that we can move beyond the current situation of making diagnoses based entirely on clinical signs and symptoms. Improvements in diagnostic validity will clearly facilitate all avenues of research into these disorders. However, in the present context, we should point out that improvements in diagnosis and classification should enhance our ability to detect further genetic and environmental risk factors, so that a positive feedback between nosology, epidemiology, and molecular genetics can be envisaged.

Molecular Epidemiology

The identification of genetic risk factors can be expected to provide a new impetus to epidemiologic studies of schizophrenia by allowing researchers to investigate the ways in which genes and environment interact. Studies of this kind will require large, epidemiologically based samples together with the collection of relevant environmental data. This work could start now with DNA being banked for future use, although in schizophrenia, the identification of plausible environmental measures might require clues from the nature of the genetic risk factors yet to be identified. A major theme in relation to this work will be the bringing together of methodologies from genetics and epidemiology, which have traditionally adopted somewhat differing analytic approaches (174). Treating susceptibility alleles as risk factors in an epidemiologic context will allow estimates of effect sizes within a population to be made. Accounting for specific genetic effects will also facilitate the search for independent environmental factors and the investigation of potential gene–environment interactions. Scientific validity is likely to be enhanced by ensuring as far as possible that control samples are drawn from the same base population as patients. In addition, the use of incident cases should guard against the risk of identifying loci related to confounds, such as chronicity of illness, rather than susceptibility. Phenotypic assessment is likely to benefit from a prospective element to studies, which counteracts the tendency of patients to forget historical details and the difficulty of making observed ratings retrospectively from case records. However, the price of improved scientific rigor is likely to be considerably more expensive studies because of the longer period and larger number of investigators that will be required to ascertain detailed data from thousands of subjects.

Genetic Testing

A further implication concerns genetic testing. This is a complex area that raises a number of ethical issues, which have been discussed elsewhere (175). However, the potential for predictive testing has probably been overstated, given that susceptibility to schizophrenia almost certainly depends on the combined effects of predisposing and protective alleles at a number of loci and their interaction with the environment. Consequently, until we have a comprehensive molecular understanding of the etiology of schizophrenia, the predictive value of genetic testing is likely to be low. This applies, for example, to apolipoprotein E testing for late-onset Alzheimer disease, and has led to a recommendation that such testing not be performed in asymptomatic persons (175). Indeed, even when all the susceptibility genes for schizophrenia have been identified, it will still not be possible to predict the development of disease with certainty until the relevant genetic and environmental risk and modifying factors have also been identified and the nature of the various interactions understood. Such interactions may be complex and unpredictable (165). However, other possible roles of genetic testing are likely to be of greater value to patients and clinicians. For example, it might be possible to optimize treatment choices by testing genes found to influence treatment responses in psychiatric disorders and so provide more individualized treatment.

CONCLUSIONS

Part of "49 - Molecular and Population Genetics of Schizophrenia "

Attempts to identify the genes that predispose to schizophrenia face formidable challenges arising from both genetic and phenotypic complexity. Research to date has largely excluded the possibility that genes of major effect exist even in a subset of families. Evidence has been obtained of the location of some genes of moderate effect, but none of these findings can be regarded as conclusive, and proof in each case will probably have to await identification of the susceptibility locus itself. The clearest molecular genetic risk factor for schizophrenia that has been identified to date is deletion of a gene or several genes on chromosome 22, which can markedly increase the risk for schizophrenia. However, fairly strong data suggest that allelic variation in genes encoding the 5-HT_{2A} and D3 dopamine receptors confer a small degree of susceptibility.

As in other common diseases, it is hoped that advances will come through the use of a new generation of genetic markers and new methods of genotyping and statistical analysis (165). However, successful application of these methods requires access to large, well-characterized patient samples, and the collection of such data is a priority at the present time. We need to focus research on the development and refinement of phenotypic measures and biological markers. Success will also depend on the traditional medical disciplines of clinical description and epidemiology, and on our ability to integrate these with genetic approaches.

Animal Models Relevant to Schizophrenia Disorders

Mark A. Geyer

Bita Moghaddam

Mark A. Geyer: Department of Psychiatry, School of Medicine, University of California at San Diego, La Jolla, California.

Bita Moghaddam: Departments of Psychiatry and Neurobiology, Yale University School of Medicine, New Haven, Connecticut.

Animal models used to study schizophrenia include both models of the full syndrome and models of specific signs or symptoms. As reviewed elsewhere (1), models are commonly explored initially because of indications of so-called face validity, but they are evaluated scientifically in terms of their construct and etiologic and predictive validity with respect to both clinical phenomena and responsiveness to antipsychotic drugs. Here, models are organized by the manipulations used to mimic the clinical phenomena. Thus, in some of these models, only specific dependent measures are utilized, whereas others are evaluated by using a range of dependent measures.

A model is defined as any experimental preparation developed to study a particular condition or phenomenon in the same or different species. Typically, models are animal preparations that attempt to mimic a human condition, in our case the human psychopathology associated with the group of schizophrenia disorders. In developing and assessing an animal model, it is important to specify the purpose intended for the model because the intended purpose determines the criteria that the model must satisfy to establish its validity. At one extreme, one can attempt to develop an animal model that mimics the schizophrenia syndrome in its entirety. In the early years of psychopharmacology, the term *animal model* often denoted such an attempt to reproduce a psychiatric disorder in a laboratory animal. Unfortunately, the group of schizophrenia disorders is characterized by considerable heterogeneity and a complex clinical course that reflects many factors that cannot be reproduced readily in animals. Thus, the frequent attempts to model the syndromes of schizophrenia in animals usually met with failure and so prompted skepticism regarding this entire approach.

At the other extreme, a more limited use of an animal model related to schizophrenia is to study systematically the effects of antipsychotic treatments. Here, the behavior of the model is intended to reflect only the efficacy of known therapeutic agents and so lead to the discovery of related pharmacotherapies. Because the explicit purpose of the model is to predict treatment efficacy, the principle guiding this approach has been termed *pharmacologic isomorphism* (2). The fact that such models are developed and validated by reference to the effects of known therapeutic drugs frequently limits their ability to identify new drugs with novel mechanisms of action. Similarly, an important limitation inherent in this approach is that it is not designed to identify new antipsychotic agents that might better treat the symptoms of schizophrenia refractory to current treatments.

Because of the complexity of schizophrenia, another approach to the development of relevant animal models relies on focusing on specific signs or symptoms associated with schizophrenia, rather than mimicking the entire syndrome. In such cases, specific observables that have been identified in schizophrenic patients provide a focus for study in experimental animals. The particular behavior being studied may or may not be pathognomonic for or even symptomatic of schizophrenia, but it must be defined objectively and observed reliably. It is important to emphasize that the reliance of such a model on specific observables minimizes a fundamental problem plaguing animal models of the syndrome of schizophrenia. Specifically, the difficulties inherent in conducting experimental studies of schizophrenic patients have limited the number of definitive clinical findings with which one can validate an animal model of schizophrenia. The validation of any animal model can only be as sound as the information available in the relevant clinical literature (3). By focusing on specific signs or symptoms rather than syndromes, one can increase the confidence in the cross-species validity of the model. The narrow focus of this approach generally leads to pragmatic advantages in the conduct of mechanistic studies addressing the neurobiological substrates of the behavior in question. By contrast, in models intended to reproduce the entire syndrome of schizophrenia, the need for multiple simultaneous endpoints

makes it relatively difficult to apply the invasive experimental manipulations required to establish underlying mechanisms.

Another approach to the development of animal models is based more theoretically on psychological constructs believed to be affected in schizophrenia. Such identification of underlying psychological processes or behavioral dimensions (2 ,3) involves the definition of a hypothetical construct and the subsequent establishment of operational definitions suitable for experimental testing of the validity of the construct. Constructs such as selective attention, perseveration, sensorimotor gating, and working memory have been used in this manner in schizophrenia research. This approach is most fruitful when conceptually or procedurally related experiments are undertaken in both the relevant patient population and the putative animal model. In other words, studies of appropriate patients are needed to establish the operational definitions of the hypothetical construct and the relevance of the construct to schizophrenia. In concert, parallel studies of the potentially homologous construct, process, or dimension are required to determine the similarity of the animal model to the human phenomena. An important and advantageous aspect of this approach is that the validation of the hypothetical construct and its cross-species homology can be established by studies of normal humans and animals in addition to studies of schizophrenic patients and experimentally manipulated animals. Thus, this approach benefits from the existing literature relevant to the hypothetical construct on which the model is based. In a sense, this approach explicitly recognizes that the experimental study of schizophrenia in humans involves as much of a modeling process as does the study of the disorder in animals.

PHENOTYPIC CHARACTERIZATION OF ANIMAL MODELS

Part of "50 - Animal Models Relevant to Schizophrenia Disorders "

Behavioral measures have been used extensively for establishing the validity of animal models of schizophrenia. Some of these measures, such as horizontal locomotion, do not correspond to schizophrenic symptomatology and have been primarily useful for providing a functional measure of the antidopaminergic activity of neuroleptics. Other behavioral measures, such as disruption of prepulse inhibition or impaired attentional set shifting, resemble characteristics of schizophrenia. These measures are useful for establishing the construct and predictive validity of putative animal models.

In addition to behavioral assessments, cellular and molecular markers that are based on described changes in human postmortem and imaging studies are potentially useful measures for establishing the validity of animal models. Furthermore, because of the inherent limitations of modeling in laboratory animals some of the most prominent behavioral abnormalities of schizophrenia, such as delusions and hallucinations, cellular and molecular characterizations can complement behavioral investigations in evaluating developmental and genetic models of schizophrenia.

Behavioral Phenotypes

Locomotor and Stereotypy

Changes in locomotor activity in rodents have often been used to assess both models of schizophrenia and the effects of antipsychotic treatments. The original impetus for the use of locomotor activity measures was derived from the psychostimulant models based on the dopamine hypothesis of schizophrenia, as reviewed elsewhere (3 ,4 and 5). These models arose because of the apparent similarity (i.e., “face validity”) between the symptoms of schizophrenia and the effects of high doses of amphetamine in presumably normal humans (6). Cross-species studies in animals treated with psychostimulants revealed both locomotor hyperactivity and, at higher doses, striking stereotyped or perseverative behaviors, which were seen as having face validity for the stereotyped behavior induced by amphetamine in humans (4 ,6 ,7). Measures of locomotor hyperactivity have been used extensively to characterize the effects of both dopaminergic psychostimulants and *N*-methyl-D-aspartate (NMDA) antagonists, such as phencyclidine (PCP), although PCP-induced hyperactivity differs markedly in qualitative features from that produced by dopaminergic psychostimulants. Although patients with schizophrenia are not typically hyperactive, they often exhibit perseverative or stereotyped behaviors. Hence, many studies in rodents have focused on the forms of stereotypy produced by psychostimulants.

Gating Measures

Clinical observations in schizophrenic patients have identified deficiencies in the processing of information, including an inability automatically to filter or “gate” irrelevant thoughts and sensory stimuli to prevent them from intruding on conscious awareness. Hence, theories of schizophrenic disorders often conceptualize the common aspect of these disorders as involving one or more deficits in the multiple mechanisms that enable normal persons to filter or gate most of the sensory stimuli they receive (8 ,9 and 10). In the most classic measure of filtering deficits, numerous studies have observed deficits in the habituation of startle responses in schizophrenic patients (e.g., 12,31,102), which may reflect failures of sensory filtering leading to disorders of cognition. A more specific class of such mechanisms is referred to as *sensory* or *sensorimotor gating*. Theoretically, impairments in either filtering or gating lead to sensory overload and cognitive fragmentation. It is also possible that the mechanisms that subserve experimental examples of filtering or gating are also responsible for the gating of cognitive information. The hypothetical construct of sensorimotor

gating has been operationalized and explored in both human and animal studies. The validity of this gating construct has been assessed most thoroughly by means of an operational measure based on cross-species homologies in the startle reflex—namely, the prepulse inhibition (PPI) of startle paradigm. In a conceptually related approach, analogous measures of event-related potentials are used across species to study sensory gating in the P50 event-related potential condition–test paradigm.

Habituation

Habituation refers to the decrement in responding when the same unimportant stimuli or cognitions occur repeatedly in the absence of any contingencies. Habituation is considered to be the simplest form of learning and is essential for the development of selective attention. Although habituation can be assessed with a variety of behavioral measures, the most common approach has been to study the gradual decrease in the startle response elicited by a series of tactile or acoustic stimuli in humans, rats, or mice. In patients with schizophrenia or schizotypy, deficits in startle habituation have been reported with the use of either modality of startling stimuli (9 ,11 ,12 and 13). A striking advantage of the startle habituation measure is the fact that extremely similar behavioral tests can be conducted in both humans and experimental animals.

Prepulse Inhibition

The PPI paradigm is based on the fact that a weak prestimulus presented 30 to 500 milliseconds before a startling stimulus reduces, or gates, the amplitude of the startle response. The generality and reliability of this robust phenomenon is clear; PPI is observed in many species, PPI is evident both within and between multiple sensory modalities when a variety of stimulus parameters are used, and PPI does not require learning or comprehension of instructions. Virtually all the evidence available supports the belief that PPI is homologous from rodents to humans, unlike most other cross-species comparisons based on often dubious arguments of similarity or, at best, analogy. As reviewed elsewhere (14 ,15), several laboratories have reported significant deficits in PPI in schizophrenic, schizotypal, and presumably psychosis-prone subjects with the use of a variety of testing procedures and stimulus parameters. Nevertheless, PPI deficits are not unique to patients in whom schizophrenia has been diagnosed; they are also observed in other psychiatric disorders involving abnormalities of gating in the sensory, motor, or cognitive domains.

P50 Gating

In the P50 sensory gating paradigm, two acoustic clicks are presented in rapid succession, usually 500 milliseconds apart. In normal persons, the P50 event-related potential to the second click is reduced or gated relative to the event-related potential to the first click. Schizophrenic patients and their first-degree relatives exhibit less sensory gating (16). An analogous form of sensory gating is studied in rodents based on the N40 event-related potential generated from the hippocampus (17).

Latent Inhibition

Latent inhibition is a relatively complex paradigm that is conceptually related to the gating theories of schizophrenic disorders. *Latent inhibition* refers to the observation that repeated exposures to a sensory stimulus (i.e., habituation) retard the rate at which a subject subsequently acquires a stimulus–response association based on this stimulus (18). Deficits in latent inhibition have been reported in schizophrenic patients (19), although it appears that such deficits may be limited to acute episodes of schizophrenia (19 ,20). This limitation has diminished interest in latent inhibition as a model for schizophrenia.

Social Behavior

Social withdrawal is included among the negative symptoms of schizophrenia and is often one of the earliest symptoms to occur. Models of social isolation have been studied in both monkeys (21) and rats (22). Naturally, given the importance of language in human social interactions, the species-specific differences in social behavior limit the direct comparisons that can be made across species.

Cognitive Measures

Cognitive deficiencies played a prominent role in the original description of schizophrenia by Kraepelin and distinguish the diagnosis of schizophrenia from manic-depressive and other forms of psychosis. Cognitive deficits are reported across all subtypes of schizophrenia and include impairments of attention, working memory, verbal memory, set shifting, and abstraction. Severe cognitive deficits appear to be a major factor contributing to impaired social and vocational functioning and treatment outcome (23). Current modes of therapy for schizophrenia (i.e., dopamine D2 or dopamine D2/serotonin 5-HT_2 antagonists, which effectively reduce the positive symptoms of schizophrenia in the majority of patients) have minimal beneficial effects on cognitive functioning. Typical antipsychotic drugs (e.g., haloperidol, chlorpromazine) may in fact lead to a deterioration in cognitive functions in schizophrenia patients (24) by producing so-called secondary deficit symptoms. Although some reports suggest that the atypical antipsychotic drug clozapine and the new generation of antipsychotics (e.g., olanzapine and risperidone, which target several subtypes of dopamine and serotonin receptors) may improve cognitive function, this effect is relatively small and has not been reproducible across laboratories (25 ,26 and 27). Thus, an important future direction of preclinical research relating to schizophrenia

is the design of animal models and novel treatments that target cognitive dysfunctions associated with this disorder. However, establishing the validity of animal models of cognitive deficits of schizophrenia and designing new pharmacologic approaches to the treatment of symptoms depends on appropriate behavioral paradigms for laboratory animals. These must provide as good an analogy as possible to the empiric measures on which schizophrenic patients are impaired. Unfortunately, the ratings of symptoms commonly assessed in clinical studies are of little value in this context.

The limited cognitive capacity of laboratory animals hinders the design of cognitive tasks that can be considered entirely "analogous" to relevant experimental paradigms, such as the Wisconsin Card Sorting Test and Continuous Performance Test. Therefore, most of the research involving cognitive tasks that are relevant to schizophrenia has been conducted in monkeys. Nevertheless, it is possible to design behavioral paradigms in rodents that can evaluate cognitive constructs "comparable" with those measured in many human experimental paradigms (40 ,41 and 42).

Among the most common of animal cognitive tasks are those with a working memory component (i.e., the ability to guide behavior by forming internal representations of stimuli that are no longer present in the environment). Human psychological tests of working memory, such as the "*n*-back" task (28), on which patients with schizophrenia exhibit an impairment (29), provide a measure of delay-dependent retention of mental representation. Several rodent tasks of working memory, such as delayed matching or nonmatching to sample (30) and discrete trial delayed alternation (31), contain important elements of human experimental paradigms and are used routinely to understand the cellular basis of working memory.

Schizophrenic patients, like patients with overt frontal lobe damage, display profound deficits in tasks that require behavioral flexibility, strategy shifting, and response to environmental feedback. These tasks include the Wisconsin Card Sorting Test (32), the Category Test (33), and the Tower of Hanoi Task (34), all of which involve an ability to utilize knowledge or feedback to change or shape behavior. Several interesting tasks have been characterized for evaluating behavioral flexibility and strategy-shifting ability in the rat. Of note is a maze-based strategy-shift task described by Ragozzino et al. (35). This task requires rats first to learn either a response strategy (unidirectional turn) or a visually cued place-discrimination strategy (black vs. white maze arm) to obtain a food reward. Following acquisition of the initial strategy, the rats are required to shift to the alternative strategy (e.g., response strategy to visual cue strategy) or to reverse the reward contingency within a strategy (e.g., right turn response to left turn response) to receive the food reward. This task is particularly useful in that it allows the experimenter to assess task acquisition, behavioral flexibility within and between strategies, and perseverative behavior, all of which appear to be relevant to the cognitive deficits associated with schizophrenia.

Attentional deficits are among the hallmarks of the clinical phenomenology of schizophrenia (36 ,37). One of the best characterized rodent attentional tasks is the Five-Choice Serial Reaction Time task, which was designed by Robbins and co-workers (38) based on the human Continuous Performance Test of Attention (39). The basic form of this task requires the rat to detect brief flashes of light occurring in one of five holes and provides a steady-state procedure in which the effect of manipulations can be determined against a baseline of stable performance. One advantage of this task is that it allows for a number of manipulations that test several variables on which patients with schizophrenia show deficits during the Continuous Performance Test, such as perseverative responding and omission errors.

The behavioral tests outlined here, albeit not without limitations, provide important tools for establishing the construct validity of animal models of schizophrenia. Although relatively few studies (e.g., 19,75,87) have utilized these measures to characterize animal models, their use may be important for defining novel pharmacologic approaches for the treatment of cognitive deficits associated with schizophrenia.

Cellular and Molecular Phenotypes

Cellular and molecular markers, identified by morphologic findings from postmortem studies, are being used increasingly to establish the validity of animal models of schizophrenia. Although a review of the schizophrenia postmortem literature is beyond the scope of this chapter, some of the findings relevant to animal models include abnormalities in the neuronal organization of the prefrontal cortex, such as a reduction in cortical volume (e.g., 7,43), altered laminar distribution of neurons that contain the enzyme nicotinamide adenine dinucleotide phosphate diaphorase (44), and reduced neuropil and elevated neuronal density (45). In addition to cytoarchitectural findings, postmortem evidence of abnormalities in cortical neurotransmitter function has also been demonstrated. These abnormalities include alterations in γ-aminobutyric acid (GABA) neurons or other indices related to GABA-mediated neurotransmission (46 ,47 and 48), decreased density of tyrosine hydroxylase immunoreactive axons (49), and changes in gene expression of the NR_{2B} and NR_1 subunits of the NMDA receptor (50 ,51). These markers have been used primarily in validating developmental animal models. Examples include alterations in cortical cell migration and neurogenesis in the gestational malnutrition model (52) and reduced thickness of neocortex and hippocampus after prenatal exposure to the influenza virus (53) or the antimitotic agent methyazoxymethanol (54).

Functional findings from imaging studies performed on patients with schizophrenia also have the potential of helping

to establish the predictive and construct validity of animal models. Of note are studies demonstrating an exaggerated dopamine release in response to amphetamine in patients with schizophrenia (55 ,56). These findings have been suggested to support the validity of the amphetamine sensitization model of schizophrenia (57).

PHARMACOLOGIC MODELS

Part of "50 - Animal Models Relevant to Schizophrenia Disorders "

The most common approach for developing animal models has been to exploit pharmacologic treatments or “drug-induced states” that produce schizophrenia-like symptoms in nonschizophrenic humans. These models generally have some predictive or construct validity and have been instrumental in establishing three of the most prominent theories of schizophrenia: the dopamine hypothesis, serotonin (or serotonin–dopamine) hypothesis, and glutamate hypothesis.

Dopamine-Agonist Models

The most widely studied class of drug-induced models of schizophrenia is based on the behavioral effects of psychostimulant drugs such as amphetamine. Although the models that evolved from this approach have demonstrated considerable predictive validity in terms of pharmacologic isomorphism, current thinking now indicates that the original appearance of face validity was actually somewhat misleading. In recent years, the dopamine hypothesis of schizophrenia has evolved into the narrower hypothesis that the mesolimbic dopamine system, distinct from the nigrostriatal dopamine system, is most relevant to schizophrenia. The nigrostriatal dopamine system is now seen as most relevant to the dyskinetic side effects of antipsychotic treatments. The mesolimbic system appears to mediate the locomotor-activating effects of lower doses of amphetamine, whereas the nigrostriatal system mediates the stereotypies that predominate at higher doses (4). Thus, the stereotypies originally proposed to have the most face validity for the human condition now appear to be more closely linked neurobiologically to phenomena that are considered side effects of the clinical treatments. Because schizophrenic patients are not generally considered to be motorically hyperactive, the amphetamine-induced hyperactivity that is mediated by what is believed to be the most relevant neurobiological substrate has seldom been considered to mimic the human disorder. Note that the failure of the model to have face validity has in no way weakened its utility in neurobiological research, which is based on the etiologic and predictive validity of the model. In fact, virtually any of the behavioral effects of amphetamine in rodents, including either locomotor hyperactivity or stereotypy, have a high degree of pharmacologic isomorphism as models for the efficacy of dopamine-antagonist treatments for schizophrenia (4 ,5); thus, the predictive validity of these models appears limited to dopaminergic treatments.

Both dopamine agonists and antagonists have been studied in rat paradigms used to assess latent inhibition. Most of these paradigms utilize three distinct stages: preexposure, conditioning, and expression. Drugs are typically given during the preexposure or conditioning stages, or both. Hence, different drugs can produce different profiles depending on the stage at which they exert their effect. Such complexity does not arise in the testing of latent inhibition in patients with schizophrenia, in whom the condition being tested is necessarily present at all stages of the test paradigm. In both rats and healthy humans, amphetamine disrupts latent inhibition in a haloperidol-sensitive manner (18). In contrast, direct dopamine agonists, such as apomorphine, do not alter latent inhibition. One of the most interesting aspects of the latent inhibition paradigm is that both typical and atypical antipsychotics can actually improve latent inhibition in rats when testing parameters are adjusted to yield low levels of latent inhibition in control animals. Hence, the latent inhibition paradigm differs from most other models in rats in that it is possible to assess the effects of a putative antipsychotic drug in a latent inhibition paradigm without first having to disrupt performance by the administration of a drug or some other manipulation.

As reviewed in detail elsewhere (14 ,15), the sensorimotor gating deficits assessed by measures of PPI of startle in schizophrenia-spectrum patients are mimicked in rats by the activation of dopamine systems. Thus, drugs such as the direct dopamine agonist apomorphine and the indirect dopamine agonists D-amphetamine and cocaine impair PPI in rodents. As in patients with schizophrenia (58), the apomorphine-induced disruption of PPI in rats is not modality-specific, being seen when acoustic prepulses are used to inhibit either acoustic or tactile startle (59). The D2-receptor family appears to mediate the apomorphine disruption of PPI in rats because it is blocked by D2 antagonists, largely insensitive to D1 antagonists, and reproduced by the D2 agonist quinpirole, but not by the D1 agonist SKF 38393. Within the D2 family of receptors, the D2 subtype appears to be the most relevant to these effects. In comparisons of knockout mice lacking either D2, D3, or D4 dopamine receptors, the effects of amphetamine on PPI were absent only in the D2-subtype knockouts (60). In addition to being blocked by typical antipsychotics, the apomorphine-induced disruption of PPI is reversed by the atypical antipsychotics clozapine, olanzapine, and quetiapine (15 ,61), which lack neuroleptic properties in some behavioral assays. For example, clozapine fails to reverse amphetamine- and apomorphine-induced stereotypy in rats, or apomorphine-induced emesis in dogs (4). The ability of antipsychotics, including atypical antipsychotics, to restore PPI in apomorphine-treated rats strongly correlates with their clinical potency (r = .99) (61). In addition to its sensitivity, the specificity of the PPI model for compounds with antipsychotic efficacy is supported by

the fact that it predicts no such efficacy for a wide variety of other psychiatric drugs. Thus, the PPI paradigm appears to be sensitive to both typical and atypical antipsychotics, but—when used with the dopamine agonist apomorphine—this paradigm clearly fails to make the important distinction between these two classes of antipsychotic agents. Thus, converging evidence indicates the important involvement of dopaminergic systems, acting via D2-family receptors, in the control of PPI. These findings in rats parallel the deficits in PPI observed in schizophrenic patients (58), which are also reported to be corrected by both typical and atypical antipsychotics (62 ,63).

It has been suggested that the increased stereotypy and submissive behavior produced by amphetamine in monkeys may mimic the stereotypy and paranoid ideation in schizophrenic patients. Accordingly, both these behavioral effects can be prevented by pretreatment with the antipsychotics haloperidol and chlorpromazine (21). In contrast, the social isolation induced by amphetamine in monkeys is generally regarded as related to the social withdrawal seen in patients with schizophrenia. As in schizophrenic patients, the animals actively avoid other animals, and these effects cannot be reversed by typical antipsychotic drugs such as haloperidol and chlorpromazine (21). Although few novel antipsychotics have been tested in this model, both clozapine and quetiapine have been shown to reverse amphetamineinduced social isolation in monkeys.

One aspect of the psychostimulant model that has generated considerable interest involves the dosage regimens required for amphetamine or related drugs to produce psychotic-like behavior in psychiatrically healthy humans. Because of the widespread belief that amphetamine-induced psychosis is produced only by repeated exposure to the drug (6 ,64), many preclinical researchers have directed their attention to the behavioral effects of amphetamine that are augmented or sensitized by repeated administration of the drug. A review of the available clinical literature, however, reveals that chronic exposure is not required and that psychotic episodes can be produced by acute administration of amphetamine or related drugs (5). The complex and limited nature of the clinical data seems to have led to mistaken interpretations that have inordinately influenced a large proportion of the basic research in this area. Although it is clear that tolerance to the psychosis-inducing effects of amphetamine does not occur in humans, it is not clear that sensitization is required for these effects. Hence, although an animal model based on the effects of chronic amphetamine could be invalidated if tolerance were observed, the development of sensitization does not provide evidence supporting the relevance of the model to schizophrenia. Indeed, it appears that the animal models having the greatest amount of predictive validity are those based on the effects of the psychostimulant that are evident after acute administration (4 ,5).

Serotonin-Agonist Models

Soon after the initial reports of the behavioral effects of lysergic acid diethylamide (LSD), researchers began to explore the idea that the class of drugs represented by LSD might appropriately be called *psychotomimetics*, or even *psychotogens*. This hypothesis was engendered by the similarities between the effects of LSD on perception and affective lability and the symptoms of the early stages of psychoses such as schizophrenia (65). Recent studies systematically comparing hallucinogen-induced psychotic states with the early stages of psychotic disorders have confirmed substantial overlap in the two syndromes (66). Despite many clear similarities, two major differences prompted the dubious albeit widely accepted conclusion that this class of drugs does not provide a useful model of schizophrenia (67 ,68). First, tolerance was found to develop rapidly to the subjective effects of LSD-like drugs, whereas the symptoms of schizophrenia persist for a lifetime. Second, the hallucinations produced by LSD and related drugs are typically visual rather than auditory, as is characteristic of schizophrenia. These two observations weaken the predictive validity of the hallucinogen model of the syndrome of schizophrenia.

Initial interest in hallucinogens was spurred by the possibility that abnormalities of biochemistry might lead to the endogenous production of such compounds and hence be responsible for some psychotic symptomatology. For example, the transmethylation hypothesis posited that serotonin could provide a substrate for the endogenous production of hallucinogens similar to *N,N*-dimethyltryptamine (DMT) (68). Initially, this etiologically based model was dismissed because of the rapid tolerance associated with traditional hallucinogens such as LSD and mescaline. Nevertheless, recent studies indicate that no tolerance occurs to the subjective effects of DMT in humans (69), which suggests that DMT may differ from other hallucinogens and that this model may still be viable. Indeed, different mechanisms may be involved in the various actions of the different hallucinogenic drugs, as suggested by the lack of cross-tolerance to DMT in human subjects made tolerant to LSD (70). Hence, further studies are warranted to provide the objective evidence needed to evaluate adequately the model of psychosis based on the hypothesis of an endogenous psychotogen.

Furthermore, it remains possible that these drugs may be psychotomimetic and therefore have relevance as models of some aspects of psychotic episodes in humans. Recent suggestions of serotoninergic abnormalities in schizophrenia (71) and of 5-HT_{2A}-receptor contributions to the clinical efficacy of atypical antipsychotics (72) have revitalized interest in this possibility. Hallucinogens are now believed to produce their characteristic subjective effects by acting as 5-HT_{2A} agonists (73). Many of the newer atypical antipsychotic drugs are clearly potent 5-HT_{2A} antagonists (72). With regard to specific abnormalities exhibited by patients

with schizophrenia, evidence indicates that the study of hallucinogen action may provide useful animal models. For example, both schizophrenic and schizotypal patients exhibit deficits in startle habituation (9 ,11 ,12 and 13). Hallucinogenic 5-HT_{2A} agonists such as LSD and mescaline produce similar deficits in startle habituation in rats (59 ,74). Conversely, opposite behavioral effects are produced by 5-HT_{2A} antagonists (74), including some antipsychotics (72). Similarly, the PPI-disruptive effects of hallucinogenic 5-HT_2-receptor agonists are blocked by the selective 5-HT_{2A} antagonist M100907, but not by the dopamine blocker haloperidol (74). Furthermore, in keeping with the similarities between acute psychotic states and the syndrome induced by hallucinogens, latent inhibition is also disrupted by LSD and other serotoninergic hallucinogens (75), as it is in acutely ill schizophrenic patients. These effects can be blocked by the putative antipsychotic M100907 (75). Thus, the effects of hallucinogens on habituation, PPI, and latent inhibition in animals have some predictive validity with regard to both specific abnormalities exhibited by patients in the early stages of schizophrenia and the effects of antipsychotics (74). The construct validity of this model is based on compelling evidence that both the symptoms of schizophrenia and the effects of hallucinogens reflect exaggerated responses to sensory and cognitive stimuli, theoretically resulting from failures in normal filtering or gating processes such as habituation, PPI, or latent inhibition (1 ,3 ,9). Accordingly, 5-HT_{2A} antagonism by itself might be effective in the treatment of certain forms of schizophrenia. Indeed, a rather selective 5-HT_{2A} antagonist, M100907, appears to have efficacy as an antipsychotic in some patients with schizophrenia, despite having negligible affinity for dopamine receptors (76). This finding suggests the possibility of a nondopaminergic mechanism for a treatment of subtypes of schizophrenia and provides important support for the predictive validity of the hallucinogen model of psychosis.

Glutamatergic Models

Dysfunctional glutamate neurotransmission has been implicated in schizophrenia, primarily because noncompetitive antagonists of the NMDA subtype of glutamate receptors, including PCP and ketamine, produce a behavioral syndrome in healthy humans that closely resembles symptoms of schizophrenia and is frequently misdiagnosed as acute schizophrenia (77 ,78). The syndrome includes positive symptoms, such as paranoia, agitation, and auditory hallucinations; negative symptoms, such as apathy, poverty of thought, and social withdrawal; and cognitive deficits, such as impaired attention and working memory. The remarkable similarity of PCP-precipitated behaviors with the diverse array of symptoms associated with schizophrenia has prompted the use of PCP (and its analogue ketamine) in pharmacologic models of schizophrenia in both basic and clinical studies. Notably, whereas psychotic episodes are generally associated with prolonged abuse of amphetamine, a single exposure to PCP or ketamine can produce the cognitive deficits and several symptoms listed above in healthy humans. Thus, acute exposure to these compounds is considered a useful pharmacologic tool for producing some aspects of schizophrenic symptomatology in the laboratory animal.

Several interesting aspects of this model distinguish it from monoamine-based models. For example, the behavioral effects of PCP and related compounds are not, for the most part, mediated by increased dopamine transmission and therefore are not blocked by typical antipsychotics (see below). Similarly, in normal human volunteers, the psychotomimetic effects of ketamine are not blocked by typical antipsychotics, but they are reduced significantly by the prototypal atypical antipsychotic clozapine (79). Therefore, this model may be especially useful for testing the effectiveness of atypical and perhaps even novel antischizophrenia drugs. In fact, the first non-monoaminergic ligands (including a glycine-site agonist and a metabotropic glutamate-receptor agonist), which have recently entered clinical trials, have been based on preclinical PCP models (41 ,80). Another attractive aspect of the NMDA antagonist model is that, unlike the dopamine-based models, it has strong construct validity for studying the cognitive and attentional deficits in schizophrenia. In laboratory animals, NMDA antagonists impair working memory, set shifting, and other cognitive functions that are related to schizophrenia (31). More importantly, in clinical studies, direct comparison of schizophrenic patients with healthy volunteers receiving subanesthetic doses of ketamine have indicated no significant difference in scores for thought disorder between the two groups (81).

In rats and monkeys, noncompetitive NMDA antagonists, including PCP and ketamine, produce a range of behavioral abnormalities that have important relationships to schizophrenic symptomatology. These drugs produce both locomotor hyperactivity and stereotyped behaviors. Although they also increase dopamine neurotransmission in limbic regions (82), their motor-activating effects appear to be dopamine-independent (83). At rather low doses, PCP retards habituation of the startle response without affecting startle reactivity (84), a pattern similar to that seen in parallel studies in schizophrenic patients (9). Also as in schizophrenia, PCP-treated rats exhibit marked deficits in social behavior. Although typical antipsychotics have no reliable effect on the PCP-induced disturbance in social behavior in rats, the atypical antipsychotics clozapine, sertindole, and olanzapine appear to reverse the effects partially (22). In terms of sensorimotor gating measures, PPI is reduced or eliminated in rats by psychotomimetic noncompetitive NMDA antagonists, including PCP, dizocilpine (MK-801), and ketamine (14 ,15). As with apomorphine and as in schizophrenia, both intramodal and cross-modal PPI is sensitive to noncompetitive NMDA antagonists (59). In contrast to

the effects of dopamine agonists on PPI, but in keeping with the results of studies of the subjective effects of ketamine in humans, the PPI-disruptive effects of NMDA antagonists are *not* reversed by typical antipsychotics such as haloperidol or selective D1 or D2 antagonists. Importantly, these effects *are* reversed by the atypical antipsychotics clozapine, olanzapine, quetiapine, and remoxipride (14 ,15). These findings raise the possibility that the PCP-induced disruption of PPI may be a useful model for identifying compounds with atypical antipsychotic potential.

In addition to acute dosing with PCP and ketamine, withdrawal from repeated administration of PCP has been proposed to be a useful model for some aspects of schizophrenia (85). Although this model lacks some of the important characteristics of acute models, such as lack of an effect on PPI, it produces an enduring cognitive impairment that is highly relevant to schizophrenic symptomatology.

DEVELOPMENTAL MODELS

Part of "50 - Animal Models Relevant to Schizophrenia Disorders "

The best-characterized animal model in this class is that proposed by Lipska and Weinberger (86 ,87), which involves neonatal excitotoxic lesions of the ventral hippocampus. These lesions produce postpubertal behavioral disturbances, such as increased spontaneous, amphetamine-induced, and NMDA antagonist-induced locomotion. They also produce potentiated apomorphine-induced stereotypies, disruption of PPI, reduced cataleptic response to haloperidol, impaired working memory, and hypersensitivity to stressful stimuli. Furthermore, this manipulation results in alterations in some cellular and molecular markers that may have relevance to schizophrenia (88), such as reduced expression of the glutamate transporter excitatory amino acid transporter 1 ($EAAT_1$) and glutamic acid decarboxylase (GAD67). To the limited extent that they have been tested, dopamine antagonists, including classic and atypical antipsychotic drugs, ameliorate the behavioral abnormalities produced by neonatal ventral hippocampal lesions. It will be important in the future to examine the predictive power of this model for the identification of antipsychotic drugs more thoroughly with measures that are not sensitive to the effects of antipsychotic drugs in sham-lesioned rats.

Other strategies that have been used to disrupt early cortical development include systemic exposure to L-nitroarginine, a nitric oxide synthase inhibitor that disrupts neuronal maturation (89), or the antimitotic agent methyazoxymethanol (54 ,90). These models produce morphologic changes relevant to schizophrenia, such as altered neurogenesis and reduced cortical volume. They also produce some of the behavioral characteristics associated with schizophrenia, such as stereotypy, cognitive impairments, and deficits in PPI. As yet, the predictive validity of this model in terms of sensitivity to antipsychotic treatments remains to be determined.

Isolation rearing of rats has also been used as a manipulation to generate models related to schizophrenia and models of depression and attention-deficit/hyperactivity disorder (ADHD). In the context of schizophrenia, the focus has been on the disruptions of PPI rather than the locomotor hyperactivity observed in isolation-reared rats. Indeed, comparisons among different strains of rats indicate that both effects are strain-dependent but appear in different strains (91 ,92 and 93). Thus, as with a variety of pharmacologic manipulations, locomotor hyperactivity and deficient PPI are readily dissociable behavioral phenomena, even though both have been used in animal models related to schizophrenia. In several laboratories, isolation-reared rats have been shown to exhibit a neuroleptic-reversible deficiency in PPI in comparison with group-reared controls (91 ,94). This effect of isolation rearing appears to be specific to development; similar isolation of adult rats fails to produce the deficit in PPI observed in isolation-reared rats (95). Furthermore, as in the most common form of schizophrenia, the PPI deficits are not evident before puberty but emerge at about that time (96). Converging evidence for an influence of isolation rearing on gating mechanisms in adulthood stem from the observation that the rat analogue of the P50 sensory gating deficit of schizophrenia is also seen in isolation-reared rats (97). Because these deficits in PPI and P50 gating are not associated with concomitant deficits in latent inhibition (95), which occurs only in acutely ill schizophrenic patients (19), it would appear that the isolation-rearing model is more relevant to chronic than to acute schizophrenia. In addition to reversals by typical antipsychotics (haloperidol, raclopride), reversals of the isolation-induced deficits in PPI by clozapine, risperidone, quetiapine, olanzapine, and the putative antipsychotic M100907 have been observed (94 ,98). Thus, PPI deficits in isolation-reared rats may be a valuable paradigm that—like the apomorphine-induced disruption of PPI—is sensitive, but not specific, in its ability to identify compounds with atypical antipsychotic properties. The potential advantage of the isolation-rearing model, as of other models involving developmental perturbations, is that it does not rely on the administration of a drug or the introduction of an artificial lesion to produce the behavior of interest. When the behavior studied in the model is induced by a drug, such as a dopamine or serotonin agonist, the model is typically effective in identifying the corresponding antagonist. Indeed, most of the animal models of schizophrenia have relied on dopaminergic psychostimulants and have proved to be largely limited to the detection of dopamine antagonists. The major message of the fact that clozapine is effective, even at doses that achieve low levels of dopamine receptor occupancy, is that new treatments can be identified for patients with schizophrenia, and that these novel treatments may not involve dopamine antagonism. The isolation-rearing manipulation presumably produces a deficit in PPI by virtue of a substantial reorganization of neural circuits through the course of development.

Hence, such a model has the potential to identify completely novel antipsychotic treatments simply because it does not require the administration of a drug.

GENETIC MODELS

Part of "50 - Animal Models Relevant to Schizophrenia Disorders "

Genetic contributions to schizophrenia have been clearly established in family studies. Although the focus of considerable research, the application of linkage analyses to schizophrenia has not generally proved successful, perhaps because schizophrenia does not represent a single phenotype. Nevertheless, it remains possible that genetic approaches will lead to etiologically based models

Strain Differences

Genetic factors appear to be critical determinants of both sensory and sensorimotor gating in rats. For example, some inbred strains of mice are deficient in gating of the N40 event-related potential (17), which is the rodent analogue of the P50 gating deficit seen in schizophrenia. Indeed, a linkage between the P50 gating deficit in patients with schizophrenia and a specific chromosomal marker associated with the gene for the α_7 subunit of the nicotinic acetylcholine receptor has been demonstrated in a series of elegant studies (16). The potential power of cross-species studies of specific behavioral abnormalities in psychiatric disorders is exemplified by the parallel between these human linkage studies and the observation that the strain of mice that is most deficient in gating of the N40 event-related potential is also the most deficient in α_7-nicotinic receptors (17). Such parallel investigations in patients and animals provide an exemplar for the application of modern molecular biological techniques to the generation and validation of animal models of psychiatric disorders. However, this genetically related deficit in sensory gating does not extend to studies of sensorimotor gating as measured by PPI of the startle response. Thus, mice in which the α_7-nicotinic receptors have been deleted by genetic engineering exhibit normal levels of PPI (99). Nevertheless, other evidence indicates that PPI is regulated by genetic factors. For example, strain-related differences in the dopaminergic modulation of PPI have been reported (100). More relevant to the recent indications that PPI deficits are evident in family members of schizophrenia patients (101), Ellenbroek et al. (102) utilized pharmacogenetic selective breeding to produce strains of rats that were either sensitive (APO-SUS) or insensitive (APO-UNSUS) to the effects of apomorphine on gnawing behavior. Within either a single generation or after many generations of selective breeding, APO-SUS rats and their offspring exhibited significantly less PPI and latent inhibition than did APO-UNSUS rats. Apparently, the physiologic substrates that regulate behavioral sensitivity to apomorphine (presumably some feature related to dopamine-receptor transduction) are associated with substrates that regulate both PPI and latent inhibition, which are transmitted genetically. In another approach, comparisons of several inbred strains of rats identified some strains that exhibit deficits in PPI (103). Because these strains did not exhibit hearing impairments, the genetically determined deficit in PPI likely represents a deficit in sensorimotor gating processes.

Genetically Modified Animals

Other examples of nonpharmacologically based models relevant to schizophrenia are emerging from the field of molecular biology, in which genetic engineering is being used to generate transgenic and knockout animals. In the absence of established candidate genes, the use of mutant animals in models of schizophrenia has focused on the identification of phenotypic differences in behaviors considered relevant to the clinical disorder (i.e., validity has been sought primarily in the dependent measure rather than in the independent variable). For example, schizophrenia-like deficits in PPI of startle have been observed in specific strains of mice (104) and in “knockout” mice in which specific genes have been deleted (105). The focus of genetic engineering in the mouse is beginning to prompt extensions of pharmacologic studies from the rat to the mouse. Although much more such work is needed, it is already abundantly clear that species differences in pharmacologic effects between mice and rats will complicate the application of some schizophrenia-related rat models to mice. For example, in rats, antipsychotic drugs by themselves have minimal effects on PPI, in contrast to their marked suppression of locomotor activity and ability to improve latent inhibition. Hence, rat PPI models can identify antipsychotic effects only if a drug reverses the effects of a disruption in PPI produced by another drug, a lesion, or a developmental manipulation such as isolation rearing. In mice, however, it appears that antipsychotics improve PPI in mice that have not been manipulated (106). This important difference means that it may be easier to detect antipsychotic effects in mice, but also that it will be much more difficult to demonstrate a reversal of a PPI deficit produced by an experimental manipulation.

In an approach that is distinctly different from the candidate gene approach, genetically modified mice have been used to test specific hypotheses of relevance to animal models of schizophrenia. For example, although most pharmacologic evidence in rat had implicated the D2 subtype of the family of dopamine receptors in the PPI-disruptive effects of dopamine agonists, gene knockout mice proved useful in testing this conclusion more definitively. Ralph et al. (60) tested the effects of amphetamine on PPI in D2-, D3-, and D4-receptor knockout mice and corresponding wild-type mice. Only the mice lacking the D2 subtype of receptor failed to show the normal effect of amphetamine on PPI. Although knockout manipulations are confounded

by developmental adaptations, such a study takes advantage of the specificity that represents the fundamental strength of the knockout technology, as no dose of a drug can ever inactivate all of a given receptor without interacting with other receptors at the same time.

Another model with relevance to the etiology and pathophysiology of schizophrenia involves the $NMDAR_1$ (NR_1) "knock-down" line of mutant mice (107). These animals display exaggerated spontaneous locomotion and stereotypy in addition to deficits in social and sexual interactions. Interestingly, preliminary studies indicate that some of these behavioral abnormalities may be ameliorated with a single dose of haloperidol or clozapine. This is an intriguing model that, with further characterization, may advance our understanding of the long-term effects of congenital NMDA-receptor hypofunction. Nevertheless, its relevance to schizophrenia may be questioned by the fact that no evidence has been found in schizophrenia for abnormalities in genes that express subunits of the NMDA receptor (108). Furthermore, these animals, as would be expected, show no behavioral reaction to the NMDA antagonists PCP and dizocilpine. Schizophrenic patients, on the other hand, exhibit a profound exacerbation of preexisting symptoms after exposure to a single dose of PCP (109) or ketamine (110).

CONCLUSIONS

Part of "50 - Animal Models Relevant to Schizophrenia Disorders "

Establishing the construct, etiologic, and predictive validity of animal models relevant to schizophrenia-related disorders is limited by the paucity of rigorous experimental data derived from clinical studies. The major source of validation remains the ability of established antipsychotic drugs to demonstrate efficacy, measured by broadly defined clinical scales in heterogeneous groups of patients. Specific measures of clinical subtypes, clinical course, and symptom-specific treatment effects that can be translated into relevant animal models are needed to overcome the limitations inherent in relying on global assessments of treatment efficacy for validity assessment. The objective study of such measures in translational research is critical for the eventual identification of new antipsychotic treatments. Such treatments not only could help patients who are resistant to treatment with typical antipsychotics but also could help in the treatment of the negative and cognitive symptoms that do not appear to be treated adequately even by the newest generation of atypical antipsychotics.

Endophenotypes in Studies of the Genetics of Schizophrenia

David L. Braff

Robert Freedman

David L. Braff: Department of Psychiatry, University of California at San Diego, La Jolla, California.

Robert Freedman: Department of Psychiatry and Pharmacology, University of Colorado, Denver, Colorado.

The power and appeal of the molecular biology mantra, “DNA to RNA to protein,” to explicate cell biology comes from its universal appearance and application in all species, from microorganisms to human beings. Based on this mantra, the genomes of viruses, bacteria, fruit flies, and now humans are being mapped and sequenced, so that all the genes and, ultimately, their corresponding biological activity can be identified. As these genes are identified, it is reasonable to ask how this information can be related to the inheritance of risk for psychiatric illness. For a bacterial enzyme, genetic coding of the amino acid sequence of proteins can be closely associated with a functional change in enzymatic activity. For a complex psychiatric illness, as defined by DSM-IV criteria, the relationship is obviously not as straightforward. Psychiatric illnesses such as schizophrenia are generally conceptualized as multifactorial and most likely reflect the combined influence and interactions of both genetic and nongenetic factors. Furthermore, there is no reason to presuppose that only one gene is responsible for a complex psychiatric disorder such as schizophrenia, as there is in some simple mendelian illnesses. Persons who are ill may differ in more than one gene from the rest of the population, and different sets of genes may be associated with illness in different populations. Thus, how best to use the power of molecular genetics to understand the inheritance and pathophysiology of complex genetic psychiatric illnesses remains an enigma that is only now beginning to be solved.

In the simplest and most commonly used strategy of molecular genetics that is applied to complex psychiatric disorders, it is assumed that the distribution of illness in a family represents the effect of a single gene, and techniques of genetic analysis are used to identify that gene. This approach does not necessarily overlook the complexity of psychiatric illness, but it assumes that the effect (i.e., signal) of a single gene will be discerned in a complex, “noisy” genetic background if samples sizes are large enough or if the population is sufficiently homogeneous (e.g., 1). An attractive feature of this approach is that the search for genes is not constrained by preexisting hypotheses about the biology of the illness, which, in the case of schizophrenia, is still unclear. A second commonly applied strategy is, in fact, the opposite approach; an assumption is made about the biology of the illness and then candidate genes associated with that biology are examined to determine if they are mutated. Both approaches have been successful to a limited extent for explicating the genetics of schizophrenia. Replicable linkages for schizophrenia have been obtained at several locations (e.g., chromosomes 1, 6, 8, 13, 15, and 22), but genetic mutations have not as yet been identified at these sites (2). On the other hand, DNA mutations have been found in candidate genes such as *NURR1*, the gene for the receptor for retinoic acid, a pathway critical in neuronal development, but these mutations seem to be found in only a small proportion of schizophrenic patients (3).

This chapter describes a third approach, which attempts to make use of the power of the molecular biology mantra by identifying brain dysfunctions that may be caused by a single genetic abnormality. The rationale comes from the mantra itself. If discrete genetic abnormalities are associated with schizophrenia, then each of them should cause a specific protein change that is reflected in a corresponding discrete functional abnormality. Even if several genes are abnormal, along with additional environmental factors, the functional abnormality resulting from each gene should generally be identifiable. Theoretically, the relationship between these functional abnormalities and genes, discovered either by genetic linkage or by candidate gene analysis, should be stronger than the association to the illness itself because the illness itself results from a mixture of genetic and nongenetic abnormalities that may vary between different individuals and families. As is true for the other approaches described above, this approach has not yet led to the identification

of the genes that are associated with and that may even cause schizophrenia in most cases. Nevertheless, the strategy has been useful for gene discovery in other complex illnesses, such as colon cancer and hemochromatosis. In colon cancer, the formation of multiple polyps, rather than cancer itself, has been found to be the genetically heritable trait (4), and in hemochromatosis, a high serum level of iron, rather than the clinically recognized illness, has been found to be the more penetrant heritable trait (5).

Endophenotype is often used as the descriptive term for these discrete, genetically determined phenotypes that may be part of a complex illness. The search for endophenotypes is not straightforward because no *a priori* criterion can be used to decide if a particular element of schizophrenia or any other psychiatric illness reflects the effect of a single gene. Putative endophenotypes have ranged from clinical characterizations, such as the presence of schizotypy in relatives of schizophrenic patients (6), to the neurophysiologic and neuropsychological measures described in this chapter, to structural measures of specific, functionally important regions of the brain and ventricular size. Because none of these phenotypes has yet led to the identification of a specific molecular deficit, it has not been proved that any one of them is actually linked to a specific genetic abnormality. In this context, even if endophenotypes turn out to be multiple, rather than single, gene phenomena, their genetic architecture, even as complex endophenotypes, may turn out to be simpler than schizophrenia in certain families. The sections below outline the stage of investigation for a number of putative phenotypes, from presence in schizophrenia probands and their relatives to statistically significant genetic linkage to a chromosomal locus.
Several points must be considered in the assessment of endophenotypes. First, because these are putative genetic traits, their biology begins at conception, so that by the time they are measured in adulthood, their expression may have been modified by such factors as development, aging, brain injury, and medication and substance abuse and. Second, most genes expressed in the brain are expressed in many different brain areas, so that their ultimate functional expression may involve much more than the simple phenotype being measured. Third, many genes expressed in the brain are also involved in the development of neurons, so that their most important functional effects may have occurred prenatally. Fourth, according to Mendel's second law, every genetic trait segregates independently in a family, so that if schizophrenia is a multifactorial trait, some siblings should express specific phenotypes independently of other phenotypes. These siblings may be better subjects for characterizing the phenotype than the patients themselves, whose multiple deficits may obscure the unique phenotype. Finally, because the aim of genetics generally is to identify affected individuals who have or do not have a particular genetic abnormality, the measurement of the putative phenotype must clearly separate most affected and unaffected individuals, regardless of whether a quantitative or discrete variable is used. The range of effect sizes for several putative endophenotypes is shown in Table 51.1 , which reflects another point. The measurement of endophenotypes is in itself a complex endeavor in which modest-appearing paradigmatic manipulations lead to significant shifts in the signal of the dependent measure being assessed.

TABLE 51.1. ENDOPHENOTYPES AND THE GENETICS OF SCHIZOPHRENIA: EFFECT SIZE DIFFERENCES BETWEEN SCHIZOPHRENIA SPECTRUM GROUPS AND NORMAL COMPARISON SUBJECTS

Phenotypes	Schizophrenia Patients	Clinically Unaffected Relatives of Schizophrenia Patients	Schizotypal Personality Disorder Patients	References
P50 Suppression	0.92–1.29	0.79	0.79	30, 31, 203
Prepulse Inhibition	0.51–0.85	1.0	1.45	46, 47, 54
Smooth-Pursuit Eye Movement	2.0–3.0	0.29–1.3	0.29	92, 93, 204
Antisaccade	4.88–6.38	1.38–3.75	0.75–1.36	101, 204
Executive Functioning (Wisconsin Card Sorting Test)	0.47–1.97	0.73–1.6	0.72	118, 126, 127, 132
Working Memory (Letter–Number Span)	1.42–2.2	0.42	0.73–1.04	126, 132, 205
Thought Disorder (Thought Disorder Index; Ego Impairment Index)	1.56–2.98	0.34–0.83	1.04–1.28	204, 206–208
Continuous Performance Test	0.45–3.30	0.46–2.97	0.45–0.78	118, 139, 140, 147
Span of Apprehension	0.5–2.5	0.6–1.5		139, 152, 209–212
Visual Backward Masking	0.33–0.65	0.43–0.57	0.45–0.67	168, 173, 213, 214
P300 Event–Related Potential	0.45–1.05	0.17	0.36	192, 215
Reaction Time	0.59–1.05	0.44	0.79–0.99	168, 216, 217

Effect sizes in schizophrenia patients, clinically unaffected relatives of schizophrenia patients, and schizotypal personality disorder patients compared with those in normal subjects. These effect sizes were computed by using the means and standard deviations for the normal comparison subjects and the means of the patient groups. The range of values differs from study to study because different investigators used different patient populations taking different types and amounts of medications; also, the experimental paradigms, although similar, often differed in terms of stimulus parameters. Of course, in some of these studies, multiple conditions were used, some of which were needed to establish floor and ceiling effects. In these cases, we generally cite the most robust effect sizes.

The search for endophenotypes takes advantage of genetic strategies to evaluate the current state of understanding the pathophysiology of schizophrenia. The initial endophenotype was schizotypy, which was proposed to be a pure expression of schizotaxia, the genetic predisposition for schizophrenia. Schizotypy itself does not generally show mendelian segregation, so that the likelihood that it reflects a single genetic trait is now considered small. However, the presence of schizotypy in family members has been related to linkage of schizophrenia at a specific chromosomal locus in a subset of families, so that a reexamination of schizotypy as an endophenotype in some families may once again be productive. Inhibitory interneurons have increasingly become a focus of interest in the biology of schizophrenia. Many of the endophenotypes described below are attempts to demonstrate inhibitory neuronal function by means of psychophysiologic and neurophysiologic techniques. Structural phenotypes have been limited to the measurement of brain volume. As functional brain-imaging techniques become more advanced, so that specific neuronal functions can be demonstrated, it is likely that these techniques will also be used. Magnetic resonance spectroscopy of the amino acids associated with neuronal function, such as *N*-acetylasparate, is an example (7).

CANDIDATE ENDOPHENOTYPES FOR GENETIC STUDIES

Part of "51 - Endophenotypes in Studies of the Genetics of Schizophrenia "

Given the considerations discussed above, it is important to stress that although the DSM-IV diagnostic criteria for schizophrenia may be clinically and administratively useful, they are not likely to be optimally useful as phenotypes in genetic studies (8 ,9 ,10 and 11). The search for and use of new, nondiagnostic, non–DSM-IV-based candidate endophenotypes parallels our search for the corresponding candidate genes in complex human genetic disorders such as schizophrenia. Also, we understand that in accounting for the genetic diathesis or vulnerability to schizophrenia, we are "accounting" for, at most, 50% to 70% of the variance of the disorder; the remaining variability resides in nongenetic "second hits," such as neonatal or *in utero* neural damage to the developing hippocampus (12 ,13 ,14 and 15) or other factors. A plethora of studies indicate that in addition to mutant genes, a second level of environmental or other generalized or specific stressor probably must act as a second hit in the central nervous system. An example of the result of this need for a second hit is illustrated by the fact that clinically "unaffected" relatives of patients with schizophrenia have endophenotypic markers of abnormalities in some or all of the measures listed below but do not have the disorder of schizophrenia. Therefore, it appears clear that some nongenetic contributions (not necessarily reflected by these endophenotypes) are crucially important in the expression of some forms of this elusively heterogeneous and complex disorder of schizophrenia. In searching for non–diagnosis-based "candidate endophenotypes," we are not alone in schizophrenia research because many disorders, from diabetes to hypertension to bipolar disorder, also present the same conundra and difficult conceptual issues.

In schizophrenia research, it seems reasonable to classify candidate endophenotypes into structural and functional abnormalities. Because of limits of chapter length, we do not discuss structural endophenotypes (e.g., widely dispersed, decreased, generalized gray matter; decreased superior temporal gyrus volume; deficits of hippocampal or temporal lobe volume (16); gray matter volume or organizational abnormalities in various subsections of the prefrontal cortex, most significantly the dorsolateral prefrontal cortex) that may be useful in genetic studies (17 ,18). It is important to note that such structural abnormalities may be correlated with some of the functional abnormalities discussed below. In Table 51.1 , some functional endophenotypes are listed, along with estimates of the effect sizes of deficits of each in schizophrenic patients, clinically unaffected relatives of schizophrenic patients, and schizotypal patients in comparison with normal subjects. In addition, reasonable and well-understood neural substrates for these measures are known, as discussed. Table 51.1 summarizes what we have selected as important and representative (but not all-inclusive) candidate endophenotypes for genetic studies in schizophrenia, with an emphasis on the information-processing abnormalities that have assumed a central role in the search for candidate endophenotypes (10 ,11). Identifying these endophenotypes for genetic studies is only a first step; after they have been identified, complex strategies must be employed, as discussed above and below, to conduct linkage, association, and other genetic studies on the candidate endophenotypes so that we can identify the candidate genes that are likely contributing to the endophenotypes (and their neural substrates) present in the complex disorder of schizophrenia. In the next section, we describe possible functional endophenotypes, with an emphasis on gating and oculomotor abnormalities.

Abnormalities of Sensorimotor Gating

The concept of deficits of sensory gating in schizophrenia derives from the clinical observation that patients report failures of information processing characterized by poor sensory gating—an inability to screen out trivial stimuli and focus on salient aspects of the environment so as to process information smoothly and successfully navigate through life (10 ,19 ,20). Gating functions are commonly assessed with P50 suppression and prepulse inhibition (PPI) of the startle response.

P50 Suppression

Initial studies at the University of Colorado have identified P50 suppression as an important candidate endophenotype in studies of schizophrenia (21 ,22 ,23 and 24). In a typical paradigm, P50 suppression occurs when two clicks are presented with a 500-millisecond interval between them. The small P50 event potential wave elicited by the click stimulus can be identified when many trials (e.g., 30 to 100 or more) are performed; this number of trials plus various filtering strategies provides investigators with a robust signal-to-noise ratio for identifying and quantifying the P50 wave. A P50 wave is generated to the first click and another to the second click. Across multiple studies, it has been found that the second P50 wave is normally suppressed; suppression can probably be attributed to the activation of inhibitory processing and circuitry by the first P50 stimulus. In normal subjects, the second P50 wave typically is diminished by 80% in comparison with the first wave (Fig. 51.1).

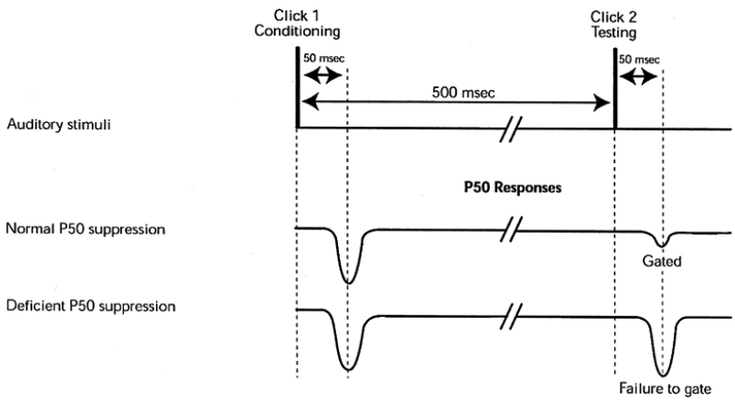

FIGURE 51.1. Pairs of auditory clicks are presented to subjects and EEG is averaged across trials. The P50 component of the auditory event-related potential is measured in response to the first and second clicks.

Initial studies (21 ,22 ,23 and 24) demonstrated an expected failure of suppression in schizophrenic patients, consistent with theories of failed inhibitory function or impaired sensorimotor gating in schizophrenia (25). These studies of deficits in P50 suppression in schizophrenic patients have been widely replicated (26 ,27 ,28 ,29 ,30 and 31). The failure of P50 suppression in schizophrenic patients is not necessarily specific to this one disorder. For example, Franks et al. (32) reported that P50 suppression is also deficient in patients with acute mania but “normalizes” with time, whereas the deficits of P50 suppression are more persistent in schizophrenic patients (32). This finding is consistent with the idea that genetic “diatheses” may be shared between schizophrenia and mania. P50 suppression deficits have also been shown (and replicated) in “clinically unaffected” family members of schizophrenic patients (24 ,31 ,33 ,34 and 35). The P50 suppression abnormalities of these family members normalize following administration of the cholinergic nicotinic receptor stimulant nicotine (36), as do those of schizophrenic patients (37). This finding has raised interest in the critical importance of the cholinergic system in P50 suppression, and some of the cholinergic neurobiological substrates of P50 suppression deficits have been elucidated.

As discussed in the section on PPI , suppression is probably the function of a more wide-ranging neural circuitry prominently involving hippocampal structures (38). The use of P50 suppression as a candidate endophenotype in genetic studies is probably the most advanced of any of the endophenotypes we discuss here; a specific linkage of P50 suppression with a genetic marker at the locus of the α_7 subunit of the nicotinic receptor gene (11) has been identified in the first study linking a candidate endophenotype of information processing in schizophrenia to a specific

chromosomal region. It is important to stress that these types of studies do not identify a “schizophrenia endophenotype,” but rather the linkage of deficits in P50 suppression (characteristic of schizophrenia) to a specific chromosome region. Future studies will have to identify the specific genetic deficit(s) (e.g., specific single-nucleotide polymorphisms) associated with abnormalities of P50 suppression.

In terms of our assessment of candidate endophenotypes and genetic studies, it is important to note that medications have an influence on P50 suppression abnormalities in schizophrenia. It appears that atypical antipsychotic medications may reverse the P50 suppression deficits in schizophrenic patients (39 ,40 ,41 and 42). If these initial results continue to be confirmed, the search for candidate endophenotypes will be complicated by the fact that atypical (and perhaps, in some circumstances, typical) antipsychotic medications are increasingly being utilized as first-line agents in the treatment of schizophrenia. We may thus face the circumstance of examining schizophrenic patients whose P50 suppression deficits have been “normalized” and then conducting family studies in which these deficits may appear in unaffected relatives of schizophrenic patients. Should this occur, genetic statistical strategies will have to be utilized that will allow us to “exclude” the “normalized” schizophrenic patient from analysis and utilize only clinically unaffected family members in genetic (e.g., linkage) studies. Much more information will be generated in the next several years, and the use of what we would term *“null proband” strategies* may be necessary as schizophrenic patients who are not medicated or are neuroleptic-naïve become more difficult to ascertain and are replaced by patients treated with atypical antipsychotic medications. In addition, the use of drug withdrawal strategies to unmask endophenotypic markers has come under increasing criticism (43) and is becoming more difficult to justify ethically in comparison with other promising research strategies (e.g., 44).

Prepulse Inhibition of the Startle Response

Since 1978 (45), PPI deficits of the startle response have been consistently identified in schizophrenic patients. PPI of the startle response occurs as follows. Normally, an intense and powerful sensory stimulus elicits a whole-body startle response in almost all mammals. This rapid, intense sensory stimulus may be sound or light, or it may be tactile (e.g., an air puff). When a weak prestimulus precedes the startling stimulus by approximately 100 milliseconds, PPI occurs. Schizophrenic patients and their relatives show deficits in PPI (45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 ,53 and 54) (Fig. 51.2). This is the second commonly studied form of sensorimotor gating (along with P50 suppression) (see ref. 25 for a discussion of gating abnormalities in schizophrenia). PPI is being increasingly used in schizophrenia research. It is important to distinguish the PPI paradigm described above from a similar but quite distinct paradigm in which attentional allocation to the prepulse (55) is used in an attempt to increase the degree of PPI. The PPI paradigm typically used in schizophrenia research, described above, is a “neutral” or “uninstructed” paradigm that largely taps into involuntary and automatic information processing (56); the instructed paradigm is different because subjects attend to the prepulse and thus the paradigm identifies so-called voluntary attentional deficits. This section describes the more widely studied uninstructed PPI.

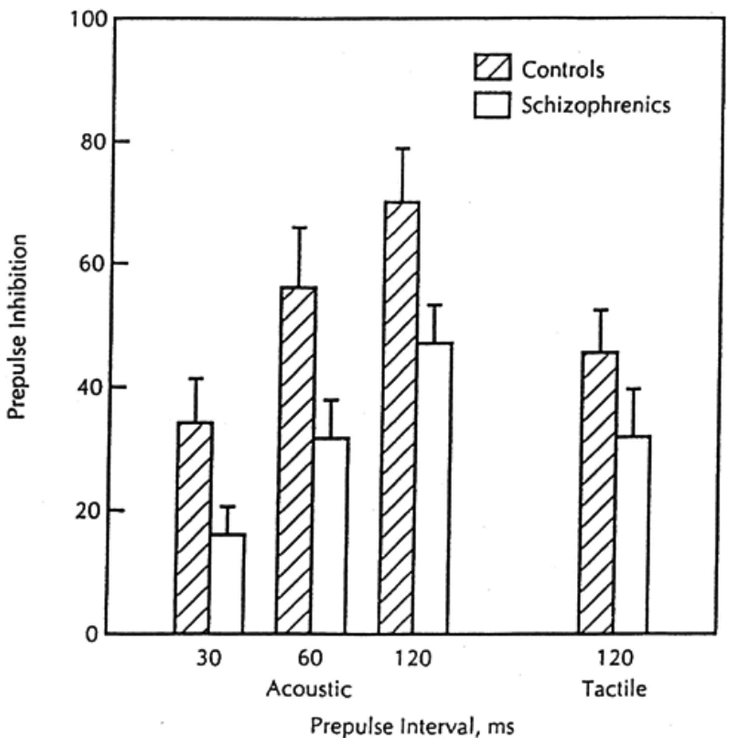

FIGURE 51.2. Across all prepulse-to-pulse intervals tested, the schizophrenic patients showed a loss of gating effect of the prepulse that preceded the startle stimulus. (From Braff DL, Grillon C, Geyer MA. Gating and habituation of the startle reflex in schizophrenic patients. *Arch Gen Psychiatry* 1992;49:206–215, with permission.)

Much like deficits of P50 suppression, PPI deficits are not unique to schizophrenia. PPI deficits are characteristic of a “family” of disorders in which cognitive, sensory, and motor information undergoes a failure of gating. Patients with gating disorders include those with schizophrenia (45 ,46 ,47 ,48 ,49 ,50 ,51 ,52 and 53), obsessive-compulsive disorder (with obsessive and ungated ideas) (57), and Huntington syndrome (58) and Tourette syndrome (59) (with ungated motor activity).

The clinical correlates of PPI in schizophrenia comprise a rich database. PPI deficits have been correlated with distractibility (60), perseverative responses on the Wisconsin Card Sorting Test (61), and most prominently thought disorder (62), especially when PPI and thought disorder are measured at the same time (63). These deficits are also associated with an earlier age of onset (51). Modest correlations have been found with both positive and negative symptoms, and the symptom correlates may be associated with subcortical dopamine hyperactivity and reciprocal frontal dopamine

hypoactivity (47). An initial report has described PPI deficits in clinically unaffected family members of schizophrenic patients (54), and further work is needed to understand the heritability pattern of PPI deficits in family members of schizophrenic patients. Much of what is known about the neural substrate of PPI can be attributed to the extensive work of Swerdlow, Geyer, Braff, and their associates. It appears that PPI is modulated mostly by the ventral cortico-striato-pallido-thalamic (CSPT) circuitry originally described by Swerdlow and Koob (64), based on the pioneering work of Penney, Alexander, and Young on the dorsal loci of the CSPT circuits. The circuitry cannot be described in detail here, but lesion infusion studies and a variety of other strategies have established the animal model of PPI deficits in schizophrenia as a robust area of study (65 ,66 and 67). For example, in rat pups with ventral hippocampal lesions, PPI levels are normal until adolescence, when PPI deficits appear (68 ,69), a finding that supports the neurodevelopmental model of PPI deficits as it applies to an integrated model of schizophrenia. Apomorphine used as a dopamine D2 agonist induces PPI deficits that are reversible with typical or atypical antipsychotic medications. Phencyclidine induces PPI deficits that are differentially reversed by atypical (but not typical) antipsychotic medications. The interested reader is referred to Swerdlow et al. (70) for further discussion of these issues.

Some initial results utilizing between-subjects rather than the more compelling within-subjects designs indicate that PPI deficits in schizophrenic patients may be reversed or “normalized” by antipsychotic medications (51 ,53); however, no linkage studies have utilized PPI, although the genetic contributions to PPI have been elucidated by the fact that PPI levels differ in different rat strains (71), and differential sensitivity to PPI deficits has been observed in these strains (72 ,73 and 74). The increasing use of isolation rearing (75 ,76 ,77 and 78) and knockout mice (79 ,80 ,81 and 82) in PPI studies will undoubtedly yield much more information about the neural and genetic contributions to PPI. In parallel, human linkage studies (already in progress) are being conducted.

Oculomotor Function

Oculomotor function is another important measure that has been used in schizophrenia research. As in gating, two fundamental paradigms have been utilized: eye tracking, or smooth pursuit, and the antisaccade task. Eye-tracking dysfunction in schizophrenic patients was first reported by Diesendorf and Dodge (83), and their work was later extended by numerous investigators, including Holzman and colleagues (84 ,85). Across quantitative and qualitative studies, the eye-tracking deficits seen in schizophrenia have been well documented (86 ,87 ,88 and 89).

Smooth-Pursuit Eye Movement

In a typical study of smooth-pursuit eye movement, a signal is presented to subjects on a computer screen and their ability to track the target smoothly is assessed. Schizophrenic patients do not track the target smoothly; they exhibit fragmented eye movements and resulting eye movement abnormalities, such as “catch-up” saccades. This task has been very useful in family studies; clinically unaffected family members of schizophrenic patients also exhibit eye movement dysfunctions that typically involve an inability to follow a target smoothly, which leads to a variety of abnormalities, including “catch up” saccades (85 ,86 ,88 ,90 ,91 ,92 ,93 and 94). In a series of studies, Siever et al. (95) and others (91 ,93 ,96 ,97) also reported abnormalities of smooth-pursuit eye movement in schizotypal patients.

Antisaccade Task

The antisaccade task has also been widely employed in schizophrenia research as another oculomotor task and as a potential endophenotype. In the antisaccade task, the subject first fixates on a centrally presented visual cue. A target stimulus is then presented to the left or right of the fixation stimulus, and the subject is instructed to look away from the target stimulus; if the stimulus is presented 3 degrees to the left of the fixation point, the subject is expected to look 3 degrees to the right and inhibit the natural tendency to “follow” the target to the left. Voluntary inhibitory functions are utilized to suppress the normal tendency to look at the target stimulus and gaze in the opposite direction. This task, like some of the other measures discussed above, uses inhibition and is largely volitional (like smooth-pursuit eye movement) rather than automatic (like gating). Schizophrenic patients show marked deficits in performing this task; an initial gaze directed toward rather than away from the target stimulus is characteristic (98 ,99 ,100 and 101). The magnitude (i.e., effect size) of the performance deficits in schizophrenic patients and clinically unaffected family members is large (Table 51.1), and the large difference in effect size between probands and normal comparison subjects makes the antisaccade task an excellent candidate endophenotype for genetic studies (101 ,102). Within the schizophrenia spectrum, it is notable that antisaccade deficits occur in family members of schizophrenic patients and in patients with schizotypal personality disorder (96 ,101 ,103 ,104). In this way, the antisaccade deficit meets the second criterion for a candidate endophenotype—that is, a candidate endophenotype should appear in clinically unaffected family members of schizophrenic patients (and perhaps in schizotypal patients).

Neuropsychological Tasks

A plethora of candidate endophenotypes have been derived from the neuropsychological literature. It is well-known that schizophrenic patients exhibit a wide range of neuropsychological deficits (105 ,106) and that these deficits extend to clinically unaffected family members (107). Deficits have

been reported in several important domains: (a) *executive function*, as assessed by the Wisconsin Card Sorting Test (108); (b) *working memory*, as assessed by the Letter–Number Span (109), and (c) *thought disorder*, commonly derived from the processing of stimuli from the Rorschach Test to yield the Thought Disorder Index (110) and the Ego Impairment Index (111). These cognitive dysfunctions are frequently found in family and twin studies in clinically unaffected family members (112 ,113 ,114 ,115 ,116 ,117 ,118 ,119 ,120 and 121), schizotypal patients (122 ,123 ,124 ,125 and 126), and clinically unaffected monozygotic twins discordant for schizophrenia itself (127). The neural substrates of many of these abnormalities are well understood and are being rapidly explicated because these tasks are very well suited to performance during functional brain imaging (e.g., 128). For example, it appears that the Wisconsin Card Sorting Test relies on dorsolateral prefrontal cortex (128 ,129 ,130 and 131) and related distributed circuit structures. Working memory utilizes a complex neural substrate that includes the prefrontal cortex and related structures. It important when working memory is utilized to be clear about whether the test assesses simple delayed recall (transient online storage) or the more complex storage, manipulation, and recall (executive functioning) of visuospatial or verbal memory; these are two distinct neuropsychological processes that probably utilize at least partially distinct neural substrates influenced by at least partially different sets of genes (132). Functional imaging experiments in thought disorder are more preliminary, and the neural substrate of thought disorder is now being explicated.

Continuous Performance Task

The Continuous Performance Task (CPT) is another measure that has been widely applied in the study of schizophrenic patients (133 ,134 ,135 and 136). In the basic form of this task, the subject is presented with a string of stimuli and asked to identify target stimuli from among background or noise stimuli. The CPT is thought to tap into the function of vigilance; schizophrenic patients commonly have significant deficits in the CPT. The CPT also has the advantage that it can be presented in a variety of “degraded” forms in which the signal-to-noise ratio of the stimulus to be identified is attenuated through a variety of parametric manipulations; these make the vigilance and identification task more difficult to perform and may correspondingly increase group separation between schizophrenic patients, their clinically unaffected relatives, and appropriate comparison subjects. The CPT is one of the most thoroughly studied tasks in schizophrenia, in no small degree because of the pioneering work of Nuechterlein et al. (135) and others (137 ,138) who have consistently demonstrated CPT deficits in schizophrenic patients. The fact that unaffected relatives of patients with schizophrenia (139 ,140 ,141 ,142 ,143 ,144 and 145) and schizotypal disorder (146 ,147 and 148) have parallel deficits supports the utility of the task as a candidate endophenotype for genetic studies of information-processing deficits in schizophrenia. These deficits appear to measure stable markers of schizophrenia that may be associated with a genetic vulnerability to the illness and are seen in neuroleptic-naïve, first-break, and neuroleptic-withdrawn schizophrenic patients and their siblings (142).

Span of Apprehension

The utility of Span of Apprehension as a candidate endophenotype, like that of the others measures discussed in this chapter, is supported by a vast amount of literature, only a brief summary of which can be presented here. In its most simplified form, Span of Apprehension refers to the number of items that can be apprehended or attended to and subsequently recalled at one time from an array of stimuli. The interested reader is referred to a particularly scholarly discussion by Asarnow et al. (149). As in the other measures discussed here, the Span of Apprehension has yielded a pattern of interesting results that makes the task another excellent candidate endophenotype in schizophrenia. Additionally, Span of Apprehension deficits have been found in clinically unaffected family members of schizophrenic patients (150 ,151 and 152) and in patients with schizotypal disorder (153 ,154). Recently, in a study of normal twins, Bartfai et al. (155) reported a significant genetic component in the Span of Apprehension task, which further strengthens its utility in genetic studies of schizophrenia.

Visual Backward Masking

In Visual Backward Masking, a simple target stimulus presented with a tachistoscope (156 ,157 and 158) or, more recently, a computer (159 ,160) is followed by a complex, usually powerful masking stimulus of interlocking *X*s that overlap the area of target presentation. A subject reports the target stimulus when it is presented alone. As the masking stimulus appears closer in time to the target (e.g., 100 milliseconds after the target, like the interstimulus interval in PPI experiments), the subject is no longer able identify the target stimulus. Schizophrenic patients are subjected to the effects of the mask on target identification at an interstimulus interval at which normal subjects have little trouble distinguishing the target stimulus (161). Explanations for the masking effect extend from integration of the mask with the target stimulus to interruption of target stimulus processing by the mask (161 ,162 ,163 and 164). Whatever the mechanism, the phenomenon is readily identified as a marker in schizophrenic patients (158 ,165 ,166 ,167 and 168), family members of schizophrenic patients (159 ,160 ,169), and schizotypal patients (170 ,171 ,172 and 173). The specificity of the deficit is unclear, although in one study, manic patients at the height of psychosis showed visual masking deficits that were reversible over time with treatment. In this study, it was reported that the deficits of schizophrenic patients with a good prognosis, who

typically respond to treatment, may also be reversible over time (174). The underlying neural mechanism linked to masking deficits involves the dorsal and ventral information-processing substrates that are supported by magnocellular and parvocellular neurons (175 ,176). Because both clinically unaffected family members and schizotypal patients exhibit deficits of Visual Backward Masking, it may well serve as an important candidate endophenotype in genetic studies.

P300 Event-Related Potential

Since the initial reports of Callaway and colleagues (177 ,178 ,179 and 180) of P300 deficits in schizophrenia, a large number of investigators have identified their topography, lateralization, and neural basis. The results of these studies make the P300 event-related potential an excellent candidate endophenotype for understanding the genetic basis of the deficits.

Schizophrenic patients have long been known to have deficits in the P300 component of the event-related potential (177 ,178 ,181). The P300 wave occurs about 300 milliseconds after stimulus presentation and is commonly thought to reflect the apportionment of attention to a stimulus that is relatively novel or rich in information. Many paradigms utilize a series of rather neutral stimuli and then use an “attention-grabbing” stimulus to elicit a large P300 wave. Although the variability of the latency properties of the P300 event-related potential wave may account for part of the diminution in schizophrenia, repeated studies report that schizophrenic patients show a decreased P300 wave amplitude over time (182 ,183 ,184 and 185). The fact that these deficits are also found in unaffected family members of schizophrenic patients (186 ,187 ,188 ,189 and 190) and in schizotypal patients (191 ,192 and 193) supports the utilization of the P300 wave as a candidate endophenotype. The original work of Callaway et al. (178) and more recent studies by McCarley and associates (182 ,194 ,195 and 196) have contributed to an understanding of the P300 neural circuitry that supports the generation of this wave. It appears that the P300 wave is generated from the temporal lobes, perhaps the superior temporal gyrus of the brain. Along with a diminution of the P300 wave in schizophrenic patients, the volume of the superior temporal gyrus gray matter is also diminished. Lateralization findings indicate that it is probably the left P300 wave that is differentially diminished in schizophrenic patients, matching the volume depletion of the left superior temporal gyrus.

Older studies of reaction time and exciting new and evolving studies of mismatch negativity (197) offer a wide range of potentially useful endophenotypes that may prove to be especially interesting in schizophrenia research.

SUMMARY

Part of "51 - Endophenotypes in Studies of the Genetics of Schizophrenia "

A multitude of interlocking studies, only some of which have been reviewed here, point to information-processing deficits and closely related inhibitory abnormalities as excellent candidate endophenotypes for genetic studies of schizophrenia. The heritability of several of these candidate endophenotypes has already been assessed in genetic studies. In addition, the neuronal mechanisms of many of the endophenotypes are currently being investigated through neurophysiologic studies in both humans (e.g., functional imaging) and related animal models. The ultimate utility of physiologic endophenotypes may be to correlate the wealth of emerging but nonfunctional genetic information with the critically important and functionally significant underlying neurobiology of these endophenotypes. The task of identifying genes that convey a risk for schizophrenia is now under way, generally with the use of either the clinical phenotype of schizophrenia or risk-related endophenotypes. Findings that many of the linkage sites are positive for both schizophrenia and bipolar disorder (e.g., 198) will undoubtedly stimulate a reexamination of what aspect of psychotic psychopathology is being transmitted at each genetic locus, and which nongenetic factors, such as neonatal ventral hippocampal lesions, interact with these genes to produce schizophrenia (e.g., 68) versus bipolar disorder. Additionally, within cohorts of schizophrenic patients, some of these information-processing endophenotypes overlap with each other, both behaviorally and in terms of their underlying neural substrates. This allows for the exciting possibility of constructing “composite” phenotypes consisting of neurologically coherent combinations of more than one of these identified markers (102).

As the molecular mantra states, the fundamental unit of genetic transmission is an abnormality in the structure or expression of a protein. Presumably, most of those protein abnormalities affect neuronal functions that can be measured as changes in physiologic functions, such as the endophenotypes we have described above. The elucidation of how different genetic abnormalities, singly or in combination, contribute to the neuronal pathophysiology of psychosis may help to redefine the nosology of psychotic illnesses and point the way to new treatment approaches. The power and value of endophenotypes is that they illuminate genetically mediated risk/vulnerability factors that often interact with nongenetic factors to produce the syndrome of schizophrenia. Thus, in the pool of genetic strategies and techniques that can be used to understand complex genetic psychiatric disorders (199 ,200 ,201 and 202), endophenotype-based strategies play an important and informative role. In colon cancer, the inherited genetic factor is familial polyposis rather than cancer itself (4). In parallel, it is quite likely that failures of information processing/inhibition are the genetically transmitted risk factors that interact with nongenetic factors to produce the clinical disorder of schizophrenia. Thus, the identification and genetic analysis of these endophenotypes should prove particularly valuable in understanding the genetic basis of schizophrenia. These studies will also facilitate a fuller understanding of how genetic

and nongenetic factors interact to produce this devastating illness and, it is hoped, point the way to more effective treatments.

Neurochemistry of Schizophrenia: Glutamatergic Abnormalities

James H. Meador-Woodruff

Joel E. Kleinman

James H. Meador-Woodruff: Department of Psychiatry, University of Michigan, Ann Arbor, Michigan.

Joel E. Kleinman: Clinical Brain Disorders Branch, National Institutes of Mental Health Neuroscience Center, Washington, DC.

Multiple neurotransmitters have been implicated in schizophrenia. Dopamine is the neurotransmitter most often hypothesized to be associated with the pathophysiology of schizophrenia for two reasons. First, dopaminergic agonists can cause or exacerbate psychotic symptoms. Second, the correlation between antipsychotic efficacy and D2 dopamine-receptor blockade is excellent. For these reasons, a number of postmortem studies have focused on the dopaminergic system in schizophrenic brain. Although the results of these studies have generally been negative, the few positive findings have rarely been replicated, with the notable exception of increased striatal D2-receptor expression, which may be secondary to prior neuroleptic treatment. These studies of dopaminergic abnormalities in postmortem brain in schizophrenia have been recently reviewed (1 ,2).

Given the lack of findings associated with the dopamine system in the brain in schizophrenia, the elucidation of other potential neurotransmitter substrates of this illness has been an area of recent investigation. Glutamatergic dysfunction has been hypothesized to occur in schizophrenia, and this has been one of the most active areas of neurotransmitter research in this illness during the past few years. In this chapter, the glutamate hypothesis of schizophrenia is reviewed, the complexity of the molecules associated with the glutamate synapse is outlined, and postmortem neurochemical data suggesting glutamatergic abnormalities in schizophrenia are presented.

GLUTAMATE AND SCHIZOPHRENIA

Part of "52 - Neurochemistry of Schizophrenia: Glutamatergic Abnormalities "

Several lines of evidence have implicated glutamatergic dysfunction in schizophrenia. Dissociative anesthetics, especially phencyclidine (PCP) and ketamine, can cause psychotic symptoms in normal humans (3 ,4), and worsen these symptoms in persons with schizophrenia (5 ,6 and 7). Unlike catecholamine agonists, PCP can produce both the positive and negative (deficit) symptoms associated with this illness. PCP and related compounds are uncompetitive inhibitors of the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptor. Hence, this pharmacologic literature has been interpreted as suggesting that schizophrenia may be associated with decreased NMDA-receptor activity (5 ,8).

Several other reasons make a glutamate-receptor hypothesis of schizophrenia attractive. Schizophrenia is believed to have a neurodevelopmental component, and the NMDA receptor is critical in guiding axons to their targets in development (9). Further, NMDA receptors may be important in processes that lead to synaptic pruning seen in adolescence, which has been hypothesized to be abnormal in schizophrenia (10). Cognitive functioning depends on the plasticity mediated in part by NMDA receptors, and schizophrenics often have cognitive deficits (11). Finally, the reduction of gray matter in several brain regions seen in schizophrenia has been suggested to be the result of neurotoxicity mediated by NMDA receptors (12). A constellation of symptoms, findings, and hypotheses of schizophrenia can be parsimoniously explained by NMDA-receptor dysfunction.

The NMDA receptor is one of multiple subtypes of the glutamate receptor, however, and all these subtypes have functional interrelationships. Thus, although NMDA-receptor abnormalities have been hypothesized in schizophrenia, apparent NMDA-receptor dysregulation could be associated with abnormalities of another receptor subtype that interacts with the NMDA receptor, which in turn results in a breakdown of normal glutamatergic transmission in schizophrenia.

GLUTAMATE-RECEPTOR SUBTYPES

Part of "52 - Neurochemistry of Schizophrenia: Glutamatergic Abnormalities "

The four classes of glutamate receptors are functionally and pharmacologically distinct (Fig. 52.1 and Fig. 52.2). The ionotropic

glutamate receptors, AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid), kainate, and NMDA are each composed of four or five subunits that form ligand-gated ion channels. The metabotropic glutamate receptors (mGluRs) are all seven transmembrane-domain, G protein-coupled receptors (13 ,14).

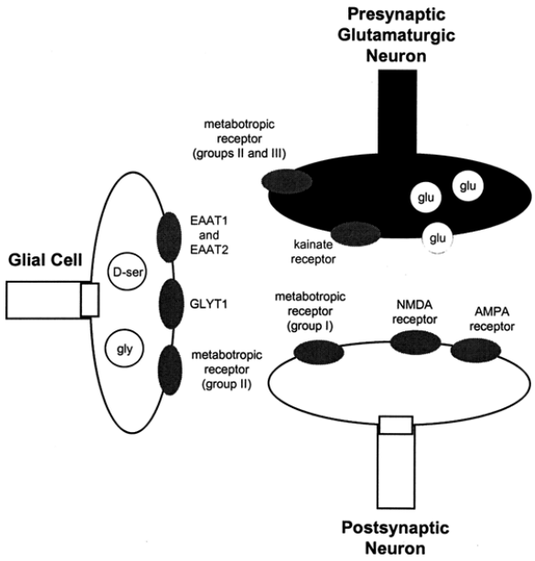

FIGURE 52.1. Diagram of a typical glutamatergic synapse. Recent data suggest that glutamatergic transmission requires three cells: a presynaptic glutamate-releasing cell, a presynaptic glial cell that releases the endogenous agonist for the glycine co-agonist site (recently reported to be D-serine), and a postsynaptic neuron. The various glutamate receptors and transporters are differentially expressed by these three distinct cell populations. The glutamate uptake transporter $EAAT_3$ (excitatory amino acid transporter 3), which is not shown on this figure, appears to be expressed primarily on the cell body and dendrites.

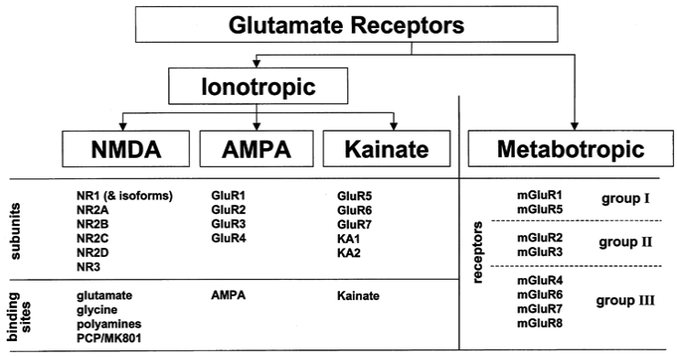

FIGURE 52.2. Subtypes of glutamate receptors. Three families of ionotropic glutamate receptors (*N*-methyl-D-aspartate, AMPA, and kainate) are known, each of which is composed of distinct subunits and has identifiable binding sites. The metabotropic receptors cluster into three groups, members of which share pharmacologic and structural features.

The AMPA-receptor subunits are derived from a family of four genes that have been named *GluR1* through *GluR4*. The transcripts from each of these genes are expressed in one of two isoforms, termed *flip* and *flop*, that result from alternative splicing. In addition, the final subunit protein of the AMPA receptor subunits has amino acids at specific locations in the ion channel that can vary according to RNA editing (13 ,14). Thus, a potential exists for considerable heterogeneity in the final assembled AMPA receptors, based on subunit composition and post-translational modification. The assembled AMPA receptors contain several binding sites: one for glutamate, another at which competitive antagonists such as CNQX (6-cyano-7-nitro-quinoxalindione) act, and yet another where desensitization modulators exert their influence. Subunit composition appears to confer unique pharmacologic properties to the final receptors (15 ,16 ,17 ,18 and 19). For example, decreased calcium influx in AMPA receptors that contain the $GluR_2$ subunit drastically diminishes the electrophysiologic activity of these receptors.

Kainate receptors are also ligand-gated ion channels composed of subunits derived from genes for the low-affinity $GluR_5$ through $GluR_7$ and high-affinity KA_1 through KA_2 subunits (13 ,14). The transcripts associated with these five subunits also undergo alternative splicing and editing. Final assembled kainate receptors may be composed of five identical subunits, or they may be heteromers composed of low- and high-affinity subunits, with pharmacologic properties that differ from those of low-affinity or high-affinity homomers.

The NMDA receptor subunits are encoded by five genes termed *NR1* and *NR2A* through *NR2D* (13 ,14). An *NR3* gene has also been identified, although this subunit appears to be expressed primarily during early development (20 ,21 and 22). NR_1 is expressed as one of eight isoforms because of alternative splicing of exons 5, 21, and 22 (13 ,14 ,23 ,24). As in the case of the AMPA and kainate receptors, transcription of the NR_1 subunit presents an important level for the regulation of the expression of functional NMDA receptors. This regulation can influence certain properties of the final functional NMDA receptors, including the pharmacology of their binding sites.

The pharmacologic regulation of the NMDA receptor depends on the unique combination of binding sites (13 ,14). A primary agonist site exists for the binding of glutamate. A separate glycine co-agonist site must also be occupied before glutamate can activate the ion channel; recent reports suggest that D-serine produced by astrocytes is the endogenous ligand for this site (25 ,26 ,27 and 28). Modulatory binding sites for polyamines, protons, neuropeptides including dynorphin, and zinc have also been identified. Additionally, magnesium ions block the ion channel of the NMDA receptor complex at physiologic concentrations. This blockade is voltage-dependent; partial depolarization of the cell membrane extrudes the magnesium ion. Therefore, presynaptic glutamate release and postsynaptic pre-depolarization are both required for NMDA receptor activity. Finally, a site within the ion channel itself is associated with the binding of uncompetitive antagonists of the NMDA receptor, such as PCP, ketamine, and MK-801. These antagonists are use-dependent (i.e., the ion channel must be opened for these compounds to bind to the receptor), so cooperativity between multiple sites is necessary for occupancy by uncompetitive antagonists.

These binding sites are associated with different subunits, and their affinities can vary depending on subunit composition. NR_1 homomers have been shown to form glycine binding sites, but an NR_2 subunit appears to be required to form both glutamate and MK-801 binding sites (29 ,30 ,31 and 32). Further, receptors containing NR_{2A} subunits have a higher affinity for compounds that bind to the glutamate agonist site, whereas receptors with NR_{2A} or NR_{2B} subunits have higher affinities for MK-801 binding than do receptors with NR_{2C} or NR_{2D} subunits (31). In addition, NMDA receptors containing particular NR_1 splice variants have a higher affinity for MK-801 than do receptors with others, irrespective of NR_2 co-assembly (33). Receptors with NR_{2B} subunits are associated with a higher affinity for polyamine modulators (31 ,34). Therefore, differential subunit combinations confer unique binding properties to the NMDA receptors and probably are associated with subtle electrophysiologic differences within a population of NMDA receptors.

Eight mGluRs have been cloned and are grouped (group I, group II, and group III) based on pharmacology, sequence homology, and linkage to signal transduction pathways (35 ,36 ,37 ,38 ,39 and 40). These mGluRs belong to a unique subset of G protein-coupled receptors with seven transmembrane domains and large, extracellular amine termini. When expressed in heterologous systems, group I mGluRs have been shown to stimulate phospholipase C, phosphoinositide hydrolysis, and the formation of cyclic adenosine monophosphate (cAMP) (41 ,42 ,43 and 44). In heterologous systems, groups II and III mGluRs inhibit forskolin-stimulated cAMP formation and adenylyl cyclase, possibly via a G_i protein (39 ,40 ,45 ,46). The metabotropic receptors have been the target of considerable recent interest because a functional relationship appears to exist between the group II metabotropic and NMDA receptors (47).

Each glutamate receptor subtype appears to have a unique role in glutamatergic neurotransmission. Glutamate receptors interact at multiple levels, as AMPA, kainate, and metabotropic receptors all affect NMDA-receptor activity. Accordingly, although the NMDA receptor is typically hypothesized to be dysregulated in schizophrenia, disturbances of any of the glutamate receptors could result in a condition

that produces the appearance of an abnormally functioning NMDA receptor.

ABNORMALITIES OF GLUTAMATE RECEPTORS IN SCHIZOPHRENIA

Part of "52 - Neurochemistry of Schizophrenia: Glutamatergic Abnormalities "

Given the possibility of glutamate-receptor dysfunction in schizophrenia, the expression of all four families of the glutamate receptor have been studied in schizophrenic brain. As would be expected, these investigations have primarily targeted limbic regions that have been implicated in schizophrenia, particularly limbic cortex, striatal areas, medial temporal lobe structures, and, more recently, the thalamus. These investigations have also targeted multiple levels of gene expression, including subunit messenger RNA (mRNA) and protein levels, and final binding sites have been studied. In the following sections, the studies that have been published for each receptor subtype in postmortem brain in schizophrenia are reviewed.

AMPA Receptors

Of all of the glutamate receptors in schizophrenia, the AMPA receptor has been studied the most, as summarized in Table 52.1 . When the AMPA-associated subunits were first cloned, Harrison et al. (48) examined the expression of the mRNA encoding the $GluR_1$ subunit in medial temporal lobe structures in schizophrenia. A consistent decrease in the expression of this subunit transcript was found in hippocampal regions, an abnormality that was statistically significant only in the CA3 region. These investigators subsequently extended their finding and demonstrated that $GluR_1$-subunit mRNA is decreased in multiple hippocampal subfields (dentate gyrus, CA3, and CA4) and also in the subiculum (49). They also reported that $GluR_2$-subunit mRNA is decreased in the medial temporal lobe in schizophrenia, particularly in the parahippocampal gyrus (49), and continued their examination of AMPA-receptor expression in the medial temporal lobe by determining the patterns of expression of the flip and flop isoforms of the $GluR_1$ and $GluR_2$ subunits. Decreased expression of $GluR_2$-subunit

mRNA was again found in hippocampal structures, and both the flip and flop variants were reduced, the flop to a greater extent (50).

TABLE 52.1. AMPA RECEPTOR BINDING AND SUBUNIT EXPRESSION IN SCHIZOPHRENIA

AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid; CNQZ, 6-cyano-7-nitro-quinoxalindione

Several studies have examined the expression of the AMPA-subunit proteins in the medial temporal lobe in schizophrenia. Using quantitative immunocytochemical analyses, Eastwood et al. (51) reported decreased expression of the AMPA subunits in medial temporal lobe structures. In particular, $GluR_1$ immunoreactivity was noted to be significantly reduced in the parahippocampal gyrus, and combined $GluR_{2/3}$ immunoreactivity was decreased in the CA4 subfield of the hippocampus. On the other hand, Breese and co-workers (52) found no differences in $GluR_1$, $GluR_2$, or $GluR_3$ immunoreactivity in schizophrenia when they used Western analysis in hippocampal samples.

AMPA-receptor binding has also been studied in medial temporal lobe structures. Using [^{3}H]CNQX to label the AMPA receptor, Kerwin et al. (53) noted decreased binding to the AMPA receptor in the schizophrenic hippocampus, particularly in the CA3 and CA4 subfields. More recently, Gao and colleagues (54) found decreased [^{3}H]AMPA binding in CA2, but not in other hippocampal fields or associated structures. The convergence of these data is that AMPA-receptor expression is decreased in the medial temporal lobe in schizophrenia, a decrease that involves alterations of subunit gene expression in addition to the final binding site.

Although the medial temporal lobe data are the most robust, AMPA-receptor expression has also been examined in other brain regions in schizophrenia. In two studies, none of the AMPA-associated subunit transcripts were changed in striatal subregions (caudate, putamen, and nucleus accumbens) in schizophrenia (55 ,56). To date, subunit protein levels have not been reported in striatal regions. Binding to the AMPA receptor has been determined in striatal regions, but results have not been consistent. Although Noga and colleagues (57) reported an increase in AMPA binding, determined with [^{3}H]CNQX, in caudate, putamen, and accumbens in schizophrenia, no differences in [^{3}H]AMPA binding were found in striatal regions in schizophrenia in three other reports (55 ,58 ,56).

The cortex has also been studied for alterations of AMPA-receptor expression in schizophrenia. In one study, no differences in the expression of any of the AMPA-associated subunit mRNAs were found in prefrontal or occipital cortex in schizophrenia (55), although Sokolov (59), using reverse transcriptase polymerase chain reaction (RT-PCR), reported decreased $GluR_1$ mRNA in superior frontal gyrus. Breese et al. (52) found no differences in $GluR_2$ or $GluR_3$ protein in cingulate cortex as determined by Western analysis. Several groups have studied [^{3}H]AMPA binding in cortical areas in schizophrenia (55 ,60), with generally negative results.

Recently, the neurochemical anatomy of the thalamus has become a subject of interest in schizophrenia research. The AMPA receptor is expressed in multiple nuclei of the human thalamus. In a recent report (61), although [^{3}H]AMPA binding was not different in limbic thalamic nuclei in schizophrenia, the transcripts encoding the $GluR_1$ and $GluR_3$ subunits were both found to be reduced in the face of normal levels of $GluR_2$ and $GluR_4$ mRNA. These results suggest that alterations in the stoichiometry of subunit composition may be associated with the AMPA receptor in the schizophrenic thalamus.

Kainate Receptors

The kainate receptor has been the subject of study in the brain in schizophrenia, as summarized in Table 52.2 . Although the medial temporal lobe has been the best-studied region in the schizophrenic brain for AMPA-receptor expression, fewer studies have systematically focused on the kainate receptor in these structures. Porter and colleagues (62) found decreased expression of $GluR_6$ and KA_2 mRNA in several hippocampal regions, results paralleling similar data for the AMPA subunits in the medial temporal lobe. In this same study, $GluR_6$ mRNA was not found to be changed in the schizophrenic cerebellum. Only one study to date has examined any of the kainate subunit proteins; $GluR_5$ was studied by Western analysis and was not changed in schizophrenic hippocampus (52), although the antisera used in this study cross-reacts with $GluR_6$ and $GluR_7$.

TABLE 52.2. KAINATE RECEPTOR BINDING AND SUBUNIT EXPRESSION IN SCHIZOPHRENIA

	Ligand or Subunit	Findings	Brain Regions Studied	Reference

	$GluR_{5,6,7}$, KA_1, KA_2	none	striatum	63
	$GluR_7$		frontal cortex	59
	$GluR_7$	none	frontal cortex	59
	KA_1		frontal cortex	59
	KA_1	none	frontal cortex	59
	$GluR_{5,6,7}$, KA_1, KA_2	none	caudate, putamen, nucleus accumbens	56

Kainate-receptor expression has been examined in multiple cortical regions. Sokolov (59) has published data suggesting that $GluR_7$- and KA_1-subunit transcripts are decreased in the superior frontal gyrus in schizophrenia, similar to the decreases this investigator noted for some of the subunits associated with the AMPA and NMDA receptors. In a recent study examining transcripts of kainate-receptor subunits in the prefrontal cortex (63), a shift in subunit stoichiometry was found in multiple cytoarchitectural regions of the prefrontal cortex, with increased expression of $GluR_7$ mRNA and decreased expression of KA_2 mRNA in the face of normal expression of the other kainate subunits. In this same study, no changes in transcripts of kainate-receptor subunits were noted in Brodmann area 17.

Several studies have examined the expression of transcripts of the kainate-receptor subunit in subcortical structures. Two reports (56 ,63) noted no alterations of these subunits in multiple striatal regions in schizophrenia. On the other hand, a recent study noted decreased levels of KA_2 mRNA but normal levels of other transcripts of kainate-receptor subunits in limbic thalamic nuclei in schizophrenia.

Kainate-receptor binding has been studied in multiple brain regions in schizophrenia by several independent groups. All these studies have used [^{3}H]kainate to label this receptor. In general, kainate-receptor binding has been reported to be altered in multiple cortical areas in schizophrenia (63 ,64 and 65). Data on the expression of kainate binding sites in medial temporal lobe structures are inconsistent;

one study reported decreased [^{3}H]kainate binding in the hippocampus and parahippocampal gyrus (53), but another found no differences in binding in medial temporal lobe structures (54). Although kainate-receptor binding has been reported to be abnormal in cortical structures, it has not been found to differ in subcortical regions in schizophrenia; [^{3}H]kainate is unchanged in both striatal subregions (56 ,57 ,63 ,65) and limbic thalamic nuclei (61) in this illness.

NMDA Receptors

Although most hypotheses of glutamatergic dysfunction in schizophrenia invoke the NMDA receptor, relatively few studies of this receptor subtype have been carried out to date (Table 52.3). Only several studies have been published that examine the expression of the NMDA subunits in schizophrenic brain, and all these have focused on mRNA levels. In a comprehensive examination of all the NMDA subunits in prefrontal cortex, Akbarian et al. (66) found no absolute differences between controls and schizophrenic patients for any of the NMDA subunits, but the contribution of NR_{2D} to the total pool of NR_2 transcripts was elevated in the schizophrenic patients. Recently, Gao et al. (54) found an altered stoichiometry of NMDA subunits in hippocampus, with decreased NR_1 and increased NR_{2B} mRNA expression but normal NR_{2A} expression, in schizophrenia. Several other studies have been published in which only the NR_1 transcript was measured; in one study, this molecule was reported to be decreased in superior temporal cortex (67), and in another, it was decreased in superior frontal cortex (59).

TABLE 52.3. NMDA RECEPTOR BINDING AND SUBUNIT EXPRESSION IN SCHIZOPHRENIA

Several recent studies have examined the expression of the NMDA receptor subunits in subcortical structures in schizophrenia. In one study (56), NR_1, NR_{2A}, NR_{2B}, NR_{2C}, and NR_{2D} mRNAs were measured in the caudate, putamen, and nucleus accumbens in schizophrenia; no significant differences were found in comparison with control striata. On the other hand, significant reductions of NR_1, NR_{2B}, and NR_{2C} transcripts (but not of NR_{2A} and NR_{2B} transcripts) were found in dorsomedial and anterior thalamic nuclei in this disorder (61).

Because of the myriad binding domains of the NMDA complex, studies of receptor binding are difficult to interpret and are subject to the selection of radioligand. Further, it has become apparent that certain subunit compositions are associated with specific binding sites, so it is possible that some but not all binding sites on the NMDA receptor are altered in schizophrenia. The best-studied of the

NMDA-associated sites is the ion channel/PCP site. In general, studies in which [^{3}H]MK-801 was used have been relatively unimpressive. In an early study (68), increased [^{3}H]MK-801 binding was reported in the schizophrenic putamen, but no differences were noted in frontal cortex or multiple medial temporal lobe regions, including the hippocampus, amygdala, and entorhinal cortex. A more recent study (57) found no differences in caudate, putamen, or nucleus accumbens. The ion channel site has also been studied with the ligand [^{3}H]TCP, and again minimal changes were noted. In one study (69), no changes were found in multiple cortical areas, putamen, or cerebellum. A subsequent report (70) observed no differences between controls and schizophrenic patients in hippocampus, amygdala, or polar frontal cortex (Brodmann area 10), but increased [^{3}H]TCP binding was noted in orbitofrontal cortex (Brodmann area 11) in the schizophrenic patients.

The other NMDA-associated binding sites have been studied more recently. The primary agonist site for glutamate has been studied with [^{3}H]glutamate in the hippocampus, and no differences have been found in schizophrenia (53 ,54). The glycine co-agonist site has also been studied. Using [^{3}H]glycine, Ishimaru and colleagues (71) reported increased binding in multiple cortical areas in schizophrenia. Recently, the glycine site was studied in striatum with [^{3}H]L-689,560, and increased binding was noted in putamen, but not caudate or accumbens, in schizophrenia (72).

Several comprehensive studies examining multiple binding sites associated with the NMDA receptor complex in subcortical structures have recently been reported. In one of them (56), binding to the glutamate (measured with [^{3}H]CGP39653) and glycine (measured with [^{3}H]MDL105,519) agonist sites, the intrachannel/PCP site ([^{3}H]MK-801), and the polyamine modulatory site ([^{3}H]ifenprodil) were determined in caudate, putamen, and nucleus accumbens in schizophrenia. In this study, no differences were noted between controls and schizophrenic subjects. On the other hand, a study in thalamus from this same group (61), in which the same ligands were used to label the four sites, found decreased expression of binding associated with the glycine and polyamine sites, but not the intrachannel/PCP site or glutamate binding domain in limbic nuclei, in schizophrenia. These changes in some but not all binding sites in the thalamus were also associated

with changes in the stoichiometry of the various NMDA-associated subunit transcripts in these nuclei.

Metabotropic Receptors

Very little has been published about this family of receptors in schizophrenic brain (Table 52.4). In one study, the mRNAs encoding the metabotropic receptors $mGluR_3$ and $mGluR_5$ were measured in prefrontal cortex (73). Although $mGluR_3$ mRNA was not changed in schizophrenia in multiple areas of the prefrontal cortex, $mGluR_5$ was increased in the orbitofrontal cortex (Brodmann area 11), but not in Brodmann areas 9 or 10. Cell-level analysis revealed that this increase was secondary to increased expression of $mGluR_5$ mRNA in pyramidal cells in lamina III of this area of prefrontal cortex. More recently, the expression of the transcripts encoding seven of the eight cloned metabotropic receptors was reported in schizophrenic and control thalamus (74). No differences were found in the expression of the mGluRs in six different thalamic nuclei in schizophrenia in this study.

Receptor	Findings	Brain Regions Studied	Reference
$mGluR_{1,2,3,4,5,7,8}$	none	thalamus	74
$mGluR_3$	none	prefrontal cortex	73
$mGluR_5$		prefrontal cortex	73

GLUTAMATE TRANSPORTERS

Part of "52 - Neurochemistry of Schizophrenia: Glutamatergic Abnormalities "

In addition to the glutamate receptors, other molecules at the glutamate synapse are critical for normal glutamatergic neurotransmission (Fig. 52.1). At least five glutamate uptake transporters, excitatory amino transporter 1 ($EAAT_1$) through $EAAT_5$, are expressed in the glutamate synapse (75). $EAAT_1$ is predominantly expressed in astrocytes of the cerebellum, although expression is also significant in the forebrain. $EAAT_2$ is expressed in both astrocytes and neurons but has a more widespread distribution in the brain (76). Severe neuropathology and epilepsy develop in knockout mice for the *EAAT2* gene, which confirms its importance in normal glutamatergic function. $EAAT_3$ is a neuronal transporter expressed in multiple limbic regions. $EAAT_4$ expression is restricted to Purkinje cells of the cerebellum, and $EAAT_5$ is confined to the retina.

Although glutamate transporters affect the function of all four glutamate receptor subtypes, the glycine transporter family may specifically affect NMDA receptor-mediated activity. Glycine is an NMDA receptor co-agonist, and glycine transporter inhibitors affect normal NMDA-receptor function and reverse PCP-induced behaviors (77 ,78 ,79 ,80 and 81). The two families of glycine transporters are $GLYT_1$ and $GLYT_2$; three isoforms of $GLYT_1$ have overlapping expression in astrocytes throughout the human brain, whereas $GLYT_2$ is restricted to the hindbrain and spinal cord (82 ,83). By altering the availability of glutamate for its receptors, changes in the expression of the transporters may induce profound changes at the level of receptor function. Further, given that the NMDA receptor may depend on glycine as a co-agonist, abnormal synaptic levels of this amino acid may be associated with disturbed function of the NMDA receptor.

Initially, the quantification of glutamate uptake sites in schizophrenia preceded the identification of the EAAT subtypes, and conflicting data have been obtained in schizophrenic prefrontal cortex and basal ganglia with use of the nonselective transporter ligand [^{3}H]D-aspartate (Table 52.5). Early studies found decreases in striatal uptake sites (84 ,85); however, later studies did not replicate these findings (57 ,86). Similarly, increases in frontal cortical uptake sites (64) were not confirmed in follow-up studies (84 ,87). The discrepancies in this literature may be in part a consequence of the nonselectivity of [^{3}H]D-aspartate for the multiple

transporter subtypes; shifts in transporter subtype expression may occur in the absence of changes in total uptake sites. Consistent with this interpretation is the recent demonstration of decreased $EAAT_2$ mRNA levels in prefrontal cortex of schizophrenics (73). This change is in the opposite direction of that noted in previous studies examining radioligand binding to the transporters (64 ,84), which suggests that a shift from $EAAT_2$ to $EAAT_1/EAAT_3$ expression may occur in prefrontal cortex in schizophrenia.

TABLE 52.5. EXCITATORY AMINO ACID BINDING IN SCHIZOPHRENIA

Ligand	Findings	Brain Regions Studied	Reference
[^{3}H]glutamate	none	caudate, putamen, nucleus accumbens	57
[^{3}H]aspartate		frontal cortex	64
[^{3}H]aspartate	none	temporal cortex	64
[^{3}H]aspartate		anterior cingulate gyrus	87
[^{3}H]aspartate	none	hippocampus, temporal cortex	87
[^{3}H]glutamate	none	CA4, CA3, CA2, CA1, dentate gyrus, parahippocampal gyrus	53
[^{3}H]glutamate	none	CA3, CA2, CA1, dentate gyrus, subiculum	54
[^{3}H]aspartate		putamen, globus pallidus caudate,	70
[^{3}H]aspartate	none	nucleus accumbens	70

OTHER NEUROMODULATORS AND MARKERS

Part of "52 - Neurochemistry of Schizophrenia: Glutamatergic Abnormalities "

An alternative mechanism for altering glutamate neurotransmission involves neuropeptide modulators of glutamate-mediated neurotransmission (88 ,89 ,90 and 91). For instance, cholecystokinin (CCK) augments glutamate-mediated neurotransmission (88 ,91). CCK is expressed in subgroups of γ-aminobutyric acid (GABA)- and glutamate-containing neurons in the entorhinal cortex (92 ,93 and 94). Several postmortem studies have found abnormalities in CCK, CCK receptors, and CCK mRNA expression in schizophrenia, both in the frontal and temporal lobes (95 ,96 ,97 and 98). A cell-based silver grain analysis confirmed the involvement of layer VI, finding a reduction in the level of CCK mRNA expression per pyramidal cell (99). This is further supported by other molecular studies involving the measurement of complexin I and complexin II mRNAs, which suggest preferential involvement of excitatory pyramidal neurons in the mesial temporal lobe in schizophrenia (100 ,101).

A second neuropeptide neuromodulator concentrated in glutamate neurons, *N*-acetylaspartylglutamate (NAAG), antagonizes the effects of glutamate at NMDA receptors (102). NAAG is cleaved by glutamate carboxypeptidase II (formerly referred to as *N*-acetyl-α-linked acidic dipeptidase), a membrane-spanning glial enzyme, to yield glutamate and *N*-acetylaspartate (NAA). One study of NAAG and glutamate carboxypeptidase II found decreased glutamate carboxypeptidase II activity in prefrontal cortex and hippocampus and increased NAAG levels in the prefrontal cortex of schizophrenic patients relative to normal controls (103). Moreover, *in vivo* magnetic resonance spectroscopic imaging has revealed selective reductions in NAA in the dorsolateral prefrontal cortex and hippocampal formation of schizophrenic subjects (104 ,105). This suggests that NAA, a marker of neuronal integrity, may be decreased specifically and regionally in schizophrenia secondary to decreases in glutamate carboxypeptidase II.

CONCLUSIONS

Part of "52 - Neurochemistry of Schizophrenia: Glutamatergic Abnormalities "

Converging evidence indicates that abnormalities of glutamatergic neurotransmission occur in specific brain regions in schizophrenia. Although the hippocampus and associated structures have been the best studied, emerging data point to glutamatergic abnormalities in other areas of the brain that are likely to be associated with the pathophysiology of schizophrenia, including limbic cortex, striatal regions, and thalamus. Pharmacologic evidence suggests involvement of the NMDA receptor in schizophrenia, but other studies and theoretic considerations indicate that other molecules associated with glutamatergic transmission are also abnormal in this illness.

Studies in postmortem samples of the molecules associated with the glutamate synapse have not been conducted in a systematic and comprehensive fashion; however, several general principles are emerging from available data. First, although abnormalities of the glutamate synapse have been reported primarily in hippocampal regions, recent data suggest that thalamocortical circuits may also be abnormal. Interestingly, the striatal subregions appear to be less affected than medial temporal lobe and thalamocortical pathways. Second, all four families of glutamate receptors have been reported to be abnormal in brain in schizophrenia, although in region- and circuit-specific patterns. Third, changes are apparent at both transcriptional and translational levels of gene expression. Fourth, the ionotropic glutamate receptors have been studied most, and results thus far reveal changes in ionotropic receptor binding sites in addition to subunit changes suggestive of altered stoichiometry of subunit composition. The metabotropic receptors are just beginning to be studied, but the few available reports do suggest abnormalities of these receptors.

The literature on postmortem neurochemical studies of glutamatergic molecules in schizophrenia supports the hypothesis of abnormal glutamatergic neurotransmission in this illness that particularly involves the ionotropic receptors. These data suggest that novel strategies that permit the modulation of these receptors may prove to be of therapeutic utility in this illness, and may also provide clues about the pathophysiologic substrate of schizophrenia.

PAST AND PREVAILING PATHOPHYSIOLOGIC MODELS OF PSYCHIATRIC DISORDERS

Part of "53 - Neural Circuitry Approaches to Understanding the Pathophysiology of Schizophrenia "

Models of the nature of brain dysfunction in major psychiatric disorders have evolved substantially over the past several decades in parallel with the progression in knowledge resulting from investigations of the neurobiological mechanisms that contribute to normal cognition, emotion, and behavior. Some models of psychopathology have emphasized, in their simplest forms, the central contribution of excesses or deficits in the functional activity of a given neurotransmitter to the disease process of interest. In general, these models have been very useful in motivating investigations of the molecular underpinnings and biochemical functions of the neurotransmitter systems of interest, and in spurring the development of novel psychopharmacologic agents that influence these systems. However, in extreme cases, these models tended to view individual psychiatric disorders as the consequences *solely* of the postulated disturbance in the neurotransmitter of interest, and consequently they tended to be conceptually similar to historic views that altered levels of the four classical bodily humors produced different forms of madness. In addition to this limited conceptual perspective, neurotransmitter-based models sometimes seemed to attribute behavioral, emotional, or cognitive functions to neurotransmitters, instead of explicitly recognizing that neurotransmitters have defined actions on receptors, whereas behaviors, emotions, and cognitive abilities represent emergent properties of the integrated activity of large networks of neurons.

Other models of psychopathology have emphasized the critical role of localized disturbances in individual brain regions, an approach that, in extreme cases, has been critiqued as “neophrenology.” Although these models have been useful in stimulating studies of the structure–function relationships of the implicated brain regions, they have been limited in a number of respects, including the inability to account for the array of signs and symptoms that typically constitute the syndromic diagnosis of a psychiatric disorder.

These two types of models were influenced, at least in part, by extrapolations from earlier successes in the study of Parkinson’s disease, which was then viewed as a single neurotransmitter (e.g., dopamine) disease owing to a localized neuropathology (e.g., cell death in the substantia nigra). However, in recent years, these two general approaches have given way to neural circuitry-based models that reflect a fuller appreciation of the fact that neurotransmitters act in an anatomically constrained fashion to produce specific biochemical effects at the cellular level, and that the localization of function(s) is a consequence of the flow of information processing through the neural circuits within a given brain region and those linking that region to other brain areas. These latter types of models (1 ,2 and 3) incorporate the recognition that complex brain functions, such as those that are disturbed in major psychiatric disorders, are subserved by the coordinated activity of distributed ensembles of neurons.

Consequently, the goal of this chapter is to examine the use of a neural circuitry-based approach to understanding the pathophysiology of a psychiatric disorder, using studies of the neurobiological basis for cognitive dysfunction in schizophrenia as an example. Specifically, this chapter: (a) considers the convergent lines of evidence that suggest that the neural circuitry involving the dorsal prefrontal cortex is disturbed in this disorder, (b) reviews the normal organization of this circuitry as revealed through studies in animals, (c) assesses the evidence regarding the integrity of this circuitry in schizophrenia, and (d) discusses new opportunities

for neural circuitry-based studies of the pathophysiology of schizophrenia.

EXAMINING SCHIZOPHRENIA AS A DISORDER OF NEURAL CIRCUITRY

Part of "53 - Neural Circuitry Approaches to Understanding the Pathophysiology of Schizophrenia "

Clues from the Clinical Syndrome

Although schizophrenia and Alzheimer's disease (AD) both received these appellations approximately a century ago, their initial descriptions were based on different types of data. For schizophrenia, the disorder was recognized by the presence of a constellation of clinical features and a particular longitudinal course, whereas the identification of AD was based on clinicopathological correlations. Indeed, the observation of neurofibrillary tangles and neuritic plaques in the cerebral cortex of the victims of AD provided the foundation for the rich array of anatomic, biochemical, and molecular genetic studies in the past two decades that have produced the wealth of current knowledge regarding the pathophysiology of this disease.

In contrast, studies of the pathophysiology of schizophrenia continue to depend, in large part, on clues derived from the clinical syndrome. Although the number and diversity of the clinical features of this illness make this approach daunting, a reasonable case can be made that the disturbances in cognition commonly seen in schizophrenia represent a core feature of the illness. For example, at least some of the other signs and symptoms of schizophrenia may be conceptualized as secondary to the cognitive disturbances (4), cognitive abnormalities can be identified during the prodromal phase of the illness and in those at increased risk for the disorder (5), cognitive symptoms appear to be persistent across the course of the illness (6), and the severity of cognitive impairment may be the best predictor of long-term outcome (7 ,8). Thus, the clinical features of schizophrenia argue for an emphasis on the neural circuitry that normally subserves the types of cognitive functions that are disturbed in the disorder.

Clues from Developmental Features

Although the idea that schizophrenia is a late consequence of an early developmental lesion (9) has many merits, direct evidence for a brain abnormality that could be explained by a mechanism operating prior to or at the onset of the clinical symptoms of the illness, and that could not be attributed to factors associated with having the illness, has proven difficult to obtain. For example, reports of cytoarchitectural disturbances in the entorhinal cortex of schizophrenic subjects (10 ,11) attracted a great deal of attention because the reported findings were strongly suggestive of an abnormality in neuronal migration (12); however, subsequent studies with larger sample sizes have both failed to confirm these reports and have provided likely methodologic explanations for the initial findings (13 ,14 ,15 and 16). The report of an altered distribution of interstitial neurons in the subcortical white matter was also conceptually very attractive because it strongly suggested an early developmental lesion (17); however, the majority of schizophrenic subjects appear to lack such abnormalities (18 ,19).

However, one of the characteristics of schizophrenia is the tendency for clinical symptoms to first appear during late adolescence or early adulthood, and it has been argued that hypotheses of the pathophysiology of schizophrenia must accommodate this age of onset (9 ,20). Although the average age of first hospitalization for patients with schizophrenia is in the early or mid-twenties for men and women, respectively (21 ,22), psychotic symptoms may appear months or even years prior to hospitalization (22 ,23 and 24). In addition, deterioration in other areas, such as scholastic performance and sociability, precedes the onset of the overt symptoms of schizophrenia by some time (5 ,23 ,24), and may represent strong predictors of the subsequent appearance of the disorder. Thus, developmental events occurring during the second decade of life may play a critical role in the appearance of cognitive dysfunction in schizophrenia.

Clues from Distributed Brain Abnormalities

Structural and functional neuroimaging studies in subjects with schizophrenia have implicated a number of brain regions as potential sites of dysfunction or morphologic abnormalities. For example, certain brain regions, such as the medial temporal lobe (including the hippocampus, amygdala, and parahippocampal gyrus), the superior temporal gyrus, the dorsal prefrontal cortex and the thalamus, have all been shown to have reduced total volume in subjects with schizophrenia, although the magnitude of the decrease and its consistency across studies has not been uniform (25). Similarly, functional imaging studies have shown alterations in the activation of some of these brain areas under different conditions, especially when subjects are performing tasks that normally are associated with a change in activation (26). Although some of the reported findings cannot be accommodated in this way, a number of the affected regions share reciprocal connections. Thus, pathophysiologic models that account for the reported abnormalities in two or more of these regions, and the connections that link them, may be particularly promising.

Incorporating These Types of Clues into Research Strategies for Identifying Neural Circuitry Abnormalities

Based on the three types of clues summarized in the preceding, one can ask whether they converge or triangulate on neural circuit(s) that may be preferentially involved in the pathophysiology of schizophrenia. Although this approach

suggests a number of possible candidate circuits for investigation, the dorsal prefrontal cortex (dPFC) may be considered a prototypic nodal point for circuit analysis in schizophrenia for the following reasons.

First, from the perspective of clinical clues, subjects with schizophrenia perform poorly on cognitive tasks that involve working memory, the ability to transiently maintain information in order to guide a subsequent response (27). For example, individuals with schizophrenia exhibit impairments on oculomotor delayed-response tasks (28), a cognitive paradigm on which nonhuman primates with structural or reversible cooling lesions of the dPFC perform poorly (29). Consistent with these observations, subjects with schizophrenia also fail to show normal activation of the dPFC when attempting to perform tasks that tap working memory (30).

Second, from the developmental perspective, the circuitry of the primate dPFC clearly undergoes marked refinements during adolescence, although certainly some other brain regions that have not been as well studied are also likely to show such changes. For example, the number of excitatory synapses in the dPFC declines by 50% during adolescence in both monkeys and humans (31 ,32). In addition, substantial changes occur in markers of excitatory, inhibitory, and modulatory inputs to pyramidal neurons in deep layer 3 of primate dPFC. The apparent laminar specificity of at least some of these changes raises the possibility that circuits involving these pyramidal cells may be preferentially affected in schizophrenia (33).

Third, from the perspective of regional brain analyses, the PFC has been shown to have subtle reductions in gray matter volume in a number of structural imaging studies of schizophrenia (25). The failure of other studies to detect such structural abnormalities in the PFC has been hypothesized to be a consequence of several factors, including a reduction in total PFC volume that approximates the level of sensitivity of MRI and the restriction of volumetric changes to certain regions or gyri of the dPFC (25). Consistent with these interpretations, postmortem observations indicate that cortical thickness in the dPFC may be reduced by 3% to 12% in subjects with schizophrenia (34 ,35 ,36 and 37), although these changes do not always achieve statistical significance. In addition, some (38 ,39 and 40), but not all (41), *in vivo* proton spectroscopy studies indicate that N-acetyl aspartate (NAA), a putative marker of neuronal and/or axonal integrity, is reduced in this brain region. Interestingly, the magnitude of these NAA changes in the dPFC was correlated with the degree of impaired activation in other brain regions during working memory tasks, raising the possibility that a neuronal abnormality in the dPFC could account for distributed functional disturbances in the working memory network (40).

Other lines of evidence suggest that these changes may reflect disturbances in the synaptic connectivity of the dPFC in schizophrenia. For example, the presence of decreased phosphomonoesters and increased phosphodiesters (42 ,43), as measured by P^{31} spectroscopy, in the PFC of schizophrenic subjects has been interpreted to reflect an increased breakdown of membrane phospholipids, and consequently a decreased number of synapses. In addition, a recent gene expression profiling study using cDNA microarrays found that the group of genes encoding proteins that regulate presynaptic secretory machinery were most consistently altered (44). Furthermore, reduced levels of synaptophysin, an integral membrane protein of small synaptic vesicles, have also been observed in the dPFC of subjects with schizophrenia in most (45 ,46 ,47 ,48 and 49), but not all (50), studies.

For these reasons, the next two sections of this chapter focus on a summary of the normal organization of dPFC circuitry and on a review of the evidence suggesting that this circuitry is disturbed in schizophrenia.

OVERVIEW OF DPFC CIRCUITRY IN PRIMATES

Part of "53 - Neural Circuitry Approaches to Understanding the Pathophysiology of Schizophrenia "

Direct studies of the circuitry of the human dPFC have obvious limitations; however, the available cross-species studies indicate that the macaque monkey brain provides an accurate and useful model system for understanding the general organization of the human dPFC. Thus, this section reviews the constituent cell types and the patterns of intrinsic and extrinsic connectivity that characterize the primate dPFC.

Cell Types

Pyramidal Neurons

About 70% of all cortical neurons are pyramidal cells (51). The majority of pyramidal cells have a characteristically shaped cell body that gives rise to a single apical dendrite that is oriented perpendicular to the cortical surface and frequently ends in a terminal tuft (Fig. 53.1). An array of shorter basilar dendrites spread in a radial fashion at the base of the cell body. Both the apical and basilar dendrites are coated with short protrusions or spines, which represent the principal targets of most excitatory synaptic inputs to pyramidal neurons. Because dendritic spines are actively formed or resorbed in response to changes in presynaptic inputs, dendritic spines provide a good estimate of the number of excitatory synapses that pyramidal cells receive (52). Typically, pyramidal neurons possess 6,000 to 10,000 dendritic spines (53). In addition to receiving one excitatory input, some dendritic spines also receive a synapse with the features suggestive of an inhibitory input. Inhibitory terminals also synapse on the dendritic shafts, cell body, and axon initial segment of pyramidal cells. Typically, pyramidal cells receive about 2,000 inhibitory synapses on dendritic shafts, 200 on the cell soma, and 20 on the axon initial segment (53).

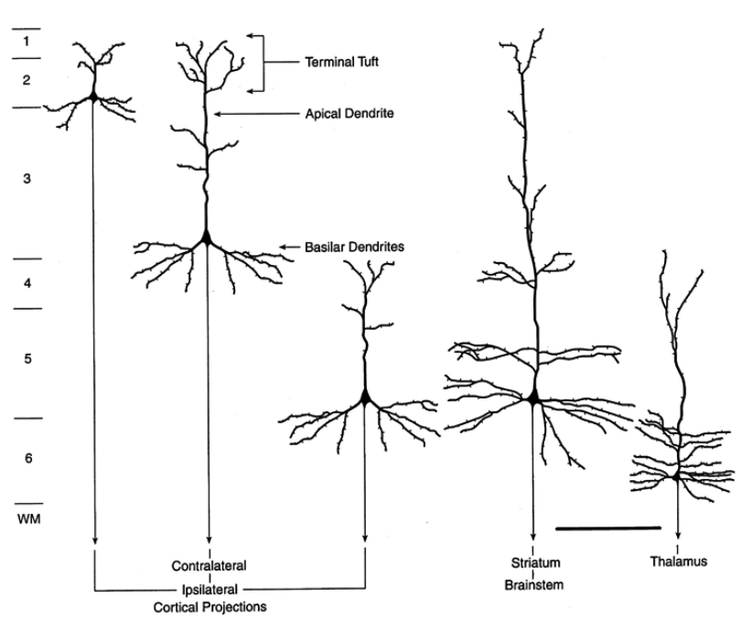

FIGURE 53.1. Schematic drawing illustrating the characteristic morphologic features of pyramidal neurons in different cortical layers. Note that the laminar location of the cell soma tends to be associated with the major projection target of the principal axon. Arabic numbers, cortical layers; WM, white matter. Adapted from Jones EG. Laminar distribution of cortical efferent cells. In: Peters A, Jones EG, eds. *Cerebral cortex*, vol 1. New York: Plenum Press, 1984:521–553.

The axons of pyramidal cells typically give rise to intrinsic collaterals, which travel either horizontally or vertically within the gray matter, and a principal axonal projection, which enters the white matter and travels to another brain region. These axons utilize excitatory amino acids, such as glutamate, as a neurotransmitter and form synapses that have the characteristic morphology associated with excitatory neurotransmission. These so-called Gray's Type I synapses are characterized by the presence of small round vesicles in the axon terminal, and a postsynaptic density that is thick and asymmetric in appearance (54).

Nonpyramidal Neurons

Of the other major type of cortical neurons, nonpyramidal cells, about 90% utilize the inhibitory neurotransmitter γ-aminobutyric acid (GABA). The axons of these generally small, local circuit or interneurons, arborize within the cortical gray matter and form Gray's Type II synapses that are characterized by pleomorphic vesicles in the axon terminal and symmetric pre- and postsynaptic densities. GABA neurons constitute approximately 25% of all neurons in the primate neocortex (55), and are comprised of about 12 distinct subtypes (56 ,57). Although the differences among subtypes can be described on the basis of the morphologic features of the cell body and proximal dendrites (e.g., bipolar, multipolar, bitufted), the most discriminating and functionally meaningful classification system is based on the organization of the axonal arbor and synaptic targets of the axon terminals. In addition, GABA neurons are chemically heterogeneous, and separate subpopulations can be identified by the presence of specific neuropeptides or calcium-binding proteins (58 ,59).

Together, these morphologic and chemical features define subpopulations of GABA neurons that appear to have different biophysical properties and different roles in dPFC circuitry (Fig. 53.2). For example, GABA neurons of the chandelier class, which may also express either the neuropeptide corticotropin-releasing factor (60) or the calcium-binding protein parvalbumin (61 ,62), are found primarily in cortical layers 2 to 5 in monkey dPFC (56). The axon terminals of these neurons, which are arrayed as distinct vertical structures (termed "cartridges"), form Gray's Type II synapses exclusively with the axon initial segment of pyramidal

neurons (63 ,64 ,65 ,66 ,67 and 68), the site of action potential generation in pyramidal cells. Each chandelier cell may contact up to 300 pyramidal neurons within a radius of 100 to 150 µm from its cell body (69). Thus, chandelier cells exert critical inhibitory control over the activity of a localized group of pyramidal neurons. In contrast, the axons of wide arbor (basket) neurons spread horizontally for considerable distances (up to 1.0 mm) within the dPFC (56) and form Gray's Type II synapses with the cell bodies, dendritic shafts, and dendritic spines of pyramidal neurons (70). Wide arbor neurons may be specialized to provide inhibitory constraints over the activity of spatially segregated populations of PFC pyramidal neurons (71 ,72). A third example, double bouquet cells, which contain the calcium-binding proteins calbindin or calretinin (58), have radially restricted axonal arbors that synapse with the dendritic shafts of both pyramidal and local circuit neurons (73).

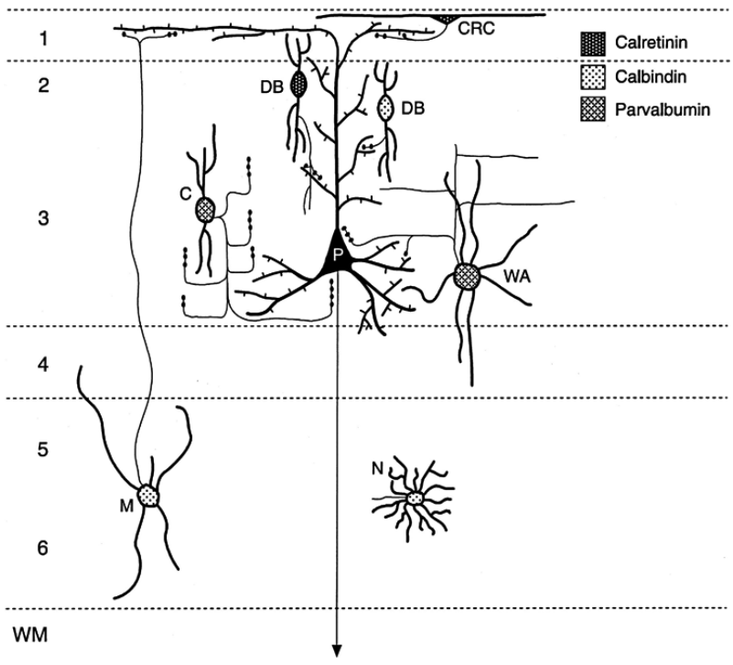

FIGURE 53.2. Schematic drawing of the synaptic interactions between different classes of local circuit neurons and a layer 3 pyramidal neuron (P) in monkey prefrontal cortex. C, parvalbumin (PV)-labeled chandelier neuron; CRC, calretinin (CR)- and/or CB (calbindin)-labeled Cajal-Retzius neuron; DB, CR- or CB-labeled double-bouquet neuron; M, CB-labeled Martinotti cell; N, CB-labeled neurogliaform neuron; WA, PV-labeled wide arbor (basket) neuron. Modified from Condé F, Lund JS, Jacobowitz DM, et al. Local circuit neurons immunoreactive for calretinin, calbindin D-28k, or parvalbumin in monkey prefrontal cortex: distribution and morphology. *J Comp Neurol* 1994,341:95–116.

Laminar Arrangement of Neurons

The dPFC, like other cortical association regions, is composed of six layers that can be distinguished according to the size and packing density of their constituent neurons (Fig. 53.3). Layer 1, which is located just below the pial surface, contains relatively few neurons, but approximately 90% of these neurons utilize GABA. Layers 2 and 4 are thin and densely packed with small "granular" cells. The majority of these neurons are small pyramidal cells, and GABA neurons constitute approximately 30% and 15% of all neurons in layers 2 and 4, respectively (55). Layers 3 and 5, the thickest cortical layers, contain prominent pyramidal neurons with a classic morphology. In both of these layers, the size and packing density of the pyramidal neurons is greater near their borders with layer 4. These patterns make it possible to subdivide layers 3 and 5 into superficial (toward the pial surface) and deep zones. Pyramidal cells in layer 6 have a modified or atypical appearance. In general, GABA cells constitute 20% to 30% of the neurons in layer 3, and about 15% of the neurons in layers 5 and 6 (55).

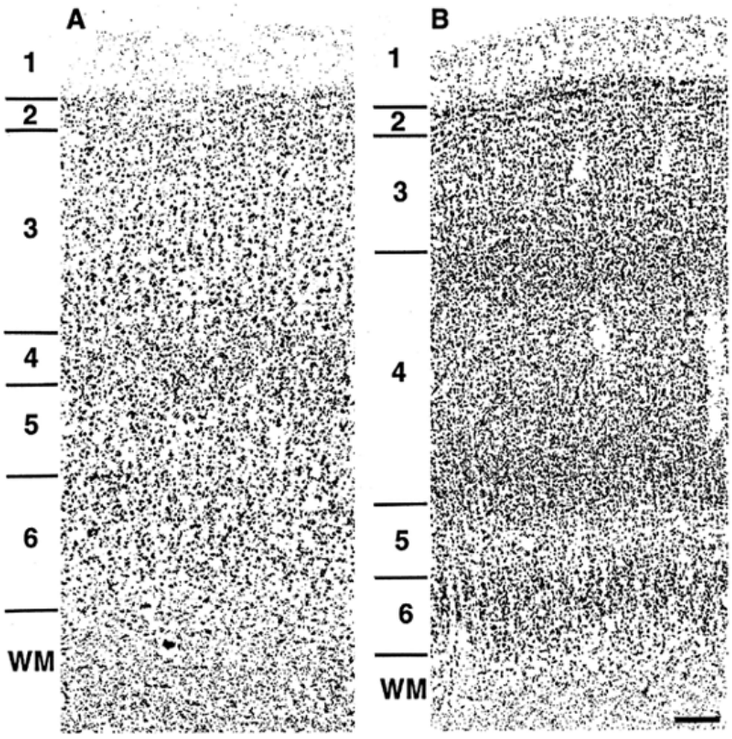

FIGURE 53.3. Nissl-stained sections showing laminar and regional differences in cell size in packing density in area 46 *(A)* of the human prefrontal cortex and area 17, primary visual cortex *(B)*. Calibration bar = 200 µm. Modified from Lewis DA. The organization of cortical circuitry. In: Harrison PJ, Roberts GW, eds. *The neuropathology of schizophrenia: progress and interpretation*. Oxford: Oxford University Press, 2000:235–256.

Different types of axonal projections to the dPFC terminate in certain cortical layers, and projections from the dPFC to other brain regions generally originate from pyramidal neurons in specific lamina. Thus, the laminar specificity of abnormalities in the dPFC in schizophrenia may reveal information about the types of connections that are affected. Nevertheless, owing to the vertical spread of the dendrites of many neurons, alterations in afferents to one layer can influence the function of neurons whose cell body is located in a different layer.

Organization of Projections from the dPFC

Pyramidal neurons located in layers 2 and superficial 3 tend to project to nearby cortical regions in the same hemisphere, whereas those in deep layer 3 frequently project to more distant ipsilateral regions or across the corpus callosum to cortical regions in the other hemisphere (Fig. 53.1). Projections within the same hemisphere are termed associational projections, whereas those to the contralateral hemisphere are termed callosal projections. Pyramidal cells in layers 5 and 6 project subcortically, with outputs from layer 5 directed to the striatum, superior colliculus, and other subcortical structures, and those from layer 6 preferentially directed to the thalamus. The efferent axons of pyramidal neurons tend to project to only one other brain region, although a small percentage of these neurons do give rise to collateral projections (74 ,75). In contrast to these extrinsic projections, the small pyramidal cells in layer 4 project primarily within the gray matter and relatively few send axons into the underlying white matter.

Although this laminar distribution of cortical efferents is generally accurate, many exceptions exist. For example, 25% to 30% of the pyramidal neurons furnishing associational projections to other PFC regions are located in the infragranular layers (layers 5 and 6) (74), and approximately 15% to 20% of neurons projecting to the striatum are located in layer 3 (76). In addition, the nature of the cortical output to a given region may vary with the location of the cell body of origin. For example, neurons in layer 6 provide “modulatory” inputs to cells in higher order thalamic nuclei (such as the mediodorsal thalamic nucleus, the principal source of thalamic projections to the dPFC) as well as inputs to the thalamic reticular nucleus, which regulates thalamocortical interactions. In contrast, thalamic projections originating in layer 5 do not innervate the reticular nucleus and appear to provide “driving” afferent inputs to higher order nuclei (77).

The innervation patterns of the intrinsic axon collaterals of pyramidal cells also tend to differ across cortical layers (71). Pyramidal neurons in layers 2 and 3 furnish local collaterals that arborize in the vicinity of the cell body, as well as horizontal axon projections that spread for considerable distances through the gray matter and then give rise to discrete clusters of axon terminals in the supragranular layers. Although pyramidal neurons in layers 5 and 6 also furnish horizontal intrinsic collaterals, these have a more limited spread and do not terminate in spatially segregated clusters. In contrast, pyramidal cells in layer 4 furnish predominantly vertically oriented axons, which appear to be specialized for interlaminar connections. The intrinsic axonal connections of pyramidal neurons in layers 2 and 3 of the dPFC also appear to be specialized relative to the homologous neurons in at least some other cortical regions. For example, although approximately 95% of the long distance intrinsic and associational axon projections of these neurons target the dendritic spines of other pyramidal cells (78), the synaptic targets of the local axon collaterals of these cells are equally divided between spines and dendritic shafts of GABA neurons (79).

Organization of Projections to the dPFC

The dPFC shares connections with a number of other cortical regions (Fig. 53.4). The inputs from these areas frequently terminate across all cortical layers, although the different layers tend to be preferentially innervated depending upon the source of the inputs. For example, inputs from cortical regions that have a well-developed layer 4 tend to terminate more prominently in layers 4 to 6, whereas those that originate in regions with a poorly developed layer 4 tend to terminate in layers 1 to 3 (80). In some cases, afferents from different regions (e.g., callosal inputs from the contralateral PFC and associational inputs from the posterior parietal cortex) tend be distributed into interdigitated columns (81).

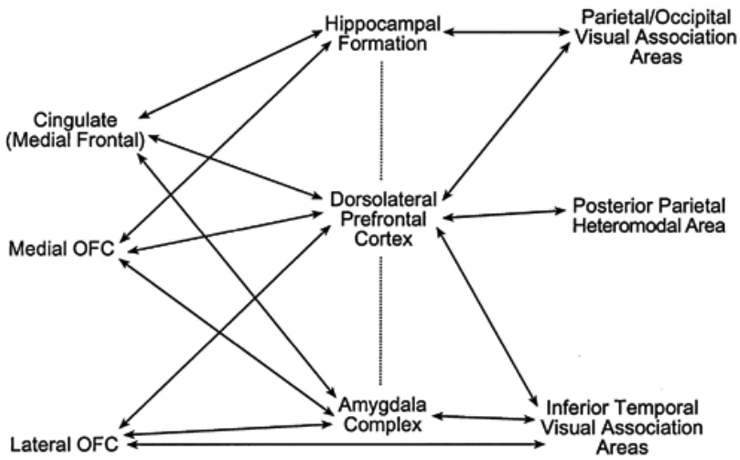

FIGURE 53.4. Schematic diagram of principal corticocortical connections within the frontal lobe regions, including primary limbic connections, and between posterior sensory cortices and frontal lobe regions. Double-head arrows indicate that most connections are reciprocal. Relatively sparse direct connections between dorsolateral prefrontal cortex and limbic structures (hippocampal formation and amygdala nuclei) are depicted with a dashed line. OFC, orbitofrontal cortex. Modified from Kaufer D, Lewis DA. Frontal lobe anatomy and cortical connectivity. In: Miller BL, Cummings JL, eds. *The human frontal lobes: functions and disorders*. New York: Guilford Publications, 1998:27–44.

In contrast to these cortical inputs, afferents from thalamic relay nuclei, such as the medial dorsal nucleus, project dominantly to layers deep 3 and 4, with a minor projection to layer 6 (82). Although afferents from the amygdala project more densely to orbital than dorsal regions of the PFC, these tend to terminate in layers 1 and 6 (83).

Subcortical nuclei containing monoamines or acetylcholine also exhibit distinct laminar patterns of termination in the PFC, along with substantial regional differences in relative

density. Dopamine (DA)-containing axons from the ventral mesencephalon have a bilaminar distribution in the PFC (84), forming a dense band in layers 1 through the most superficial portion of layer 3 and a second band of lower density in layers deep 5 and 6. In more densely innervated regions, such as dorsomedial PFC (area 9), labeled axons are also present in high density in the middle cortical layers, forming a third distinctive band in deep layer 3. The noradrenergic (NA) projection from the locus coeruleus exhibits a different, and in some ways complementary, laminar innervation pattern to that of DA axons (85 ,86). The density of NA axons is substantially greater in the deep cortical layers, especially layer 5, than in the more superficial cortical laminae. In particular, few NA axons are present in layer 1, which receives a dense DA innervation. In contrast, the relatively uniform laminar distribution of cholinergic (87) and serotonergic (88) axons contrasts with the substantial heterogeneity exhibited by both DA and NA axons.

INTEGRITY OF PREFRONTAL CORTICAL CIRCUITRY IN SCHIZOPHRENIA

Part of "53 - Neural Circuitry Approaches to Understanding the Pathophysiology of Schizophrenia "

In this section, we consider how this knowledge about the normal organization of dPFC circuitry can be used to interpret studies of the integrity of different types of neural elements in subjects with schizophrenia. As noted, several lines of evidence support the hypothesis that schizophrenia is associated with a decrease in the synaptic connectivity of the dPFC. However, these abnormalities do not appear to be a consequence of a decreased complement of dPFC neurons, because several postmortem studies (34 ,37 ,89) have reported either a normal or increased cell packing density in the dPFC. In addition, the one study that used unbiased approaches to determine the total number of PFC neurons did not observe a reduction in subjects with schizophrenia (90); however, the approaches used in these studies probably lacked adequate sensitivity to detect reduced numbers of small subpopulations of PFC neurons. Some studies that focused on certain neuronal subpopulations have reported decreases in density of small neurons in layer 2 (91) or of the parvalbumin-containing subpopulation of GABA neurons (92). However, the latter abnormality was not observed in another study (35), and it should be noted that a reduction in neuronal density when using immunocytochemical markers might reflect an alteration in the target protein rather than in the number of cells.

Smaller neuronal cell bodies could also contribute to the observed reduction in PFC gray matter in schizophrenia. Interestingly, two groups have reported that the somal volume of pyramidal cells in deep layer 3 of dPFC area 9 is decreased in subjects with schizophrenia (89 ,93). In addition, this reduction in somal volume may be associated with a decrease in total length of the basilar dendrites of these neurons (94). In contrast, the size of GABA neurons does not appear to be reduced (35 ,95), although less rigorous methods were employed in these studies.

In summary, although a reduction in neuron number cannot be completely excluded, the subtle reduction in dPFC gray matter in schizophrenia may be attributable to a combination of smaller neurons and a decrease in dPFC neuropil, the axon terminals, distal dendrites and dendritic spines that represent the principal components of cortical synapses. Indeed, as described in more detail below, these two factors may be interrelated.

Candidate Sources for Synaptic Reductions

The apparent reduction in synaptic connectivity in the dPFC of subjects with schizophrenia may be attributable to one or more of the following sources of synapses: axon terminals intrinsic to the dPFC, or afferents from other cortical regions, the thalamus, or other subcortical locations. Although none of these sources can be excluded at present, some are more likely to be major contributors than others. For example, one subcortical source, the DA projections from the mesencephalon, may be reduced in number in schizophrenia as evidenced by the report of diminished densities of axons immunoreactive for tyrosine hydroxylase, the rate limiting enzyme in catecholamine synthesis, and the DA membrane transporter in the dPFC (96). However, these reductions appeared to be restricted to the deep cortical layers. Furthermore, an *in vivo* neuroimaging study found a reduced density of DA D1 receptors in the dPFC of subjects with schizophrenia (97); however, DA axons are estimated to contribute less than 1% of cortical synapses (84). Consequently, even the complete loss of DA projections to the dPFC could not, in isolation, account for the observed reductions in gray matter volume or synaptophysin protein levels. The relatively small contributions that NA-, serotonin-, and acetylcholine-containing axons make to the total number of synapses in the dPFC also argues against disturbances in these systems as the principal cause of reduced synaptic connectivity in this brain region.

The fact that layer 3 pyramidal cells, which give rise to a substantial number of intrinsic excitatory synapses, have reduced somal volume in subjects with schizophrenia (89 ,93) may suggest that the synapses furnished by the intrinsic axon collaterals of these neurons are reduced in number, because somal volume tends to be correlated with the size of a neuron’s axonal arbor (98 ,99). Evidence for a disturbance in intrinsic connectivity is supported by recent studies using cDNA microarray profiling of the expression of over 7,000 genes in dPFC area 9 of subjects with schizophrenia (44). Among 250 functional gene groups, the most marked changes in expression were present in the group of genes that encode for proteins involved in the regulation of presynaptic neurotransmitter release. Although these findings very likely indicate a general impairment in the efficacy of synaptic

transmission within the dPFC in schizophrenia, whether they represent a “primary” abnormality intrinsic to the dPFC or a “secondary” response to altered afferent drive to this brain region remains to be determined. Furthermore, because the specific genes in this group that were most altered appeared to differ across subjects, it seems unlikely that these findings can be explained solely by reduction in the number of intrinsic dPFC synapses. Consistent with this view, the expression of synaptophysin mRNA does not appear to be reduced in the dPFC of subjects with schizophrenia (50 ,100), suggesting that the reduction in this synaptic protein marker in the dPFC may have an extrinsic source. Consistent with this interpretation, synaptophysin mRNA levels are reduced in cortical areas that do furnish projections to the dPFC (101 ,102). However, whether these transcriptional changes are present in PFC-projecting neurons, and if so, whether they result in reduced levels of synaptophysin protein in the terminal fields of these neurons, have not been assessed.

Decreased synaptic connectivity within the PFC might also be attributable to altered inputs from the thalamus. For example, some structural MRI studies have revealed a reduction in thalamic volume in subjects with schizophrenia (103 ,104 ,105 and 106). In addition, thalamic volume was correlated with prefrontal white matter volume in schizophrenic subjects (107), suggesting that a reduction in thalamic volume was associated with fewer axonal projections to the PFC. Consistent with these observations, postmortem studies have revealed reductions of 17% to 25% in volume and 27% to 40% in total neuron number of the medial dorsal thalamic nucleus (MDN), the principal source of thalamic projections to the PFC (108 ,109 and 110). Interestingly, the available data suggest that these abnormalities exhibit topographic specificity. For example, reduced cell numbers have been reported in the MDN and the anterior thalamic nuclei (which project to the PFC and anterior cingulate cortex), whereas the ventral posterior medial nucleus, a sensory relay nucleus, appears to be unaffected (109 ,110). In addition, within the MDN, one study indicates that neuron number is significantly decreased in the parvocellular subdivision (which projects principally to the dPFC), but not in the magnocellular subdivision (which projects principally to the ventral PFC) (110). Finally, studies in both subjects with schizophrenia who never received antipsychotic medications (111) and monkeys treated for 1 year with haloperidol (112) suggest that these medications do not account for the reduction in MDN neuron number. However, despite the apparent consistency of the published studies, a deficient number of MDN neurons in schizophrenia must still be considered a preliminary finding given the relatively small sample sizes reported to date, and the fact that potential confounds, such as comorbid conditions (e.g., alcoholism), have not been adequately assessed.

Certainly, a reduction in cell number in the MDN could contribute both to the decrease in synaptic markers in the PFC, and, given the dependence of working memory tasks on the integrity of thalamo–prefrontal connections (29), to the disturbances in working memory observed in schizophrenia. However, in contrast to other species, the primate MDN contains both cortically projecting neurons and local circuit neurons. Thus, it is critical to determine which subpopulation(s) of MDN neurons are affected in schizophrenia. Interestingly, the density of neurons in the anterior thalamic nuclei that contain parvalbumin (113), a calcium-binding protein present in thalamic projection neurons (114), is reduced in schizophrenia; however, whether this reduction represents an actual loss of neurons, as opposed to an activity-dependent decrease in parvalbumin expression, is not known.

Within the dPFC, five other lines of evidence are also consistent with a reduction in inputs from the MDN (Fig. 53.5). First, a preliminary report notes that subjects with schizophrenia, but not those with major depression, have a decreased density of parvalbumin-labeled varicosities (putative axon terminals) in layers deep 3 and 4, the principal termination zone of thalamic projections to the PFC (115). In contrast, parvalbumin-labeled varicosities were not decreased in layers 2 to superficial 3, suggesting that the reduction in layers deep 3 and 4 might not be attributable to changes in the axon terminals of the parvalbumin-containing subset of cortical GABA neurons present in cortical layers 2 to 5 (35). Thus, the laminar-specific reduction of

parvalbumin varicosities in schizophrenia is consistent with a decreased number of MDN terminals in the dPFC, although a laminar-specific reduction in the axon terminals of local circuit neurons cannot be conclusively excluded.

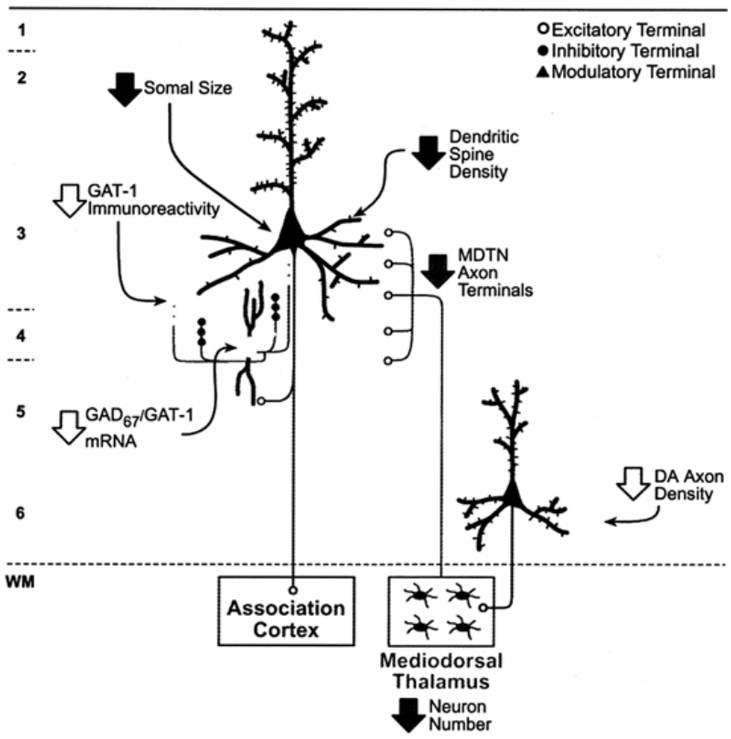

FIGURE 53.5. Schematic diagram summarizing disturbances in the connectivity between the mediodorsal (MD) thalamic nucleus and the dorsal prefrontal cortex (PFC) in schizophrenia. See text for details. Modified from Lewis DA, Lieberman JA. Catching up on schizophrenia: natural history and neurobiology. *Neuron* 2000;28:325=n334.

Second, the thalamic projections to the dPFC principally target the dendritic spines of pyramidal neurons (116). In experimental animals, the elimination of presynaptic axon terminals leads to a resorption of the postsynaptic dendritic spine (117), suggesting that a reduction in MDN projection neurons would be associated with decreased dendritic spine density in the dPFC. The two studies that have examined this issue both found decreased spine density on the basilar dendrites of PFC layer 3 pyramidal neurons (94 ,118), with this decrease most marked for pyramidal neurons located in deep layer 3 (94), those most likely to be targeted by projections from the thalamus. Although the well-documented, remarkable plasticity of dendritic spines must be considered when interpreting these findings, these observations are consistent with a reduction in MDN–dPFC connectivity in schizophrenia. However, the presence of more modest reductions in spine density on pyramidal neurons in cortical layers that do not directly receive MDN input suggest that the observed decrease in deep layer 3 may reflect the combined effect of a deficient number of thalamic and cortical synapses (94).

Third, the size of layer 3 pyramidal neurons is reduced in the dPFC of schizophrenic subjects (89 ,119). Although the possible relationship of these findings to a decrease in MDN inputs is less clear, studies in animals have provided evidence of denervation atrophy of layer 3 pyramidal cells following the loss of other afferent inputs (120).

Fourth, in the primate visual system, monocular deprivation, which results in reduced afferent drive from the thalamus, is associated with a decline in markers of activity in cortical GABA neurons (121), including decreased expression of the mRNA for glutamic acid decarboxylase (GAD_{67}), the synthesizing enzyme for GABA (122). Although the experimental manipulation of the visual system did not involve a partial reduction in thalamic neuron number, if these findings in the visual cortex can be generalized to a deficient number of MDN projections to the dPFC, a reduction in GAD_{67} in the dPFC of schizophrenic subjects might be expected. Consistent with this prediction, both GAD_{67} mRNA and protein levels have been reported to be reduced in the dPFC of schizophrenic subjects (26 ,123 ,124), observations supported by other evidence of reduced GABA neurotransmission in the PFC of schizophrenic subjects. (See ref. 125 for review.)

Finally, the reduction in GAD_{67} mRNA expression in schizophrenia appears to be restricted to a subpopulation of PFC GABA neurons (approximately 25% to 30%), especially those neurons located in the middle cortical layers (124). Consistent with this finding, other studies suggest that the affected subpopulation of GABA neurons includes chandelier cells. The axon terminals of chandelier cells form distinctive vertical arrays (termed cartridges) that synapse exclusively on the axon initial segment of pyramidal neurons (126). Interestingly, expression of the mRNA for GABA membrane transporter (GAT-1) is also undetectable in approximately 25% to 30% of GABA neurons, which have a laminar distribution similar to the neurons with undetectable GAD_{67} mRNA expression (127). In addition, the density of GAT-1 immunoreactive chandelier neuron axon cartridges is decreased in the dPFC of schizophrenic subjects, with the reduction most evident in the middle cortical layers (128 ,129). Thus, given the powerful inhibitory control that chandelier neurons exert over pyramidal cell output, decreased excitatory thalamic drive to the PFC may be partially compensated for by a reduction in chandelier cell-mediated inhibition at the axon initial segment of layer 3 pyramidal cells. This effect could occur via the local axon collaterals of layer 3 pyramidal cells, approximately 50% of which target the dendritic shafts of GABA neurons (79). However, it is important to note that other causes and consequences of the observed alterations in chandelier neurons have not been excluded. (See ref. 124 for a discussion.)

Together, these data are all consistent with the hypothesis that schizophrenia is associated with abnormalities in the projection from the MDN to the dPFC. As in other cortical regions, the connections between the MDN and dPFC are reciprocal, which raises the question of whether the abnormal thalamocortical projection is paralleled by a disturbance in the corticothalamic projection. Studies that have examined PFC neurons in layers 5 and 6, the principal location of corticothalamic projection neurons, have generally not found evidence of a decrease in neuron size or number (34 ,89 ,91), although one study (95) did report decreased neuronal density in layer 6 of PFC (region not specified); however, a reduced density of DA axons was observed selectively in layer 6 of dPFC area 9 in schizophrenic subjects (96). Interestingly, the dendritic shafts and spines of pyramidal cells are the principal synaptic targets of DA axon terminals in layer 6, and DA appears to play a critical role in regulating the influence of other inputs on pyramidal cell activity (130). Thus, a shift in DA neurotransmission in dPFC layer 6 could reflect a change in the modulation of corticothalamic feedback in response to abnormal thalamocortical drive (96).

The significance of these findings depends, in part, on the extent to which they are unique to the diagnosis of schizophrenia, and not a consequence of other factors associated with schizophrenia, such as antipsychotic drug treatment. Some of these findings have been examined for diagnostic specificity, whereas others have not. For example, the reduction in dendritic spine density on deep layer 3 pyramidal neurons was not found in subjects with major depressive disorder (94), and the reduction in density of GAT-1 immunoreactive axon cartridges was not apparent in subjects with nonschizophrenic psychiatric disorders (129). Similarly, to the extent to which it has been examined, these

findings do not appear to be attributable to the abuse of alcohol or other substances, which frequently accompanies the diagnosis of schizophrenia, although further studies in this area certainly are needed.

Similarly, the available evidence suggests that these disturbances in thalamo-prefrontal circuitry are not attributable to treatment with antipsychotic medications. Globally, the increase in cell packing density in the dPFC observed in subjects with schizophrenia was not found in monkeys treated for 6 months with a variety of antipsychotic agents (131). Similarly, treatment of monkeys for 12 months with haloperidol and benztropine at blood levels known to be therapeutic in humans was not associated with a reduction in the size or total neuron number of the MDN (112). The potential influence of antipsychotic drugs on GAT-1–labeled axon cartridges has been examined in several ways with interesting results (129). The density of labeled cartridges was greater in schizophrenic subjects who were on than off antipsychotic medications at the time of death (although both groups showed reduced levels compared to normal controls). In addition, compared to matched control animals, the density of GAT-1-positive cartridges was elevated in monkeys treated for 1 year with haloperidol. Thus, the convergence of these findings suggests both that the pathophysiology of schizophrenia may actually be associated with more marked reductions in GAT-1–immunoreactive cartridge density than those observed in postmortem studies.

OPPORTUNITIES FOR NEURAL CIRCUITRY-BASED STUDIES OF SCHIZOPHRENIA

Part of "53 - Neural Circuitry Approaches to Understanding the Pathophysiology of Schizophrenia "

The data summarized in the preceding section suggest that neural circuitry-based approaches to the study of brain abnormalities in schizophrenia provide: (a) a useful framework to account for the abnormalities observed in individual studies, (b) a platform for the formulation of predictions regarding the outcome of future studies, and (c) the promise of an enhanced ability to understand the neurobiological bases of clinical phenomena. However, a truly neural circuitry-based model of schizophrenia requires an appreciation of the mechanistic relations among the abnormalities observed in different components of the circuitry. Specifically, understanding the pathophysiology of schizophrenia (or any other psychiatric disorder) depends ultimately on knowing how abnormalities in one brain region or circuitry component produce and/or result from disturbances in others, a task that involves a consideration of cause, consequence, and compensation (132). Does a given abnormality represent a primary pathogenetic event (cause), does it reflect a downstream or upstream (given the reciprocal nature of many links between brain regions), secondary, deleterious event (consequence), or does it reveal a homeostatic response intended to restore normal brain function (compensation)? Distinguishing among these three possibilities for each component of a neural network will be necessary for understanding the pathophysiology of the disease as well as for developing novel therapies designed to correct causes and consequences and/or to augment compensatory responses.

Clearly, addressing these types of questions for schizophrenia requires several additional types of investigations. First, it is essential to further assess the normal organization of MDN–dPFC connectivity in nonhuman primates. For example, what patterns of connectivity within the dPFC link inputs from the MDN to the neurons that provide outputs to the MDN or to other brain regions such as the striatum? Second, MDN–dPFC circuitry needs to be further probed in subjects with schizophrenia in ways that inform an understanding of its functional integrity. For example, what are the postsynaptic consequences in pyramidal neurons of the apparent alterations in GABA neurotransmission in chandelier cells? Third, the direction of the pathophysiological changes in MDN–dPFC circuitry in schizophrenia need to be assessed in experimental animal models. For example, can the observations of altered spine density and decreased GAD_{67} mRNA expression in the dPFC be replicated by partial lesions of the MDN in monkeys? Do manipulations of neurotrophin expression in dPFC layer 3 pyramidal cells result in a loss of the MDN neurons that project to the dPFC?

It is also critical to extend these types of investigations to other brain regions that may integrate MDN–dPFC circuitry with broader neural networks. Besides the dPFC, the hippocampal formation is probably the brain region that has been most extensively studied in schizophrenia. Multiple imaging and postmortem studies have documented a slight bilateral reduction in the volume of the hippocampal formation (25 ,133), an observation supported by more recent *in vivo* proton spectroscopy findings of reduced hippocampal N-acetyl aspartate in both unmedicated adult and childhood onset subjects with schizophrenia (134). Although initial reports of hippocampal neuron disarray or misplaced neurons in the superficial layers of the adjacent entorhinal cortex have been widely cited, these observations have not been replicated in other studies. (See ref. 133 for review.) Reduced hippocampal volume also does not appear to be attributable to decreased neuronal number, but several independent studies have found reductions in neuronal cell body size in various subregions of the hippocampus proper (135 ,136 and 137). In addition, there are consistent reports of reductions in the gene products for synaptophysin and related presynaptic markers and in dendritic markers, such as microtubule-associated protein, in certain subdivisions of the hippocampus. (See ref. 12 for review.) Thus, these observations bear some similarity to findings in the dPFC in that disturbances in synaptic connectivity appear to be present in both regions in schizophrenia. How these findings inform our understanding of alterations in the intrinsic connectivity of the hippocampal formation in schizophrenia remains to be

determined, but their possible relation to dPFC abnormalities is suggested by experimental studies in rodents that indicate that dysfunction of the PFC appears postpubertally following perinatal lesions of the hippocampus (138).

As noted in the preceding section, it is also important to consider these findings within the context of the developmental time course of schizophrenia, especially the tendency for prodromal and clinical symptoms to become evident during the second and third decades of life. Although the adolescence-related pruning of excitatory (but not inhibitory) synapses (31 ,32) and their targets, pyramidal cell dendritic spines (139), in the primate dPFC has been well documented, little information exists regarding the extent to which different connections are actually affected by these changes. Interestingly, limited data suggest that the terminals of intrinsic axon collaterals from dPFC layer 3 pyramidal cells may be more extensively pruned than associational cortical projections to the dPFC (140). Knowing whether projections from the MDN are particularly vulnerable to this process might provide critical information for hypotheses regarding the mechanisms underlying disturbances in MDN–dPFC circuitry in schizophrenia.

Another current challenge to the types of neural circuitry-based models of schizophrenia illustrated herein is to understand how the genetic factors that confer susceptibility for the disease contribute to the observed alterations in neural circuitry. In other words, how can molecular genetic and systems neuroscience approaches be integrated in the study of schizophrenia? Schizophrenia appears to be a consequence of multiple interacting genes that individually may have relatively little effect; it is unlikely that all such genes are involved in every individual who meets diagnostic criteria for the disorder. Thus, assessment of the patterns of altered gene expression in the affected brain circuits of subjects with schizophrenia (using cDNA microarray technology or related techniques), and comparison of the chromosomal locations of these genes with regions implicated in schizophrenia through linkage studies (141), may provide convergent approaches to the identification of specific susceptibility genes. For example, as noted, a recent study of gene expression profiling in the dPFC of subjects with schizophrenia revealed that the group of genes encoding proteins involved in the regulation of presynaptic function were most consistently altered (44). In addition, although the subjects with schizophrenia appeared to share a common abnormality in the control of synaptic transmission, they differed in terms of the specific combination of genes that showed reduced expression, a finding that may be consistent with a polygenic model for this disorder. Interestingly, a number of the chromosomal loci that have been implicated in schizophrenia contain genes encoding proteins related to presynaptic function (44). However, this strategy, and the subsequent integration of potential susceptibility genes with neural circuitry models of the illness, rests on the prediction that genes regulating presynaptic function are not homogeneously expressed across classes of neurons and brain regions.

Finally, neural circuitry-based models must also be considered in relation to the clinical heterogeneity of schizophrenia. Is the magnitude of the abnormalities within MDN–dPFC circuitry related to the age of onset or severity of cognitive impairment? Can other clinical features be understood within the context of abnormalities in broader circuits that include connections with MDN and dPFC? Given the limitations involved in making rigorous clinicopathologic correlations in schizophrenia, the answers to these questions may await the development and application of *in vivo* imaging techniques with greater sensitivity, such as those that will permit functional assessments at the levels of individual cortical layers or thalamic nuclei.

Functional Neuroimaging in Schizophrenia

Karen Faith Berman

Karen Faith Berman: National Institute of Mental Health, Intramural Research Program, Bethesda, Maryland

THEORETICAL PERSPECTIVE

Part of "54 - Functional Neuroimaging in Schizophrenia "

The search for a biological basis of schizophrenia includes a long chapter in which alterations in the characteristics and localization of neural activity are the focus. It is in this arena that functional neuroimaging has had the broadest application and greatest impact in psychiatry. This now extensive body of work has left no doubt that schizophrenia is associated with measurable, objective signs of altered brain function, and clinical and pathophysiologic correlations have begun to emerge. Certain cerebral concomitants of this illness have been consistently demonstrated, although no single pathognomonic neurofunctional abnormality has been delineated yet. Increasingly, it appears that dysfunction of a system of functionally and/or structurally interconnected cortical and limbic brain regions is present to lesser or greater degrees, producing more or less psychopathology in individual patients, and that certain brain regions, such as frontal cortex, may play a special role in this larger picture. Abnormal neurotransmission within these neural circuits appears to be related to core features of schizophrenia, particularly cognitive impairment. Although it is likely that at least some of the functional abnormalities are generative of these features and not simply a response to them, clarification of this “chicken versus egg” issue must be a crucial component of any research program in this area, and the elucidation of the underlying mechanisms is the most important quest of this research at present. Current functional neuroimaging has much to offer in guiding this quest, particularly when combined with new information now available from other fields such as genetics and cognitive science. In this light, the following sections review existing findings, delineate their relationship to other neurobiological and clinical properties of the illness, discuss conceptual issues and controversies, examine methodologic considerations (including technical constraints), summarize new techniques and the new approaches to research design that they allow, and finally describe the most important areas for future research.

HISTORIC PERSPECTIVE

Part of "54 - Functional Neuroimaging in Schizophrenia "

Functional neuroimaging studies utilize the fact that neuronal activation results in regionally increased blood flow and metabolism. This can be measured either by radiotracer methods (e.g., [positron emission tomography] PET regional cerebral blood flow [rCBF] or cerebral glucose metabolic rate) or by a regional effect on the ratio of deoxyhemoglobin to oxyhemoglobin imaged by magnetic resonance techniques (the blood oxygenation level dependent [BOLD] effect). This work began in earnest some 50 years ago with the pioneering studies of Seymour Kety and colleagues who developed the first reproducible, quantitative technique for measuring cerebral blood flow (CBF) as an indicator of neuronal activity, in humans by using nitrous oxide, an inert but soluble gas. When this method was applied to schizophrenia (1), these investigators found no alteration in the overall average CBF level in patients, a result that has largely been confirmed by more recent studies; however, this finding did not rule out the existence of neurophysiologically meaningful changes in specific brain structures.

The next advance came in the 1970s with the establishment of rigorous methods that could differentiate the functional level of specific cortical regions, albeit with only 2-cm anatomic accuracy at best (2). This method, administration of tracer amounts of radioactive xenon, was rapidly applied to the study of schizophrenia. The resulting findings of functional abnormality in the frontal lobe spurred a shift in focus throughout many research domains in the field that remains a prevailing force today. In the 1980s, the advent of tomographic methods, such as single photon emission computed tomography (SPECT) and PET, which both use radioactive compounds as tracers, brought improved interregional spatial resolution on the order of 5 to 6 mm and allowed measurement of subcortical regional function.

In the last decade, functional magnetic resonance imaging (fMRI) has emerged as the premier technique for neuropsychiatric functional neuroimaging. By taking advantage of the differential paramagnetic properties of oxyhemoglobin versus deoxyhemoglobin and the altered ratio between them that occurs when blood volume and blood flow change in response to neural activation, BOLD fMRI uses intrinsic properties of the blood itself rather than an extrinsic contrast or tracer agent, to generate maps of brain function. It is, thus, entirely noninvasive, and measurements can be repeated over time, conferring significant advantage in experiments designed to address important clinical questions in schizophrenia, such as response to medication, correlation with clinical course, differentiation of state versus trait phenomena, determination of the dynamic range of neurophysiological response, and learning. This new methodologic advance brought further improvements in spatial resolution as well as enhanced temporal resolution, which, although still slow (several seconds) compared to neuronal signaling (on the order of 200 ms), improved to the degree that event-related neural activity could be recorded with anatomic precision heretofore unavailable with electrophysiologic methods.

TECHNICAL PERSPECTIVE

Part of "54 - Functional Neuroimaging in Schizophrenia "

As can be seen in the preceding brief history, over the years the sophistication of the questions that could be asked and the hypotheses about schizophrenia that could be tested have paralleled the development of new brain imaging technologies and analytic methods. This parallel development is evident in the evolution of the science from the search for regionally specific pathologic function to that in neural systems, and from measures sensitive only to static pathophysiology to explorations of the dynamic interplay among regions in those neural systems. Therefore, a brief discussion follows of the newest methodologic approaches and latest vistas for research in schizophrenia that they offer.

New Vistas in Data Acquisition

Event-related fMRI is a relatively recent class of experimental design within functional neuroimaging that exploits the superior temporal resolution of fMRI. Unlike previous fMRI and PET approaches that blocked together relatively long (e.g., 20 to 60 sec) periods of similar behavioral trials or conditions and examined average neural response over that time period, event-related fMRI documents the neural response during each individual trial or short behavioral period. This approach has much in common with traditional evoked-potential electrophysiology and offers advantages in experimental design. Because different trial types can be randomly intermixed and then separated for analysis, order effects and habituation can not only be controlled for, but also explicitly investigated. A particular advantage for research in schizophrenia is that neural activity during correct and incorrect trials can be measured separately and compared, allowing more incisive study of the mechanism of cognitive failure and better experimental control of potential confounds based in performance discrepancies that often occur between patient and control groups. Eventrelated fMRI has very recently come into wide use in neuroimaging of cognitive systems in healthy subjects, but as of this writing has had only limited application to the study of schizophrenia.

Multimodal neuroimaging, which seeks to determine the relationship of the neurofunctional abnormalities in patients to other neurobiological features, will have an increasingly important role in delineating the mechanism of schizophrenia. In this approach, blood flow and other measures such as MR spectroscopy, neuroreceptor measurements, and electrophysiology (with MEG or EEG) are determined in the same patients. One example of the richness of the data that can be gleaned is the use of PET or fMRI to measure blood flow in conjunction with EEG or MEG. PET and fMRI allow *localization* of the brain regions that work together during cognition (spatial resolution 3 to 6 mm), but provide relatively little temporal information (temporal resolution in seconds). On the other hand, EEG and MEG have relatively poorer spatial resolution, but provide fine *time resolution* (i.e., milliseconds). Combining these methods, together with the application of the advanced computational cross-registration and source localization techniques that now exist, provides exponentially more information than any of these techniques alone. For example, this allows the determination of the sequence in which various finely localized regions are activated during cognition and the testing of the hypothesis that this sequence of events is altered in schizophrenia. Although this specific multimodal approach has not been applied in schizophrenia, other examples are described in the following.

New Vistas in Data Analysis

The analytic approaches for the two data collection modalities discussed, event-related fMRI and fusion of spatial and temporal neurofunctional data (i.e., PET or fMRI with EEG or MEG), are in their infancy and beyond the scope of this chapter. Another recent set of analytic methods addresses the growing appreciation that the transduction between neural and mental events is not anatomically segregated (i.e., one brain region per one mental or cognitive activity), but rather that even the simplest of cognitive activities requires coordinated actions across widely distributed components of neural systems (interregional integration of neural function). Questions about functional integration and coordinated interregional activity are likely to have particular relevance for schizophrenia, as discussed in later sections. Although the segregational view can be

tested with univariate statistics (multiple *t*-tests or ANOVAs), hypotheses about interregional integration require multivariate approaches. The influence that one brain region exerts or experiences from another is most simply examined via the correlations between brain activity measures for the two anatomic structures; as an operational definition two brain regions can be considered to be functionally coupled if their activities are correlated (3); however, this approach cannot elucidate how other nodes in the network mediate these relationships. To model this mediation requires analysis of the covariance matrix of regions studied in its entirety. Several new methods have been developed. These include structural equation modeling (SEM) and eigenimage analysis. SEM, used in conjunction with acknowledged anatomical models, can characterize and quantify the “functional connectivity” among the multiple components of neural systems. A model of known or hypothesized anatomic pathways is defined first; then a functional model of interest is tested against this model by iterative fitting of the interregional correlational weights. It should be borne in mind that the regional components examined are preselected based on putative pathways and the results from this approach are only as good as the model. In contrast, eigenimage analysis is a data-driven approach that examines patterns of correlation across the entire brain and how they vary in a time-series, revealing distributed brain systems and their temporal dynamics. Single value decomposition or principal component analysis is used to present the percentage of variance accounted for by different patterns of activity or spatial modes, and canonical variates analysis, conceptually similar to factor analysis, can be used to extract connectivity patterns across the entire brain that are most different between the studied groups. Thus, these recently developed methods permit characterization of normal and altered neural connectivity using neuroimaging.

THE FINDINGS

Part of "54 - Functional Neuroimaging in Schizophrenia "

The explosion of functional neuroimaging studies of schizophrenia has resulted in many “findings” and many discrepancies. Nonetheless, several trends spanning the various experimental and methodologic techniques were apparent several years ago (4). First, when brain activity or metabolism is averaged across the entire brain (i.e., “global” function), patients have relatively normal values, unlike in primary degenerative disorders. Second, when scanned during so-called resting conditions (i.e., with no cognitive or motor activities required and no specific sensory input), abnormalities are inconsistent when seen. Although patients may have relatively normal regional patterns of resting brain activity, there appear to be associations between specific resting regional CBF patterns and symptom profiles (5). Changes in lateralization of brain function also have been described (6 ,7). Third, when scanned during cognitive activation, patients tend to be different from normal controls. In particular, they show abnormal prefrontal activity (8) during tests involving working memory (i.e., the system used to hold information in temporary storage to complete a task). They show deficits in cingulate cortex as well as alterations in frontal–temporal and other intracortical functional relationships (12 ,13) during other cognitive tasks, such as cued verbal recall (9) and the Stroop test (10), and in some studies at rest (11). In general, most of these findings have been reproduced in acute, untreated patients, thus excluding a primary role for medication artifacts.

More recent functional brain imaging studies in schizophrenia have focused on: (a) further characterization of the locales and cognitive and behavioral context of neurophysiologic deficits in schizophrenia; (b) delineation of the relationship of the deficits to clinical symptoms and other neurobiological features of the illness; and, most important; (c) attempts to elucidate the pathophysiologic mechanism(s) of the deficits. The following section reviews these areas of observation and others. The most enlightening of these results have emerged from experimental paradigms designed to actively engage neural systems in cognitive or other activities; the most consistent findings concern the function of the prefrontal cortex.

Frontal Lobe Circuits

The frontal lobes have played a prominent role in formulations of schizophrenia since the conceptualization of the illness. In earlier times this role was inferred by clinical analogy with known frontal lobe disorders and findings in neuropsychology and nonhuman primate studies. Substantial indirect but compelling evidence from these multiple domains conferred the status of best studied and most implicated region in schizophrenic pathophysiology on the frontal lobes. Early functional neuroimaging studies substantiated this role, beginning with Ingvar and Franzen’s 1974 seminal finding that patients with schizophrenia had relatively lower blood flow to frontal regions (14). Changes in rCBF in response to cognitive activation were also first observed in these early studies; this approach has been greatly refined and now has largely replaced the inherently ill-defined and variable resting state as the cornerstone of functional brain imaging studies in schizophrenia. These data presaged the body of literature that emerged over the ensuing 15 to 20 years, most of which had similar frontal lobe findings (Table 54.1).

TABLE 54.1. FRONTAL LOBE FINDINGS WITH ACTIVATION PARADIGMS IN SCHIZOPHRENIA SINCE 1985

Characterization of Dorsolateral Prefrontal Functional Alterations

The relatively subtle prefrontal functional alterations observed in schizophrenia have been increasingly brought into focus by recent advances in the available neuroimaging armamentarium. Table 54.1 lists activation studies published

over the past 15 years that report frontal lobe results. The overwhelming majority of these investigations have detected abnormal prefrontal responses to a variety of cognitive activities designed to access and/or control frontal neural circuitry, particularly working memory. The prefrontal site most commonly affected is the dorsolateral prefrontal cortex (DLPFC), and, until recently, the physiologic abnormality in this brain region was consistently seen as hyporesponsivity. Indeed, from the time of Ingvar and Franzen's first study and throughout most of the last decade researchers were satisfied that the qualitative nature of the frontal lobe abnormalities was known. However, the relative universality with which the schizophrenic prefrontal cortex had been reported to be hypofunctional, in the past several years, has given way to the notion that the aberrant neural responses in prefrontal cortex are more complex, including *hyper*function under some circumstances. It is noteworthy that abnormally increased prefrontal response has been primarily seen in studies carried out with fMRI, rather than PET, and mainly when the cognitive paradigms take advantage of the temporal properties of fMRI in order to employ shorter blocks of task performance, and/or require task switching. This fact suggests that the anatomic and/or chemical perturbations of the schizophrenic prefrontal cortex can be manifest by inappropriate over recruitment of prefrontal neural circuitry during relatively brief cognitive challenge and failure to sustain this recruitment over longer periods; however, more work is required to understand the implications of these recent observations and to fully characterize them. Regardless of the direction of prefrontal physiologic abnormality, the functional neuroimaging literature leaves little doubt that such abnormality exists. A variety of potential epiphenomenological explanations for this pathophysiology have been considered, and a number of neurobiologically plausible mechanisms have been proposed.

Effect of Neuroleptic Treatment

One potential epiphenomonological confound is the possibility of a causative role of antipsychotic medications, an important consideration because the majority of functional neuroimaging studies have been carried out in patients who were either receiving neuroleptics at the time of study or previously treated and then withdrawn for some prior period. However, taken as a whole, the literature provides little evidence that neuroleptics generate the functional neuroimaging abnormalities. First, although additional longitudinal investigations with newer techniques are necessary, an 18-year follow up (15) showed that prefrontal hypofunction in chronic patients is remarkably stable over time and unaffected by long-term consistent neuroleptic treatment. Second, prefrontal abnormalities like those observed in schizophrenia are not seen in other illnesses in which neuroleptics are used, such as Huntington's disease (16 ,17). Third, a study of monozygotic twins concordant for schizophrenia, but with differing lifetime histories of neuroleptic intake, found that in most pairs the twin with less exposure to neuroleptics was actually the more hypofrontal of the pair during a prefrontally linked task (18), a result opposite to that expected if neuroleptics caused hypofrontality. Fourth, studies examining metabolic or rCBF changes occurring when patients go from the unmedicated to the medicated state are quite inconsistent (4 ,8). Fifth, frontal lobe functional abnormalities have been found in first-degree relatives of patients with schizophrenia who have not been treated with neuroleptics or hospitalized (19 ,20 and 21). Finally and perhaps most conclusively, frontal lobe abnormalities during cognition have been found in a number of studies of young patients who have never received neuroleptics (22 ,23 ,24 ,25 and 26). Thus, in summary, there are little convincing data that neuroleptic treatment is a major factor in frontal lobe functional abnormalities.

The Link with Cognitive Performance

Most prominent among potential epiphenomena and confounds examined has been the effect of poor performance. It is undisputed that patients with schizophrenia perform poorly on the very cognitive tasks that best show prefrontal pathophysiology—the Wisconsin Card Sorting test (WCST), the N-back test, the Tower of London, or others. This is not surprising for the reason that the tasks are chosen because they are thought to reflect core deficits of the illness and they access neural systems relevant to it; however, considerable controversy has arisen around the possibility that the poor performance—or differences in attention or effort and motivation—somehow cause the frontal pathophysiology, rather than the more neurobiologically plausible explanation that underlying pathophysiology is responsible for the poor performance. It is clear that if patients are simply not engaged in a cognitive task during scanning they will not activate relevant brain regions; such results are obviously artifactual. It is less clear what should be predicted if patients (or healthy subjects) are manifestly working at a task, but performing it abnormally.

The relationship between performance level and the degree to which the brain neurophysiologically responds is complex, even in the presumptive absence of pathology in healthy control subjects. Several studies have found significant correlations between prefrontal neural activity and cognitive function, suggesting that these two variables are paradigmatically linked, but both positive and negative (27) relationships have been described (8). The research challenge has been to (a) understand this relationship and (b) tease apart abnormal cognitive performance and abnormal brain activity in patients to determine which is primary. This is a difficult issue to investigate experimentally, and no single study alone can answer the question; however, convergent evidence derived from several different research

directions leads to the conclusion that prefrontal pathophysiology cannot be accounted for as an epiphenomenon (8).

First, studies have been carried out on patient populations who, like schizophrenics, perform poorly on frontal lobe tasks but who have disorders other than schizophrenia. In principal, if the prefrontal physiologic deficit found in patients with schizophrenia is an epiphenomenon of poor performance per se, then other subjects who perform as poorly should have similar prefrontal function. Pathophysiology quite distinct from that characterizing schizophrenia has been reported in Huntington's disease (28) and normal aging (29 ,30) where performance is matched to that in schizophrenia, as well as in Down's syndrome (31) in which performance is worse. These findings indicate that poor performance per se does not necessarily produce the pathophysiologic picture seen in schizophrenia.

A second way to experimentally attack this "chicken and egg" question, and at least on the face of it the most direct way, is to match patients and normal controls for level of performance. However, ensuring good performance in patients (by using different versions of the task for patients and controls or by making the task extremely easy) does not guarantee that the effort involved or the cognitive operations used by the two groups are equated. Moreover, in the absence of neuropsychologic impairment, the neural systems accessed and findings may have very little to do with the illness. Thus, the strategy of employing "easy" tasks that result in some measures of performance being "normal" in patients is not as straightforward an approach to exploring neurophysiologic abnormalities in schizophrenia as it may appear (4 ,8). An alternative to "matching" for good performance is to study normal controls who perform as *poorly* on a given task as the patients. This strategy at least addresses the question of whether normals and patients fail by the same pathophysiologic mechanisms. In a study designed on this premise, patients performing the WCST were found to activate DLPFC less overall than performance-matched normals, but they activated a more anterior area of prefrontal cortex that is not recruited in normals as a group. Moreover, the more a given normal subject activated this "schizophrenic card sort area," the more he or she perseverated (8).

This overactivation of an aberrant area (or of an appropriate area, for that matter) would be difficult to explain on the basis of disengagement from the task and poor performance per se. In a similar example, affected members of monozygotic co-twins discordant for schizophrenia showed hypofunction of prefrontal cortex accompanied by hippocampal hyperfunction during the WCST (32). Analogous results have been described by Friston and colleagues using paced verbal production (33) and have recently been demonstrated with eigenimage analysis in a study of medication-free patients performing the N-back working memory task (34).

Yet a third approach to inform the performance conundrum is to model the abnormal cognition in normal controls. Both underactivation and overactivation have been described in the context of performance difficulties. Goldberg and associates (1998) found that healthy subjects performing a dual task, working memory plus auditory and verbal shadowing, had significant decrements in both performance and DLPFC blood flow (35). Callicott and co-workers (1999) demonstrated that normal controls pushed beyond their working memory capacities also demonstrate reduced DLPFC responses (36). Electrophysiologic recordings in working memory-related neurons of nonhuman primates provide a neurobiological framework for these observations, where failed working memory trials are accompanied by decreased firing rates (37 ,38). Thus, findings of decreased prefrontal response in schizophrenia can be seen as part of an expected curve between working memory load and neural response—a dose–response curve that is shifted in the face of patients' reduced prefrontal capacities. Given the fact that other poorly performing patient populations with pathology that is different than schizophrenia do not show the same prefrontal response one (28 ,30 ,31), this particular shift in the dose–response curve with poor performance is neither inevitable nor the only possible one.

The DLPFC overactivtion response in schizophrenia also has a precedent in the normal neurocognitive imaging literature. Rypma and D'Esposito (1999) found in healthy subjects that the longer the reaction time (an indicator of difficulty with a task), the greater the DLPFC neural response (27). Although this may simply represent increased "time on task," it again provides a context in which to view recent findings of overactivation in patients. Although some clues about the cellular mechanism underlying patients' aberrant prefrontal function are discussed in the following, it remains for future research to determine whether patients and controls share the same source for abnormal prefrontal responses (both underactivation and overactivation) in the context of performance difficulties.

The data summarized in the preceding leave little doubt that, although the patients' poor performance is certainly an integral, primary component of their illness, it is not the cause of the abnormal neural function, rather it is an effect of that pathophysiology. Given this conclusion and the now extensive literature documenting it, the most efficacious use of functional neuroimaging in future schizophrenia research will occur if the poor performance and prefrontal abnormalities are considered as inextricably linked and studies are designed to elucidate the mechanism of these linked phenomena.

Putative Underlying Mechanisms

A number of clues about potential pathophysiologic mechanisms emerge when the neuroimaging findings are considered in light of other neurobiological hallmarks of schizophrenia and findings from different clinical neuroscience research modalities. First, it is likely that cellular pathology in DLPFC contributes to the cognitively linked dysfunction.

The degree of both hyperfunction and hypofunction of DLPFC in patients are predicted by decreased *n*-acetyl-aspartate (NAA), an MR spectroscopy measure of cellular integrity (39 ,40). Second, several compelling lines of evidence suggest a prominent role for dopaminergic dysfunction. It is well documented in nonhuman primates that optimal dopamine function is necessary for maximal working memory and DLPFC physiologic function (41). Similar, albeit less direct, evidence also exists in humans: Pharmacologically altering dopaminergic tone with agents such as amphetamine affects DLPFC activity in both healthy subjects (42 ,43) and patients (44); and a relationship between DLPFC rCBF during the WCST and CSF levels of the dopamine metabolite homovanillic acid has been found in schizophrenia (45). Third, converging data increasingly point to developmental mechanisms. A considerable body of literature now documents that disruption of corticolimbic connectivity in neonatal animals via hippocampal lesions models many features of schizophrenia, including working memory impairment, reduced prefrontal NAA, and dopamine dysregulation (53). Developmental pathology with a genetic basis also appears likely. A recent study links a genetic attribute that affects prefrontal dopamine to both working memory performance and DLPFC activation in patients, their sibs, and unrelated healthy individuals (21). Moreover, an association of schizophrenia with the allele that confers poor prefrontal function (a functional polymorphism in the catechol-o-methyl transferase [COMT] gene that affects enzyme activity) is indicated by several family-based studies. Investigations of this type, which explore the interaction of genetic and neurophysiologic characteristics, hold the greatest promise for elucidating the etiology of the illness and effecting innovative treatments.

Other Frontal Lobe Subregions

Dysfunction, primarily hypofunction, of portions of the frontal lobes other than the DLPFC has also been described. Just as a cognitive foundation for DLPFC dysfunction has been found in working memory and executive function, the dorsal anterior cingulate is classically considered to play an important role in vigilance, attention, and effort. It may, thus, be especially prone to epiphenomenologic effects. In normal subjects the region is activated by a variety of cognitively demanding tasks requiring stimulus-response selection in the face of competing information, such as the Stroop test, complex motor control tasks, verbal fluency, and working memory. These observations have led cognitive neuroscientists to propose more refined cognitive roles such as on line monitoring, conflict monitoring, and error detection (46). Further research is necessary to clarify which of these putative cognitive roles, or which epiphenomena, may be linked to the finding of anterior cingulate underactivation in schizophrenia (9 ,10 and 11). Orbitofrontal cortex, along with the ventral portion of the anterior cingulate, has been most linked to emotion. Few studies have been carried out that formally investigate the function of these regions in schizophrenia.

Lateral And Medial Temporal Lobe

The temporal lobe is of interest in schizophrenia for several reasons. Diseases of the medial temporal lobe can be associated with psychotic symptoms, and some neuropsychological aspects of schizophrenia implicate both lateral and medial temporal lobe. A number of neuroimaging studies have reported functional abnormalities in both lateral and medial temporal lobe structures (47). The data as a whole, however, are less compelling than for frontal lobe, and confounds and potential mechanisms are less well explored. Findings of both hyperfunction and hypofunction have been reported, but the bulk of the evidence leans toward overactivity. Heckers and colleagues (48) reported reduced hippocampal activation during the effort to retrieve poorly encoded material; however, it is of interest that, hippocampal activity appeared to be increased at baseline, again emphasizing the task-dependence of neurofunctional findings in general (48). Several studies point to a role for lateral temporal cortex in hallucinations and other positive symptoms—abnormal functional interactions between temporolimbic and prefrontal structures are also discussed in the following.

Miscellaneous Regional Changes

Functional abnormalities, primarily hypofunction, of many other regions have been reported. Although most are unreplicated, several are worth mentioning. Both increased and decreased basal ganglia activity have been found, but a role for neuroleptic treatment in such findings must be considered. Several investigators have suggested that schizophrenia is characterized by increased posterior cortical activity. In fact, Ingvar and Franzen's seminal 1974 rCBF study of schizophrenia suggested that the hypofrontal pattern represented a redistribution of flow with relatively lower flow to frontal areas as well as relatively higher flow to posterior cortex (14).

Such changes in activity patterns or distributions have received considerable attention. In particular, the notion that schizophrenia may involve disordered functional lateralization has been explored using a variety of methods. Left temporal overactivation was seen in this light in early studies. More recent work suggests that apparent alterations in functional laterality in schizophrenia may not actually reflect abnormal lateralization per se, but rather a failure to organize a lateralized response (6 ,49). For example, Mattay and associates (1997) reported less lateralized and localized lateral premotor area activation in patients during a simple finger movement paradigm (50). This may also be viewed

within the more general context of nonfocalized, less efficient, neurophysiologic responses in schizophrenia.

Interregional Relationships and Functional Connectivity

As the foregoing indicates, a number of brain areas have been shown to function abnormally in schizophrenia, often depending on the cognitive or other conditions under which the scanning is performed. It has been proposed that such multiple, seemingly local changes may be indicators of more ubiquitous dysfunction throughout widely distributed and interactive brain networks (12 ,51), a heuristically appealing pathophysiologic model for schizophrenia given the apparent subtlety of the neurophysiologic abnormalities in the face of the devastating and complex nature of the illness. This conceptualization is consistent with recent trends in viewing higher brain processes as parallel and distributed functions.

Because of the particularly extensive connectivity of the frontal lobe with other cortical and thalamic relay areas and its special role in schizophrenia, it is not surprising that many putative aberrant networks in the illness also involve it. Although the specifics of this network will obviously vary by task, a consistent finding in studies of working memory is a coactivation of prefrontal, anterior cingulate and parietal structures. Consistent with this, Bertolino and colleagues found a tight correlation between DLPFC NAA (indicative of neuronal integrity) and rCBF activation during the WCST, not only in DLPFC, but also with the other nodes in the working memory pathway (39). Because this was not evident in healthy controls, these findings appear to reflect a rate-limiting factor related to the disease process of schizophrenia.

Neurofunctional evidence of abnormal interactions between prefrontal and temporal/limbic areas has accrued for a number of years. Weinberger and associates (52) found in monozygotic twins discordant for schizophrenia an inverse relationship between the volume of the hippocampus (the structural variable that best differentiated well from ill twins) and the degree of dorsolateral prefrontal activation during prefrontal cognition (the physiologic variable that best differentiated the co-twins). This suggests dysfunction of neocortical–limbic connectivity in schizophrenia and is consistent with, if not confirmatory of, a neurodevelopmental mechanism (53). It has been suggested that abnormal development or plasticity of hippocampal connectivity affects the development and function of prefrontal cortex or, alternatively, that both regions are “put at risk” by the same pathologic mechanism (e.g., genetic variation) (54).

The new analytic tools recently developed to search more incisively for evidence of subtle and multidimensional abnormalities across the entire brain (see the foregoing) have provided results that are consistent with and extend the notion of temporohippocampal and prefrontal circuitry failure (13 ,33). During working memory, Meyer-Lindenberg and colleagues (34), using an eigenimage method (discussed in the preceding), uncovered differences between patients and controls in task-independent functional connectivity patterns charcterized by hypofrontality coexisting with increased temporal/hippocampal and cerebellar overactivity in the patients; another, task-related, pattern involving the working memory system (including DLPFC and inferior parietal lobule) was found to be more variable (i.e., showed altered modulation) in the patients, specifically during the working memory condition. Friston and Frith (12), using PET data from a verbal fluency experiment and a method that allowed them to assess patterns of activation most different between normals and patients, found that the prefrontal and temporal coactivations in normals were uncoupled (i.e., did not appear in the same pattern) in the patients. Fletcher and colleagues (55) reported similar results, and Jennings and co-workers (56) using structural equation modeling found altered neural interactions among frontal regions as well as between the frontal and temporal cortices in schizophrenics during a semantic processing task. Disruption of frontal–temporal connectivity has also been found using an EEG coherence measure (57).

Other studies have focused on medial prefrontal and cortical–striatal–thalamic circuit abnormalities (49); Biver and colleagues (58) and Mallet and associates (59), calculating correlations between various regions of glucose metabolic rate in PET, found decreased intrafrontal, as well as frontal–posterior connectivity. Andreasen (60) has advanced a hypothesis implicating compromised connectivity among prefrontal regions, several thalamic nuclei, and the cerebellum as the cause of a fundamental cognitive deficit in schizophrenia. She called the disruption in this circuitry “cognitive dysmetria,” signifying “poor coordination of mental activities” that manifests itself in difficulty in prioritizing, processing, coordinating, and responding to information. This hypothesis is based on a number of studies from her group (61 ,62 and 63) in which the structures enumerated above were found to differ in activation between schizophrenics and controls during several unrelated tasks and in different cohorts, and on the fact that the circuit described is anatomically connected.

In summary, taken together, the functional brain imaging evidence is consistent with the notion that schizophrenia involves dissolution of neuronal interactions and that many features of schizophrenia may best be viewed as dysfunctional interregional circuitry. The details of this circuitry dysfunction differ, depending on the distributed network called into play during the particular behavior, but prefrontal cortex may play a special role.

The Relationship of the Neurofunctional Abnormalities to Clinical Hallmarks

The importance of linking pathophysiologic findings in schizophrenia to clinical aspects of the illness was recognized

early on. Ingvar and Franzen (14) noted that “hypofrontality” was most prominently seen in the most withdrawn, inactive, socially isolative, and “hypointentional” patients, whereas they related the hyperfunction in posterior areas that they observed to a “hypergnostic” component of the illness. The attempt to delineate the clinical and neurobiological implications of the physiologic abnormalities remains an important focus. Studies have primarily searched for neurophysiologic associations with cognitive deficits, symptom clusters, and individual clinical features such as hallucinations. The small sample sizes of some studies and the necessarily phenomenologic nature of research into the neurophysiologic underpinnings of clinical symptoms makes firm conclusions difficult, but some consistent findings have emerged. Frontal lobe dysfunction is consistently linked to negative symptoms and cognitive deficits, particularly working memory and executive function. For example, Goldberg and colleagues (64) used an intra-twin pair difference method in which unaffected co-twins served as individual controls for each patient in the NIMH monozygotic twin sample. Although left hippocampal size predicted a parameter of verbal memory, prefrontal blood flow and perseveration on the WCST were related. These data are part of a growing literature implicating medial temporal and prefrontal regions in symptom expression and some neurocognitive deficits of the illness.

In general, hallucinations are associated with sensory modality-specific activation in brain regions involved in normal sensory processing (65). For example, auditory hallucinations appear linked to language-related regions such as Broca’s area (66) and left superior temporal cortex. Silberswieg and co-workers (67) made similar findings using a technique that quantifies the relationship between brain activity and density of hallucinations during the scanning period.

Specific cerebral blood flow patterns have been associated with distinct syndromes of schizophrenic symptoms (5): psychomotor poverty with decreased activity in DLPFC; disorganization and impaired suppression of inappropriate responses with increased activity in the right anterior cingulate gyrus; and reality distortion, which may arise from disordered internal monitoring, with increased activity medial temporal lobe at a locus activated in normal subjects during internal monitoring of eye movements. Thought disorder has been linked to temporal lobe overactivity. Kaplan and associates (68) found an association of marked psychomotor poverty with superior parietal as well as prefrontal areas, hallucinations and delusions with abnormalities in left temporal cortex, and disorganization with left inferior parietal lobule abnormalities. Further work undoubtedly will refine these interesting clinical and pathophysiologic correlates.

QUESTIONS FOR THE FUTURE

Further characterization of the abnormalities delineated by functional neuroimaging in schizophrenia is a clear goal for the future. One important advance will come from temporal dissection of the abnormal neurophysiologic signals that have now been localized with great anatomic precision. For example, the particularly high degree of both segregation and interaction of the frontal lobe complex appears to be essential for regulating and monitoring the functions it supports via multisynaptic feedback loops modulating posterior brain areas. It is likely that the functional disconnection in schizophrenia described in the preceding includes abnormalities in these feedback loops, which operate on a time scale less than 200 msec. Progress in understanding the etiology of frontal lobe dysfunction in schizophrenia, therefore, requires a methodology that has optimal resolution both spatially (in order to reliably differentiate functionally segregated areas) and temporally (to tap into the time scale in which the feedback loop organization operates). The simultaneous combination of PET or fMRI studies (which afford relatively high spatial resolution) with methods having excellent temporal resolution such as EEG or MEG (which provide temporal resolution in the order of milliseconds) will allow explicit investigation of specific hypotheses about prolongation of the feedback and feed-forward latencies and about disease-related changes in the order in which components of distributed neural systems come into play in schizophrenia.

A second important way in which characterization of the abnormal neurophysiologic signals must advance is further investigation into their relationship to other neurobiological features of the illness. One question that requires closer scrutiny is the relation of the neurophysiologic abnormalities to dopaminergic and other neurochemical parameters. Hypotheses about neurochemical mechanisms can be tested directly with functional brain imaging, both by examining the effects of pharmacologic interventions and direct *in vivo* measurements of various components of neurochemical systems. Also, the relationship of the functional abnormalities to the neurostructural and neurochemical findings described in other chapters must be further elucidated. Not only does such a multimodal approach provide critical cross-validation of the information gleaned from the different technologies and help to rule out epiphenomena, but it is also a means to more closely approach causality and mechanism. For example, links with dopaminergic dysfunction can elucidate putative genetic mechanisms (21). Similarly, the fact that the prefrontal functional abnormalities may relate to structural pathology in other (particularly limbic) areas lends credence to the notion of a neurodevelopmental mechanism, although it does not provide proof; further work, perhaps expanding on insights from animal models (53), will be necessary to test the roles of the temporal lobe and aberrant neural development in the genesis of schizophrenic psychopathology.

Clarifying the mechanism by which the pathophysiology and illness arise is the most important question that can be addressed with functional brain imaging. Considerable

work remains to be done, although some clues have emerged, particularly with regard to the frontal lobe. Longitudinal studies are necessary to differentiate trait from state phenomena. Brain imaging undoubtedly will also continue to impact the current effort on many fronts to uncover the genetic foundations of schizophrenia, by offering new targets for linkage and association studies and providing clues to direct hypothesis-driven genetic investigations, as discussed in this chapter. Such studies provide a unique perspective from which to view brain function, one that offers the possibility of uncovering basic fundamental principals important in the genesis of schizophrenia and that has the potential to lead to direct intervention.

Structural Magnetic Resonance Imaging Studies in Schizophrenia

Robert W. McCarley

Robert W. McCarley: Harvard Department of Psychiatry, Brockton VAMC and VA Boston Healthcare System, Brockton, Massachusetts

> … We thus come to the conclusion that, in dementia praecox, partial damage to, or destruction of, cells of the cerebral cortex must probably occur, which may be compensated for in some cases, but which mostly brings in its wake a singular, permanent impairment of the inner life (1).

The window on the brain provided by structural imaging has transformed our view of schizophrenia to one that views the very structure of the brain as altered, a view echoing Kraepelin's prescient statement. Beginning with Johnstone's CT findings of enlarged ventricles (which actually confirmed earlier, less systematic pneumoencephalographic studies), subsequent reports using magnetic resonance imaging (MRI) have provided key information detailing volume reductions in particular brain anatomic regions of interest (ROI). These data have provided the major evidence in support of our current view that schizophrenia is a brain disorder with altered brain structure, and consequently involving more than a simple disturbance in neurotransmission.

Section Organization

The next section is a nontechnical introduction to some of the basic concepts of MRI, and may be read independently of the other sections or skipped by those who wish to concentrate on the clinical data. Subsequent sections discuss the application of structural MRI to questions in schizophrenia research, standards for technical quality and reviews of studies, current MRI findings in schizophrenia (limited to studies with defined ROI), and newer technologies.

THE BASIS OF STRUCTURAL MRI AND PULSE SEQUENCES

Part of "55 - Structural Magnetic Resonance Imaging Studies in Schizophrenia "

Addressing the physics of structural MRI is a major topic on its own, and Brown and Smeleka's book (2) is recommended as a good introduction that demands only a limited background in mathematics and physics. The reader is warned that the following brief exposition is highly (over)simplified. Essentially, the tissue characteristics sensed by MRI depend on disruptions of a strong external magnetic field. This external field has aligned the orientation of atomic nuclei by aligning the magnetic field of each nucleus that is associated with its spin direction. Because of its biological ubiquity and good magnetic properties, the most commonly used basis element for MRI is hydrogen, which has a single proton in its nucleus. The reader may want to think of hydrogen nuclei as analogous to a large set of spinning tops or gyroscopes. In a state without an external magnetic field, their direction of spin is random, and so is the net magnetization (a vector), because each rotating proton has a magnetic field that is parallel to its axis of rotation. Applying a strong external magnetic field can be thought of as aligning this set of spinning tops in a uniform direction of spin, snapping them to attention, as it were. The resultant population net magnetization can be thought of as vector aligned with the z-axis (vertical axis in our example), perpendicular to the x-y plane, and in the direction of the external magnetic field. The magnetic field strength is described in units of tesla (T) and most current clinical imagers use an external field of 1.5 T.

This vertically aligned population of protons (vertical magnetization vector) is then perturbed by applied radiofrequency (rf) pulses, which can be thought of as having the effect of moving the magnetization vector away from the vertical axis (z-axis); for example, in our analogy, moving the tops from their average vertical orientation to a "tilt." This applied change of the magnetization vector then decays, and, during the course of the decay, give off energy in the form of radiofrequency emissions. It is this emitted energy that provides the key information for MRI scans.

There are two main kinds of information about tissue characteristics derived from this perturbation decay, often referred to as a "relaxation." The T1 relaxation time is the

time constant describing the time course followed by the “tilted” magnetization vector in returning to its original orientation. The T1 relaxation time is the time required for this vector to return to 63% of its original vertical orientation value following an rf excitation pulse. Again, in our analogy to spinning tops subjected to a tilt, this T1 is the time required to return to about two-thirds of its original vertical orientation.

The second measure, T2 relaxation time, requires us to think about each nucleus (spinning top) individually. Again and again crudely, one can visualize a group of spinning tops oriented upward (z-axis) and then simultaneously tipped away from this vertical orientation. As everyone who has spun tops or played with a gyroscope knows, if one tilts a top from a vertical orientation, the top will not only tilt but will rotate about the vertical (z-axis), a wobble technically called precessing. Figure 55.1 illustrates this process. In the beginning all the individual tops will wobble (precess) about the z-axis with the same frequency, but gradually they will lose their coherence and wobble at different frequencies, leading to progressively less net magnetization in the x-y plane. T2 is the time required for the coherence to decrease to 37% of its original value. This “dephasing time” or T2 relaxation is always less than or equal to T1. Often the term T2* is used to take into account the observed variations in relaxation time owing to inhomogeneities in the tissue being imaged and in the applied magnetic field. The web site, http://ej.rsna.org/ej3/0095-98.fin/index.htm has a nice animated illustration of T2 relaxation (on the menu page, select Diffusion and Magnetic Resonance). Of relevance to this description, Pfefferbaum and colleagues (3) found T2 relaxation times were longer in schizophrenic patients than in controls in both gray and white matter, suggesting possible differences in fundamental tissue organization in schizophrenia.

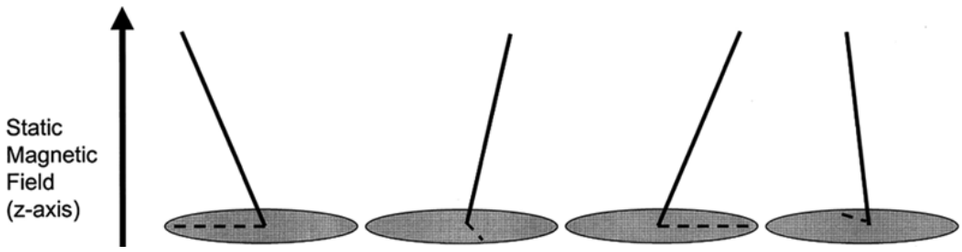

FIGURE 55.1. Illustration of effects of applied magnetic field on hydrogen nuclei (protons, *images 1 to 4*). With only a static magnetic field *(left arrow)* present, all nuclei have the same vertically aligned spin directions parallel to the static magnetic field and the z axis (this state is not illustrated). Application of an rf pulse “tilts” the orientation so there is a transverse plane component *(broken line)* in Image 1. Initially all protons precess uniformly, so that images 1, 2, 3, and 4 can be thought of as successive snapshots (successive moments in time) of the counterclockwise precession (rotation) of the net magnetization vector about the z-axis. Over time the protons dephase and show different precession frequencies; as an illustration of this case, images 1 to 4 should be thought of as a single snapshot of individual protons at the same instant in time. There is no net transverse plane magnetic vector because the individual protons show no uniformity of phase.

In terms of T1, an rf pulse may “tilt” the net magnetization (spin) vector, but usually a second pulse is applied before there is a full return to the vertical orientation, and subsequent rf pulse repetitions lead to a steady-state orientation prior to each new pulse. This new vector depends on a number of values; two are of particular relevance: the T1 relaxation time (how efficiently the protons give up their energy) and number of protons per unit of tissue, *proton density*.

Spatial Localization

The resonance frequency of protons, the frequency at which energy is maximally absorbed by protons, is dependent on the strength of the magnetic field. By applying small magnetic field gradients (typically less than 1% of the total field strength) for short periods of time it is possible to spatially localize the signals resulting from the applied rf pulses. In the presence of a magnetic gradient field each proton will resonate at a unique frequency that depends on its exact position within the gradient field. The MR image is a frequency and phase map of the protons at each point or picture element (pixel) throughout the image. The pixel intensity is proportional to: the number of protons present in the volume represented by the pixel weighted by the T1 and T2 relaxation times. *Different sequences of rf pulses will produce images that mainly reflect one of these variables, and these images are often referred to as proton density-, T1-, or T2-weighted images*. Operationally, the initial step in spatial localization is localization of the rf excitation to a region of space (slice) by the slice selection gradient. When images are viewed, the slice selection direction is always perpendicular to the surface. A second spatial direction is determined by a phase encoding gradient, which differentially alters the precessional frequency of protons at different positions in

the phase encoding direction, thereby enabling spatial localization. In MRI the signal is always detected in the presence of a readout gradient, perpendicular to the slice selection and phase encoding gradient, and producing the third dimension of the image. The readout gradient detects differences arising from both the slice selection gradient and the phase encoding gradient, with the latter varying in amplitude with each repetition of the slice selection and readout gradient.

Pulse Sequences

Appendix A describes commonly used pulse sequences in terms of our knowledge about the relaxation processes for the reader wishing insight into the terminology and rationale of pulse sequences.

STRUCTURAL MRI: WHAT CAN IT TELL US ABOUT SCHIZOPHRENIA?

Part of "55 - Structural Magnetic Resonance Imaging Studies in Schizophrenia "

Structural MRI

In 1984 Smith and co-workers (4) performed the first MRI study of schizophrenia. The capability of structural MRI to provide information about gray and white matter parenchyma of the brain and CSF-filled spaces is new with MRI studies; it represents an important advance over CT studies that poorly visualize parenchyma and can not differentiate gray and white matter. This gray–white differentiation is important for schizophrenia studies, because abnormal tissue classes (tumors, infarcted areas, etc.), which may be detected by CT, have not been found to characterize schizophrenia. The term “structural MRI” is used to differentiate it from “functional MRI,” where indices of short-duration change (e.g., blood oxygenation) are used; this topic is treated in the second part of this chapter.

Our use of the term schizophrenia is in the sense of a syndrome and not a single disease entity. The current major questions about the schizophrenia syndrome include:

1. What are the brain changes in this disorder? Which areas of the brain are affected?
2. What is the cause of the brain changes?
3. At what life stage do brain abnormalities occur and are they static or progressive? Are they developmental (prenatal and perinatal) and/or progressive?
4. How are brain abnormalities related to clinical symptom abnormalities?
5. Are brain findings in schizophrenia distinct from those in affective psychosis?
6. What are the most effective treatments? Is treatment neuroprotective?
7. Are there structural endophenotypes that will help us in the genetic analysis of the disorder?

Structural MRI studies of schizophrenia have the potential of addressing all of these questions, although space restrictions confine our focus primarily on the first question, which has also been the major focus of empirical studies.

WHAT ARE THE DESIRABLE FEATURES OF A STRUCTURAL MRI STUDY?

Part of "55 - Structural Magnetic Resonance Imaging Studies in Schizophrenia "

We here briefly summarize the features.

1. *Thinner is better*. Smaller units of volume analysis (called voxels, for volume element) allow for more precise determination of the irregular contours of brain regions, by reducing the voxel mixing of the desired region with neighboring structures in the voxel. This mixing is called partial voluming. Many earlier studies used MRI acquisitions with “gaps” between slices, with interpolation used to estimate the volume in the “gap”; this obviously limits precision of measurement. Thus studies with thinner slices (1.5 mm is the current standard), and no gaps between slices, will likely lead to more precise MR morphometric volume measures.
2. *Quantitative versus qualitative analysis*. Early studies relied on subjective, visual ratings of abnormalities. There is now general agreement that computation of volumes of the ROI examined is essential. When raters are used, as is generally the case, inter-rater reliability is important, and should be $r \geq 0.85$. Moreover, the ROI should be objectively and clearly defined, so that others can measure the same entity. Such objectively defined criteria should include detailed specification of the internal landmarks used to define each ROI.
3. *Segmentation*. Segmentation involves sorting the tissue classes into gray matter, white matter, or cerebrospinal fluid (CSF). It seems to us that all studies of cortical gyri should, whenever possible, separate gray and white matter in the analysis, because this is a fundamental distinction in brain tissue; however, not all studies distinguish between gray and white matter, making comparisons with studies that do segment gray and white matter problematic. Finally, segmentation is often automated or semiautomated; unfortunately, there is no agreed-on gold standard for the quality of segmentation, because “phantoms” with known composition do not reflect the complexity of the outlines of brain gray or white matter, and postmortem estimates of tissue and fluid volumes may not exactly parallel those *in vivo*. (See ref. 5 for discussion.) Figure 55.2 provides an example of a segmented image with ROI tracing and three-dimensional (3D) reconstruction.

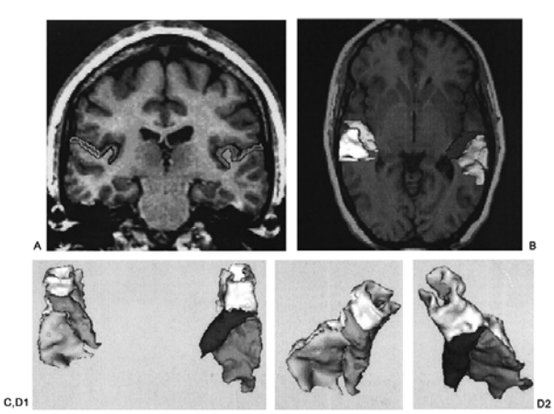

FIGURE 55.2. A: Coronal slice (1.5 mm) through the temporal lobe of a normal control subject. This is a SPGR proton density-weighted image. The regions of interest for the structures are outlined: the gray matter of Heschl’s gyrus (HG) is red on subject left and green on subject right. The gray matter of planum temporale (PT) is labeled yellow on subject left and blue on subject right. **B:** Top-down view of the three-dimensional (3D) reconstruction of HG and PT placed atop an axial magnetic resonance slice. This axial slice has been constructed by reformatting the coronal images. Anterior is top. HG is red on subject left and green on subject right, and PT is blue on subject left and yellow on subject right. **C:** 3D reconstruction of the left and right ROI (color-coded as in *B* but from a slightly different angle of rotation than *B*). Note the tubular structure of the gray matter of the STG, most clearly seen anteriorly, where gray codes non-HG, non-PT portions of STG. **D:** 3D reconstructions viewed from a different angle than *C*. (D1 is subject right and D2 is subject left). (Reproduced from Hirayasu Y, McCarley RW, Salisbury DF, et al. Planum temporale and Heschl’s gyrus volume reduction in schizophrenia: an MRI study of first-episode patients. *Arch Gen Psychiatry* 2000;57:692–699.)

4. *Quality of imager and postacquisition processing*. The quality of the MR scanner is also important and should include technical assessments such as the homogeneity of the magnetic field, which greatly influences the postprocessing segmentation of tissue into different tissue components. Day-to-day assessment of inhomogeneities in the magnetic field is thus a critical quality assurance feature for the quality

of the MR scans, and consequently also the quality of the postprocessing of MR images. Most modern imagers have magnetic fields of 1.5 T or greater, which is important for signal-to-noise ratio. Additionally, postacquisition filtering may improve signal-to-noise ratio (6).

5. *Variability and reliability of MRI findings*. An important question is the variability in MRI findings that is to be expected, not only from variation in measurement techniques, but also from physiologic changes. This becomes increasingly important because MR imaging is done at different time points in the disorder. Unfortunately, there are currently very few studies that have examined the extent of changes in MR over multiple measurements, and more careful controlled studies would be useful. Our laboratory found less than 1% variation over gray–white–CSF segmentation values in one subject who had an MR scan on two different days (5). Kikinis and colleagues (7) presented data from a female subject who received 23 MR scans during 1 year. The variance of the intracranial cavity was only 1.2% over the course of the 23 MR scans. Also, there is little evidence of the idea of a physiologic variation in gray or white matter volume throughout the brain in studies with high-resolution MRI techniques. For example, Gur and associates (8) found changes in volume over 2.5 years in whole frontal lobe in schizophrenia without finding changes in volumes of whole-brain and CSF, a finding difficult to reconcile with the idea

of “whole brain variability” in gray or white matter, or CSF caused by hydration or other factors affecting all brain tissue, for example.

HOW SHOULD LITERATURE FINDINGS BE REPORTED IN REVIEWS? EXPERT OPINION VERSUS COUNTING VERSUS METAANALYSIS

Part of "55 - Structural Magnetic Resonance Imaging Studies in Schizophrenia "

The reader trying to shape an informed opinion on the current state of the field (not only structural MRI but any field) relies on reviews with essentially three main approaches, which can be combined.

Expert Opinion

One approach for reviewers is to survey the literature, and then provide an informed opinion as to the summary trends and findings, with specific citations to drive home the points. Many reviews, in fact, adopt this approach of “trust the reviewer.” The disadvantage is that the reader cannot form a judgment of the *accuracy of the review's conclusions based on the data presented* without reading the literature.

Counting

This approach tabulates the number of studies with findings supporting or not supporting an abnormality in a particular region. The disadvantage of this approach is that the subject *N* of each study and the effect size are not taken into account.

Metaanalysis

Metaanalysis essentially involves weighting each individual study by a function of its *N* and effect size, and then using this information to produce an estimate of the combined effect size (9 ,10 and 11). *If all studies used equivalent technology and subject populations, this would be the method of choice. However, they do not*, and the reader should realize that: (a) MR scanner technology in the past decade has been changing rapidly; therefore, studies are not quantitatively comparable; (b) the extent of detail varies in anatomically based ROI information used in the measurement of images; (c) there is a wide difference in moderator variables of subject gender, chronicity (age of onset), medication, parental SES, etc.; and (d) metaanalysis, especially of MRI studies, is beset with the difficulty of estimating the number of studies with negative findings that did not get published—Rosenthal’s “file drawer” problem (11). Practically, this means one cannot do a review that is both comprehensive and metaanalytically valid, unless the items (a) through (c) had remained constant. Another disadvantage is that many studies must be rejected for reasons of subject or methodologic consistency; this omission has a potential effect of distorting results by omitting technically good studies that could not be included; for example, the metaanalytic study of Nelson and colleagues (12) omitted 45% of the studies on medial temporal lobe found in the literature.

Our summary relies on a combination of these approaches. The conclusions are congruent with our subjective opinions and we provide tabulation of more than a decade’s results of MRI studies; however, we are sympathetic to the need to provide more than a simple “box score” of positive and negative results. Accordingly, we have followed a suggestion of Rosenthal (11), and computed the probability of the observed number of positive and negative findings for each region. This is simply done by using a two-tailed alpha level of $p < .05$ for each study finding positive results, and then using the binomial theorem to calculate the overall probability of finding the observed number of positive studies. The resulting overall probability does not assume a normal distribution, but does assume comparability of the studies. (*Caution:* This assumption does not necessarily hold.) Whatever the degree of comparability, this statistic does have the distinct advantage of providing the reader with a sense of the weight of current evidence for each region of interest beyond that of a simple “majority vote,” which neglects the odds against an individual study’s finding positive results at the $p < .05$ level. We see this as an improvement on simply saying “some studies find… but others…” and providing the reader a backdrop of estimating the weight of evidence from peer-reviewed studies based on a probability of .05, assuming the prerequisites of metaanalysis hold, and then allowing a subjective “dilution factor” for all of the problems of a metaanalytic analysis.

CURRENT STRUCTURAL FINDINGS IN SCHIZOPHRENIA

Part of "55 - Structural Magnetic Resonance Imaging Studies in Schizophrenia "

A complete review is not appropriate here because the explicit focus of this volume is on summary of main trends and new developments. However, because it seemed essential to us that the reader have at least an overview of structural results in schizophrenia (with references), we have drawn on data from a recent comprehensive review (13). This covered all peer-reviewed schizophrenia studies with control groups during the time period 1987 to May 1998, and to our knowledge is the most recently published comprehensive review.

We summarize here the results from this review, whereas Table 55.1 presents the results and references in tabular form. (Table 2 in the original article summarized the subject *N* and characteristics, and should be consulted for further detail [13].)

TABLE 55.1. SUMMARY OF MRI STUDIES REPORTING POSITIVE AND NEGATIVE FINDINGS IN SCHIZOPHRENIA FROM 1987 TO MAY 1998 (FROM McCARLEY ET AL., 1999)

Most studies (81% of 31) did not find abnormalities

of whole brain/intracranial contents, but lateral ventricle enlargement was reported in 77% of 43 studies, third ventricle enlargement in 67% of 24 studies, whereas none of the three studies evaluating the fourth ventricle found abnormalities.

The temporal lobe was the brain parenchymal region with the most consistently documented abnormalities, with 62% of 37 studies finding whole lobe volume decreases. Of all cortical areas surveyed, the superior temporal gyrus most consistently showed volume reduction (81% of 16 studies) and, if the gray matter of this structure was evaluated separately from white matter, all seven studies showed a volume reduction. Fully 77% of the 30 studies of the medial temporal lobe reported abnormalities in one or more of its constituent structures (hippocampus, amygdala, or parahippocampal gyrus). Neuropathologic studies in general support the presence of temporal lobe limbic system abnormalities in schizophrenia (14 ,15), although some do not (16). Unfortunately, there is a lack of quantitative postmortem studies of temporal lobe neocortex.

Despite the presence of functional abnormalities, frontal lobe structural MRI investigations did not consistently find abnormalities, with 55% of the 33 studies describing volume reduction. In a postmortem quantitative study, Selemon and associates (17) found only a small (8%) reduction in prefrontal cortical thickness, a reduction that was not statistically significant, although noteworthy abnormalities in density of various cell types were present in schizophrenia. This and the MRI findings suggest that frontal lobe volume reductions may be small, and near the threshold for MRI detection. The parietal and occipital lobes have been much less studied, and there are about the same percentage of positive and negative findings in each. Most of the seven studies of cortical gray matter (86%) find that volume reductions are not diffuse, but are more pronounced in certain areas, as might be anticipated from the preceding statistics on individual regions of interest.

About two-thirds of the studies of subcortical structures report positive findings, including the six studies of the thalamus, 18 studies of the corpus callosum, and 17 studies of the basal ganglia. Basal ganglia tended to show increased volume when patients were on typical but not on atypical neuroleptics. The cerebellum had mainly negative findings (in four of the six studies), but was not studied with the same volumetric precision as other ROI. Almost all (91%) of the 11 studies of cavum septi pellucidi (CSP) showed that schizophrenics have less fusion of the septum, a developmental abnormality probably linked to limbic system pathology.

Statistics

The binomial theorem computation (using $p < .05$ for a positive study) shows that *all ROI* surveyed in Table 55.1 show a two-tailed $p < .05$ for the number of positive studies, except for the fourth ventricle and cerebellum ($p = .66$), and all ROI had p's $\leq .002$ except for the occipital lobe (.004). Again, caution should be exercised on the strength of these probability estimates because comparability is not strict and an (unknown) percentage of studies with negative results may not have been published.

Clinical Symptom Implications

Clinical scale data suggest that positive symptoms (and disorganization in a three-factor model) may be most closely related to temporal lobe volumetric abnormalities, whereas more limited evidence supports, in some studies, a relationship between negative symptoms and frontal lobe MRI abnormalities. Finally, there now appears to be growing evidence that MRI abnormalities differ in affective (bipolar) psychosis and schizophrenia, with reductions in neocortical gray matter, especially in temporal and prefrontal neocortex being especially prominent in schizophrenia. (See McCarley and co-workers 1999 for a more complete review and Sheline [this volume] for a review of structural MRI in affective disorder [13].)

The presence of CSP and sulco-gyral abnormalities (for the latter, see Kikinis and colleagues) (18) and abnormalities in first-episode patients all suggest a possible developmental origin. However, there are growing (although still limited) data pointing to progression of volumetric abnormalities over time. This suggests that both developmental and progressive features may be present in schizophrenia; these are consistent with, we hypothesize, a “two-hit” model of schizophrenia.

AUTOMATING STRUCTURAL MRI ANALYSIS: BRAIN WARPING AND VOXEL-BASED ANALYSIS

Part of "55 - Structural Magnetic Resonance Imaging Studies in Schizophrenia "

The tedious task of manual definition of regions of interest by tracing outlines—even if assisted by automated segmentation—has prompted interest in using automated methods of MRI analysis. The two (closely related) major classes of methods are: (a) brain warping, using a standard or “atlas brain” to compare and define features on subject brains, and (b) voxel-based analyses. Because these techniques, although promising, are new and thus far have limited data on validity, we have not included the studies in the summary table of ROI findings. This section concludes with a brief discussion of shape analysis, often based on the brain warping techniques described in the first part of this section.

Brain Warping

In one use of this technique the ROI definitions and anatomic features of an index template (atlas brain image) are warped (mapped) onto a new case (target image). In this

context, the atlas brain can be compared to a rubber brain, which is stretched and compressed nonlinearly in order to match the contours of the new brain. At the end of the registration, all the structures previously defined for the atlas brain are also defined for the new brain image. In general, the first step in matching the atlas brain and subject (patient or object brain) is *linear registration* to correct for the differences in size, rotation, and translation between the two brain images. This step is illustrated in the first panel of Fig. 55.3 . (Parenthetically, linear transforms use scaling, translation and rotation uniformly for each element [voxel], whereas nonlinear transforms use different and more complicated transforms for different voxels.)

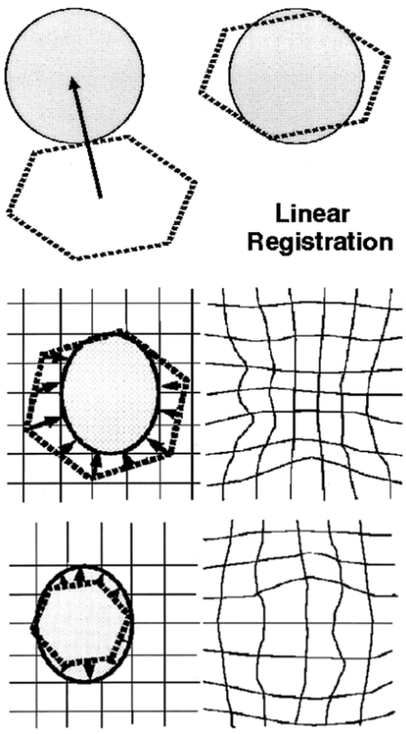

FIGURE 55.3. Schematic of brain image warping. An "atlas" image *(red hexagon)* is warped (mapped) onto a new "patient" image *(yellow oval)*. **Top:** A simple uniform linear transformation (translation, rotation or scaling) does not work. Instead, nonlinear transformations are used to "warp" the "atlas" image onto the "patient" image *(middle and bottom panels)*. This warping resulted in a "vector field" *(blue arrows)*. The nonuniform displacement of each pixel is then represented in the right field of Fig. 55.1, by means of the deformation of the rectangular grid (the elastic membrane). Examples are presented for atlas contraction *(middle panel)* and dilatation *(bottom panel)*.

Nonlinear Elastic Matching

The atlas information can then be projected into other MRI scans by applying an elastic match (i.e., warping the atlas into the shape of the new brain image). The global registration technique used by our lab (19) to match an anatomic MR atlas with defined ROI onto new-segmented MR images, was based on the theory of elastic membranes (20 ,21), and was similar to Grenander and Miller's (22) approach. The elastic membrane model can be intuitively understood as the deformations occurring when a set of points on the membrane is stretched. The goal of the elastic matching algorithm was to find a 3D *vector deformation field* that transformed the source data set (atlas) so that it matched the target data set (patient) with the greatest fidelity, that is, maximized the local similarity between the two data sets under the constraint of using a restricted set of "stretches" of the membrane. The middle and bottom panels of Fig. 55.3 show, in a cartoon, how contraction and expansion of particular voxels lead to a match between the atlas brain and the target brain. The right-hand part of these panels graphically illustrate the voxel-by-voxel deformation (stretching or compression) resulting from the *vector deformation field* used to transform the atlas image. We note that other choices of an "index brain" include the probabilistic atlas used by the Montreal Group (23) and interpolated data from an anatomic atlas, as used by Gee and colleagues (24).

Brain Warping: How Good Is It?

Any new technique must be validated, and brain warping is no exception. The current gold standard is manual ROI definition. The technique used by Iosifescu and co-workers (19 and unpublished data) was compared with manual ROI definition for volumes. Agreement on volumes over 28 subjects (half schizophrenia patients and half controls) was 97% for whole brain volume, 97% for whole white matter, 91% for whole gray matter, 96% for thalamus (both sides), 93% for putamen, 91% for caudate nucleus, and 76% for globus pallidus. A more rigorous and better method of comparison is the extent of overlap of voxels in the manually defined ROI with those in the automated definitions. In measurements of 20 brain cortical and subcortical brain structures on one brain image the extent of voxel-by-voxel correspondence, was defined as:

$$\frac{(\#\text{ voxels in manual ROI also in automated ROI})}{(\#\text{ voxels in manual ROI})}$$

This averaged 90% for subcortical structures and 98% for total gray and white matter volumes; however, for cortical gyri the overlap averaged only 60%. The automated computer algorithm assumed the neuroanatomic variability among subjects to be a topologic invariant. However, cerebral gyri frequently split in two in some subjects, whereas they remain one single structure in others. These differences could not be taken into account by the automated registration in its present form. Taken together, these data suggest:

1. Each automated warping procedure should be compared with the results using manual ROI definitions.
2. Accuracy may be good for subcortical structures (because of their relatively small variability in shape) and total brain gray and white matter.
3. Accuracy is questionable for the neocortex, because of the irregularity of sulco-gyral patterns.

A recent use of the technique of warping is to use the *vector deformation field* to provide a statistical test of whether each voxel is significantly displaced or not (25). (See Fig. 55.3 for a description of extent and direction of warp.) This methodology does not attempt to map gyrally defined ROI, but rather looks at changes in gray matter on a global or regional basis, often using Talairach space.

Gaser and colleagues (26) compared the 3D vector deformation fields required to warp each voxel of an index brain (source not specified, presumably that of the Talairach atlas) onto spatially normalized brains of a large group of schizophrenic patients (n = 85) and controls (n = 75). They then computed the statistical significance of the difference between the schizophrenic patients' and controls' deformation fields, finding volume reduction bilaterally in Talairach spatial locations corresponding to thalamus and superior temporal gyrus and unilateral reductions in the superior and middle frontal gyrus, precentral gyrus, lingual gyrus, and cerebellum. This study forms a good transition to the next section because the spatial normalization techniques and the nonlinear registration method, those of SPM99 and Ashburner and Friston (27), respectively, are described in the following section.

Voxel-Based Morphometry

Ashburner and Friston (27) define this technique as "a voxel-wise comparison of the local concentration of gray matter between two groups of subjects," and have provided a detailed description of this methodology, closely related to that of SPM99. As a first step, this method takes all subject images and normalizes them to the same stereotaxic space, using procedures similar to those used in SPM for fMRI and PET data. This procedure involves an initial linear (affine) match (similar to that described for brain warping) followed by a nonlinear registration using smooth spatial basis functions. These authors emphasize that this spatial normalization "does not attempt to match every cortical feature exactly, but merely corrects for global brain shape differences," thereby differentiating it from more exact attempts at a match, as discussed in the brain warping section. The second step involves segmentation of the normalized images into gray matter, white matter, and CSF. The third step is smoothing using a convolution with a Gaussian kernel, which leads to each voxel being the mean of gray matter density for it and, to a spatially progressively lesser degree, its neighbors. The last step is statistical analysis using the general linear model to identify regions of gray matter concentration that are significantly related to the variable under study (if normality is not present a nonparametric statistical analysis is used).

Compared with manually drawn ROI, this technique has the following clear advantages: (a) enabling of regional comparisons throughout the whole brain without the restrictions of a few selected areas used in the typical manually drawn region of interest methodology; (b) the reduction of labor; and (c) the ability to use large samples with an attendant increase in statistical power as a corollary to (b).

Unfortunately, however, there as been an absence of work comparing the spatial specificity and sensitivity of voxel-based analysis with manual ROI analysis, the current standard, and thus the question of validity has been incompletely addressed.

Wright and co-workers (28) have undertaken some comparisons with manual ROI. They performed manual area measurements of the head of the caudate in the transverse slice 12 mm superior to the intercommissural plane in the untransformed data. They then compared these with voxel values in the transformed data at coordinates corresponding to the center of the caudate in Talairach space for each of 20 the subjects. They found Pearson product-moment correlations between the area measurement and the voxel gray matter values for the transformed data for the 20 subjects to be about r = 0.8. These data do not, unfortunately, provide information on spatial specificity in terms of a measurement of the boundaries of the caudate in the untransformed data for the 20 subjects and the transformed data. Nor do these data, taken from the center point of a regular structure, provide any clear information on how well the transformation would work on the much more irregular cerebral cortex. Because one of the findings with transformed data was decreased gray matter in the schizophrenic group in the voxels corresponding to the right amygdala, one would have liked to see a comparison with manually drawn ROI in this structure as a way of validating the voxel analysis (and/or a comparison in the other regions found to be abnormal, the temporal pole/insula, and left dorsolateral prefrontal cortex). Wright and associates did find that voxel analysis could detect artificial "lesions," created by setting gray matter content to zero in a group of voxels, including a 4- × 4-mm bar and a 12- × 25-mm grid. They did not try more realistic "lesions" with parametric variation of degrees of lesser gray matter content; nor did they quantify

the spatial specificity. In concluding the discussion of this technique, Wright and colleagues voiced the important caveats that voxel based morphometry may not detect “very small gray matter reductions, gray matter reduction in areas of high variability in gray matter volume or gray matter reductions with an inconsistent location.”

A direct comparison of manual ROI and voxel-based analysis would seem to be a high priority, because some estimate of the specificity and sensitivity of voxel analysis for various brain regions and ROI could be formed. Until such validation procedures are done, any results with voxel-based morphometry (VBM) will, of necessity, be viewed by many workers in the field as tentative. Because of the importance of the validity question, our laboratory has recently begun to compare SPM99 VBM results with traditional ROI analysis (Kubicki and colleagues, unpublished data). For VBM applied to whole brain, only the left posterior superior temporal gyrus region was significantly different between schizophrenic and control groups, a finding consistent with our ROI analysis. In a less statistically less stringent analysis (taking into account peak z values and voxel cluster extent), there was significance bilaterally in the anterior cingulate gyri and insula (regions not examined with ROI), but not in medial temporal lobe where ROI analysis showed differences.

Taken together, these data suggest the following methodologic conclusions:

1. Each VBM study should be compared with manual ROI definitions until validity is established.
2. VBM may be useful for generating hypotheses to be validated with traditional ROI analyses.
3. Much work remains to be done in comparing the validity of VBM and ROI analysis, and formulating reasons for any differences.

Shape Analysis

It is readily apparent that ROI shape as well as volume may carry information about pathology. Casanova and colleagues (29) used 3D Fourier techniques to characterize shape of temporal lobe regions, finding schizophrenics and controls differed. However, Fourier techniques cannot pinpoint where in the shape the abnormality occurs, as can brain warping and other methodologies. Csernansky and associates (30), using a variant (based on Grenander’s work) of the brain warping techniques described in the preceding, found that maximal differences between controls and the schizophrenia subjects were localized to the lateral aspect of the head of the hippocampus and medial aspect of the body, where the subiculum is found. The study of shape using a number of different algorithms is a current area of very active interest in MR schizophrenia research, especially in the study of the corpus callosum.

DIFFUSION TENSOR MR IMAGING

Part of "55 - Structural Magnetic Resonance Imaging Studies in Schizophrenia "

This is a new MRI technology that is able to provide information on the orientation and integrity of fiber tracts. In diffusion tensor imaging (DTI), a tensor describing local water diffusion is acquired for each voxel; crudely, this tensor can be thought of as a mathematical description of the direction and velocity component of diffusion relative to the orientation of the chosen coordinate system, or “basis.” Diffusion may be “isotropic,” equal in all directions, as occurs in CSF, and the diffusion volume (3D representation of diffusion pathways) has a spherical geometry in this case. Or diffusion may be “anisotropic” (e.g., not isotropic) and greater in one direction, in which case there is an ellipsoid shape. The limiting case for maximal anisotropy is an infinitely long and thin cylinder. In white matter fiber tracts diffusion is mainly in the direction of the fibers. Factors that affect the shape of the apparent diffusion tensor (shape of the diffusion ellipsoid) in the white matter include the density of fibers, degree of myelination, average fiber diameter, and directional similarity of the fibers in the voxel. For example, the DTI-measured diffusion coefficients are larger when measured along (parallel to) white matter fibers (in the range of 1.0×10^{-3} mm^2/sec) than across the fibers (in the range of 0.6×10^{-3} mm^2/sec). The geometric nature of the measured diffusion tensor within a voxel is thus a meaningful measure of fiber tract organization.

The degree of anisotropy in schizophrenia has been investigated in two recent studies. Using DTI, Buchsbaum and associates (31) reported evidence of lower diffusion anisotropy in some inferior portions of prefrontal white matter in patients with schizophrenia than in controls. Lim and co-workers (32) found that abnormally low white matter anisotropy in patients with schizophrenia was present in both hemispheres and was widespread, extending from frontal to occipital brain regions. For group statistics, Lim and co-workers used the median value of voxel anisotropy (measured as fractional anisotropy; 1 is maximal and 0 minimal) in each slice within the white matter regions of interest in the control and schizophrenia groups. These studies raised the important question of whether white matter connectivity is disturbed in schizophrenia, although Lim and colleagues caution that the proper statistical measures for DTI are still being worked out.

A recent technical advance in DTI has been line scan diffusion imaging (LSDI). This method, in contrast to the commonly used diffusion-sensitized, ultrafast, echo-planar imaging (EPI) technique, is less sensitive to gross motion and cardiovascular pulsations. LSDI also has higher resolution, exhibits minimal image distortion, and does not require cardiac gating, head restraints, or post-processing image correction. It also can be implemented without specialized hardware on all standard MRI scanners.

Recent work has focused on measurements extending beyond the scalar measurement of the degree of anisotropy

in a voxel to characterizing the spatial trajectory and orientation of fiber tracts. Although the individual axons and the surrounding myelin sheaths cannot be revealed with the limited spatial resolution of *in vivo* imaging, distinct bands of white matter fibers with parallel orientation may be distinguished from others running in different directions if MRI techniques are sensitized to water diffusion and the preferred direction of diffusion is determined. Figure 55.4 shows the degree to which orientation of fiber tracts can be quantified and displayed using color-coding. An important point for summarizing data made by Westin and associates (33) is that remaining within the tensor domain when processing is useful, as contrasted with operating on scalars and vectors to produce summary statistics. In processing DTI images, it is important to note that averaging of a diffusion tensor field and then deriving a scalar measure from the averaged field is not the same as averaging a scalar field derived from the original field. By using geometrically defined diffusion measures on locally averaged tensors local directionality consistency can be determined (e.g., existence of larger fiber tracts). This averaging approach can be used to derive a tensor field that will describe macrostructural features in the tensor diffusion data. For example, a measure of linearity derived from the averaged tensor field can be used for quantitative evaluation of fiber tract organization.

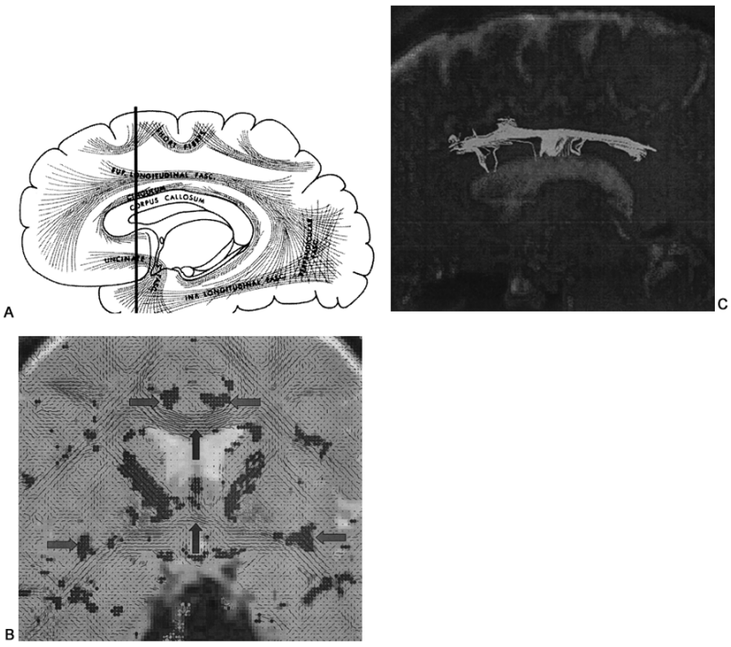

FIGURE 55.4. A: Sagittal schematic of brain fiber tracks. The vertical line shows the approximate plane of the coronal diffusion tensor image to the right. (Adapted from Gray H, Bannister LH, eds. *Gray's anatomy: the anatomical basis of medicine and surgery*, thirty-eighth ed. London: Churchill Livingstone, 1995.) **B:** In this diffusion tensor imaging (DTI) image, white matter tracts that are within the coronal plane are color-coded blue. Note the corpus callosum *(top blue arrow)* and anterior commissure *(bottom blue arrow)*. White matter tracts perpendicular to the plane are coded red-orange. Note the cingulum bundle *(top arrows)*, the white matter tract within the cingulate gyrus, and the uncinate fasiculus *(bottom arrows)*, the tract connecting anterior temporal lobe with inferior frontal lobe. (Unpublished image from our laboratory, Shenton et al., 2000; technique and application discussed in Kubicki M, Maier SE, McCarley RW, et al. *Uncinate fasciculus in schizophrenia: a diffusion tensor study*. American Psychiatric Association New Research Abstracts, 2000.) **C:** Parasagittal image showing anterior–posterior course of the cingulate bundle as constructed from DTI. (Unpublished image courtesy of Stephan Maier and Carl-Fredrik Westin, Surgical Planning Laboratory, Brigham and Women's Hospital).

Still another promising application of DTI is tracking white matter tracts. The operation begins with a seed point in a voxel element and then generates a tracking sequence

if the adjacent elements have similar linear orientation. This similarity is at the voxel level, and does not, of course, permit tracking of individual fibers; rather, it tracks groups of fibers.

CONCLUSION

Part of "55 - Structural Magnetic Resonance Imaging Studies in Schizophrenia "

A clear current and positive trend is to use as much automation as possible in structural MRI analysis because of the labor involved in traditional ROI analysis. Currently, however, the field is still in a state of flux with respect to the validity of the new techniques, such as VBM and brain warping, because of the absence of detailed comparisons with ROI analysis and formulation of the reasons for differences. Validity evaluation for new technologies is thus a high priority item.

Another clear and positive trend is employ new technologies, and to use multimodal imaging, with diffusion tensor imaging as the prime example within the structural field. Similarly, as discussed in another chapter in this volume by Dr. Berman, “functional” imaging is becoming increasingly multimodal and a desideratum is the combination of structural and functional approaches, just as anatomy and physiology are inextricably linked in basic neuroscience studies. The reader will likely notice a certain “mismatch” in the brain regions emphasized in the functional imaging chapter (frontal lobe) and in this structural imaging chapter (temporal lobe). It is clear that functional studies have defined more prominent abnormalities in frontal lobe than in temporal lobe, whereas structural studies have tended to show a greater degree of abnormality in temporal lobe. The mismatch may arise, in part, because the frontal lobe receives input from and communicates with virtually all cortical (and many subcortical) areas. Functional neuroimaging “activation” in a region primarily represents postsynaptic potentials; these and not action potentials constitute the major metabolic and energetic load and hence the main signals used in functional analysis. It is consequently often very difficult to disambiguate abnormalities in input to frontal lobe from intrinsic abnormalities. Similarly, although temporal lobe gray matter volume changes appear quantitatively larger than those in frontal cortex, no brain region acts on its own and interconnections and abnormalities of interconnections, as well as intrinsic volume changes must be considered in the explanation of the features of schizophrenia. This task of seamlessly integrating information from multiple technologies is both one of the most exciting and also the most challenging for work in the next few years.

APPENDIX A: STRUCTURAL MRI PULSE SEQUENCES

STRUCTURAL MRI PULSE SEQUENCES

Spin echo pulse sequences use at least two pulses. The first is an initial excitation pulse (tilting the magnetization vector 90 degrees from the steady-state field orientation), followed by one or more refocusing pulses, and directed 180 degrees from the orientation of the steady-state field. These refocusing pulses reintroduce phase coherence (again, the web site http://ej.rsna.org/ej3/0095-98.fin/index.htm provides a useful animated illustration of this). The reformation of phase coherence induces another signal known as a “spin echo,” which does not have the potential confounds of magnet and tissue inhomogeneity (they remain constant over pulses), and thus this signal provides a better measure of T2. In spin echo pulse sequences the repetition time (TR) is the time between excitation pulses, whereas the echo time (TE) is the time from the excitation pulse to the echo maximum.

Relatively short TR and TE standard single echo sequences produce T1-weighted images. Multiecho sequences produce proton density weighted images at short TE (less than 30 ms) and T2-weighted images at long TE (more than 80 ms) when TR is long enough to allow for nearly compete T1 relaxation (more than 2,000 ms for most tissues). Fast spin echo sequences are a variant of multiecho sequences that maximize efficiency of data collection and shorten acquisition time. They are commonly used to produce T2-weighted images. Inversion recovery pulse sequences are still another variation of the spin echo sequence, in which an additional 180-degree pulse is applied before the excitation pulse, thereby increasing T1 weighting (commonly used for improving contrast between different tissues).

Gradient Echo Pulse Sequences

These sequences do not use 180-degree refocusing pulses. The most commonly used pulse sequence in volumetric work is a spoiled gradient echo sequence, called spoiled GRASS (SPGR) in GE imagers and FLASH in Siemens imagers. This pulse sequence uses a “spoiling scheme” to dephase the transverse (x-y plane) magnetization following signal detection, commonly using “spoiler” (also called “crusher”) gradient pulses that have the same duration and magnitude as the first excitation pulse, but the opposite polarity. This has as a consequence that, at the time of the next excitation, only the longitudinal direction (vertical direction in our analogy) has any remaining coherence. If the first pulse has a low excitation angle (small “tilt” of the tops in our analogy) this allows shorter repetition times to be used, speeding acquisition.

Signal Intensity of Tissue Elements and T1 and T2 Weighting

SPGR pulses lead to proton density-weighted images, because the small “tilt” and short TR diminishes any T1 or T2 effects. In a proton density image produced by the SPGR sequence most commonly used in schizophrenia research, CSF appears dark, gray matter is gray, and white matter

has the most signal (is brightest). Spin-echo sequences can produce proton density, T2- or T1-weighted images. The normal CSF T1 relaxation time is 3,000 ms at 1.5 T, whereas that of fat is 200 to 250 ms; gray matter has a longer T1 relaxation time than white matter and thus shows a brighter signal with sequences allowing longer T1 relaxation times. Because the ability to capture relatively complete T1 relaxation depends on longer TRs, longer TRs thus give brighter CSF and gray matter brighter than white matter. The tissue intensity in T2-weighted images depends on the TE in spin echo sequences. CSF has longer T2 values than other brain tissues and shows up as a bright signal in T2-weighted acquisitions with the long TE values commonly used in schizophrenia volumetric studies. In general, a long TR allows more time for T1 relaxation and produces more signal from tissues with long T1 values, whereas a long TE allows more time for T2 relaxation and produces more signal from tissues with long T2 values.

The introduction of the first antipsychotic medication in the early 1950s revolutionized mental health care strategies and led to the era of deinstitutionalization, a period in which patients with schizophrenia and related psychotic disorders were released from state hospitals in large numbers to be cared for in the community (1). Nonetheless, with the growing understanding that a significant percentage of patients responds poorly to conventional antipsychotics, as well as the recognition of discouraging long-term outcomes for schizophrenia, the need to develop new therapeutic agents that work rapidly, potently, broadly, and with fewer side effects has become increasingly appreciated. The reintroduction of clozapine heralded the second generation of atypical antipsychotic drugs and a new pharmacotherapy of schizophrenia. To date, the greater benefits of the atypical antipsychotic drugs in many outcome domains have been demonstrated (2), and novel medications are replacing the conventional antipsychotics as treatments of choice. The development of additional novel strategies to obtain potentially new antipsychotic compounds possessing unique pharmacologic profiles with few side effects is being pursued based on specific hypotheses (3). This chapter provides a review and critique of currently available pharmacologic and psychosocial treatments in schizophrenia, and focuses on investigational treatments and potential strategies for future pharmacotherapy.

HISTORY OF ANTIPSYCHOTIC DRUG DEVELOPMENT

Part of "56 - Therapeutics of Schizophrenia "

Since the discovery of the prototypical antipsychotic chlorpromazine in the early 1950s, a number of neuroleptics were developed based on the hypothesis that schizophrenia reflected a disorder of hyperdopaminergic activity, with the dopamine D_2 receptor most strongly associated with antipsychotic response (4). In many patients with schizophrenia, the widely used conventional antipsychotic drugs (e.g., chlorpromazine and haloperidol) are effective in the treatment of the positive symptoms of schizophrenia, and also in preventing psychotic relapse (5); however, there are crucial limitations in the use of these agents. As many as 25% to 60% of patients treated with conventional antipsychotics remain symptomatic and are labeled either treatment-refractory, or partially responsive (3). In addition, these drugs at best only modestly improve negative symptoms of the deficit syndrome and a range of cognitive impairments, which may be fundamental to the disease (6). Further, conventional antipsychotics cause a variety of side effects both acutely (e.g., extrapyramidal side effects [EPS]) and with long-term exposure (e.g., tardive dyskinesia [TD]) (7 ,8). Such adverse effects may reduce compliance and represent a major drawback of these drugs.

For a number of years, there was a widely held view that any compound that was an effective antipsychotic agent must also induce EPS. The availability of clozapine and other newer atypical antipsychotic agents, however, have disproved this notion. The development of atypical antipsychotic drugs was aimed at increasing the ratio between doses that produce therapeutic effects and those that produce side effects, as well as improving efficacy (e.g., against a broader spectrum of psychopathologic symptoms and the treatment-resistant aspects of the disorder) (1). Although there is currently no uniform definition of the term “atypical,” in its broadest sense it is used to refer to drugs that have at least equal antipsychotic efficacy compared to conventional drugs, without producing EPS or prolactin elevation (1). A more restrictive definition would require that atypical drugs also have superior antipsychotic efficacy (i.e., they are effective in treatment resistant schizophrenic patients, and against negative symptoms and/or neurocognitive deficits).

Although agents like thioridazine were first suggested to

have atypical characteristics, it now is generally accepted that clozapine, first synthesized in 1958, is the prototypical “atypical” antipsychotic (9). Clozapine underwent extensive clinical testing in the 1970s, but its development was halted in the United States, and limited in other countries, because of a relatively high incidence of a potential fatal side effect, agranulocytosis. Nevertheless, its superior outcomes ultimately led to further development and eventual reintroduction beginning in 1990 (10). The renaissance of clozapine was based on several advantages: It appears to be more effective than typical neuroleptic drugs (e.g., chlorpromazine and haloperidol) in treatment refractory schizophrenia (11); it can ameliorate some of the negative as well as positive symptoms of schizophrenia (12); it can reduce relapse; it may improve certain cognitive functions; it may alleviate mood symptoms associated with schizophrenia and reduce the likelihood of suicidal behavior; it has very low liability for EPS and TD; and it does not induce sustained hyperprolactinemia (10). The reintroduction of clozapine represented a breakthrough in the treatment of schizophrenia. In recent years, concerted research and development efforts have been made to produce a second generation of “atypical” antipsychotic drugs, including risperidone, olanzapine, quetiapine, and ziprasidone, with the therapeutic advantages of clozapine, without the properties contributing to its serious side effects (13). Ongoing clinical evaluation of the new “atypical” antipsychotic drugs will eventually allow comprehensive assessment of their efficacy and safety.

REVIEW AND CRITIQUE OF CURRENT SCHIZOPHRENIA PHARMACOTHERAPY

Part of "56 - Therapeutics of Schizophrenia "

Conventional Antipsychotic Drugs

Pharmacology

Conventional or typical antipsychotic drugs can be classified as high, intermediate, or low potency based on their affinity for dopamine D_2 receptors and the average therapeutic dose, compared with a 100-mg dose of chlorpromazine (14). Haloperidol, the prototypical high-potency typical antipsychotic, has relatively high affinity for D_2 receptors and a dose of 2 to 4 mg of haloperidol is equivalent to approximately 100 mg of chlorpromazine. Low-potency drugs (e.g., thioridazine) have a chlorpromazine equivalent dose of more than 40 mg. There is a good correlation between antipsychotic potency and D_2 affinity for conventional antipsychotics of several chemical classes (4). Conventional drugs have various interactions with serotonin receptors, ranging from slight (e.g., haloperidol) to moderate (e.g., chlorpromazine).

Positron emission tomography (PET) and single photon emission computed tomography (SPECT) studies have further elucidated the importance of dopamine receptor occupancy as a predictor of antipsychotic response and adverse effects. Prospective studies have demonstrated that antipsychotic effects require a striatal D_2 receptor occupancy of 65% to 70% (15 ,16 ,17 and 18), and D_2 occupancy greater than 80% significantly increases the risk of EPS (15). Thus, a threshold between 65% and 80% D_2 occupancy appears to represent the optimal therapeutic range to minimize the risk of EPS for typical antipsychotic drugs (18 ,19 and 20). It should be noted, however, that despite adequate D_2 occupancy, many patients do not respond to medication (17). Moreover, results of studies with atypical drugs such as olanzapine indicate that receptor occupancy levels above 80% are not invariably associated with the occurrence of EPS, thus casting some doubt over the generalizability of the D_2 occupancy model with regard to atypical antipsychotics (21).

In preclinical studies, acute treatment with conventional antipsychotics (e.g., haloperidol and fluphenazine) increases the expression of c-fos mRNA or Fos protein in the dorsolateral striatum, as well as the shell of nucleus accumbens in rats (22 ,23 ,24 and 25). Neuroleptic-induced expression of Fos in the nucleus accumbens has been postulated to relate to the antipsychotic activity of both conventional and atypical drugs (26 ,27). The Fos expression in the dorsolateral striatum, which is not induced by clozapine, has been proposed to be predictive of a liability to induce EPS (23 ,27). More recently, it has been reported that haloperidol, but not clozapine, increased the immediate-early gene, arc (activity-regulated cytoskeleton-associated gene) mRNA levels in the rat striatum (28). After chronic treatment, haloperidol also induces an increase in D_2 receptor density and D_{2L} receptor mRNA in the striatum (29 ,30 and 31). Interestingly, several investigators have reported striatal enlargement after chronic treatment with conventional antipsychotics, but not atypical drugs, in both schizophrenic patients (32 ,33) and rats (34). Thus, available data suggest that conventional antipsychotic drugs may induce long-term plastic changes that lead to morphologic alterations in the striatum, and that the efficacy and side-effect profile of typical antipsychotics relate to antagonistic actions at D_2 dopamine receptors.

Efficacy

Although typical neuroleptics vary in side-effect profile and hence tolerability, there is little evidence for differences in efficacy between these drugs (3). However, in rare cases, patients failing a trial of one class may respond to the other. Although conventional neuroleptic drugs are effective for alleviating positive symptoms of schizophrenia, and preventing their recurrence in many patients, they have serious limitations. Approximately 30% of patients with acutely exacerbated psychotic symptoms have little or no response to conventional antipsychotics, and up to 50% of patients have only partial response to medication (5 ,7). Negative symptoms, mood symptoms, and cognitive deficits are marginally responsive to conventional neuroleptics. In particular, primary negative symptoms are very resistant to the

typical drugs (7 ,35). The presence of negative symptoms and cognitive impairment often leads to poor social and vocational function (36 ,37). Thus, in the absence of a clinical response at acute phase of the illness, clinicians often switch to a newer atypical agent (38).

Safety

Most conventional antipsychotics are associated with a wide range and a variable degree of undesirable acute and long-term adverse effects, including EPS; sedation; anticholinergic, autonomic, and cardiovascular effects; weight gain; sexual dysfunction; hyperprolactinemia; and neuroleptic malignant syndrome, a condition that is potentially life threatening (7 ,39). Up to 70% of patients given recommended therapeutic dosages of conventional antipsychotics develop acute EPS (40). The most troublesome neurologic side effect, tardive dyskinesia (TD), can be irreversible, and incidence rates have been estimated at about 5% per year in the nonelderly and as high as 30% per year in the elderly (41). Further, the anticholinergic drugs that are often used to reduce EPS, can also produce serious side effects (e.g., dry mouth, constipation, delirium and memory deficits) (42). All these adverse effects can contribute to treatment noncompliance, and hence increase rates of relapse and rehospitalization during the course of the chronic illness (7 ,39).

Effectiveness
